Preface: General Chair

In 2005, the Human Language Technology Conference (HLT) and the Conference on Empirical Methods in Natural Language Processing (EMNLP) were held together as a joint conference for the first time. The conference was co-sponsored by the organization traditionally behind HLT, the Human Language Technology Advisory Board, and the organization traditionally behind EMNLP, SIGDAT: The Association for Computational Linguistics (ACL) Special Interest Group on linguistic data and corpus-based approaches to natural-language processing. The joint conference was held in Vancouver, B.C., Canada on October 6–8, co-located with the 2005 Document Understanding Conference (DUC) and the 9th International Workshop on Parsing Technologies (IWPT).

In the HLT tradition, the conference especially encouraged submissions involving synergistic combinations of language technologies from the sometimes disjoint areas of natural-language processing, speech processing, and information retrieval. To encourage such cross-fertilization, each of the major chair positions were filled by three people, one from each of these research areas.

First, I would like to thank the Program Chairs, **Chris Brew**, **Lee-Feng Chien**, and **Katrin Kirchhoff**, for handling the unexpectedly large number of submissions under a very tight schedule and putting together an excellent program for the conference. Please see their preface for further information on the submissions, the program committee, and the conference program.

Priscilla Rasmussen deserves our enduring gratitude for agreeing to serve as a remote Local Arrangements Chair, and gracefully handling the multitude of responsibilities that this important position requires.

Joyce Chai did an excellent job as Publications Chair and managing the myriad of details required to assemble this proceedings in the small amount of time allotted for this important step. Thanks also go to **Chen Zhang** and **Shaolin Qu** for helping with the proceedings and to **Jason Eisner** and **Philipp Koehn** for making the publication software available and providing many good suggestions.

Donna Byron, **Anand Venkataraman**, and **Dell Zhang** served as Demonstrations Chairs and carefully reviewed 31 proposals to select 20 interesting demos that were a great addition to the conference program.

David Elworthy and **Marius Pasca** served in the important role of Sponsorship and Exhibits Chairs and helped raise important corporate financial support for the conference. Thanks are also due to our corporate sponsors (listed on the previous page) for their gracious support.

Srinivas Bangalore, **Zak Shafran**, and **Hsin-Min Wang** served as Publicity Chairs and provided important support in advertising the conference to the NLP, speech, and IR communities.

Anoop Sarkar and **Fred Popowich** served as Local Preparation and Student Volunteer Coordinators, providing important local support in Vancouver and assembling and managing a team of student volunteers that provided important services at the conference. The students volunteers themselves also deserve our gratitude.

Yuk Wah Wong, **Razvan Bunescu**, **Ruifang Ge**, and **Rohit Kate** dedicated significant effort as

Webmasters, putting together and constantly updating the conference web site.

Graeme Hirst provided important support and advice as Chair of the HLT Board, particularly in the site selection and initial formation of the conference committee. The members of the HLT Board, **Karen Kukich**, **Donna Harman**, **Mary Harper**, **Julia Hirschberg**, **Sanjeev Khudanpur**, **Joseph Olive**, **John Prange**, **Drago Radev**, and **Ellen Riloff**, also provided important support and advice.

Ken Church also provided important support and advice as chair of SIGDAT in the initial formation of the conference committee and continuing advice on conference organization.

Also thanks to **Donna Harman** for organizing the co-located DUC meeting and **Harry Bunt**, **Rob Malouf** and **Alon Lavie** for organizing the co-located IWPT meeting.

Finally, I would to thank all of the authors, demo presenters, and conference attendees for helping to make the first joint HLT/EMNLP meeting a successful and engaging scientific venue!

Raymond J. Mooney
HLT/EMNLP-05 General Chair
August 24, 2005

Preface: Program Co-chairs

It is our pleasure to welcome you to HLT/EMNLP 2005 in the beautiful city of Vancouver. For the third time, HLT is being held in combination with a conference sponsored by an ACL organization, thus continuing the tradition of bringing together researchers from three different communities: natural language processing, information retrieval, and speech processing. During the last few years, these fields have experienced a growing trend towards interaction across their traditional boundaries, as evidenced by the exchange of approaches and methodologies, and the development of large-scale systems integrating speech and language processing as well as information retrieval components.

We hope that this conference will further encourage this trend. In order to facilitate the interaction between researchers from different fields, all papers have been organized into a single track rather than two or three different tracks. We are also pleased to welcome three invited speakers whose work spans several areas in the HLT/EMNLP field: Ellen Vorhees, Larry Hunter, and Sanjeev Khudanpur. We would like to thank them again for accepting our invitation and for their exciting and stimulating contributions to our program.

The joint organization of HLT and EMNLP generated an unusually large load of papers. A total of 402 submissions were received, of which 127 were accepted, resulting in an acceptance rate of 31.6%. We would like to thank our technical chairs, who did an excellent job at selecting the program committee and managed to handle the large number of submissions efficiently and on time. Our thanks also go to the program committee members for their expert reviews. We are particularly grateful to those PC members who were willing to take on additional reviews beyond their original assignments.

For the demonstrations track, thirty-one submissions were received, twenty of which were accepted. Donna Byron, Anand Venkataramanan and Dell Zhang did a superb job at managing the demo submissions and reviews, and we are looking forward to a very interesting session.

We are please to announce that, for the first time, a prize for the best student paper will be awarded at this year's conference. We are especially grateful to IBM for sponsoring this award – educating future generations of researchers in our community is of prime importance, and the public acknowledgment of students' research achievements is a significant contribution towards this goal.

Finally, we would like to thank our general chair, Ray Mooney, for his help and guidance, and all organizers, PC members, technical chairs, authors, and attendees for their efforts and contributions. We wish you a pleasant time at HLT/EMNLP 2005!

Chris Brew, Lee-Feng Chien, and Katrin Kirchhoff
Program Co-chairs

Table of Contents

Conference Program

Thursday, October 6, 2005

8:45–9:00	Opening Session
9:00–10:00	Invited Talk: Larry Hunter
10:00-10:30	Break
	Session 1A: Anaphora and Information Structure
10:30–10:55	*Improving LSA-based Summarization with Anaphora Resolution* Josef Steinberger, Mijail Kabadjov, Massimo Poesio and Olivia Sanchez-Graillet
10:55–11:20	*Data-driven Approaches for Information Structure Identification* Oana Postolache, Ivana Kruijff-Korbayova and Geert-Jan Kruijff
11:20–11:45	*Using Semantic Relations to Refine Coreference Decisions* Heng Ji, David Westbrook and Ralph Grishman
11:45–12:10	*On Coreference Resolution Performance Metrics* Xiaoqiang Luo
	Session 1B: Error Detection and Correction
10:30–10:55	*Improving Multilingual Summarization: Using Redundancy in the Input to Correct MT errors* Advaith Siddharthan and Kathleen McKeown
10:55–11:20	*Error Detection Using Linguistic Features* Yongmei Shi and Lina Zhou
11:20–11:45	*Semantic Similarity for Detecting Recognition Errors in Automatic Speech Transcripts* Diana Inkpen and Alain Désilets
11:45–12:10	*Redundancy-based Correction of Automatically Extracted Facts* Roman Yangarber and Lauri Jokipii

Abstract

We propose an approach to summarization exploiting both lexical information and the output of an automatic anaphoric resolver, and using Singular Value Decomposition (SVD) to identify the main terms. We demonstrate that adding anaphoric information results in significant performance improvements over a previously developed system, in which only lexical terms are used as the input to SVD. However, we also show that how anaphoric information is used is crucial: whereas using this information to add new terms does result in improved performance, simple substitution makes the performance worse.

1 Introduction

Many approaches to summarization can be very broadly characterized as TERM-BASED: they attempt to identify the main 'topics,' which generally are TERMS, and then to extract from the document the most important information about these terms (Hovy and Lin, 1997). These approaches can be divided again very broadly in 'lexical' approaches, among which we would include LSA-based approaches, and 'coreference-based' approaches . Lexical approaches to term-based summarization use lexical relations to identify central terms (Barzilay and Elhadad, 1997; Gong and Liu, 2002); coreference- (or anaphora-) based approaches (Baldwin and Morton, 1998; Boguraev and Kennedy, 1999; Azzam et al., 1999; Bergler et al., 2003; Stuckardt, 2003) identify these terms by running a coreference- or anaphoric resolver over the text.[1] We are not aware, however, of any attempt to use both lexical and anaphoric information to identify the main terms. In addition, to our knowledge no authors have convincingly demonstrated that feeding anaphoric information to a summarizer significantly improves the performance of a summarizer using a standard evaluation procedure (a reference corpus and baseline, and widely accepted evaluation measures).

In this paper we compare two sentence extraction-based summarizers. Both use Latent Semantic Analysis (LSA) (Landauer, 1997) to identify the main terms of a text for summarization; however, the first system (Steinberger and Jezek, 2004), discussed in Section 2, only uses lexical information to identify the main topics, whereas the second system exploits both lexical and anaphoric information. This second system uses an existing anaphora resolution system to resolve anaphoric expressions, GUITAR (Poesio and Kabadjov, 2004); but, crucially, two different ways of using this information for summarization were tested. (Section 3.) Both summarizers were tested over the CAST corpus (Orasan et al., 2003), as discussed in Section 4, and sig-

[1]The terms 'anaphora resolution' and 'coreference resolution' have been variously defined (Stuckardt, 2003), but the latter term is generally used to refer to the coreference task as defined in MUC and ACE. We use the term 'anaphora resolution' to refer to the task of identifying successive mentions of the same discourse entity, realized via any type of noun phrase (proper noun, definite description, or pronoun), and whether such discourse entities 'refer' to objects in the world or not.

nificant improvements were observed over both the baseline CAST system and our previous LSA-based summarizer.

2 An LSA-based Summarizer Using Lexical Information Only

LSA (Landauer, 1997) is a technique for extracting the ‘hidden’ dimensions of the semantic representation of terms, sentences, or documents, on the basis of their contextual use. It is a very powerful technique already used for NLP applications such as information retrieval (Berry et al., 1995) and text segmentation (Choi et al., 2001) and, more recently, multi- and single-document summarization.

The approach to using LSA in text summarization we followed in this paper was proposed in (Gong and Liu, 2002). Gong and Liu propose to start by creating a term by sentences matrix $A = [A_1, A_2, \ldots, A_n]$, where each column vector A_i represents the weighted term-frequency vector of sentence i in the document under consideration. If there are a total of m terms and n sentences in the document, then we will have an $m \times n$ matrix A for the document. The next step is to apply Singular Value Decomposition (SVD) to matrix A. Given an $m \times n$ matrix A, the SVD of A is defined as:

(1) $A = U\Sigma V^T$

where $U = [u_{ij}]$ is an $m \times n$ column-orthonormal matrix whose columns are called left singular vectors, $\Sigma = diag(\sigma_1, \sigma_2, \ldots, \sigma_n)$ is an $n \times n$ diagonal matrix, whose diagonal elements are non-negative singular values sorted in descending order, and $V = [v_{ij}]$ is an $n \times n$ orthonormal matrix, whose columns are called right singular vectors.

From a mathematical point of view, applying SVD to a matrix derives a mapping between the m-dimensional space spawned by the weighted term-frequency vectors and the r-dimensional singular vector space. From a NLP perspective, what the SVD does is to derive the *latent semantic structure* of the document represented by matrix A: a breakdown of the original document into r linearly-independent base vectors (‘topics’). Each term and sentence from the document is jointly indexed by these ‘topics’.

A unique SVD feature is that it is capable of capturing and modelling interrelationships among terms so that it can semantically cluster terms and sentences. Furthermore, as demonstrated in (Berry et al., 1995), if a word combination pattern is salient and recurring in document, this pattern will be captured and represented by one of the singular vectors. The magnitude of the corresponding singular value indicates the importance degree of this pattern within the document. Any sentences containing this word combination pattern will be projected along this singular vector, and the sentence that best represents this pattern will have the largest index value with this vector. As each particular word combination pattern describes a certain topic in the document, each singular vector can be viewed as representing a salient topic of the document, and the magnitude of its corresponding singular value represents the degree of importance of the salient topic.

The summarization method proposed by Gong and Liu (2002) should now be easy to understand. The matrix V^T describes the importance degree of each ’implicit topic’ in each sentence: the summarization process simply chooses the most informative sentence for each term. In other words, the kth sentence chosen is the one with the largest index value in the kth right singular vector in matrix V^T.

The summarization method proposed by Gong and Liu has some disadvantages as well, the main of which is that it is necessary to use the same number of dimensions as is the number of sentences we want to choose for a summary. However, the higher the number of dimensions of reduced space is, the less significant topic we take into a summary. In order to remedy this problem, we (Steinberger and Jezek, 2004) proposed the following modifications to Gong and Liu’s summarization method. After computing the SVD of a term by sentences matrix, we compute the length of each sentence vector in matrix V. This is to favour the index values in the matrix V that correspond to the highest singular values (the most significant topics). Formally:

(2) $s_k = \sqrt{\sum_{i=1}^{r} v_{k,i}^2 \cdot \sigma_i^2}$,

where s_k is the length of the vector of k’th sentence in the modified latent vector space, and its significance score for summarization too. The level of dimensionality reduction (r) is essentially learned from the data. Finally, we put into the summary the sentences with the highest values in vector s. We showed in previous work (Steinberger and Jezek,

2004) that this modification results in a significant improvement over Gong and Liu's method.

3 Using Anaphora Resolution for Summarization

3.1 The case for anaphora resolution

Words are the most basic type of 'term' that can be used to characterize the content of a document. However, being able to identify the most important *objects* mentioned in the document clearly would lead to an improved analysis of what is important in a text, as shown by the following news article cited by Boguraev and Kennedy (1999):

(3) PRIEST IS CHARGED WITH POPE ATTACK

A Spanish priest was charged here today with attempting to murder the Pope. *Juan Fernandez Krohn*, aged 32, was arrested after a man armed with a bayonet approached the Pope while he was saying prayers at Fatima on Wednesday night. According to the police, *Fernandez* told the investigators today that *he* trained for the past six months for the assault. ... If found guilty, *the Spaniard* faces a prison sentence of 15-20 years.

As Boguraev and Kennedy point out, the title of the article is an excellent summary of the content: an entity (the priest) did something to another entity (the pope). Intuitively, understanding that Fernandez and the pope are the central characters is crucial to provide a good summary of texts like these.[2] Among the clues that help us to identify such 'main characters', the fact that an entity is repeatedly mentioned is clearly important.

Purely lexical methods, including the LSA-based methods discussed in the previous section, can only capture part of the information about which entities are frequently repeated in the text. As example (3) shows, stylistic conventions forbid verbatim repetition, hence the six mentions of Fernandez in the text above contain only one lexical repetition, 'Fernandez'. The main problem are pronouns, that tend to share the least lexical similarity with the form used to express the antecedent (and anyway are usually removed by stopword lists, therefore do not get included in the SVD matrix). The form of definite descriptions (*the Spaniard*) doesn't always overlap with that of their antecedent, either, especially when the antecedent was expressed with a proper name. The form of mention which more often overlaps to a degree with previous mentions is proper nouns, and even then at least some way of dealing with acronyms is necessary (cfr. *European Union* / *E.U.*). The motivation for anaphora resolution is that it should tell us which entities are repeatedly mentioned.

[2]It should be noted that for many newspaper articles, indeed many non-educational texts, only a 'entity-centered' structure can be clearly identified, as opposed to a 'relation-centered' structure of the type hypothesized in Rhetorical Structures Theory (Knott et al., 2001; Poesio et al., 2004).

In this work, we tested a mixed approach to integrate anaphoric and word information: using the output of the anaphoric resolver GUITAR to modify the SVD matrix used to determine the sentences to extract. In the rest of this section we first briefly introduce GUITAR, then discuss the two methods we tested to use its output to help summarization.

3.2 GUITAR: A General-Purpose Anaphoric Resolver

The system we used in these experiments, GUITAR (Poesio and Kabadjov, 2004), is an anaphora resolution system designed to be high precision, modular, and usable as an off-the-shelf component of a NL processing pipeline. The current version of the system includes an implementation of the MARS pronoun resolution algorithm (Mitkov, 1998) and a partial implementation of the algorithm for resolving definite descriptions proposed by Vieira and Poesio (2000). The current version of GUITAR does not include methods for resolving proper nouns.

3.2.1 Pronoun Resolution

Mitkov (1998) developed a robust approach to pronoun resolution which only requires input text to be part-of-speech tagged and noun phrases to be identified. Mitkov's algorithm operates on the basis of antecedent-tracking preferences (referred to hereafter as "antecedent indicators"). The approach works as follows: the system identifies the noun phrases which precede the anaphor within a distance of 2 sentences, checks them for gender and number agreement with the anaphor, and then applies genre-specific antecedent indicators to the remaining candidates (Mitkov, 1998). The noun phrase with the highest aggregate score is proposed as antecedent.

3.2.2 Definite Description Resolution

The Vieira / Poesio algorithm (Vieira and Poesio, 2000) attempts to classify each definite description as either direct anaphora, discourse-new, or bridging description. The first class includes definite descriptions whose head is identical to that of their antecedent, as in *a house* … *the house*. Discourse-new descriptions are definite descriptions that refer to objects not already mentioned in the text and not related to any such object. Bridging descriptions are all definite descriptions whose resolution depends on knowledge of relations between objects, such as definite descriptions that refer to an object related to an entity already introduced in the discourse by a relation other than identity, as in *the flat* … *the living room*. The Vieira / Poesio algorithm also attempts to identify the antecedents of anaphoric descriptions and the anchors of bridging ones. The current version of GUITAR incorporates an algorithm for resolving direct anaphora derived quite directly from Vieira / Poesio, as well as a statistical version of the methods for detecting discourse new descriptions (Poesio et al., 2005).

3.3 SVD over Lexical and Anaphoric Terms

SVD can be used to identify the ‘implicit topics’ or main terms of a document not only when on the basis of words, but also of coreference chains, or a mixture of both. We tested two ways of combining these two types of information.

3.3.1 The Substitution Method

The simplest way of integrating anaphoric information with the methods used in our earlier work is to use anaphora resolution simply as a preprocessing stage of the SVD input matrix creation. Firstly, all anaphoric relations are identified by the anaphoric resolver, and anaphoric chains are identified. Then a second document is produced, in which all anaphoric nominal expressions are replaced by the first element of their anaphoric chain. For example, suppose we have the text in (4).

(4) **S1:** *Australia’s new conservative government* on Wednesday began selling *its tough deficit-slashing budget*, which sparked *violent protests by Aborigines, unions, students and welfare groups* even before *it* was announced.

S2: Two days of *anti-budget street protests* preceded *spending cuts* officially unveiled by *Treasurer Peter Costello*.

S3: ”If *we* don’t do *it* now, *Australia* is going to be in *deficit* and debt into the next century.”

S4: As *the protesters* had feared, *Costello* revealed a cut to *the government’s* Aboriginal welfare commission among *the hundreds of measures implemented to claw back the deficit*.

An ideal resolver would find 8 anaphoric chains:

Chain 1 *Australia - we - Australia*

Chain 2 *its new conservative government (Australia’s new conservative government) - the government*

Chain 3 *its tough deficit-slashing budget (Australia’s tough deficit-slashing budget) - it*

Chain 4 *violent protests by Aborigines, unions, students and welfare groups - anti-budget street protests*

Chain 5 *Aborigines, unions, students and welfare groups - the protesters*

Chain 6 *spending cuts - it - the hundreds of measures implemented to claw back the deficit*

Chain 7 *Treasurer Peter Costello - Costello*

Chain 8 *deficit - the deficit*

By replacing each element of the 8 chains above in the text in (4) with the first element of the chain, we get the text in (5).

(5) **S1:** *Australia’s new conservative government* on Wednesday began selling *Australia’s tough deficit-slashing budget*, which sparked *violent protests by Aborigines, unions, students and welfare groups* even before *Australia’s tough deficit-slashing budget* was announced.

S2: Two days of *violent protests by Aborigines, unions, students and welfare groups* preceded *spending cuts* officially unveiled by *Treasurer Peter Costello*.

S3: ”If *Australia* doesn’t do *spending cuts* now, *Australia* is going to be in *deficit* and debt into the next century.”

S4: As *Aborigines, unions, students and welfare groups* had feared, *Treasurer Peter Costello* revealed a cut to *Australia’s new conservative government’s* Aboriginal welfare commission among *the spending cuts*.

This text is then used to create the SVD input matrix, as done in the first system.

3.3.2 The Addition Method

An alternative approach is to use SVD to identify ‘topics’ on the basis of two types of ’terms’: terms in the lexical sense (i.e., words) and terms in the sense of objects, which can be represented by anaphoric chains. In other words, our representation of sentences would specify not only if they contain a certain word, but also if they contain a mention of a discourse entity (See Figure 1.) This matrix would then be used as input to SVD.

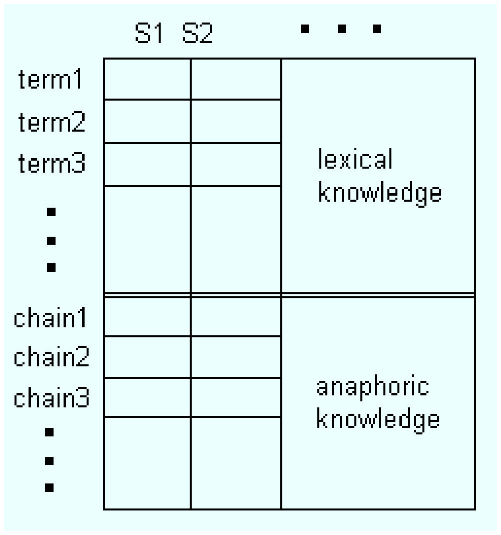

Figure 1: Addition method.

The chain 'terms' tie together sentences that contain the same anaphoric chain. If the terms are lexically the same (direct anaphors - like *deficit* and *the deficit*) the basic summarizer works sufficiently. However, Gong and Liu showed that the best weighting scheme is boolean (i.e., all terms have the same weight); our own previous results confirmed this. The advantage of the addition method is the opportunity to give higher weights to anaphors.

4 Evaluation

4.1 The CAST Corpus

To evaluate our system, we used the corpus of manually produced summaries created by the CAST project[3] (Orasan et al., 2003). The CAST corpus contains news articles taken from the Reuters Corpus and a few popular science texts from the British National Corpus. It contains information about the importance of the sentences (Hasler et al., 2003). Sentences are marked as **essential** or **important**. The corpus also contains annotations for linked sentences, which are not significant enough to be marked as important/essential, but which have to be considered as they contain information essential for the understanding of the content of other sentences marked as essential/important.

[3]The goal of this project was to investigate to what extent Computer-Aided Summarization can help humans to produce high quality summaries with less effort.

Four annotators were used for the annotation, three graduate students and one postgraduate. Three of the annotators were native English speakers, and the fourth had advanced knowledge of English. Unfortunately, not all of the documents were annotated by all of the annotators. To maximize the reliability of the summaries used for evaluation, we chose the documents annotated by the greatest number of the annotators; in total, our evaluation corpus contained 37 documents.

For acquiring manual summaries at specified lengths and getting the sentence scores (for relative utility evaluation) we assigned a score 3 to the sentences marked as essential, a score 2 to important sentences and a score 1 to linked sentences. The sentences with highest scores are then selected for ideal summary (at specified lenght).

4.2 Evaluation Measures

Evaluating summarization is a notoriously hard problem, for which standard measures like Precision and Recall are not very appropriate. The main problem with P&R is that human judges often disagree what are the top n% most important sentences in a document. Using P&R creates the possibility that two equally good extracts are judged very differently. Suppose that a manual summary contains sentences [1 2] from a document. Suppose also that two systems, A and B, produce summaries consisting of sentences [1 2] and [1 3], respectively. Using P&R, system A will be ranked much higher than system B. It is quite possible that sentences 2 and 3 are equally important, in which case the two systems should get the same score.

To address the problem with precision and recall we used a combination of evaluation measures. The first of these, relative utility (RU) (Radev et al., 2000) allows model summaries to consist of sentences with variable ranking. With RU, the model summary represents all sentences of the input document with confidence values for their inclusion in the summary. For example, a document with five sentences [1 2 3 4 5] is represented as [1/5 2/4 3/4

Evaluation Method	Lexical LSA	Manual Substitution	Manual Addition
Relative Utility	0.595	0.573	**0.662**
F-score	0.420	0.410	**0.489**
Cosine Similarity	0.774	0.806	**0.823**
Main Topic Similarity	0.686	0.682	**0.747**

Table 1: Evaluation of the manual annotation improvement - summarization ratio: 15%.

Evaluation Method	Lexical LSA	Manual Substitution	Manual Addition
Relative Utility	0.645	0.662	**0.688**
F-score	0.557	0.549	**0.583**
Cosine Similarity	0.863	0.878	**0.886**
Main Topic Similarity	0.836	0.829	**0.866**

Table 2: Evaluation of the manual annotation improvement - summarization ratio: 30%.

4/1 5/2]. The second number in each pair indicates the degree to which the given sentence should be part of the summary according to a human judge. This number is called the utility of the sentence. Utility depends on the input document, the summary length, and the judge. In the example, the system that selects sentences [1 2] will not get a higher score than a system that chooses sentences [1 3] given that both summaries [1 2] and [1 3] carry the same number of utility points (5+4). Given that no other combination of two sentences carries a higher utility, both systems [1 2] and [1 3] produce optimal extracts. To compute relative utility, a number of judges, $(N \geq 1)$ are asked to assign utility scores to all n sentences in a document. The top e sentences according to utility score[4] are then called a sentence extract of size e. We can then define the following system performance metric:

$$(6) \qquad RU = \frac{\sum_{j=1}^{n} \delta_j \sum_{i=1}^{N} u_{ij}}{\sum_{j=1}^{n} \epsilon_j \sum_{i=1}^{N} u_{ij}},$$

where u_{ij} is a utility score of sentence j from annotator i, ϵ_j is 1 for the top e sentences according to the sum of utility scores from all judges and δ_j is equal to 1 for the top e sentences extracted by the system. For details see (Radev et al., 2000).

The second measure we used is Cosine Similarity, according to the standard formula:

$$(7) \qquad cos(X,Y) = \frac{\sum_i x_i \cdot y_i}{\sqrt{\sum_i (x_i)^2} \cdot \sqrt{\sum_i (y_i)^2}},$$

where X and Y are representations of a system summary and its reference summary based on the vector space model. The third measure is Main Topic Similarity. This is a content-based evaluation method based on measuring the cosine of the angle between first left singular vectors of a system summary's and its reference summary's SVDs. (For details see (Steinberger and Jezek, 2004).) Finally, we measured ROUGE scores, with the same settings as in the Document Understanding Conference (DUC) 2004.

4.3 How Much May Anaphora Resolution Help? An Upper Bound

We annotated all the anaphoric relations in the 37 documents in our evaluation corpus by hand using the annotation tool MMAX (Mueller and Strube, 2003).[5] Apart from measuring the performance of GUITAR over the corpus, this allowed us to establish the upper bound on the performance improvements that could be obtained by adding an anaphoric resolver to our summarizer. We tested both methods of adding the anaphoric knowledge to the summarizer discussed above. Results for the 15% and 30% ratios[6] are presented in Tables 1 and 2. The baseline is our own previously developed LSA-based summarizer without anaphoric knowledge. The result is that the substitution method did not lead to significant improvement, but the addition method did:

[4]In the case of ties, some arbitrary but consistent mechanism is used to decide which sentences should be included in the summary.

[5]We annotated personal pronouns, possessive pronouns, definite descriptions and also proper nouns, who will be handled by a future GUITAR version.

[6]We used the same summarization ratios as in CAST.

Evaluation Method	Lexical LSA	CAST	GUITAR Substitution	GUITAR Addition
Relative Utility	0.595	0.527	0.530	**0.640**
F-score	0.420	0.348	0.347	**0.441**
Cosine Similarity	0.774	0.726	0.804	**0.805**
Main Topic Similarity	0.686	0.630	0.643	**0.699**

Table 3: Evaluation of the GUITAR improvement - summarization ratio: 15%.

Evaluation Method	Lexical LSA	CAST	GUITAR Substitution	GUITAR Addittion
Relative Utility	0.645	0.618	0.626	**0.678**
F-score	0.557	0.522	0.524	**0.573**
Cosine Similarity	0.863	0.855	0.873	**0.879**
Main Topic Similarity	0.836	0.810	0.818	**0.868**

Table 4: Evaluation of the GUITAR improvement - summarization ratio: 30%.

addition could lead to an improvement in Relative Utility score from .595 to .662 for the 15% ratio, and from .645 to .688 for the 30% ratio. Both of these improvements were significant by t-test at 95% confidence.

4.4 Results with GUITAR

To use GUITAR, we first parsed the texts using Charniak's parser (Charniak, 2000). The output of the parser was then converted into the MAS-XML format expected by GUITAR by one of the preprocessors that come with the system. (This step includes heuristic methods for guessing agreement features.) Finally, GUITAR was ran to add anaphoric information to the files. The resulting files were then processed by the summarizer.

GUITAR achieved a precision of 56% and a recall of 51% over the 37 documents. For definite description resolution, we found a precision of 69% and a recall of 53%; for possessive pronoun resolution, the precision was 53%, recall was 53%; for personal pronouns, the precision was 44%, recall was 46%.

The results with the summarizer are presented in Tables 3 and 4 (relative utility, f-score, cosine, and main topic). The contribution of the different anaphora resolution components is addressed in (Kabadjov et al., 2005). All versions of our summarizer (the baseline version without anaphora resolution and those using substitution and addition) outperformed the CAST summarizer, but we have to emphasize that CAST did not aim at producing a high-performance generic summarizer; only a system that could be easily used for didactical purposes. However, our tables also show that using GUITAR and the addition method lead to significant improvements over our baseline LSA summarizer. The improvement in Relative Utility measure was significant by t-test at 95% confidence. Using the ROUGE measure we obtained improvement (but not significant). On the other hand, the substitution method did not lead to significant improvements, as was to be expected given that no improvement was obtained with 'perfect' anaphora resolution (see previous section).

5 Conclusion and Further Research

Our main result in this paper is to show that using anaphora resolution in summarization can lead to significant improvements, not only when 'perfect' anaphora information is available, but also when an automatic resolver is used, provided that the anaphoric resolver has reasonable performance. As far as we are aware, this is the first time that such a result has been obtained using standard evaluation measures over a reference corpus. We also showed however that the way in which anaphoric information is used matters: with our set of documents at least, substitution would not result in significant improvements even with perfect anaphoric knowledge.

Further work will include, in addition to extending the set of documents and testing the system with other collections, evaluating the improvement to be achieved by adding a proper noun resolution algorithm to GUITAR.

Abstract

This paper investigates automatic identification of Information Structure (IS) in texts. The experiments use the Prague Dependency Treebank which is annotated with IS following the Praguian approach of Topic Focus Articulation. We automatically detect t(opic) and f(ocus), using node attributes from the treebank as basic features and derived features inspired by the annotation guidelines. We present the performance of decision trees (C4.5), maximum entropy, and rule induction (RIPPER) classifiers on all tectogrammatical nodes. We compare the results against a baseline system that always assigns f(ocus) and against a rule-based system. The best system achieves an accuracy of 90.69%, which is a 44.73% improvement over the baseline (62.66%).

1 Introduction

Information Structure (IS) is a partitioning of the content of a sentence according to its relation to the discourse context. There are numerous theoretical approaches describing IS and its semantics (Halliday, 1967; Sgall, 1967; Vallduví, 1990; Steedman, 2000) and the terminology used is diverse — see (Kruijff-Korbayová and Steedman, 2003) for an overview. However, all theories consider at least one of the following two distinctions: (i) a Topic/Focus[1] distinction that divides the linguistic meaning of the sentence into parts that link the sentence content to the discourse context, and other parts that advance the discourse, i.e., add or modify information; and (ii) a background/kontrast[2] distinction between parts of the utterance which contribute to distinguishing its actual content from alternatives the context makes available.

Information Structure is an important factor in determining the felicity of a sentence in a given context. Applications in which IS is crucial are text-to-speech systems, where IS helps to improve the quality of the speech output (Prevost and Steedman, 1994; Kruijff-Korbayová et al., 2003; Moore et al., 2004), and machine translation, where IS improves target word order, especially that of free word order languages (Stys and Zemke, 1995).

Existing theories, however, state their principles using carefully selected illustrative examples. Because of this, they fail to adequately explain how different linguistic dimensions cooperate to realize Information Structure.

In this paper we describe data-driven, machine learning approaches for automatic identification of Information Structure; we describe what aspects of IS we deal with and report results of the performance of our systems and make an error analysis. For our experiments, we use the Prague Dependency Treebank (PDT) (Hajič, 1998). PDT follows the theory of Topic-Focus Articulation (Hajičová et al., 1998) and to date is the only corpus annotated with IS. Each node of the underlying structure of sentences in PDT is annotated with a TFA value: t(opic), differentiated in contrastive and non-contrastive, and f(ocus). Our system identifies these two TFA values automatically. We trained three different clas-

[1] We use the Praguian terminology for this distinction.

[2] The notion 'kontrast' with a 'k' has been introduced in (Vallduví and Vilkuna, 1998) to replace what Steedman calls 'focus', and to avoid confusion with other definitions of focus.

sifiers, C4.5, RIPPER and MaxEnt using basic features from the treebank and derived features inspired by the annotation guidelines. We evaluated the performance of the classifiers against a baseline system that simulates the preprocessing procedure that preceded the manual annotation of PDT, by always assigning f(ocus), and against a rule-based system which we implemented following the annotation instructions. Our best system achieves a 90.69% accuracy, which is a 44.73% improvement over the baseline (62.66%).

The organization of the paper is as follows. Section 2 describes the Prague Dependency Treebank and the Praguian approach of Topic-Focus Articulation, from two perspectives: of the theoretical definition and of the annotation guidelines that have been followed to annotate the PDT. Section 3 presents our experiments, the data settings, results and error analysis. The paper closes with conclusions and issues for future research (Section 4).

2 Prague Dependency Treebank

The Prague Dependency Treebank (PDT) consists of newspaper articles from the Czech National Corpus (Čermák, 1997) and includes three layers of annotation:

1. The morphological layer gives a full morphemic analysis in which 13 categories are marked for all sentence tokens (including punctuation marks).
2. The analytical layer, on which the "surface" syntax (Hajič, 1998) is annotated, contains analytical tree structures, in which every token from the surface shape of the sentence has a corresponding node labeled with main syntactic functions like SUBJ, PRED, OBJ, ADV.
3. The tectogrammatical layer renders the deep (underlying) structure of the sentence (Sgall et al., 1986; Hajičová et al., 1998). Tectogrammatical tree structures (TGTSs) contain nodes corresponding only to the autosemantic words of the sentence (e.g., no preposition nodes) and to deletions on the surface level; the condition of projectivity is obeyed, i.e., no crossing edges are allowed; each node of the tree is assigned a functor such as ACTOR, PATIENT, ADDRESSEE, ORIGIN, EFFECT, the repertoire of which is very rich; elementary coreference links are annotated for pronouns.

2.1 Topic-Focus Articulation (TFA)

The tectogrammatical level of the PDT was motivated by the ever increasing need for large corpora to include not only morphological and syntactic information but also semantic and discourse-related phenomena. Thus, the tectogrammatical trees have been enriched with features indicating the information structure of sentences which is a means of showing their contextual potential.

In the Praguian approach to IS, the content of the sentence is divided into two parts: the Topic is "what the sentence is about" and the Focus represents the information asserted about the Topic. A prototypical declarative sentence asserts that its Focus holds (or does not hold) about its Topic: Focus(Topic) or not-Focus(Topic).

The TFA definition uses the distinction between Context-Bound (CB) and Non-Bound (NB) parts of the sentence. To distinguish which items are CB and which are NB, the question test is applied, (i.e., the question for which a given sentence is the appropriate answer is considered). In this framework, weak and zero pronouns and those items in the answer which reproduce expressions present in the question (or associated to those present) are CB. Other items are NB.

In example (1), (b) is the sentence under investigation, in which CB and NB items are marked. Sentence (a) is the context in which the sentence (b) is uttered, and sentence (c) is the question for which the sentence (b) is an appropriate answer:

(1) (a) Tom and Mary both came to John's party.
(b) John$_{CB}$ invited$_{CB}$ only$_{NB}$ her$_{NB}$.
(c) Whom did John invite?

It should be noted that the CB/NB distinction is not equivalent to the given/new distinction, as the pronoun "her" is NB although the cognitive entity, Mary, has already been mentioned in the discourse (therefore is given).

The following rules determine which lexical items (CB or NB) belong to the Topic or to the Focus of the sentence (Hajičová et al., 1998; Hajičová and Sgall, 2001):

1. The main verb and any of its direct dependents belong to the Focus if they are NB;
2. Every item that does not depend directly on the main verb and is subordinated to a Focus element belongs to the Focus (where "subordinated to" is defined as the irreflexive transitive closure of "depend on");
3. If the main verb and all its dependents are CB, then those dependents d_i of the verb which have subordinated items s_m that are NB are called 'proxi foci'; the items s_m together with all items subordinated to them belong to the Focus ($i, m > 1$);
4. Every item not belonging to the Focus according to 1 – 3 belongs to the Topic.

Applying these rules for the sentence (b) in example (1) we find the Topic and the Focus of the sentence: [John invited]$_{Topic}$ [only her]$_{Focus}$.

It is worth mentioning that although most of the time, CB items belong to the Topic and NB items belong to the Focus (as it happens in our example too), there may be cases when the Focus contains some NB items and/or the Topic contains some CB items. Figure 1 shows such configurations: in the top-left corner the tectogrammatical representation of sentence (1) (b) is presented together with its Topic-Focus partitioning. The other three configurations are other possible tectogrammatical trees with their Topic-Focus partitionings; the top-right one corresponds to the example (2), the bottom-left to (3), and bottom-right to (4).

(2) Q: Which teacher did Tom meet?
A: Tom$_{CB}$ met$_{CB}$ the teacher$_{CB}$ of chemistry$_{NB}$.

(3) Q: What did he think about the teachers?
A: He$_{CB}$ liked$_{NB}$ the teacher$_{CB}$ of chemistry$_{NB}$.

(4) Q: What did the teachers do?
A: The teacher$_{CB}$ of chemistry$_{NB}$ met$_{NB}$ his$_{CB}$ pupils$_{NB}$.

2.2 TFA annotation

Within PDT, the TFA attribute has been annotated for all nodes (including the restored ones) from the tectogrammatical level. Instructions for the assignment of the TFA attribute have been specified in

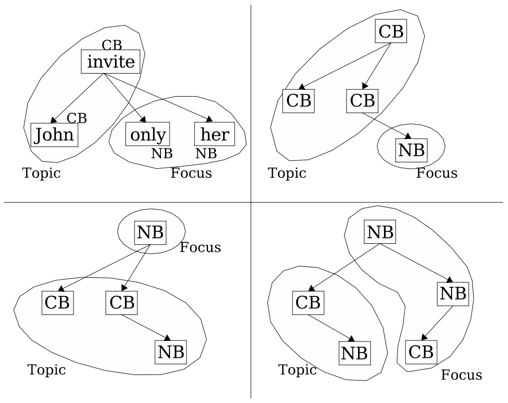

Figure 1: Topic-Focus partitionings of tectogrammatical trees.

(Buráňová et al., 2000) and are summarized in Table 1. These instructions are based on the surface word order, the position of the sentence stress (intonation center – IC)[3] and the canonical order of the dependents.

The TFA attribute has three values:

1. t — for non-contrastive CB items;
2. f — for NB items;
3. c — for contrastive CB items.

In this paper, we do not distinguish between contrastive and non-contrastive items, considering both of them as being just t. In the PDT annotation, the notation t (from topic) and f (from focus) was chosen to be used because, as we mentioned earlier, in the most common cases and in prototypical sentences, t-items belong to the Topic and f-items to the Focus.

Prior the manual annotation, the PDT corpus was preprocessed to mark all nodes with the TFA attribute of f, as it is the most common value. Then the annotators corrected the value according to the guidelines in Table 1.

Figure 2 illustrates the tectogramatical tree structure of the following sentence:

(5)	Sebevědomím	votroků	to	ale	neotřáslo.
	self-confidence	bastards	it	but not	shake

'But it did not shake the self-confidence of those bastards'.

[3] In the PDT the intonation center is not annotated. However, the annotators were instructed to use their judgement where the IC would be if they uttered the sentence.

1.	The bearer of the IC (typically, the rightmost child of the verb)	f
2.	If IC is not on the rightmost child, everything after IC	t
3.	A left-side child of the verb (unless it carries IC)	t
4.	The verb and the right children of the verb before the f-node (cf. 1) that are canonically ordered	f
5.	Embedded attributes (unless repeated or restored)	f
6.	Restored nodes	t
7.	Indexical expressions (*já* I, *ty* you, *těd* now, *tady* here), weak pronouns, pronominal expressions with a general meaning (*někdo* somebody, *jednou* once) (unless they carry IC)	t
8.	Strong forms of pronouns not preceded by a preposition (unless they carry IC)	t

Table 1: Annotation guidelines; IC = Intonation Center.

Each node is labeled with the corresponding word's lemma, the TFA attribute, and the functor attribute. For example, *votroků* has lemma *votrok*, the TFA attribute *f*, and the functor *APP* (appurtenance).

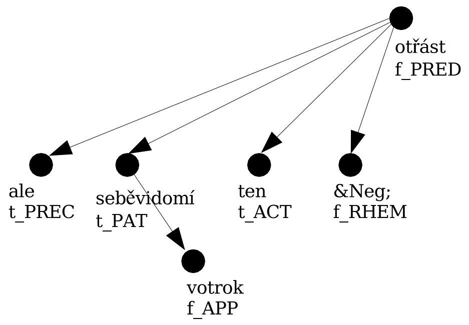

Figure 2: Tectogramatical tree annotated with t/f.

In order to measure the consistency of the annotation, Interannotator Agreement has been measured (Veselá et al., 2004).[4] During the annotation process, there were four phases in which parallel annotations have been performed; a sample of data was chosen and annotated in parallel by three annotators.

Agreement	1	2	3	4	Avg
t/c/f	81.32	81.89	76.21	89.57	82.24
t/f	85.42	83.94	84.18	92.15	86.42

Table 2: Interannotator Agreement for TFA assignment in PDT 2.0.

The agreement for each of the four phases, as well as an average agreement, is shown in Table 2. The second row of the table displays the percentage of nodes for which all three annotators assigned the same TFA value (be it t, c or f). Because in our experiments we do not differentiate between t and c, considering both as t, we computed, in the last row of the table, the agreement between the three annotators after replacing the TFA value c with t.[5]

3 Identification of topic and focus

In this section we present data-driven, machine learning approaches for automatic identification of Information Structure. For each tectogrammatical node we detect the TFA value t(opic) or f(ocus) (that is CB or NB). With these values one can apply the rules presented in Subsection 2.1 in order to find the Topic-Focus partitioning of each sentence.

3.1 Experimental settings

Our experiments use the tectogrammatical trees from The Prague Dependency Treebank 2.0.[6] Statistics of the experimental data are shown in Table 3.

Our goal is to automatically label the tectogrammatical nodes with topic or focus. We built machine learning models based on three different well known techniques, decision trees (C4.5), rule induction (RIPPER) and maximum entropy (MaxEnt), in order to find out which approach is the most suitable for our task. For C4.5 and RIPPER we use the Weka implementations (Witten and Frank, 2000) and for MaxEnt we use the openNLP package.[7]

[4] In their paper the authors don't give Kappa values, nor the complete information needed to compute a Kappa statistics ourselves.

[5] In (Veselá et al., 2004), the number of cases when the annotators disagreed when labeling t or c is reported; this allowed us to compute the t/f agreement, by disregarding this number.

[6] We are grateful to the researchers at the Charles University in Prague for providing us the data before the PDT 2.0 official release.

PDT DATA	TRAIN	DEV	EVAL	TOTAL
#files	2,536 80%	316 10%	316 10%	3,168 100%
#sentences	38,737 78.3%	5,228 10.6%	5,477 11.1%	49,442 100%
#tokens	652,700 78.3%	87,988 10.6%	92,669 11.1%	833,356 100%
#tecto-nodes	494,759 78.3%	66,711 10.5%	70,323 11.2%	631,793 100%

Table 3: PDT data: Statistics for the training, development and evaluation sets.

All our models use the same set of 35 features (presented in detail in Appendix A), divided in two types:

1. Basic features, consisting of attributes of the tectogrammatical nodes whose values were taken directly from the treebank annotation. We used a total of 25 basic features, that may have between 2 and 61 values.

2. Derived features, inspired by the annotation guidelines. The derived features are computed using the dependency information from the tectogrammatical level of the treebank and the surface order of the words corresponding to the nodes.[8] We also used lists of forms of Czech pronouns that are used as weak pronouns, indexical expressions, pronouns with general meaning, or strong pronouns. All the derived features have boolean values.

3.2 Results

The classifiers were trained on 494,759 instances (78.3%) (cf. Table 3) (tectogrammatical nodes) from the training set. The performance of the classifiers was evaluated on 70,323 instances (11.2%) from the evaluation set. We compared our models against a baseline system that assigns focus to all nodes (as it is the most common value) and against a deterministic, rule-based system, that implements the instructions from the annotation guidelines.

Table 4 shows the percentages of correctly classified instances for our models. We also performed a 10-fold cross validation, which for C4.5 gives accuracy of 90.62%.

BASELINE	RULE-BASED	C4.5	RIPPER	MAXENT
62.66	58.92	90.69	88.46*	88.97

Table 4: Correctly classified instances (the numbers are given as percentages). *The RIPPER classifier was trained with only 40% of the training data.

The baseline value is considerably high due to the topic/focus distribution in the test set (a similar distribution characterizes the training set as well). The rule-based system performs very poorly, although it follows the guidelines according to which the data was annotated. This anomaly is due to the fact that the intonation center of the sentence, which plays a very important role in the annotation, is not marked in the corpus, thus the rule-based system doesn't have access to this information.

The results show that all three models perform much better than the baseline and the rule-based system. We used the χ^2 test to examine if the difference between the three classifiers is statistically significant. The C4.5 model significantly outperforms the MaxEnt model (χ^2 = 113.9, $p < 0.001$) and the MaxEnt model significantly outperforms the RIPPER model although with a lower level of confidence (χ^2 = 9.1, $p < 0.01$).

The top of the decision tree generated by C4.5 in the training phase looks like this:

```
coref = true
|    is_member = true
|    |    POS = ...
|    is_member = false
|    |    is_rightmost = ...
coref = false
|    is_generated = true
|    |    nodetype = ...
|    is_generated = false
|    |    iterativeness = ...
```

It is worth mentioning that the RIPPER classifier was built with only 40% of the training set (with more data, the system crashes due to insufficient memory). Interestingly and quite surprisingly, the values of all three classifiers are actually greater than the interannotator agreement which has an average of 86.42%.

What is the cause of the classifiers' success? How come that they perform better than the annotators themselves? Is it because they take advantage of a

[8] In the tectogramatical level in the PDT, the order of the nodes has been changed during the annotation process of the TFA attribute, so that all t items precede all f items. Our features use the surface order of the words corresponding to the nodes.

large amount of training data? To answer this question we have computed the learning curves. They are shown in the figure 3, which shows that, actually, after using only 1% of the training data (4,947 instances), the classifiers already perform very well, and adding more training data improves the results only slightly. On the other hand, for RIPPER, adding more data causes a decrease in performance, and as we mentioned earlier, even an impossibility of building a classifier.

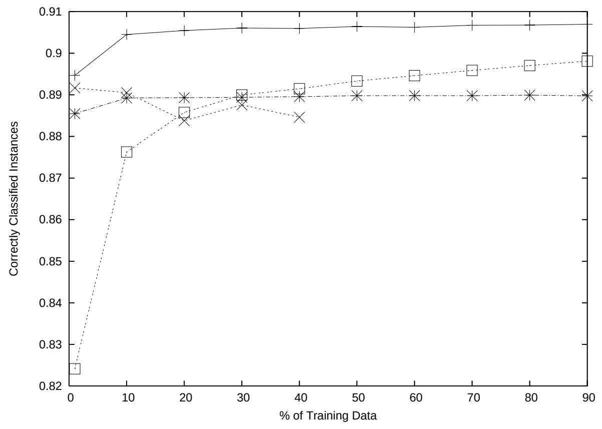

Figure 3: Learning curves for C4.5 (+), RIPPER(×), MaxEnt(∗) and a naïve predictor (□) (introduced in Section 3.3).

3.3 Error Analysis

If errors don't come from the lack of training data, then where do they come from? To answer this question we performed an error analysis. For each instance (tectogrammatical node), we considered its *context* as being the set of values for the features presented in Appendix A. Table 5 displays in the second column the number of all contexts. The last three columns divide the contexts in three groups:

1. Only t — all instances having these contexts are assigned t;
2. Only f — all instances having these contexts are assigned f;
3. Ambiguous — some instances that have these contexts are assigned t and some other are assigned f.

The last row of the table shows the number of instances for each type of context, in the training data.

	All	Only t	Only f	Ambiguous
#contexts	27,901	9,901	13,009	4,991
#instances	494,759 100%	94,056 19.01%	42,048 8.49%	358,655 72.49%

Table 5: Contexts & Instances in the training set.

Table 5 shows that the source of ambiguity (and therefore of errors) stays in 4,991 contexts that correspond to nodes that have been assigned both t and f. Moreover these contexts yield the largest amount of instances (72.49%). We investigated further these ambiguous contexts and we counted how many of them correspond to a set of nodes that are mostly assigned t (#t $>$ #f), respectively f (#t $<$ #f), and how many are highly ambiguous (half of the corresponding instances are assigned t and the other half f (#t $=$ #f)). The numbers, shown in Table 6, suggest that in the training data there are 41,851 instances (8.45%) (the sum of highlighted numbers in the third row of the Table 6) that are exceptions, meaning they have contexts that usually correspond to instances that are assigned the other TFA value. There are two explanations for these exceptions: either they are part of the annotators disagreement, or they have some characteristics that our set of features fail to capture.

	#t $>$ #f	#t $=$ #f	#t $<$ #f
#ambiguous contexts	998	833	3,155

#instances	t=50,722
	f=**4,854**
	all=55,576
	11.23%
		t=**602**
		f=**602**
		all=1,204
		0.24%
			t=**35,793**
			f=266,082
			all=301,875
			61.01%

Table 6: Ambiguous contexts in the training data.

The error analysis led us to the idea of implementing a naïve predictor. This predictor trains on the training set, and divides the contexts into five groups. Table 7 describes these five types of contexts and displays the TFA value assigned by the naïve predictor for each type.

If an instance has a context of type #t $=$ #f, we decide to assign f because this is the most common value. Also, for the same reason, new contexts in the test set that don't appear in the training set are assigned f.

The performance of the naïve predictor on the evaluation set is 89.88% (correctly classified instances), a value which is significantly higher than

Context Type	In the training set, instances with a context of this type are:	Predicted TFA value
Only t	all t	t
Only f	all f	f
#t > #f	more t than f	t
#t = #f	half t, half f	f
#t < #f	more f than t	f
unseen	not seen	f

Table 7: Naïve Predictor: its TFA prediction for each type of context.

the one obtained by the MaxEnt and RIPPER classifiers (χ^2 = 30.7, $p < 0.001$ and respectively χ^2 = 73.3, $p < 0.001$), and comparable with the C4.5 value, although the C4.5 classifier still performs significantly better (χ^2 = 26.3, $p < 0.001$).

To find out whether the naïve predictor would improve if we added more data, we computed the learning curve, shown in Figure 3. Although the curve is slightly more abrupt than the ones of the other classifiers, we do not have enough evidence to believe that more data in the training set would bring a significant improvement. We calculated the number of new contexts in the development set, and although the number is high (2,043 contexts), they correspond to only 2,125 instances. This suggests that the new contexts that may appear are very rare, therefore they cannot yield a big improvement.

4 Conclusions

In this paper we investigated the problem of learning Information Structure from annotated data. The contribution of this research is to show for the first time that IS can be successfuly recovered using mostly syntactic features. We used the Prague Dependency Treebank which is annotated with Information Structure following the Praguian theory of Topic Focus Articulation. The results show that we can reliably identify t(opic) and f(ocus) with over 90% accuracy while the baseline is at 62%.

Issues for further research include, on the one hand, a deeper investigation of the Topic-Focus Articulation in the Prague Dependency Treebank of Czech, by improving the feature set, considering also the distinction between contrastive and non-contrastive t items and, most importantly, by investigating how we can use the t/f annotation in PDT (and respectively our results) in order to detect the Topic/Focus partitioning of the whole sentence.

We also want to benefit from our experience with the Czech data in order to create an English corpus annotated with Information Structure. We have already started to exploit a parallel English-Czech corpus, in order to transfer to the English version the topic/focus labels identified by our systems.

Using Semantic Relations to Refine Coreference Decisions

Abstract

We present a novel mechanism for improving reference resolution by using the output of a relation tagger to rescore coreference hypotheses. Experiments show that this new framework can improve performance on two quite different languages -- English and Chinese.

1 Introduction

Reference resolution has proven to be a major obstacle in building robust systems for information extraction, question answering, text summarization and a number of other natural language processing tasks.

Most reference resolution systems use representations built out of the lexical and syntactic attributes of the noun phrases (or “mentions”) for which reference is to be established. These attributes may involve string matching, agreement, syntactic distance, and positional information, and they tend to rely primarily on the immediate context of the noun phrases (with the possible exception of sentence-spanning distance measures such as Hobbs distance). Though gains have been made with such methods (Tetreault 2001; Mitkov 2000; Soon et al. 2001; Ng and Cardie 2002), there are clearly cases where this sort of local information will not be sufficient to resolve coreference correctly.

Coreference is by definition a semantic relationship: two noun phrases corefer if they both refer to the same real-world entity. We should therefore expect a successful coreference system to exploit world knowledge, inference, and other forms of semantic information in order to resolve hard cases. If, for example, two nouns refer to people who work for two different organizations, we want our system to infer that these noun phrases cannot corefer. Further progress will likely be aided by flexible frameworks for representing and using the information provided by this kind of semantic relation between noun phrases.

This paper tries to make a small step in that direction. It describes a robust reference resolver that incorporates a broad range of semantic information in a general news domain. Using an ontology that describes relations between entities (the Automated Content Extraction program[1] relation ontology) along with a training corpus annotated for relations under this ontology, we first train a classifier for identifying relations. We then apply the output of this relation tagger to the task of reference resolution.

The rest of this paper is structured as follows. Section 2 briefly describes the efforts made by previous researchers to use semantic information in reference resolution. Section 3 describes our own method for incorporating document-level semantic context into coreference decisions. We propose a representation of semantic context that isolates a particularly informative structure of interaction between semantic relations and coreference. Section 4 explains in detail our strategies for using relation information to modify coreference decisions, and the linguistic intuitions behind these strategies. Section 5 then presents the system architectures and algorithms we use to incorporate relational information into reference resolution.

[1] The ACE task description can be found at http://www.itl.nist.gov/iad/894.01/tests/ace/ and the ACE guidelines at http://www.ldc.upenn.edu/Projects/ACE/

Section 6 presents the results of experiments on both English and Chinese test data. Section 7 presents our conclusions and directions for future work.

2 Prior Work

Much of the earlier work in anaphora resolution (from the 1970's and 1980's, in particular) relied heavily on deep semantic analysis and inference procedures (Charniak 1972; Wilensky 1983; Carbonell and Brown 1988; Hobbs et al. 1993). Using these methods, researchers were able to give accounts of some difficult examples, often by encoding quite elaborate world knowledge. Capturing sufficient knowledge to provide adequate coverage of even a limited but realistic domain was very difficult. Applying these reference resolution methods to a broad domain would require a large scale knowledge-engineering effort.

The focus for the last decade has been primarily on broad coverage systems using relatively shallow knowledge, and in particular on corpus-trained statistical models. Some of these systems attempt to apply shallow semantic information. (Ge et al. 1998) incorporate gender, number, and animaticity information into a statistical model for anaphora resolution by gathering coreference statistics on particular nominal-pronoun pairs. (Tetreault and Allen 2004) use a semantic parser to add semantic constraints to the syntactic and agreement constraints in their Left-Right Centering algorithm. (Soon et al. 2001) use WordNet to test the semantic compatibility of individual noun phrase pairs. In general these approaches do not explore the possibility of exploiting the global semantic context provided by the document as a whole.

Recently Bean and Riloff (2004) have sought to acquire automatically some semantic patterns that can be used as contextual information to improve reference resolution, using techniques adapted from information extraction. Their experiments were conducted on collections of texts in two topic areas (terrorism and natural disasters).

3 Relational Model of Semantic Context

Our central goal is to model semantic and coreference structures in such a way that we can take advantage of a semantic context larger than the individual noun phrase when making coreference decisions. Ideally, this model should make it possible to pick out important features in the context and to distinguish useful signals from background noise. It should, for example, be able to represent such basic relational facts as whether the (possibly identical) people referenced by two noun phrases work in the same organization, whether they own the same car, etc. And it should be able to use this information to resolve references even when surface features such as lexical or grammatical attributes are imperfect or fail altogether.

In this paper we present a Relational Coreference Model (abbreviated as RCM) that makes progress toward these goals. To represent semantic relations, we use an ontology (the ACE 2004 relation ontology) that describes 7 main types of relations between entities and 23 subtypes (Table 1).[2] These relations prove to be more reliable guides for coreference than simple lexical context or even tests for the semantic compatibility of heads and modifiers. The process of tagging relations implicitly selects relevant items of context and abstracts raw lists of modifiers into a representation that is deeper, but still relatively lightweight.

Relation Type	Example
Agent-Artifact (ART)	Rubin Military Design, the **makers** of the **Kursk**
Discourse (DISC)	**each** of **whom**
Employment/ Membership (EMP-ORG)	Mr. Smith, a senior **programmer** at **Microsoft**
Place-Affiliation (GPE-AFF)	**Salzburg** Red Cross **officials**
Person-Social (PER-SOC)	**relatives** of the **dead**
Physical (PHYS)	a **town** some 50 miles south of **Salzburg**
Other-Affiliation (Other-AFF)	**Republican senators**

Table 1. Examples of the ACE Relation Types

Given these relations we can define a semantic context for a candidate mention coreference pair (Mention 1b and Mention 2b) using the structure

[2] See http://www.ldc.upenn.edu/Projects/ACE/docs/EnglishRDCV4-3-2.PDF for a more complete description of ACE 2004 relations.

depicted in Figure 1. If both mentions participate in relations, we examine the types and directions of their respective relations as well as whether or not their relation partners (Mention 1a and Mention 2a) corefer. These values (which correspond to the edge labels in Figure 1) can then be factored into a coreference prediction. This RCM structure assimilates relation information into a coherent model of semantic context.

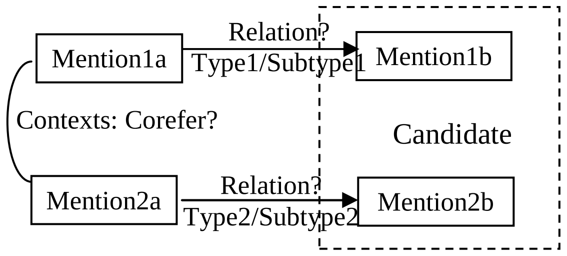

Figure 1. The RCM structure

4 Incorporating Relations into Reference Resolution

Given an instance of the RCM structure, we need to convert it into semantic knowledge that can be applied to a coreference decision. We approach this problem by constructing a set of RCM patterns and evaluating the accuracy of each pattern as positive or negative evidence for coreference. The resulting knowledge sources fall into two categories: rules that improve precision by pruning incorrect coreference links between mentions, and rules that improve recall by recovering missed links.

To formalize these relation patterns, based on Figure 1, we define the following clauses:

A: RelationType1 = RelationType2
B: RelationSubType1 = RelationSubType2
C: Two Relations have the same direction
Same_Relation: $A \wedge B \wedge C$
CorefA: Mention1a and Mention2a corefer
CorefBMoreLikely: Mention1b and Mention2b are more likely to corefer
CorefBLessLikely: Mention1b and Mention2b are less likely to corefer

From these clauses we can construct the following plausible inferences:

Rule (1)
$Same\_Relation \wedge \neg CorefA \Rightarrow CorefBLessLikely$
Rule (2)
$\neg Same\_Relation \wedge CorefA \Rightarrow CorefBLessLikely$
Rule (3)
$Same\_Relation \wedge CorefA \Rightarrow CorefBMoreLikely$

Rule (1) and (2) can be used to prune coreference links that simple string matching might incorrectly assert; and (3) can be used to recover missed mention pairs.

The accuracy of Rules (1) and (3) varies depending on the type and direction of the particular relation shared by the two noun phrases. For example, if Mention1a and Mention 2a both refer to the same nation, and Mentions 1b and 2b participate in citizenship relations (GPE-AFF) with Mentions 1a and 2a respectively, we should not necessarily conclude that 1b and 2b refer to the same person. If 1a and 2a refer to the same person, however, and 1b and 2b are nations in citizenship relations with 1a and 2a, then it would indeed be the rare case in which 1b and 2b refer to two different nations. In other words, the relation of a nation to its citizens is one-to-many.

Our system learns broad restrictions like these by evaluating the accuracy of Rules (1) and (3) when they are instantiated with each possible relation type and direction and used as weak classifiers. For each such instantiation we use cross-validation on our training data to calculate a reliability weight defined as:

$$\frac{|\text{Correct decisions by rule for given instance}|}{|\text{Total applicable cases for given instance}|}$$

We count the number of correct decisions for a rule instance by taking the rule instance as the only source of information for coreference resolution and making only those decisions suggested by the rule's implication (interpreting CorefBMoreLikely as an assertion that mention 1b and mention 2b do in fact corefer, and interpreting CorefBLessLikely as an assertion that they do not corefer).

Every rule instance with a reliability weight of 70% or greater is retained for inclusion in the final system. Rule (2) cannot be instantiated with a single type because it requires that the two relation types be different, and so we do not perform this filtering for Rule (2) (Rule (2) has 97% accuracy across all relation types).

This procedure yields 58 reliable (reliability weight > 70%) type instantiations of Rule (1) and (3), in addition to the reliable Rule 2. We can recover an additional 24 reliable rules by conjoining additional boolean tests to less reliable rules. Tests include equality of mention heads, substring matching, absence of temporal key words such as “current” and “former,” number agreement, and high confidence for original coreference decisions (Mention1b and Mention2b). For each rule below the reliability threshold, we search for combinations of 3 or fewer of these restrictions until we achieve reliability of 70% or we have exhausted the search space.

We give some examples of particular rule instances below.

Example for Rule (1)

> Bush campaign officials ... decided to tone down a post-debate rally, and were even considering canceling it.
> …
> The Bush and Gore campaigns did not talk to each other directly about the possibility of postponement, but went through the debate commission's director, Janet Brown...Eventually, Brown recommended that the debate should go on, and neither side objected, according to campaign officials.

Two mentions that do not corefer share the same nominal head (“officials”). We can prune the coreference link by noting that both occurrences of “officials” participate in an Employee-Organization (EMP-ORG) relation, while the Organization arguments of these two relation instances do not corefer (because the second occurrence refers to officials from both campaigns).

Example for Rule (2)

> Despite the increases, college remains affordable and a good investment, said College Board President Gaston Caperton in a statement with the surveys. …
> A majority of students need grants or loans -- or both -- but their exact numbers are unknown, a College Board spokesman said.

“Gaston Caperton” stands in relation EMP-ORG/Employ-Executive with “College Board”, while "a College Board spokesman" is in relation EMP-ORG/Employ-Staff with the same organization. We conclude that “Gaston Caperton” does not corefer with "spokesman."

Example for Rule (3)

> In his foreign policy debut for Syria, this Sunday Bashar Assad met Sunday with Egyptian President Hosni Mubarak in talks on Mideast peace and the escalating violence in the Palestinian territories.
> …
> The Syrian leader's visit came on a fourth day of clashes that have raged in the West Bank, Gaza Strip and Jerusalem……

If we have detected a coreference link between “Syria” and “Syrian,” as well as EMP-ORG/ Employ-Executive relations between this country and two noun phrases “Bashar Assad” and “leader”, it is likely that the two mentions both refer to the same person. Without this inference, a resolver might have difficulty detecting this coreference link.

Figure 2. System Pipeline (Test Procedure)

In this section we will describe our algorithm for incorporating semantic relation information from the RCM into the reference resolver. In a nutshell, the system applies a baseline statistical resolver to generate multiple coreference hypotheses, applies a relation tagger to acquire relation information, and uses the relation information to rescore the coreference hypotheses. This general system architecture is shown in Figure 2.

In section 5.1 below we present our baseline coreference system. In Section 5.2 we describe a system that combines the output of this baseline system with relation information to improve performance.

5.1 Baseline System

Baseline reference resolver

As the first stage in the resolution process we apply a baseline reference resolver that uses no relation information at all. This baseline resolver goes through two successive stages.

First, high-precision heuristic rules make some positive and negative reference decisions. Rules include simple string matching (e.g., names that match exactly are resolved), agreement constraints (e.g., a nominal will never be resolved with an entity that doesn't agree in number), and reliable syntactic cues (e.g., mentions in apposition are resolved). When such a rule applies, it assigns a confidence value of 1 or 0 to a candidate mention-antecedent pair.

The remaining pairs are assigned confidence values by a collection of maximum entropy models. Since different mention types have different coreference problems, we separate the system into different models for names, nominals, and pronouns. Each model uses a distinct feature set, and for each instance only one of these three models is used to produce a probability that the instance represents a correct resolution of the mention. When the baseline is used as a standalone system, we apply a threshold to this probability: if some resolution has a confidence above the threshold, the highest confidence resolution will be made. Otherwise the mention is assumed to be the first mention of an entity. When the baseline is used as a component of the system depicted in figure 2, the confidence value is passed on to the rescoring stage described in 5.2 below.

Both the English and the Chinese coreference models incorporate features representing agreement of various kinds between noun phrases (number, gender, humanness), degree of string similarity, synonymy between noun phrase heads, measures of distance between noun phrases (such as the number of intervening sentences), the presence or absence of determiners or quantifiers, and a wide variety of other properties.

Relation tagger

The relation tagger uses a K-nearest-neighbor algorithm. We consider a mention pair as a possible instance of a relation only when: (1) there is at most one other mention between their heads, and (2) the coreference probability produced for the pair by the baseline resolver is lower than a threshold. Each training / test example consists of the pair of mentions and the sequence of intervening words. We defined a distance metric between two examples based on:

- ❑ whether the heads of the mentions match
- ❑ whether the ACE types of the heads of the mentions match (for example, both are people or both are organizations)
- ❑ whether the intervening words match

To tag a test example, we find the k nearest training examples, use the distance to weight each neighbor, and then select the most heavily weighted class in the weighted neighbor set.

Name tagger and noun phrase chunker

Our baseline name tagger consists of a HMM tagger augmented with a set of post-processing rules. The HMM tagger generally follows the Nymble model (Bikel et al. 1997), but with a larger number of states (12 for Chinese, 30 for English) to handle name prefixes and suffixes, and, for Chinese, transliterated foreign names separately. For Chinese it operates on the output of a word segmenter from Tsinghua University. Our nominal mention tagger (noun phrase chunker) is a maximum entropy tagger trained on treebanks from the University of Pennsylvania.

5.2 Rescoring stage

To incorporate information from the relation tagger into the final coreference decision, we split the maxent classification into two stages. The first stage simply applies the baseline maxent models, without any relation information, and produces a probability of coreference. This probability becomes a feature in the second (rescoring) stage of maxent classification, together with features representing the relation knowledge sources. If a high reliability instantiation of one of the RCM rules (as defined in section 4 above) applies to a given mention-antecedent pair, we include the following features for that pair: the type of the RCM rule, the reliability of the rule instantiation, the relation type and subtype, the direction of the relation, and the tokens for the two mentions.

The second stage helps to increase the margin between correct and incorrect links and so effects better disambiguation. See figure 3 below for a more detailed description of the training and testing processes.

Training

1. Calculate reliability weights of relation knowledge sources using cross-validation (for each of k divisions of training data, train relation tagger on k – 1 divisions, tag relations in remaining division and compute reliability of each relation knowledge source using this division).
2. Use high reliability relation knowledge sources to generate relation features for 2nd stage Maxent training data.
3. Apply baseline coreference resolver to 2nd stage training data.
4. Using output of both 2 and 3 as features, train 2nd stage Maxent resolver.

Test

1. Tag relations.
2. Convert relation knowledge sources into features for second stage Maxent models.
3. Use baseline Maxent models to get coreference probabilities for use as features in second stage Maxent models.
4. Using output of 2 and 3 as features for 2nd stage Maxent model, apply 2nd stage resolver to make final coreference decisions.

Figure 3. Training and Testing Processes

6 Evaluation Results

6.1 Corpora

We evaluated our system on two languages: English and Chinese. The following are the training corpora used for the components in these two languages.

English

For English, we trained the baseline maxent coreference model on 311 newswire and newspaper texts from the ACE 2002 and ACE 2003 training corpora. We trained the relation tagger on 328 ACE 2004 texts. We used 126 newswire texts from the ACE 2004 data to train the English second-stage model, and 65 newswire texts from the ACE 2004 evaluation set as a test set for the English system.

Chinese

For Chinese, the baseline reference resolver was trained on 767 texts from ACE 2003 and ACE 2004 training data. Both the baseline relation tagger and the rescoring model were trained on 646 texts from ACE 2004 training data. We used 100 ACE texts for a final blind test.

6.2 Experiments

We used the MUC coreference scoring metric (Vilain et al 1995) to evaluate[3] our systems.

To establish an upper limit for the possible improvement offered by our models, we first did experiments using perfect (hand-tagged) mentions and perfect relations as inputs. The algorithms for

[3] In our scoring, we use the ACE keys and only score mentions which appear in both the key and system response. This therefore includes only mentions identified as being in the ACE semantic categories by both the key and the system response. Thus these scores cannot be directly compared against coreference scores involving all noun phrases. (Ng 2005) applies another variation on the MUC metric to several systems tested on the ACE data by scoring all response mentions against all key mentions. For coreference systems that don't restrict themselves to mentions in the ACE categories (or that don't succeed in so restricting themselves), this scoring method could lead to some odd effects. For example, systems that recover more correct links could be penalized for this greater recall because all links involving non-ACE mentions will be incorrect according to the ACE key. For the sake of comparison, however, we present here English system results measured according to this metric: On newswire data, our baseline had an F of 62.8 and the rescoring method had an F of 64.2. Ng's best F score (on newspaper data) is 69.3. The best F score of the (Ng and Cardie 2002) system (also on newspaper data) is 62.1. On newswire data the (Ng 2005) system had an F score of 54.7 and the (Ng and Cardie 2002) system had an F score of 50.1. Note that Ng trained and tested these systems on different ACE data sets than those we used for our experiments.

these experiments are identical to those described above except for the omission of the relation tagger training. Tables 2 and 3 show the performance of the system for English and Chinese.

Performance	Recall	Precision	F-measure
Baseline	74.5	86.6	80.1
Rescoring	78.3	87.0	82.4

Table 2. Performance of English system with perfect mentions and perfect relations

Performance	Recall	Precision	F-measure
Baseline	87.5	83.2	85.3
Rescoring	88.8	84.7	86.7

Table 3. Performance of Chinese system with perfect mentions and perfect relations

We can see that the relation information provided some improvements for both languages. Relation information increased both recall and precision in both cases.

We then performed experiments to evaluate the impact of coreference rescoring when used with mentions and relations produced by the system. Table 4 and Table 5 list the results.[4]

Performance	Recall	Precision	F-measure
Baseline	77.2	87.3	81.9
Rescoring	80.3	87.5	83.7

Table 4. Performance of English system with system mentions and system relations

Performance	Recall	Precision	F-measure
Baseline	75.0	76.3	75.6
Rescoring	76.1	76.5	76.3

Table 5. Chinese system performance with system mentions and system relations

[4] Note that, while English shows slightly less relative gain from rescoring when using system relations and mentions, all of these scores are higher than the perfect mention/perfect relation scores. This increase may be a byproduct of the fact that the system mention tagger output contains almost 8% fewer scoreable mentions than the perfect mention set (see footnote 3). With a difference of this magnitude, the particular mention set selected can be expected to have a sizable impact on the final scores.

The improvement provided by rescoring in trials using mentions and relations detected by the system is considerably less than the improvement in trials using perfect mentions and relations, particularly for Chinese. The performance of our relation tagger is the most likely cause for this difference. We would expect further gain after improving the relation tagger.

A sign test applied to a 5-way split of each of the test corpora indicated that for both languages, for both perfect and system mentions/relations, the system that exploited relation information significantly outperformed the baseline (at the 95% confidence level, judged by F measure).

6.3 Error Analysis

Errors made by the RCM rules reveal both the drawbacks of using a lightweight semantic representation and the inherent difficulty of semantic analysis. Consider the following instance:

> Card's interest in politics began when he became **president** of **the class of 1965 at Holbrook High School**…In 1993, he became **president** and chief executive of **the American Automobile Manufacturers Association**, where he oversaw the lobbying against tighter fuel-economy and air pollution regulations for automobiles…

The two occurrences of “president” should corefer even though they have EMP-ORG/Employ-Executive relations with two different organizations. The relation rule (Rule 1) fails here because it doesn't take into account the fact that relations change over time (in this case, the same person filling different positions at different times). In these and other cases, a little knowledge is a dangerous thing: a more complete schema might be able to deal more thoroughly with temporal and other essential semantic dimensions.

Nevertheless, performance improvements indicate that the rewards of the RCM’s simple semantic representation outweigh the risks.

7 Conclusion and Future Work

We have outlined an approach to improving reference resolution through the use of semantic relations, and have described a system which can exploit these semantic relations effectively. Our experiments on English and Chinese data showed that these small inroads into semantic territory do indeed offer performance improvements. Furthermore, the method is low-cost and not domain-specific.

These experiments also suggest that some gains can be made through the exploration of new architectures for information extraction applications. The "resolve coreference, tag relations, resolve coreference" procedure described above could be seen as one and a half iterations of a "resolve coreference then tag relations" loop. Seen in this way, the system poses the question of whether further gains could be made by pushing the iterative approach further. Perhaps by substituting an iterative procedure for the pipeline architecture's linear sequence of stages we can begin to address the knotty, mutually determining nature of the interaction between semantic relations and coreference relations. This approach could be applied more broadly, to different NLP tasks, and also more deeply, going beyond the simple one-and-a-half-iteration procedure we present here. Ultimately, we would want this framework to boost the performance of each component automatically and significantly.

We also intend to extend our method both to cross-document relation detection and to event detection.

Abstract

The paper proposes a Constrained Entity-Alignment F-Measure (CEAF) for evaluating coreference resolution. The metric is computed by aligning reference and system entities (or coreference chains) with the constraint that a system (reference) entity is aligned with at most one reference (system) entity. We show that the best alignment is a maximum bipartite matching problem which can be solved by the Kuhn-Munkres algorithm. Comparative experiments are conducted to show that the widely-known MUC F-measure has serious flaws in evaluating a coreference system. The proposed metric is also compared with the ACE-Value, the official evaluation metric in the Automatic Content Extraction (ACE) task, and we conclude that the proposed metric possesses some properties such as symmetry and better interpretability missing in the ACE-Value.

1 Introduction

A working definition of coreference resolution is partitioning the noun phrases we are interested in into equivalence classes, each of which refers to a physical entity. We adopt the terminologies used in the Automatic Content Extraction (ACE) task (NIST, 2003a) and call each individual phrase a *mention* and equivalence class an *entity*. For example, in the following text segment,

> (1): "The American Medical Association voted yesterday to install the heir apparent as its president-elect, rejecting a strong, upstart challenge by a district doctor who argued that the nation's largest physicians' group needs stronger ethics and new leadership."

mentions are underlined, "American Medical Association", "its" and "group" refer to the same organization (object) and they form an entity. Similarly, "the heir apparent" and "president-elect" refer to the same person and they form another entity. It is worth pointing out that the entity definition here is different from what used in the Message Understanding Conference (MUC) task (MUC, 1995; MUC, 1998) – ACE entity is called coreference chain or equivalence class in MUC, and ACE mention is called entity in MUC.

An important problem in coreference resolution is how to evaluate a system's performance. A good performance metric should have the following two properties:

- Discriminativity: This refers to the ability to differentiate a good system from a bad one. While this criterion sounds trivial, not all performance metrics used in the past possess this property.

- Interpretability: A good metric should be easy to interpret. That is, there should be an intuitive sense of how good a system is when a metric suggests that a certain percentage of coreference results are correct. For example, when a metric reports 95% or above correct for a system, we would expect that the vast majority of mentions are in right entities or coreference chains.

A widely-used metric is the link-based F-measure (Vilain et al., 1995) adopted in the MUC task. It is computed by first counting the number of common links between the reference (or "truth") and the system output (or "response"); the link precision is the number of common links divided by the number of links in the system output, and the link recall is the number of common links divided by the number of links in the reference. There are known problems associated with the link-based F-measure. First, it ignores single-mention entities since no link can be found in these entities; Second, and more importantly, it fails to distinguish system outputs with different qualities: the link-based F-measure intrinsically favors systems producing fewer entities, and may result in higher F-measures for worse systems. We will revisit these issues in Section 3.

To counter these shortcomings, Bagga and Baldwin (1998) proposed a B-cubed metric, which first computes a precision and recall for each individual mention, and then takes the weighted sum of these individual precisions and recalls as the final metric. While the B-cubed metric fixes some of the shortcomings of the MUC F-measure, it has its own problems: for example, the mention precision/recall is computed by comparing entities containing the mention and therefore an entity can be used more than once. The implication of this drawback will be revisited in Section 3.

In the ACE task, a value-based metric called ACE-value (NIST, 2003b) is used. The ACE-value is computed by counting the number of false-alarm, the number of miss, and the number of mistaken entities. Each error is associated with a cost factor that depends on things such as entity type (e.g., "LOCATION", "PERSON"), and mention level (e.g., "NAME," "NOMINAL," and "PRONOUN"). The total cost is the sum of the three costs, which is then normalized against the cost of a nominal system that does not output any entity. The ACE-value is finally computed by subtracting the normalized cost from 1. A perfect coreference system will get a 100% ACE-value while a system outputs no entities will get a 0 ACE-value. A system outputting many erroneous entities could even get negative ACE-value. The ACE-value is computed by aligning entities and thus avoids the problems of the MUC F-measure. The ACE-value is, however, hard to interpret: a system with 90% ACE-value does not mean that 90% of system entities or mentions are correct, but that the cost of the system, relative to the one outputting no entity, is 10%.

In this paper, we aim to develop an evaluation metric that is able to measure the quality of a coreference system – that is, an intuitively better system would get a higher score than a worse system, and is easy to interpret. To this end, we observe that coreference systems are to recognize *entities* and propose a metric called Constrained Entity-Aligned F-Measure (CEAF). At the core of the metric is the optimal one-to-one map between subsets of reference and system entities: system entities and reference entities are aligned by maximizing the total entity similarity under the constraint that a reference entity is aligned with at most one system entity, and vice versa. Once the total similarity is defined, it is straightforward to compute recall, precision and F-measure. The constraint imposed in the entity alignment makes it impossible to "cheat" the metric: a system outputting too many entities will be penalized in precision while a system outputting two few entities will be penalized in recall. It also has the property that a perfect system gets an F-measure 1 while a system outputting no entity or no common mentions gets an F-measure 0. The proposed CEAF has a clear meaning: for mention-based CEAF, it reflects the percentage of mentions that are in the correct entities; For entity-based CEAF, it reflects the percentage of correctly recognized entities.

The rest of the paper is organized as follows. In Section 2, the Constrained Entity-Alignment F-Measure is presented in detail: the constraint entity alignment can be represented by a bipartite graph and the optimal alignment can be found by the Kuhn-Munkres algorithm (Kuhn, 1955; Munkres, 1957). We also present two entity-pair similarity measures that can be used in CEAF: one is the absolute number of common mentions between two entities, and the other is a "local" mention F-measure between two entities. The two measures lead to the mention-based and entity-based CEAF, respectively. In Section 3, we compare the proposed metric with the MUC link-based metric and ACE-value on both artificial and real data, and point out the problems of the MUC F-measure.

2 Constrained Entity-Alignment F-Measure

Some notations are needed before we present the proposed metric and the algorithm to compute the metric.

Let reference entities in a document d be

$$\mathcal{R}(d) = \{R_i : i = 1, 2, \cdots, |\mathcal{R}(d)|\},$$

and system entities be

$$\mathcal{S}(d) = \{S_i : i = 1, 2, \cdots, |\mathcal{S}(d)|\}.$$

To simplify typesetting, we will omit the dependency on d when it is clear from context, and write $\mathcal{R}(d)$ as $\mathcal{R}$ and $\mathcal{S}(d)$ as $\mathcal{S}$.

Let

$$\begin{aligned} m &= \min\{|\mathcal{R}|, |\mathcal{S}|\} \\ M &= \max\{|\mathcal{R}|, |\mathcal{S}|\}, \end{aligned}$$

and let $\mathcal{R}_m \subset \mathcal{R}$ and $\mathcal{S}_m \subset \mathcal{S}$ be any subsets with m entities. That is, $|\mathcal{R}_m| = m$ and $|\mathcal{S}_m| = m$. Let $G(\mathcal{R}_m, \mathcal{S}_m)$ be the set of one-to-one entity maps from $\mathcal{R}_m$ to $\mathcal{S}_m$, and G_m be the set of all possible one-to-one maps between the size-m subsets of $\mathcal{R}$ and $\mathcal{S}$. Or

$$\begin{aligned} G(\mathcal{R}_m, \mathcal{S}_m) &= \{g : \mathcal{R}_m \mapsto \mathcal{S}_m\}, \\ G_m &= \cup_{(\mathcal{R}_m, \mathcal{S}_m)} G(\mathcal{R}_m, \mathcal{S}_m). \end{aligned}$$

The requirement of one-to-one map means that for any $g \in G(\mathcal{R}_m, \mathcal{S}_m)$, and any $R \in \mathcal{R}_m$ and $R' \in \mathcal{R}_m$, we have that $R \neq R'$ implies that $g(R) \neq g(R')$, and $g(R) \neq g(R')$ implies that $R \neq R'$. Clearly, there are $m!$ one-to-one maps from $\mathcal{R}_m$ to $\mathcal{S}_m$ (or $|G(\mathcal{R}_m, \mathcal{S}_m)| = m!$), and $|G_m| = \binom{M}{m} m!$.

Let $\phi(R, S)$ be a "similarity" measure between two entities R and S. $\phi(R, S)$ takes non-negative value: zero value means that R and S have nothing in common. For example, $\phi(R,S)$ could be the number of common mentions shared by R and S, and $\phi(R,R)$ the number of mentions in entity R.

For any $g \in G_m$, the total similarity $\Phi(g)$ for a map g is the sum of similarities between the aligned entity pairs: $\Phi(g) = \sum_{R \in \mathcal{R}_m} \phi(R, g(R))$. Given a document d, and its reference entities $\mathcal{R}$ and system entities $\mathcal{S}$, we can find the best alignment maximizing the total similarity:

$$\begin{aligned} g^* &= \arg\max_{g \in G_m} \Phi(g) \\ &= \arg\max_{g \in G_m} \sum_{R \in \mathcal{R}_m} \phi(R, g(R)). \end{aligned} \tag{1}$$

Let $\mathcal{R}_m^*$ and $\mathcal{S}_m^* = g^*(\mathcal{R}_m^*)$ denote the reference and system entity subsets where g^* is attained, respectively. Then the maximum total similarity is

$$\Phi(g^*) = \sum_{R \in \mathcal{R}_m^*} \phi(R, g^*(R)). \tag{2}$$

If we insist that $\phi(R,S) = 0$ whenever R or S is empty, then the non-negativity requirement of $\phi(R,S)$ makes it unnecessary to consider the possibility of mapping one entity to an empty entity since the one-to-one map maximizing $\Phi(g)$ must be in G_m.

Since we can compute the entity self-similarity $\phi(R,R)$ and $\phi(S,S)$ for any $R \in \mathcal{R}$ and $S \in \mathcal{S}$ (i.e., using the identity map), we are now ready to define the precision, recall and F-measure as follows:

$$p = \frac{\Phi(g^*)}{\sum_i \phi(S_i, S_i)} \tag{3}$$

$$r = \frac{\Phi(g^*)}{\sum_i \phi(R_i, R_i)} \tag{4}$$

$$F = \frac{2pr}{p+r}. \tag{5}$$

The optimal alignment g^* involves only $m = \min\{|\mathcal{R}|, |\mathcal{S}|\}$ reference and system entities, and entities not aligned do not get credit. Thus the F-measure (5) penalizes a coreference system that proposes too many (i.e., lower precision) or too few entities (i.e., lower recall), which is a desired property.

In the above discussion, it is assumed that the similarity measure $\phi(R,S)$ is computed for all entity pair (R,S). In practice, computation of $\phi(R,S)$ can be avoided if it is clear that R and S have nothing in common (e.g., if no mention in R and S overlaps, then $\phi(R,S) = 0$). These entity pairs are not linked and they will not be considered when searching for the optimal alignment. Consequently the optimal alignment could involve less than m reference and system entities. This can speed up considerably the F-measure computation when the majority of entity pairs have zero similarity. Nevertheless, summing over m entity pairs in the general formulae (2) does not change the optimal total similarity between $\mathcal{R}$ and $\mathcal{S}$ and hence the F-measure.

In formulae (3)-(5), there is only one document in the test corpus. Extension to corpus with multiple test documents is trivial: just accumulate statistics on the per-document basis for both denominators and numerators in (3) and (4), and find the ratio of the two.

So far, we have tacitly kept abstract the similarity measure $\phi(R,S)$ for entity pair R and S. We will defer the discussion of this metric to Section 2.2. Instead, we first present the algorithm computing the F-measure (3)-(5).

2.1 Computing Optimal Alignment and F-measure

A naive implementation of (1) would enumerate all the possible one-to-one maps (or alignments) between size-m (recall that $m = \min\{|\mathcal{R}|, |\mathcal{S}|\}$) subsets of $\mathcal{R}$ and size-m subsets of $\mathcal{S}$, and find the best alignment maximizing the similarity. Since this requires computing the similarities between mM entity pairs and there are $|G_m| = \binom{M}{m} m!$ possible one-to-one maps, the complexity of this implementation is $O(Mm + \binom{M}{m} m!)$. This is not satisfactory even for a document with a moderate number of entities: it will have about 3.6 million operations for $M = m = 10$, a document with only 10 reference and 10 system entities.

Fortunately, the entity alignment problem under the constraint that an entity can be aligned at most once is the classical maximum bipartite matching problem and there exists an algorithm (Kuhn, 1955; Munkres, 1957) (henceforth Kuhn-Munkres Algorithm) that can find the optimal solution in polynomial time. Casting the entity alignment problem as the maximum bipartite matching is trivial: each entity in $\mathcal{R}$ and $\mathcal{S}$ is a vertex and the node pair (R,S), where $R \in \mathcal{R}$, $S \in \mathcal{S}$, is connected by an edge with the weight $\phi(R,S)$. Thus the problem (1) is exactly the maximum bipartite matching.

With the Kuhn-Munkres algorithm, the procedure to compute the F-measure (5) can be described as Algorithm 1.

Algorithm 1 Computing the F-measure (5).

```
Input: reference entities:$\mathcal{R}$;    system entities: $\mathcal{S}$
Output: optimal alignment $g^*$; F-measure (5).
1:Initialize: $g^* = \emptyset$; $\Phi(g^*) = 0$.
2:For $i = 1$ to $|\mathcal{R}|$
3:   For $j = 1$ to $|\mathcal{S}|$
4:       Compute $\phi(R_i, S_j)$.
5:[$g^*$,$\Phi(g^*)$]=KM$\big(\{\phi(R,S) : R \in \mathcal{R}, S \in \mathcal{S}\}\big)$.
6:$\Phi(\mathcal{R}) = \sum_{R \in \mathcal{R}} \phi(R,R)$; $\Phi(\mathcal{S}) = \sum_{S \in \mathcal{S}} \phi(S,S)$.
7:$r = \frac{\Phi(g^*)}{\Phi(\mathcal{R})}$; $p = \frac{\Phi(g^*)}{\Phi(\mathcal{S})}$; $F = \frac{2pr}{p+r}$.
8:return $g^*$ and $F$.
```

The input to the algorithm are reference entities $\mathcal{R}$ and system entities $\mathcal{S}$. The algorithm returns the best one-to-one map g^* and F-measure in equation (5). Loop from line 2 to 4 computes the similarity between all the possible reference and system entity pairs. The complexity of this loop is $O(Mm)$. Line 5 calls the Kuhn-Munkres algorithm, which takes as input the entity-pair scores $\{\phi(R,S)\}$ and outputs the best map g^* and the corresponding total similarity $\Phi(g^*)$. The worst case (i.e., when all entries in $\{\phi(R,S)\}$ are non-zeros) complexity of the Kuhn-Algorithm is $O(Mm^2 \log m)$. Line 6 computes "self-similarity" $\Phi(\mathcal{R})$ and $\Phi(\mathcal{S})$ needed in the F-measure computation at Line 7.

The core of the F-measure computation is the Kuhn-Munkres algorithm at line 5. The algorithm is initially discovered by Kuhn (1955) and Munkres (1957) to solve the matching (a.k.a assignment) problem for square matrices. Since then, it has been extended to rectangular matrices (Bourgeois and Lassalle, 1971) and parallelized (Balas et al., 1991). A recent review can be found in (Gupta and Ying, 1999), which also details the techniques of fast implementation. A short description of the algorithm is included in Appendix for the sake of completeness.

2.2 Entity Similarity Metric

In this section we consider the entity similarity metric $\phi(R,S)$ defined on an entity pair (R,S). It is desirable that $\phi(R,S)$ is large when R and S are "close" and small when R and S are very different. Some straight-forward choices could be

$$\phi_1(R,S) = \{ \begin{array}{ll} 1, & \text{if } R = S \\ 0, & \text{otherwise.} \end{array} \quad (6)$$

$$\phi_2(R,S) = \{ \begin{array}{ll} 1, & \text{if } R \cap S \neq \emptyset \\ 0, & \text{otherwise.} \end{array} \quad (7)$$

(6) insists that two entity are the same if all the mentions are the same, while (7) goes to the other extreme: two entities are the same if they share at least one common mention.

(6) does not offer a good granularity of similarity: For example, if $R = \{a,b,c\}$, and one system response is $S_1 = \{a,b\}$, and the other system response $S_2 = \{a\}$, then clearly S_1 is more similar to R than S_2, yet $\phi(R,S_1) = \phi(R,S_2) = 0$. For the same reason, (7) lacks of the desired discriminativity as well.

From the above argument, it is clear that we want to have a metric that can measure the degree to which two entities are similar, not a binary decision. One natural choice is measuring how many common mentions two entities share, and this can be measured by the absolute number or relative number:

$$\phi_3(R,S) = |R \cap S| \quad (8)$$

$$\phi_4(R,S) = \frac{2|R \cap S|}{|R| + |S|}. \quad (9)$$

Metric (8) simply counts the number of common mentions shared by R and S, while (9) is the mention F-measure between R and S, a relative number measuring how similar R and S are. For the abovementioned example,

$$\begin{aligned} \phi_3(R,S_1) &= \phi_3(\{a,b,c\},\{a,b\}) = 2 \\ \phi_3(R,S_2) &= \phi_3(\{a,b,c\},\{a\}) = 1 \\ \phi_4(R,S_1) &= \phi_4(\{a,b,c\},\{a,b\}) = 0.8 \\ \phi_4(R,S_2) &= \phi_4(\{a,b,c\},\{a\}) = 0.5, \end{aligned}$$

thus both metrics give the desired ranking $\phi_3(R,S_1) > \phi_3(R,S_2)$, $\phi_4(R,S_1) > \phi_4(R,S_2)$.

If $\phi_3(\cdot,\cdot)$ is adopted in Algorithm 1, $\Phi(g^*)$ is the number of total common mentions corresponding to the best one-to-one map g^* while the denominators of (3) and (4) are the number of proposed mentions and the number of system mentions, respectively. The F-measure in (5) can be interpreted as the ratio of mentions that are in the "right" entities. Similarly, if $\phi_4(\cdot,\cdot)$ is adopted in Algorithm 1, the denominators of (3) and (4) are the number of proposed entities and the number of system entities, respectively, and the F-measure in (5) can be understood as the ratio of correct entities. Therefore, (5) is called mention-based CEAF and entity-based CEAF when (8) and (9) are used, respectively.

$\phi_3(\cdot,\cdot)$ and $\phi_4(\cdot,\cdot)$ are two reasonable entity similarity measures, but by no means the only choices. At mention level, partial credit could be assigned to two mentions with different but overlapping spans; or when mention type is available, weights defined on the type confusion matrix can be incorporated. At entity level, entity attributes, if avaiable, can be weighted in the similarity measure as well. For example, ACE data defines three entity classes: NAME, NOMINAL and PRONOUN. Different weights can be assigned to the three classes.

No matter what entity similarity measure is used, it is crucial to have the constraint that the document-level similarity between reference entities and system entities is calculated over the best one-to-one map. We will see examples in Section 3 that misleading results could be produced without the alignment constraint.

Another observation is that the same evaluation paradigm can be used in any scenario that needs to measure the "closeness" between a set of system and reference objects, provided that a similarity between two objects is defined. For example, the 2004 ACE tasks include detecting and recognizing relations in text documents. A relation instance can be treated as an object and the same evaluation paradigm can be applied.

3 Comparison with Other Metrics

In this section, we compare the proposed F-measure with the MUC link-based F-measure (and its variation B-cube F-measure) and the more recent ACE-value. The

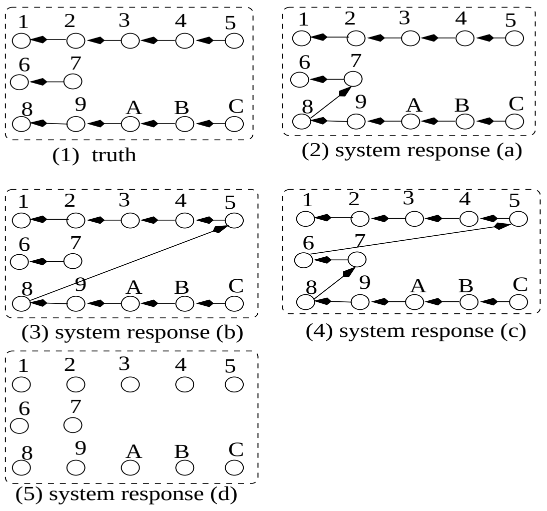

Figure 1: Example entities: (1)truth; (2)system response (a); (3)system response (b); (4)system response (c); (5)system response (d)

proposed metric has fixed problems associated with the MUC and B-cube F-measure, and has better interpretability than the ACE-value.

3.1 Comparison with the MUC F-measure and B-cube Metric on Artificial Data

We use the example in Figure 1 to compare the MUC link-based F-measure, B-cube, and the proposed mention- and entity-based CEAF. In Figure 1, mentions are represented in circles and mentions in an entity are connected by arrows. Intuitively, if each mention is treated equally, the system response (a) is better than the system response (b) since the latter mixes two big entities, $\{1, 2, 3, 4, 5\}$ and $\{8, 9, A, B, C\}$, while the former mixes a small entity $\{6, 7\}$ with one big entity $\{8, 9, A, B, C\}$. System response (b) is clearly better than system response (c) since the latter puts all the mentions into a single entity while (b) has correctly separated the entity $\{6, 7\}$ from the rest. The system response (d) is the worst: the system does not link any mentions and outputs 12 single-mention entities.

Table 1 summarizes various F-measures for system response (a) to (d): the first column contains the indices of the system responses found in Figure 1; the second and third columns are the MUC F-measure and B-cubic F-measure respectively; the last two columns are the proposed CEAF F-measures, using the entity similarity metric $\phi_3(\cdot,\cdot)$ and $\phi_4(\cdot,\cdot)$, respectively.

As shown in Table 1, the MUC link-based F-measure fails to distinguish the system response (a) and the system response (b) as the two are assigned the same F-measure. The system response (c) represents a trivial output: all mentions are put in the same entity. Yet the MUC metric will lead to a 100% recall (9 out of 9 reference links are

System response	MUC	B-cube	CEAF	
			$\phi_3(\cdot,\cdot)$	$\phi_4(\cdot,\cdot)$
(a)	0.947	0.865	0.833	0.733
(b)	0.947	0.737	0.583	0.667
(c)	0.900	0.545	0.417	0.294
(d)	–	0.400	0.250	0.178

Table 1: Comparison of coreference evaluation metrics

correct) and a 81.2% precision (9 out of 11 system links are correct), which gives rise to a 90% F-measure. It is striking that a "bad" system response gets such a high F-measure. Another problem with the MUC link-based metric is that it is not able to handle single-mention entities, as there is no link for a single mention entity. That is why the entry for system response (d) in Table 1 is empty.

B-cube F-measure ranks the four system responses in Table 1 as desired. This is because B-cube metric (Bagga and Baldwin, 1998) is computed based on mentions (as opposed to links in the MUC F-measure). But B-cube uses the same entity "intersecting" procedure found in computing the MUC F-measure (Vilain et al., 1995), and it sometimes can give counter-intuitive results. To see this, let us take a look at recall and precision for system response (c) and (d) for B-cube metric. Notice that all the reference entities are found after intersecting with the system responsce (c): $\{\{1, 2, 3, 4, 5\}, \{6, 7\}, \{8, 9, A, B, C\}\}$. Therefore, B-cube recall is 100% (the corresponding precision is $\frac{1}{12} * (10 * \frac{5}{12} + 2 * \frac{2}{12}) = 0.375$). This is counter-intuitive because the set of reference entities is not a subset of the proposed entities, thus the system response should not have gotten a 100% recall. The same problem exists for the system response (d): it gets a 100% B-cube precision (the corresponding B-cube recall is $\frac{1}{12}(5 * \frac{1}{5} + 2 * \frac{1}{2} + 5 * \frac{1}{5}) = 0.25$), but clearly not all the entities in the system response (d) are correct! These numebrs are summarized in Table 2, where columns with R and P represent recall and precision, respectively.

System response	B-cube		CEAF			
	R	P	ϕ_3-R	ϕ_3-P	ϕ_4-R	ϕ_4-P
(c)	1.0	0.375	0.417	0.417	0.196	0.588
(d)	0.25	1.0	0.250	0.250	0.444	0.111

Table 2: Example of counter-intuitive B-cube recall or precision: system repsonse (c) gets 100% recall (column R) while system repsonse (d) gets 100% precision (column P). The problem is fixed in both CEAF metrics.

The counter-intuitive results associated with the MUC and B-cube F-measures are rooted in the procedure of "intersecting" the reference and system entities, which allows an entity to be used more than once! We will come back to this after discussing the CEAF numbers.

From Table 1, we see that both mention-based (column under $\phi_3(\cdot,\cdot)$) CEAF and entity-based ($\phi_4(\cdot,\cdot)$) CEAF are able to rank the four systems properly: system (a) to (d) are increasingly worse. To see how the CEAF numbers are computed, let us take the system response (a) as an example: first, the best one-one entity map is determined. In this case, the best map is: the reference entity $\{1,2,3,4,5\}$ is aligned to the system entity $\{1,2,3,4,5\}$, the reference entity $\{8,9,A,B,C\}$ is aligned to the system $\{6,7,8,9,A,B,C\}$ and the reference entity $\{6,7\}$ is unaligned. The number of common mentions is therefore 10 which results in a mention-based ($\phi_3(\cdot,\cdot)$) recall $\frac{5}{6}$ and precision $\frac{5}{6}$. Since $\phi_4(\{1,2,3,4,5\},\{1,2,3,4,5\}) = 1$, and $\phi_4(\{8,9,A,B,C\},\{6,7,8,9,A,B,C\}) = \frac{10}{12}$, $\Phi(g^*) = 1 + \frac{10}{12}$ (c.f. equation (4) and (3)), and the entity-based F-measure (c.f. equation (9)) is therefore

$$\frac{2 * (1+\frac{10}{12})}{3+2} = \frac{11}{15} = 0.733.$$

CEAF for other system responses are computed similarly.

CEAF recall and precision breakdown for system (c) and (d) are listed in column 4 through 7 of Table 1. As can be seen, neither mention-based nor entity-based CEAF has the abovementioned problem associated with the B-cube metric, and the recall and precision numbers are more or less compatible with our intuition: for instance, for system (c), based on ϕ_3-CEAF number, we can say that about 41.7% mentions are in the right entity, and based on the ϕ_4-CEAF recall and precision, we can state that about 19.6% of "true" entities are recovered (recall) and about 58.8% of the proposed entities are correct.

A comparison of the procedures of computing the MUC F-measure/B-cube and CEAF reveals that the crucial difference is that the MUC and B-cube F-measure allow an entity to be used multiple times while CEAF insists that entity map be one-to-one. So an entity will never get double credit. Take the system repsonse (c) as an example, intersecting three reference entity in turn with the reference entities produces the same set of reference entities, which leads to 100% recall. In the intersection step, the system entity is effectively used three times. In contrast, the system entity is aligned to only one reference entity when computing CEAF.

3.2 Comparisons On Real Data

3.2.1 MUC F-measure and CEAF

We have seen the different behaviors of the MUC F-measure, B-cube F-measure and CEAF on the artificial data. We now compare the MUC F-measure, CEAF, and ACE-value metrics on real data (compasion between the MUC and B-cube F-measure can be found in (Bagga and Baldwin, 1998)). Comparsion between the MUC F-measure and CEAF is done on the MUC6 coreference test set, while comparison between the CEAF and ACE-value is done on the 2004 ACE data. The setup reflects the fact that the official MUC scorer and ACE scorer run on their own data format and are not easily portable to the other data set. All the experiments in this section are done on true mentions.

Penalty	#sys-ent	MUC-F	ϕ_3-CEAF
-0.6	561	.851	0.750
-0.8	538	.854	0.756
-0.9	529	.853	0.753
-1	515	.853	0.753
-1.1	506	.856	0.764
-1.2	483	.857	**0.768**
-1.4	448	.863	0.761
-1.5	425	.862	0.749
-1.6	411	.864	0.740
-1.7	403	.865	0.741
-10	113	**.902**	0.445

Table 3: MUC F-measure and mention-based CEAF on the official MUC6 test set. The first column contains the penalty value in decreasing order. The second column contains the number of system-proposed entities. The column under MUC-F is the MUC F-measure while ϕ_3-CEAF is the mention-based CEAF.

The coreference system is similar to the one used in (Luo et al., 2004). Results in Table 3 are produced by a system trained on the MUC6 training data and tested on the 30 official MUC6 test documents. The test set contains 460 reference entities. The coreference system uses a penalty parameter to balance miss and false alarm errors: the smaller the parameter, the fewer entities will be generated. We vary the parameter from -0.6 to -10, listed in the first column of Table 3, and compare the system performance measured by the MUC F-measure and the proposed mention-based CEAF.

As can be seen, the mention-based CEAF has a clear maximum when the number of proposed entities is close to the truth: at the penlaty value -1.2, the system produces 483 entities, very close to 460, and the ϕ_3-CEAF achieves the maximum 0.768. In contrast, the MUC F-measure increases almost monotonically as the system proposes fewer and fewer entities. In fact, the best system according to the MUC F-measure is the one proposing only 113 entities. This demonstrates a fundamental flaw of the MUC F-measure: the metric intrinsically favors a system producing fewer entities and therefore lacks of discriminativity.

3.2.2 ACE-Value and CEAF

Now let us turn to ACE-value. Results in Table 4 are produced by a system trained on the ACE 2002 and 2004 training data and tested on a separate test set, which contains 853 reference entities. Both ACE-value and the mention-based CEAF penalizes systems over-producing or under-producing entities: ACE-value is maximum

Penalty	#sys-ent	ACE-value(%)	ϕ_3-CEAF
0.6	1221	88.5	0.726
0.4	1172	89.1	0.749
0.2	1145	89.4	0.755
0	1105	89.7	0.766
-0.2	1050	**89.7**	0.775
-0.4	1015	89.7	0.780
-0.6	990	89.5	0.782
-0.8	930	88.6	**0.794**
-1	891	86.9	0.780
-1.2	865	86.7	0.778
-1.4	834	85.6	0.769
-1.6	790	83.8	0.761

Table 4: Comparison of ACE-value and mention-based CEAF. The first column contains the penalty value in decreasing order. The second column contains the number of system-proposed entities. ACE-values are in percentage. The number of reference entities is 853.

when the penalty value is -0.2 and CEAF is maximum when the penalty value is -0.8. However, the optimal CEAF system produces 930 entities while the optimal ACE-value system produces 1050 entities. Judging from the number of entities, the optimal CEAF system is closer to the "truth" than the counterpart of ACE-value. This is not very surprising since ACE-value is a weighted metric while CEAF treats each mention and entity equally. As such, the two metrics have very weak correlation.

While we can make a statement such as "the system with penalty -0.8 puts about 79.4% mentions in right entities", it is hard to interpret the ACE-value numbers.

Another difference is that CEAF is symmetric[1], but ACE-Value is not. Symmetry is a desirable property. For example, when comparing inter-annotator agreement, a symmetric metric is independent of the order of two sets of input documents, while an asymmetric metric such as ACE-Value needs to state the input order along with the metric value.

4 Conclusions

A coreference performance metric – CEAF – is proposed in this paper. The CEAF metric is computed based on the best one-to-one map between reference entities and system entities. Finding the best one-to-one map is a maximum bipartite matching problem and can be solved by the Kuhn-Munkres algorithm. Two example entity-pair similarity measures (i.e., $\phi_3(\cdot,\cdot)$ and $\phi_4(\cdot,\cdot)$) are proposed, resulting one mention-based CEAF and one entity-based CEAF, respectively. It has been shown that the proposed CEAF metric has fixed problems associated with the MUC link-based F-measure and B-cube F-measure. The proposed metric also has better interpretability than ACE-value.

Appendix: Kuhn-Munkres Algorithm

Let i index the reference entities $\mathcal{R}$ and j index the system entities $\mathcal{S}$, and $\phi(i,j)$ be the similarity between the i^{th} reference entity and the j^{th} system entity. Algebraically, the maximum bipartite matching can be stated as an integer programming problem:

$$\max_{\{x_{ij}\}} \phi(i,j)x_{ij} \quad (10)$$

$$\text{subject to:} \quad \sum_j x_{ij} \leq 1, \forall i \quad (11)$$

$$\sum_i x_{ij} \leq 1, \forall j \quad (12)$$

$$x_{ij} \in \{0,1\}, \forall i,j. \quad (13)$$

If $x_{ij} = 1$, the i^{th} reference entity and the j^{th} system entity are aligned. Constraint (11) (or (12)) implies that a reference (or system) entity cannot be aligned more than once with a system (or reference) entity.

Observe that the coefficients of (11) and (12) are unimodular. Thus, Constraint (13) can be replaced by

$$x_{ij} \geq 0, \forall i,j. \quad (14)$$

The dual (cf. pp. 219 of (Fletcher, 1987)) to the optimization problem (10) with constraints (11),(12) and (14) is:

$$\min_{\{u_i\},\{v_j\}} \sum_i u_i + \sum_j v_j \quad (15)$$

$$s.t.: \; u_i + v_j \geq \phi(i,j), \forall i,j \quad (16)$$

$$u_i \geq 0, \forall i \quad (17)$$

$$v_j \geq 0, \forall j. \quad (18)$$

The dual has the same optimal objective value as the primal.

It can be shown that the optimal conditions for the dual problem (and hence the maximum similarity match) are:

$$u_i + v_j = \phi(i,j), \text{if } (i,j) \text{ is aligned} \quad (19)$$

$$u_i = 0, \text{if } i \text{ is free (i.e., not aligned)} \quad (20)$$

$$v_j = 0, \text{if } j \text{ is free.} \quad (21)$$

The Kuhn-Munkres algorithm starts with an empty match and an initial feasible set of $\{u_i\}$ and $\{v_j\}$, and iteratively increases the cardinality of the match while satisfying the optimal conditions (19)-(21). Notice that conceptually, a matching problem with a rectangular matrix $[\phi(i,j)]$ can always reduce to a square one by padding zeros (this is not necessary in practice, see, for instance (Bourgeois and Lassalle, 1971)). For this reason, we state the Kuhn-Munkres algorithm for the case where $|\mathcal{R}| = |\mathcal{S}|$ (or $M = m$) in Algorithm 2. The proof of correctness is omitted due to space limit.

Note that $P_{aug}(i,j)$ on line 9 stands for the augmenting (i.e., a free node followed by an aligned node, followed by a free node, ...) path from i to j in the corresponding bipartite graph. $A \oplus P_{aug}(i,j)$ is understood as edge "exclusive-or:" if an edge (k,l) is in A and on the path $P_{aug}(i,j)$, it will be removed from A; if the edge is in either A or $P_{aug}(i,j)$, it will be added.

Algorithm 2 Kuhn-Munkres Algorithm

```

Improving Multilingual Summarization: Using Redundancy in the Input to Correct MT errors

Advaith Siddharthan and **Kathleen McKeown**

{as372,kathy}@cs.columbia.edu

Abstract

In this paper, we use the information redundancy in multilingual input to correct errors in machine translation and thus improve the quality of multilingual summaries. We consider the case of multi-document summarization, where the input documents are in Arabic, and the output summary is in English. Typically, information that makes it to a summary appears in many different lexical-syntactic forms in the input documents. Further, the use of multiple machine translation systems provides yet more redundancy, yielding different ways to realize that information in English. We demonstrate how errors in the machine translations of the input Arabic documents can be corrected by identifying and generating from such redundancy, focusing on noun phrases.

1 Introduction

Multilingual summarization is a relatively nascent research area which has, to date, been addressed through adaptation of existing extractive English document summarizers. Some systems (e.g. SUMMARIST (Hovy and Lin, 1999)) extract sentences from documents in a variety of languages, and translate the resulting summary. Other systems (e.g. Newsblaster (Blair-Goldensohn et al., 2004)) perform translation before sentence extraction. Readability is a major issue for these extractive systems. The output of machine translation software is usually errorful, especially so for language pairs such as Chinese or Arabic and English. The ungrammaticality and inappropriate word choices resulting from the use of MT systems leads to machine summaries that are difficult to read.

Multi-document summarization, however, has information available that was not available during the translation process and which can be used to improve summary quality. A multi-document summarizer is given a set of documents on the same event or topic. This set provides redundancy; for example, each document may refer to the same entity, sometimes in different ways. It is possible that by examining many translations of references to the same entity, a system can gather enough accurate information to improve the translated reference in the summary. Further, as a summary is short and serves as a surrogate for a large set of documents, it is worth investing more resources in its translation; readable summaries can help end users decide which documents they want to spend time deciphering.

Current extractive approaches to summarization are limited in the extent to which they address quality issues when the input is noisy. Some new systems attempt substituting sentences or clauses in the summary with similar text from extraneous but topic related English documents (Blair-Goldensohn et al., 2004). This improves readability, but can only be used in limited circumstances, in order to avoid substituting an English sentence that is not faithful to the original. Evans and McKeown (2005) consider the task of summarizing a mixed data set that contains both English and Arabic news reports. Their approach is to separately summarize information that is contained in only English reports, only Arabic reports, and in both. While the only-English and in-both information can be summarized by selecting text from English reports, the summaries of only-Arabic suffer from the same readability issues.

In this paper, we use principles from information theory (Shannon, 1948) to address the issue of readability in multilingual summarization. We take as input, multiple machine translations into English of a cluster of news reports in Arabic. This input is characterized by high levels of linguistic noise and by high levels of information redundancy (multiple documents on the same or related topics and multiple translations into English). Our aim is to use automatically acquired knowledge about the English language in conjunction with the information redundancy to perform error correction on the MT. The main benefit of our approach is to make machine summaries of errorful input easier to read and comprehend for end-users.

We focus on noun phrases in this paper. The amount of error correction possible depends on the amount of redundancy in the input and the depth of knowledge about English that we can utilize. We begin by tackling the problem of generating references to people in English summaries of Arabic texts (§2). This special case involves large amounts of redundancy and allows for relatively deep English language modeling, resulting in good error correction. We extend our approach to arbitrary NPs in §3.

The evaluation emphasis in multi-document summarization has been on evaluating content (not readability), using manual (Nenkova and Passonneau, 2004) as well as automatic (Lin and Hovy, 2003) methods. We evaluate readability of the generated noun phrases by computing precision, recall and f-measure of the generated version compared to multiple human models of the same reference, computing these metrics on n-grams. Our results show that our system performs significantly better on precision over two baselines (most frequent initial reference and randomly chosen initial reference). Precision is the most important of these measures as it is important to have a correct reference, even if we don't retain all of the words used in the human models.

2 References to people

2.1 Data

We used data from the DUC 2004 Multilingual summarization task. The Document Understanding Conference (http://duc.nist.gov) has been run annually since 2001 and is the biggest summarization evaluation effort, with participants from all over the world. In 2004, for the first time, there was a multilingual multi-document summarization task. There were 25 sets to be summarized. For each set consisting of 10 Arabic news reports, the participants were provided with 2 different machine translations into English (using translation software from ISI and IBM). The data provided under DUC includes 4 human summaries for each set for evaluation purposes; the human summarizers were provided a human translation into English of each of the Arabic New reports, and did not have to read the MT output that the machine summarizers took as input.

2.2 Task definition

An analysis of premodification in initial references to people in DUC human summaries for the monolingual task from 2001–2004 showed that 71% of premodifying words were either title or role words (eg. *Prime Minister, Physicist* or *Dr.*) or temporal role modifying adjectives such as *former* or *designate*. Country, state, location or organization names constituted 22% of premodifying words. All other kinds of premodifying words, such as *moderate* or *loyal* constitute only 7%. Thus, assuming the same pattern in human summaries for the multilingual task (cf. section 2.6 on evaluation), our task for each person referred to in a document set is to:

1. Collect all references to the person in both translations of each document in the set.
2. Identify the correct roles (including temporal modification) and affiliations for that person, filtering any noise.
3. Generate a reference using the above attributes and the person's name.

2.3 Automatic semantic tagging

As the task definition above suggests, our approach is to identify particular semantic attributes for a person, and generate a reference formally from this semantic input. Our analysis of human summaries tells us that the semantic attributes we need to identify are `role`, `organization`, `country`, `state`, `location` and `temporal modifier`. In addition, we also need to identify the `person name`. We used BBN's IDENTIFINDER (Bikel et al., 1999) to mark up person names, organizations and locations. We marked up countries and (American) states using a list obtained from the CIA factsheet[1].

[1]*http://www.cia.gov/cia/publications/factbook* provides a list of countries and states, abbreviations and adjectival forms, for example *United Kingdom/U.K./British/Briton* and *California/Ca./Californian*.

To mark up roles, we used a list derived from WordNet (Miller et al., 1993) hyponyms of the *person* synset. Our list has 2371 entries including multi-word expressions such as *chancellor of the exchequer*, *brother in law*, *senior vice president* etc. The list is quite comprehensive and includes roles from the fields of sports, politics, religion, military, business and many others. We also used WordNet to obtain a list of 58 temporal adjectives. WordNet classifies these as pre- (eg. *occasional*, *former*, *incoming* etc.) or post-nominal (eg. *elect*, *designate*, *emeritus* etc.). This information is used during generation. Further, we identified elementary noun phrases using the LT TTT noun chunker (Grover et al., 2000), and combined `NP of NP` sequences into one complex noun phrase. An example of the output of our semantic tagging module on a portion of machine translated text follows:

> ...<NP> <ROLE> representative </ROLE> of <COUNTRY> Iraq </COUNTRY> of the <ORG> United Nations </ORG> <PERSON> Nizar Hamdoon </PERSON> </NP> that <NP> thousands of people </NP> killed or wounded in <NP> the <TIME> next </TIME> few days four of the aerial bombardment of <COUNTRY> Iraq </COUNTRY> </NP>...

Our principle data structure for this experiment is the attribute value matrix (AVM). For example, we create the following AVM for the reference to Nizar Hamdoon in the tagged example above:

$$\begin{bmatrix} \texttt{name} & \text{Nizar Hamdoon} \\ \texttt{role} & \text{representative} \\ \texttt{country} & \text{Iraq } (arg1) \\ \texttt{organization} & \text{United Nations } (arg2) \end{bmatrix}$$

Note that we store the relative positions (*arg 1* and *arg 2*) of the country and organization attributes. This information is used both for error reduction and for generation as detailed below. We also replace adjectival country attributes with the country name, using the correspondence in the CIA factsheet.

2.4 Identifying redundancy and filtering noise

We perform coreference by comparing AVMs. Because of the noise present in MT (For example, words might be missing, or proper names might be spelled differently by different MT systems), simple name comparison is not sufficient. We form a coreference link between two AVMs if:

1. The last name and (if present) the first name match.
2. OR, if the role, country, organization and time attributes are the same.

The assumption is that in a document set to be summarized (which consists of related news reports), references to people with the same affiliation and role are likely to be references to the same person, even if the names do not match due to spelling errors. Thus we form one AVM for each person, by combining AVMs. For Nizar Hamdoon, to whom there is only one reference in the set (and thus two MT versions), we obtain the AVM:

$$\begin{bmatrix} \texttt{name} & \text{Nizar Hamdoon(2)} \\ \texttt{role} & \text{representative(2)} \\ \texttt{country} & \text{Iraq(2) } (arg1) \\ \texttt{organization} & \text{United Nations(2) } (arg2) \end{bmatrix}$$

where the numbers in brackets represents the counts of this value across all references. The *arg* values now represent the most frequent ordering of these organizations and countries in the input references. As an example of a combined AVM for a person with a lot of references, consider:

$$\begin{bmatrix} \texttt{name} & \text{Zeroual(24), Liamine Zeroual(20)} \\ \texttt{role} & \text{president(23), leader(2)} \\ \texttt{country} & \text{Algeria(18) } (arg1) \\ \texttt{organization} & \text{Renovation Party(2) } (arg1), \\ & \text{AFP(1) } (arg1) \\ \texttt{time} & \text{former(1)} \end{bmatrix}$$

This example displays common problems when generating a reference. Zeroual has two affiliations - Leader of the Renovation Party, and Algerian President. There is additional noise - the values *AFP* and *former* are most likely errors. As none of the organization or country values occur in the same reference, all are marked *arg1*; no relative ordering statistics are derivable from the input. For an example demonstrating noise in spelling, consider:

$$\begin{bmatrix} \texttt{name} & \text{Muammar Qaddafi(10),} \\ & \text{Muammar Gaddafi(10),} \\ & \text{Qaddafi(4), Gaddafi(4)} \\ \texttt{role} & \text{leader colonel(12), colonel(4)} \\ & \text{leader(3), minister(2), justice(1)} \\ \texttt{country} & \text{Libya(7) } (arg1) \\ \texttt{organization} & \text{Peace Country(2) } (arg2), \\ & \text{Country Peace(1) } (arg1) \end{bmatrix}$$

Our approach to removing noise is to:

1. Select the most frequent name with more than one word (this is the most likely full name).
2. Select the most frequent role.
3. Prune the AVM of values that occur with a frequency below an empirically determined threshold.

Thus we obtain the following AVMs for the three examples above:

$$\begin{bmatrix} \texttt{name} & \text{Nizar Hamdoon} \\ \texttt{role} & \text{representative} \\ \texttt{country} & \text{Iraq } (arg1) \\ \texttt{organization} & \text{United Nations } (arg2) \end{bmatrix}$$

$$\begin{bmatrix} \texttt{name} & \text{Liamine Zeroual} \\ \texttt{role} & \text{president} \\ \texttt{country} & \text{Algeria } (arg1) \end{bmatrix}$$

$$\begin{bmatrix} \texttt{name} & \text{Muammar Qaddafi} \\ \texttt{role} & \text{leader colonel} \\ \texttt{country} & \text{Libya } (arg1) \end{bmatrix}$$

This is the input semantics for our generation module described in the next section.

2.5 Generating references from AVMs

In order to generate a reference from the words in an AVM, we need knowledge about syntax. The syntactic frame of a reference to a person is determined by the role. Our approach is to automatically acquire these frames from a corpus of English text. We used the Reuters News corpus for extracting frames. We performed the semantic analysis of the corpus, as in §2.3; syntactic frames were extracted by identifying sequences involving locations, organizations, countries, roles and prepositions. An example of automatically acquired frames with their maximum likelihood probabilities for the role *ambassador* is:

ROLE=ambassador

(p=.35)	COUNTRY ambassador PERSON
(.18)	ambassador PERSON
(.12)	COUNTRY ORG ambassador PERSON
(.12)	COUNTRY ambassador to COUNTRY PERSON
(.06)	ORG ambassador PERSON
(.06)	COUNTRY ambassador to LOCATION PERSON
(.06)	COUNTRY ambassador to ORG PERSON
(.03)	COUNTRY ambassador in LOCATION PERSON
(.03)	ambassador to COUNTRY PERSON

These frames provide us with the required syntactic information to generate from, including word order and choice of preposition. We select the most probable frame that matches the semantic attributes in the AVM. We also use a default set of frames shown below for instances where no automatically acquired frames exist:

ROLE=<Default>

COUNTRY ROLE PERSON
ORG ROLE PERSON
COUNTRY ORG ROLE PERSON
ROLE PERSON

If no frame matches, organizations, countries and locations are dropped one by one in decreasing order of argument number, until a matching frame is found. After a frame is selected, any prenominal temporal adjectives in the AVM are inserted to the left of the frame, and any postnominal temporal adjectives are inserted to the immediate right of the role in the frame. Country names that are not objects of a preposition are replaced by their adjectival forms (using the correspondences in the CIA factsheet). For the AVMs above, our generation module produces the following referring expressions:

- Iraqi United Nations representative Nizar Hamdoon
- Algerian President Liamine Zeroual
- Libyan Leader Colonel Muammar Qaddafi

2.6 Evaluation

To evaluate the referring expressions generated by our program, we used the manual translation of each document provided by DUC. The drawback of using a summarization corpus is that only one human translation is provided for each document, while multiple model references are required for automatic evaluation. We created multiple model references by using the initial references to a person in the manual translation of each input document in the set in which that person was referenced. We calculated unigram, bigram, trigram and fourgram precision, recall and f-measure for our generated references evaluated against multiple models from the manual translations. To illustrate the scoring, consider evaluating a generated phrase *"a b d"* against three model references *"a b c d"*, *"a b c"* and *"b c d"*. The bigram precision is $1/2 = 0.5$ (one out of two bigrams in generated phrase occurs in the model set), bigram recall is $2/7 = 0.286$ (two out of 7 bigrams in the models occurs in the generated phrase) and f-measure ($f = 2p \times r/(p + r)$) is 0.364. For fourgrams, P, R and F are zero, as there is a fourgram in the models, but none in the generated NP.

We used 6 document sets from DUC'04 for development purposes and present the average P, R and F for the remaining 18 sets in Table 1. There were 210 generated references in the 18 testing sets. The table also shows the popular BLEU (Papineni et al., 2002) and NIST[2] MT metrics. We also provide two baselines - most frequent initial reference to the person in the input (Base1) and a randomly selected initial reference to the person (Base2). As Table 1 shows, Base1 performs better than random selection. This

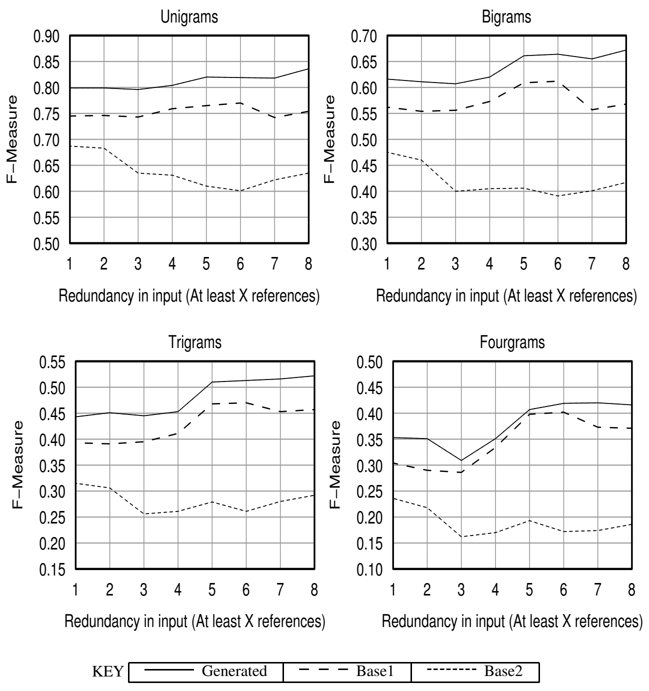

Figure 1: Improvement in F-measure for n-grams in output with increased redundancy in input.

is intuitive as it also uses redundancy to correct errors, at the level of phrases rather than words. The generation module outperforms both baselines, particularly on precision - which for unigrams gives an indication of the correctness of lexical choice, and for higher ngrams gives an indication of grammaticality. The unigram recall of 0.786 indicates that we are not losing too much information at the noise filtering stage. Note that we expect a low R_{av} for our approach, as we only generate particular attributes that are important for a summary. The important measure is P_{av}, on which we do well. This is also reflected in the high scores on BLEU and NIST.

It is instructive to see how these numbers vary as the amount of redundancy increases. Information theory tells us that information should be more recoverable with greater redundancy. Figure 1 plots f-measure against the minimum amount of redundancy. In other words, the value at X=3 gives the f-measure averaged over all people who were mentioned at least thrice in the input. Thus X=1 includes all examples and is the same as Table 1.

As the graphs show, the quality of the generated reference improves appreciably when there are at least 5 references to the person in the input. This is a convenient result for summarization because people who are mentioned more frequently in the input are more likely to be mentioned in the summary.

2.7 Advantages over using extraneous sources

Our approach performs noise reduction and generates a reference from information extracted from the machine translations. Information about a person can be obtained in other ways; for example, from a database, or by collecting references to the person from extraneous English-language reports. There are two drawbacks to using extraneous sources:

1. People usually have multiple possible roles and affiliations, so descriptions obtained from an external source might not be appropriate in the current context.
2. Selecting descriptions from external sources can change perspective — one country's terrorist is another country's freedom fighter.

In contrast, our approach generates references that are appropriate and reflect the perspectives expressed in the source.

3 Arbitrary noun phrases

In the previous section, we showed how accurate references to people can be generated using an information theoretic approach. While this is an important result in itself for multilingual summarization, the same approach can be extended to correct errors in noun phrases that do not refer to people. This extension is trickier to implement, however, because:

1. *Collecting redundancy*: Common noun coreference is a hard problem, even within a single clean English text, and harder still across multiple MT texts.

2. *Generating*: The semantics for an arbitrary noun phrase cannot be defined sufficiently for formal generation; hence our approach is to select the most plausible of the coreferring NPs according to an inferred language model. When sufficient redundancy exists, it is likely that there is at least one option that is superior to most.

Interestingly, the nature of multi-document summarization allows us to perform these two hard tasks. We follow the same theoretical framework (identify redundancy, and then generate from this), but the techniques we use are necessarily different.

3.1 Alignment of NPs across translations

We used the BLAST algorithm (Altschul et al., 1997) for aligning noun phrases between two translations of the same Arabic sentence. We obtained the best results when each translation was analyzed for noun chunks, and the alignment operation was performed over sequences of words and <*NP*> and <*/NP*> tags. BLAST is an efficient alignment algorithm that assumes that words in the two sentences are roughly in the same order from a global perspective. As neither of the MT systems used performs much clause or phrase reorganization, this assumption is not a problem for our task. An example of two aligned sentences is shown in figure 2. We then extract coreferring noun phrases by selecting the text between aligned <*NP*> and <*/NP*> tags; for example:

1. the Special Commission in charge of disarmament of Iraq's weapons of mass destruction
2. the Special Commission responsible disarmament Iraqi weapons of mass destruction

3.2 Alignment of NPs across documents

This task integrates well with the clustering approach to multi-document summarization (Barzilay, 2003), where sentences in the input documents are first clustered according to their similarity, and then one sentence is generated from each cluster. This clustering approach basically does at the level of sentences what we are attempting at the level of noun phrases. After clustering, all sentences within a cluster should represent similar information. Thus, similar noun phrases in sentences within a cluster are likely to refer to the same entities. We do noun phrase coreference by identifying lexically similar noun phrases within a cluster. We use *SimFinder* (Hatzivassiloglou et al., 1999) for sentence clustering and the f-measure for word overlap to compare noun phrases. We set a threshold for deciding coreference by experimenting on the 6 development sets (cf. §2.6)– the most accurate coreference occurred with a threshold of f=0.6 and a constraint that the two noun phrases must have at least 2 words in common that were neither determiners nor prepositions. For the reference to the *UN Special Commission* in figure 2, we obtained the following choices from alignments and coreference across translations and documents within a sentence cluster:

1. the United nations Special Commission in charge of disarmament of Iraq's weapons of mass destruction
2. the the United Nations Special Commission responsible disarmament Iraqi weapons of mass destruction
3. the Special Commission in charge of disarmament of Iraq's weapons of mass destruction
4. the Special Commission responsible disarmament Iraqi weapons of mass destruction
5. the United nations Special Commission in charge of disarmament of Iraq's weapons of mass destruction
6. the Special Commission of the United Nations responsible disarmament Iraqi weapons of mass destruction

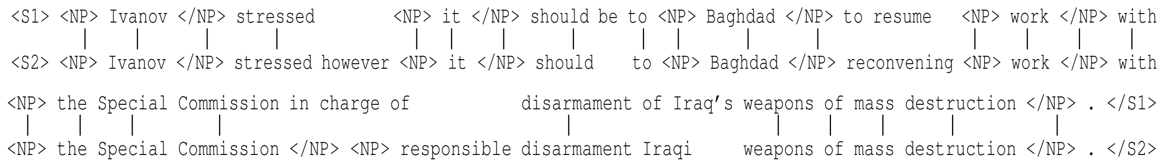
Larger sentence clusters represent information that is repeated more often across input documents; hence the size of a cluster is indicative of the importance of that information, and the summary is composed by considering each sentence cluster in decreasing order of size and generating one sentence from it. From our perspective of fixing errors in noun phrases, there is likely to be more redundancy in a large cluster; hence this approach is likely to work better within clusters that are important for generating the summary.

3.3 Generation of noun phrases

As mentioned earlier, formal generation from a set of coreferring noun phrases is impractical due to the unrestricted nature of the underlying semantics. We thus focus on selecting the best of the possible options — the option with the least garbled word order; for example, selecting 1) from the following:

1. the malicious campaigns in some Western media
2. the campaigns tendentious in some of the media Western European

The basic insight that we utilize is — when two words in a NP occur together in the original documents more often than they should by chance, it is likely they really should occur together in the generated NP. Our approach therefore consists of identifying collocations of length two. Let the number of words in the input documents be N. For each



```
<S1> <NP> Ivanov </NP> stressed         <NP> it </NP> should be to <NP> Baghdad </NP> to resume   <NP> work </NP> with
<S2> <NP> Ivanov </NP> stressed however <NP> it </NP> should    to <NP> Baghdad </NP> reconvening <NP> work </NP> with

<NP> the Special Commission in charge of           disarmament of Iraq's weapons of mass destruction </NP> . </S1>
<NP> the Special Commission </NP> <NP> responsible disarmament Iraqi     weapons of mass destruction </NP> . </S2>
```

Figure 2: Two noun chunked MT sentences (S1 and S2) with the words aligned using BLAST.

pair of words a and b, we use maximum likelihood to estimate the probabilities of observing the strings "$a\,b$", "a" and "b". The observed frequency of these strings in the corpus divided by the corpus size N gives the maximum likelihood probabilities of these events $p(a, b)$, $p(a)$ and $p(b)$. The natural way to determine how dependent the distributions of a and b are is to calculate their mutual information (Church and Hanks, 1991):

$$I(a, b) = \log_2 \frac{p(a, b)}{p(a) \times p(b)}$$

If the occurrences of a and b were completely independent of each other, we would expect the maximum likelihood probability $p(a, b)$ of the string "$a\ \ b$" to be $p(a) \times p(b)$. Thus mutual information is zero when a and b are independent, and positive otherwise. The greater the value of $I(a, b)$, the more likely that "$a\ \ b$" is a collocation. Returning to our problem of selecting the best NP from a set of coreferring NPs, we compute a score for each NP (consisting of the string of words $w_1...w_n$) by averaging the mutual information for each bigram:

$$Score(w_1...w_n) = \frac{\sum_{i=1}^{i=n-1} I(w_i, w_{i+1})}{n-1}$$

We then select the NP with the highest score. This model successfully selects *the malicious campaigns in some Western media* in the example above and *the United nations Special Commission in charge of disarmament of Iraq's weapons of mass destruction* in the example in §3.2.

3.4 Automatic Evaluation

Our approach to evaluation is similar to that for evaluating references to people. For each collection of coreferring NPs, we identified the corresponding model NPs from the manual translations of the input documents by using the BLAST algorithm for word alignment between the MT sentences and the corresponding manually translated sentence. Table 2 below gives the average unigram, bigram, trigram and fourgram precision, recall and f-measure for the

UNIGRAMS	P_{av}	R_{av}	F_{av}

NIST	5.886	4.979	4.680

Table 2: Evaluation of noun phrase selection

selected NPs, evaluated against the models. We excluded references to people as these were treated formally in §2. This left us with 961 noun phrases from the 18 test sets to evaluate. Table 2 also provides the BLEU and NIST MT evaluation scores.

We again provide two baselines - most frequent NP in the set (Base1) and a randomly selected NP from the set (Base2). The numbers in Table 2 are lower than those in Table 1. This is because generating references to people is a more restricted problem – there is less error in MT output, and a formal generation module is employed for error reduction. In the case of arbitrary NPs, we only select between the available options. However, the information theoretic approach gives significant improvement for the arbitrary NP case as well, particularly for precision, which is an indicator of grammaticality.

3.5 Manual Evaluation

To evaluate how much impact the rewrites have on summaries, we ran our summarizer on the 18 test sets, and manually evaluated the selected sentences and their rewritten versions for accuracy and fluency. There were 118 sentences, out of which 94 had at least one modification after the rewrite process. We selected 50 of these 94 sentences at random and asked 2 human judges to rate each sentence and its rewritten form on a scale of 1–5 for accuracy and fluency[3]. We used 4 human judges, each judging 25 sentence pairs. The original and rewritten sentences were presented in random order, so judges did not know which sentences were rewritten. Fluency judgments were made before seeing the human translated sentence, and accuracy judgments were made by comparing with the human translation. The average scores before and after rewrite were 2.08 and 2.26 respectively for fluency and 3.00 and 3.19 respectively for accuracy. Thus the rewrite operations increases both scores by around 0.2.

4 Conclusions and future work

We have demonstrated how the information redundancy in the multilingual multi-document summarization task can be used to reduce MT errors. We do not use any related English news reports for substituting text; hence our approach is not likely to change the perspectives expressed in the original Arabic news to those expressed in English news reports. Further, our approach does not perform any corrections specific to any particular MT system. Thus the techniques described in this paper will remain relevant even with future improvements in MT technology, and will be redundant only when MT is perfect. We have used the Arabic-English data from DUC'04 for this paper, but our approach is equally applicable to other language pairs. Further, our techniques integrate easily with the sentence clustering approach to multi-document summarization – sentence clustering allows us to reliably identify noun phrases that corefer across documents.

In this paper we have considered the case of noun phrases. In the future, we plan to consider other types of constituents, such as correcting errors in verb groups, and in the argument structure of verbs. This will result in a more generative and less extractive approach to summarization - indeed the case for generative approaches to summarization is more convincing when the input is noisy.

[3]We followed the DARPA/LDC guidelines from http://ldc.upenn.edu/Projects/TIDES/Translation/TranAssessSpec.pdf. For fluency, the scale was 5:Flawless, 4:Good, 3:Non-native, 2:Disfluent, 1:Incomprehensible. The accuracy scale for information covered (comparing with human translation) was 5:All, 4:Most, 3:Much, 2:Little, 1:None.

Abstract

Recognition errors hinder the proliferation of speech recognition (SR) systems. Based on the observation that recognition errors may result in ungrammatical sentences, especially in dictation application where an acceptable level of accuracy of generated documents is indispensable, we propose to incorporate two kinds of linguistic features into error detection: lexical features of words, and syntactic features from a robust lexicalized parser. Transformation-based learning is chosen to predict recognition errors by integrating word confidence scores with linguistic features. The experimental results on a dictation data corpus show that linguistic features alone are not as useful as word confidence scores in detecting errors. However, linguistic features provide complementary information when combined with word confidence scores, which collectively reduce the classification error rate by 12.30% and improve the F measure by 53.62%.

1 Introduction

The proliferation of speech recognition (SR) systems is hampered by the ever-presence of recognition errors and the significant amount of effort involved in error correction. A user study (Sears et al., 2001) showed that users spent one-third of their time finding and locating errors and another one-third of the time correcting errors in a hand-free dictation task. Successfully detecting SR errors can speed up the entire process of error correction. Therefore, we focus on error detection in this study.

A common approach to detecting SR errors is annotating confidence at the word level. The majority of confidence annotation methods are based on feature combination, which follows two steps: (i) extract useful features characteristics of the correctness of words either from the inner components of an SR system (SR-dependent features) or from the recognition output (SR-independent features); and (ii) develop a binary classifier to separate words into two groups: correct recognitions and errors.

Various features extracted from different components of an SR system, such as the acoustic model, the language model, and the decoder, have been proven useful to detecting recognition errors (Chase, 1997; Pao et al., 1998; San-Segundo et al., 2001). Nonetheless, merely using these features is inadequate, because the information conveyed by these features has already been considered when SR systems generate the output. A common observation is that the combination of SR-dependent features can only marginally improve the performance achieved by using only the best single feature (Zhang and Rudnicky, 2001; Sarikaya et al., 2003). Hence information sources beyond the SR system are desired in error detection.

High-level linguistic knowledge is a good candidate for additional information sources. It can be extracted from the SR output via natural language processing, which compensates for the lack of high-level linguistic knowledge in a typical SR system. A user study (Brill et al., 1998) showed that humans can utilize linguistic knowledge at various levels to improve the SR output by selecting the best utterance hypotheses from N-best lists. Linguistic features from syntactic, semantic, and dialogue discourse analyses have proven their values in error detection in domain specific spoken dialogue systems, e.g. (Rayner et al., 1994; Carpenter et al., 2001; Sarikaya et al., 2003). However, few studies have investigated the merit of linguistic knowledge for error detection in dictation, a domain-independent application.

Transformation-based learning (TBL) is a rule-based learning method. It has been used in error correction (Mangu and Padmanabhan, 2001) and error detection (Skantze and Edlund, 2004). The rules learned by TBL show good interpretability as well as good performance. Although statistical learning methods have been widely used in confidence annotation (Carpenter et al., 2001; Pao et al., 1998; Chase, 1997), their results are difficult to interpret. Therefore, we select TBL to derive error patterns from the SR output in this study.

The rest of the paper is organized as follows. In Section 2, we review the extant work on utilizing linguistic features in error detection. In Section 3, we introduce linguistic features used in this study. In Section 4, we describe transformation-based learning and define the transformations, followed with reporting the experimental results in Section 5. Finally, we summarize the findings of this study and suggest directions for further research in Section 6.

2 Related Work

When the output of an SR system is processed, the entire utterance is available and thus utterance-level contextual information can be utilized. Features generated from high-level language processing such as syntactic and semantic analyses may complement the low-level language knowledge (usually n-gram) used in the SR systems.

Most of the previous work on utilizing linguistic features in error detection focused on utterance-level confidence measures. Most of features were extracted from the output of syntactic or semantic parsers, including full/robust/no parse, number of words parsed, gap number, slot number, grammar rule used, and so on (Rayner et al., 1994; Pao et al., 1998; Carpenter et al., 2001; San-Segundo et al., 2001). Some discourse-level features were also employed in spoken dialogue systems such as number of turns, and dialog state (Carpenter et al., 2001).

Several studies incorporated linguistic features into word-level confidence measures. Zhang and Rudnicky (2001) selected two features, i.e., parsing mode and slot backoff mode, extracted from the parsing result of Phoenix, a semantic parser. The above two features were combined with several SR-dependent features using SVM, which achieved a 7.6% relative classification error rate reduction over SR-dependent features on the data from CMU Communicator system.

Sarikaya et al. (2003) explored two sets of semantic features: one set from a statistical classer/parser, and the other set from a maximum entropy based semantic-structured language model. When combined with the posterior probability using the decision tree, both sets achieved about 13-14% absolute improvement on correct acceptance at 5% false acceptance over the baseline posterior probability on the data from IBM Communicator system.

Skantze and Edlund (2004) focused on lexical features (e.g., part-of-speech, syllables, and content words) and dialogue discourse features (e.g., previous dialogue act, and mentioned word), but did not consider parser-based features. They employed transformation-based learning and instance-based learning as classifiers. When combined with confidence scores, the linguistic features achieved 7.8% absolute improvement in classification accuracy over confidence scores on one of their dialogue corpora.

It is shown from the related work that linguistic features have merit in judging the correctness of words and/or utterances. However, such features have only been discussed in the context of conversational dialogue in specific domains such as ATIS (Rayner et al., 1994), JUPITER (Pao et al., 1998), and Communicator (Carpenter et al., 2001; San-Segundo et al., 2001; Zhang and Rudnicky, 2001; Sarikaya et al., 2003).

In an early study, we investigated the usefulness of linguistic features in detecting word errors in dictation recognition (Zhou et al., 2005). The linguistic features were extracted from the parsing result of the link grammar. The combination of linguistic features with various confidence score based features using SVM can improve F measure for error detection from 42.2% to 55.3%, and classification accuracy from 80.91% to 83.53%. However, parser-based features used were limited to the number of links that a word has.

3 Linguistic Features

For each output word, two sets of linguistic features are extracted: lexical features and syntactic features.

3.1 Lexical Features

For each word w, the following lexical features are extracted:

- word: w itself
- pos: part-of-speech tag from Brill's tagger (Brill, 1995)
- syllables: number of syllables in w, estimated based on the distribution patterns of vowels and consonants
- position: the position of w in the sentence: beginning, end, and middle

3.2 Syntactic Features

Speech recognition errors may result in ungrammatical sentences under the assumption that the speaker follows grammar rules while speaking. Such an assumption holds true especially for dictation application because the general purpose of dictation is to create understandable documents for communication.

Syntactic parsers are considered as the closest approximation to this intuition since there is still a lack of semantic parsers for the general domain. Moreover, robust parsers are preferred so that an error in a recognized sentence does not lead to failure in parsing the entire sentence. Furthermore, lexicalized parsers are desired to support error detection at the word level. As a result, we select *Link Grammar*[1] to generate syntactic features.

[1]Available via http://www.link.cs.cmu.edu/link/

3.2.1 Link Grammar

Link Grammar is a context-free lexicalized grammar without explicit constituents (Sleator and Temperley, 1993). In link grammar, rules are expressed as link requirements associated with words. A link requirement is a set of disjuncts, each of which represents a possible usage of the word. A sequence of words belongs to the grammar if the result linkage is a planar, connected graph in which at most one link is between each word pair and no cross link exists. Link grammar supports robust parsing by incorporating null links (Grinberg et al., 1995).

3.2.2 Features from Link Grammar

We hypothesize that a word without any link in a linkage of the sentence is a good indicator of the occurrence of errors. Either the word itself or words around it are likely to be erroneous. It has been shown that null links can successfully ignore false starts and connect grammatical phrases in ungrammatical utterances, which are randomly selected from the Switchboard corpus (Grinberg et al., 1995).

A word with links may still be an error, and its correctness may affect the correctness of words linked to it, especially those words connected with the shortest links that indicate the closest connections.

Accordingly, for each word w, the following features are extracted from the parsing result:

- haslink: whether w has left links, right links, or no link
- llinkto/rlinkto: the word to which w links via the shortest left/right link

An example of parsing results is illustrated in Figure 1. Links are represented with dotted lines which are annotated with labels (e.g., Wd, Xp) representing link types. In Figure 1, word "since" has no link, and word "around" has one left link and one right link. The word that has the shortest left link to "world" is "the".

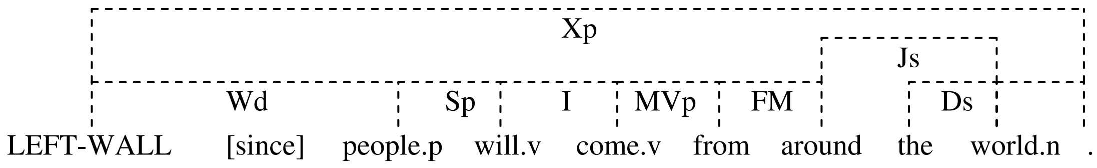

Figure 1: An Example of Parsing Results of Link Grammar

4 Error Detection based on Transformation-Based Learning

4.1 Transformation-Based Learning

Transformation-Based Learning is a rule-based approach, in which rules are automatically learned from the data corpus. It has been successfully used in many natural language applications such as part-of-speech tagging (Brill, 1995). Three prerequisites for using TBL are: an initial state annotator, a set of possible transformations, and an objective function for choosing the best transformations.

Before learning, the initial state annotator adds labels to the training data. The learning goes through the following steps iteratively until no improvement can be achieved: (i) try each possible transformation on the training data, (ii) score each transformation with the objective function and choose the one with the highest score, and (iii) apply the selected transformation to update the training data and append it to the learned transformation list.

4.2 Error Detection Based on TBL

Pre-defined transformation templates are the rules allowed to be used, which play a vital role in TBL. The transformation templates are defined in the following format:

Change the word label of a word w from X to Y, if condition C is satisfied

where, X and Y take binary values: 1 (correct recognition) and -1 (error). Each condition C is the conjunction of sub-conditions in form of $f \ op \ v$, where f represents a feature, v is a possible categorical value of f, and op is the possible operations such as $<$, $>$ and $=$.

In addition to the linguistic features introduced in Section 3, two other features are used:

- word confidence score (CS): an SR dependent feature generated by an SR system.
- word label (label): the target of the transformation rules. Using it as a feature enables the propagation of the effect of preceding rules.

As shown in Table 1, conditions are classified into three categories based on the incrementally enlarged context from which features are extracted: *word alone*, *local context*, and *sentence context*. The three categories are further split into seven groups according to the features they used.

- **L**: the correctness of w depends solely on itself. Conditions only include lexical features of w.
- **Local**: the correctness of w depends not only on itself but also on its surrounding words. Conditions incorporate lexical features of surrounding words as well as those of w. Furthermore, word labels of surrounding words are also employed as a feature to capture the effect of the correctness of surrounding words of w.
- **Long**: the scope of conditions for the correctness of w is expanded to include syntactic features. Syntactic features of w and its surrounding words as well as the features in Local are incorporated into conditions. In addition, the lexical features and word labels of words that have the shortest links to w are also incorporated.
- **CS**: the group in which conditions only include confidence scores of w.
- **LCS, CSLocal, CSLong**: these three groups are generated by combining the features from L, Local, and Long with the confidence scores of w as an additional feature respectively.

$lrHaslink$ and $llinkLabel$ are combinations of basic features. $lrHaslink$ represents whether the preceding word and the following word have links,

Category	Group	Example
Word Alone	CS	$cs(w_i) < c_i$
	L	$position(w_i) = t_i$ & $syllables(w_i) = s_i$
	LCS	$cs(w_i) < c_i$ & $pos(w_i) = p_i$
Local Context	Local	$position(w_i) = t_i$ & $label(w_{i-1}) = l_{i-1}$ & $word(w_i) = d_i$
	CSLocal	$cs(w_i) < c_i$ & $position(w_i) = t_i$ & $label(w_{i-1}) = l_{i-1}$ & $label(w_{i+1}) = l_{i+1}$
Sentence Context	Long	$position(w_i) = t_i$ & $lrHaslink(w_i) = h_i$ & $haslink(w_i) = hl_i$
	CSLong	$cs(w_i) < c_i$ & $position(w_i) = t_i$ & $llinkLabel(w_i) = ll_i$ & $pos(w_i) = p_i$

Table 1: Condition Categories and Examples

and $llinkLabel$ represents the label of the word to which w has the shortest left link. c_i, t_i, s_i, p_i, l_i, d_i, h_i, hl_i, and ll_i are possible values of the corresponding features.

The initial state annotator initializes all the words as correct words. A Prolog based TBL tool, μ-TBL (Lager, 1999) [2] is used in this study. Classification accuracy is adopted as the objective function. For each transformation, its *positive effect* (*PE*) is the number of words whose labels are correctly updated by applying it, and its *negative effect* (*NE*) is the number of words wrongly updated. Two cut-off thresholds are used to select transformations with strong positive effects: net positive effect ($PE - NE$), and the ratio of positive effect ($PE/(PE + NE)$).

5 Experimental Results and Discussion

Experiments were conducted at several levels. Starting with transformation rules with word alone conditions, additional rules with local context and sentence context conditions were incorporated incrementally by enlarging the scope of the context. As such, the results help us not only identify the additional contribution of each condition group to the task of error detection but also reveal the importance of enriching contextual information to error detection.

5.1 Data Corpus

The data corpus was collected from a user study on a composition dictation task (Feng et al., 2003). A total of 12 participants were native speakers and none of them used their voice for professional purposes. Participants spoke to IBM ViaVoice (Millennium edition), which contains a general vocabulary of 64,000 words. The dictation task was completed in a quiet lab environment with high quality microphones.

During the study, participants were given one predesigned topic and instructed to compose a document of around 400 words on that topic. Before starting the dictation, they completed enrollments to build personal profiles and received training on finishing the task with a different topic. They were asked to make corrections only after they finished composing a certain length of text. The data corpus consists of the recognition output of their dictations excluding corrections. Word recognition errors were first marked by the participants themselves and then validated by researchers via cross-referencing the recorded audios. The data corpus contains 4,804 words.

5.2 Evaluation Metrics

To evaluate the overall performance of the error detection, classification error rate (CER) (Equation 1), commonly used metric to evaluate classifiers, is used. CER is the percentage of words that are wrongly classified.

$$CER = \frac{\#\ of\ wrongly\ classified\ words}{total\#\ of\ words} \quad (1)$$

The baseline CER is derived by assuming all the words are correct, and it has the value as the ratio of the total number of insertion and substitution errors to the total number of output words.

Precision (PRE) and recall (REC) on errors are used to measure the performance of identifying er-

[2] Available via http://www.ling.gu.se/˜lager/mutbl.html

rors. PRE is the percentage of words classified as errors that are in fact recognition errors. REC denotes the proportion of actual recognition errors that are categorized as errors by the classifier. In addition, F measure (Equation 2), a single-valued metric reflecting the trade-off between PRE and REC, is also used. The baselines of PRE, REC, and F for error are zeros, for all of the output words are assumed correct.

$$F = \frac{2 * PRE * REC}{PRE + REC} \quad (2)$$

5.3 Results

3-fold cross-validation was used to test the system. When dividing the data corpus, sentence is treated as an atomic unit. The 3-fold cross-validation was run 9 times, and the average performance is reported in Table 2. The labels of rule combinations are defined by the connections of several symbols defined in Section 4.2. For each rule combination, the types of rules can be included are decided by all the possible combinations of those symbols which are in Table 1. For example, L-CS-Local-Long includes rules with conditions L, CS, Local, Long, LCS, CSLocal and CSLong.

The threshold of net positive effect is set to 5 to ensure that enough evidence has been observed, and that of the ratio of the positive effect is set to 0.5 to ensure that selected transformations have the positive effects.

For the combinations without CS, L-Local-Long achieves the best performance in terms of both CER and F measure. A relative improvement of 4.85% is achieved over the baseline CER, which is relatively small. One possible explanation concerns the large vocabulary size in the data set. Although the participants were asked to compose the documents on the same topic, the word usage was greatly diversified. An analysis of the data corpus shows that the vocabulary size is 993.

Despite its best performance in linguistic feature groups, L-Local-Long produces worse performance than CS in both CER and F measure. Therefore, linguistic features by themselves are not as useful as confidence scores.

When linguistic features are combined with CS, they provide additional improvement. L-CS achieves a 4.58% relative improvement on CER and a 31.37% relative improvement on F measure over CS. L-CS-Local only achieves marginal improvement on CER and a 7.54% relative improvement on F measure over L-CS.

The best performance is generated by L-CS-Local-Long. In particular, it boosts CER by a relative improvement of 12.30% over CS and a relative improvement of 7.02% over L-CS-Local. In addition, it improves F measure by 53.62% and 8.74% in comparison with CS and L-CS-Local respectively. Therefore, enlarging the scope of context can lead to improved performance on error detection.

It is revealed from Table 2 that the improvement on F measure is due to the improvement on recall without hurting the precision. After combining linguistic features with CS, L-CS and L-CS-Local-Long achieve 43.77% and 75.57% relative improvements on recall over CS separately. Hence, the linguistic features can improve the system's ability in finding more errors. Additionally, L-CS-Local-Long achieves a 7.32% relative improvement on precision over CS.

The average numbers of learned rules are shown in Table 2. With the increased number of possible used pre-defined rules, the number of learned rules increases moderately. L-CS-Local-Long and L-CS-Local have the largest number of rules, 14, which is rather a small set of rules. As discussed above, these rules are straightforward and easy to understand.

Figure 2 shows CERs when the learned rules are incrementally applied in one run for L-CS-Local-Long. Three lines represent each of the three folds separately, and the number of learned rules differs among folds.

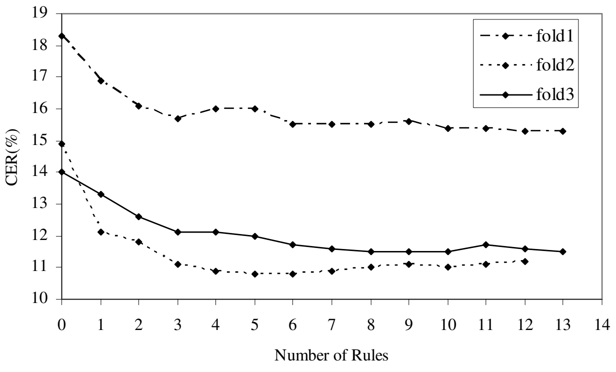

Figure 2: Relations of CERs with Number of Rules

Combination	Mean CER (%)	Std. Dev	Mean PRE (%)	Mean REC (%)	Mean F (%)	Mean # of rules
Baseline	15.66	0.06	-	-	-	-
L	15.55	0.11	61.85	2.04	3.88	3
L-Local	15.58	0.14	60.88	2.19	4.17	4
L-Local-Long	14.90	0.10	61.67	13.83	22.37	8
CS	14.64	0.09	61.03	21.98	31.50	1
L-CS	13.97	0.15	61.48	31.60	41.38	8
L-CS-Local	13.81	0.18	61.28	35.52	44.50	14
L-CS-Local-Long	12.84	0.21	65.50	38.59	48.39	14

Table 2: Performance of Transformation Rule Combinations

After the first several rules are applied, CERs drop significantly. Then the changes in CERs become marginal as additional rules are applied. The fold 1 and 3 reach the lowest CER after the last rule is applied, and fold 2 reaches the lowest CERs in the middle. Thus, the top ranked rules are mostly useful.

One advantage of TBL is that the learning result can be easily interpreted. The following is the top six rules learned in fold 3 in Figure 2.

Mark a word as an error, if :

- its confidence score is less than 0; it is in the middle of a sentence; and it is a null-link word.
- its confidence score is less than -5; it is in the middle of a sentence; and it has links to preceding words.
- its confidence score is less than 0; it is the first word of a sentence; and it is a null-link word.
- its confidence score is less than 2; it is in the middle of a sentence; it has 1 syllable; and the word following it also has 1 syllable and is an error.
- its confidence score is less than -1; and both its preceding and following words are errors.

Mark a word as a correct word, if :

- its confidence score is greater than -1; and both its preceding and following words are correct words.

All of the above six rules include word confidence score as a feature. Rule 1 and rule 3 suggest that null-link words are good indicators of errors, which confirms our hypothesis. Rule 2 shows that a word with low confidence score may also be an error even if it is part of the linkage of the sentence. Rule 4 shows continuous short words are possible errors. Rule 5 indicates that a word with low confidence score may be an error if its surrounding words are errors. Rule 6 is a rule to compensate for the wrongly labeled words by previous rules.

6 Conclusion and Future Works

We introduced an error detection method based on feature combinations. Transformation-based learning was used as the classifier to combine linguistic features with word confidence scores. Two kinds of linguistic features were selected: lexical features extracted from words themselves, and syntactic features from the parsing result of link grammar. Transformation templates were defined by varying scope of the context. Experimental results on a dictation corpus showed that although linguistic features alone were not as useful as word confidence scores to error detection, they provided complementary information when combined with word confidence score. Moreover, the performance of error detection was improved incrementally as the scope of context was enlarged, and the best performance was achieved when sentence context was considered. In particular, enlarging the context modeled by linguistic features improved the capability of error detection by finding more errors without deteriorating and even improving the precision.

The proposed method has been tested using a dictation corpus on a topic related to office environment. We are working on evaluating the method on spontaneous dictation utterances from the CSR-II corpus, and other monologue corpora such as Broadcast News. The method can be extended by incorporating lexical semantic features from the semantic analysis of recognition output to detect semantic errors that are likely overlooked by syntactic analysis.

Abstract

Browsing through large volumes of spoken audio is known to be a challenging task for end users. One way to alleviate this problem is to allow users to gist a spoken audio document by glancing over a transcript generated through Automatic Speech Recognition. Unfortunately, such transcripts typically contain many recognition errors which are highly distracting and make gisting more difficult. In this paper we present an approach that detects recognition errors by identifying words which are semantic outliers with respect to other words in the transcript. We describe several variants of this approach. We investigate a wide range of evaluation measures and we show that we can significantly reduce the number of errors in content words, with the trade-off of losing some good content words.

1 Introduction

Spoken audio documents are becoming more and more common place due to the rising popularity of technologies such as: video and audio conferencing, video web-casting and digital cameras for the consumer market. Unfortunately, speech documents are inherently hard to browse because of their transient nature. For example, imagine trying to locate the audio segment in the recording of a 60-minute meeting, where John talked about project X. Typically, this would require fast forwarding through the audio by some amount, then listening and trying to remember if the current segment was spoken before or after the desired segment, then fast-forwarding or backtracking by a small amount, and so on.

One way to make audio browsing of audio documents more efficient is to allow the user to navigate through a textual transcript that is cross-referenced with corresponding time points into the original audio (Nakatani *et al.* 1998; Hirschberg *et al.* 1999). Such transcripts can easily be produced with Automatic Speech Recognition (ASR) systems today. Unfortunately, such transcripts typically contain recognition errors that make them hard to browse and understand. Although Word Error Rates (WER) of the order of 20% can be achieved for broadcast quality audio, the WER for more common situations (ex: less-than-broadcast quality recordings of meetings) is typically in the order of 50% or more.

The work we present in this paper aims at automatically identifying recognition errors and removing them from the transcript, in order to make gisting and browsing of the corresponding audio more efficient. For example, consider the following portion of a transcript that was produced with the Dragon NaturallySpeaking speech recognition system from the audio of a meeting:

"Weenie to decide quickly whether local for large expensive plasma screen aura for a bunch of smaller and cheaper ones and Holland together"

Now consider the following **filtered transcript** where recognition errors were automatically blotted out using our proposed algorithm*:*

" ... to decide quickly whether ... large expensive plasma screen ... for a bunch of smaller and cheaper ones and ... together"

We believe that transcripts like this second one may be more efficient for gisting and browsing the

content of the original audio whose **correct transcript** is:
"We need to decide quickly whether we will go for a large expensive plasma screen or for a bunch of smaller and cheaper ones and tile them together."

Our approach to filtering recognition errors is to identify **semantic outliers**. By this, we mean words that do not cohere well semantically with other words in the transcript. More often than not, such outliers turn out to be mistranscribed words. We present several variants of an algorithm for identifying semantic outliers, and evaluate them in terms of how well they are able to filter out recognition errors.

2 Related Work

Hirschberg *et al.* (1999), and Nakatani *et al.* (1998) proposed the idea of using automatic transcripts for gisting and navigating audio documents. Text-based summarization techniques on automatic speech transcription have also been used. For example, the method of Désilets *et al.* (2001) was found to produce accurate keyphrases for transcriptions with Word Error Rates (WER) in the order of 25%, but performance was less than ideal for transcripts with WER in the order of 60%. With such transcripts, a large proportion of the extracted keyphrases included serious transcription errors. Inkpen and Désilets (2004) presented an experiment that filters out errors in keywords extracted from speech, by identifying the keywords that are not semantically close to the rest of the keywords.

Semantic similarity measures were used for many tasks. Two examples are: real-word error correction (Budanitsky and Hirst, 2000) and answering synonym questions (Turney, 2001), (Jarmasz and Szpakowicz, 2003).

There is a lot of research on confidence measures for identifying errors in speech recognition output. Most papers on this topic use information that is internal to the ASR system, generated by the decoder during the recognition process. Examples are likelihood ratios derived by a Viterbi decoder (Gillick *et al.*, 1997), measures of competing words at a word boundary (Cox and Rose, 1996), word score densities in N-best lists, and various acoustic and phonetic features. Machine learning techniques were used to identify the best combinations of features for classification (Chase, 1997) (Schaaf and Kemp, 1997) (Ma *et al.*, 2001) (Skantze and Edlund, 2004) (Zhou and Meng, 2004) (Zhou *et al.*, 2005). Some of these methods achieve good performance, although they use different test sets and report different evaluation measures from the set we enumerate in Section 6.

In our work, we use information that is external to the ASR system, because new knowledge seems likely to help in the detection of semantic outliers. In this respect, the work of Cox and Dasmahapatra (2000) is closest to ours. They compared the accuracy of a measure based on Latent Semantic Analysis (LSA) (Landauer and Dumais, 1997) to an ASR-based confidence measure, and found that the ASR-based measure (using N-best lists) outperformed the LSA approach. While the N-best lists approach was better at the high-Recall end of the spectrum, the LSA was better at the high-Precision end. They also showed that a hybrid combination of the two approaches worked best. Our work is similar to the LSA-based part of Cox and Dasmahapatra, except that we use **Point-wise Mutual Information** (PMI) instead of LSA. Because PMI scales up to very large corpora, it has been shown to work better than LSA for assessing the semantic similarity of words (Turney, 2001). Another distinguishing feature is that Cox and Dasmahapatra only looked at transcripts with moderate WER, whereas we additionally evaluate the technique for the purpose of doing error filtering on transcripts with high WER, which are more typical of non-broadcast conversational audio.

3 The Data

We evaluated our algorithms on a randomly selected subset of 100 stories from the TDT2 English Audio corpus. We conducted experiments with two types of automatically-generated speech transcripts. The first ones were generated by the NIST/BBN time-adaptive speech recognizer and have a moderate WER (27.6%), which is representative of what can be obtained with a speaker-independent ASR system tuned for the Broadcast News domain. In the rest of this paper, we refer to these moderate accuracy transcripts as the **BBN dataset**. The second set of transcripts was obtained using the Dragon NaturallySpeaking speaker-dependent recognizer. Their WER (62.3%) was much higher because the voice model was not trained for speaker-independent broadcast quality audio. These transcripts approximate the type of high WER seen in more casual less-than-broadcast quality audio. We refer to these transcripts as the **Dragon dataset**.

4 The method

Our algorithm tries to detect recognition errors by identifying and filtering semantic outliers in the transcripts. In other words, it declares as recognition errors all the words with low semantic similarity to other words in the transcript. The algorithm focuses on **content words**, i.e., words that do not appear in a list of 779 stopwords (including closed-class words, such as prepositions, articles, etc.). The reason to ignore stopwords is that they tend to co-occur with most words, and are therefore semantically coherent with most words. The basic algorithm for determining if a word **w** is a recognition error is as follows.

1. Compute the **neighborhood** N(w) of w as the set of content words that occur before and after w in a context window (including w itself).

2. Compute **pair-wise semantic similarity** scores $S(w_i, w_j)$ between all pairs of words $w_i \neq w_j$ (including w) in the neighborhood N(w), using a semantic similarity measure. Scale up those $S(w_i, w_j)$ by a constant so that they are all non-negative, and the smallest one is 0.

3. For each w_i in the neighborhood N(w) (including w), compute its **semantic coherence** $SC(w_i)$. by "aggregating" the pair-wise semantic similarities $S(w_i, w_j)$ of w_i with all its neighbors ($w_i \neq w_j$) into a single number.

4. Let SC_{avg} be the average of $SC(w_i)$ over all w_i in the neighborhood N(w).

5. Label w as a recognition error if $SC(w) < K \cdot SC_{avg}$, where K is a parameter that allows us to control the amount of error filtering (K% of the average semantic coherence score). Low values of K mean little error filtering and high values of K mean a lot of error filtering.

We tested a number of variants of Steps 1-3. For Step 1, we experimented with two ways of computing the neighborhood N(w). The first approach was to set N(w) to be all the words in the transcript (the **All** variant). The second neighborhood approach was to set N(w) to be the set of 10 content words before and after w in the transcript (the **Window** variant).

For Step 2 we experimented with two different measures for evaluating the pair-wise semantic similarities $S(w_i, w_j)$. The first measure used a hand-crafted dictionary (the **Roget** variant) whereas the second one used a statistical measure based on a large corpus (the **PMI** variant).

For Step 3 we experimented with different schemes for "aggregating" the pair-wise semantic similarities $S(w_i, w_j)$ into a single semantic coherence number $SC(w_i)$ for a given word w_i. The first aggregation scheme was simply to average the $SC(w_i)$ values (the **AVG** variant). Note that with this scheme, we filter words that do not cohere well with all the words in the neighborhood N(w). This might be too aggressive in the case of the **All** variant, especially for longer or multi-topic audio documents. Therefore, we investigated other aggregation schemes that only required words to cohere well with a subset of the words in N(w). The second aggregation scheme was to set $SC(w_i)$ to the value of the most similar neighbor in N(w) (the **MAX** variant). The third aggregation scheme was to set $SC(w_i)$ to the average of the 3 most similar neighbors in N(w) (the **3MAX** variant).

Thus, there are altogether 2x2x3 = 12 possible configurations of the algorithm. In the rest of this paper, we will refer to specific configurations using the following naming scheme: **Step1Variant-Step2Variant-Step3Variant**. For example, All-PMI-AVG means the configuration that uses the All variant of Step 1, the PMI variant of Step 2, and the AVG variant of step 3.

It is worth noting that all configurations of this algorithm are computationally intensive, mainly because of Step 2. However, since our aim is to provide transcripts for browsing audio recordings, we do not have to correct errors in real time.

5 Choosing a semantic similarity measure

Semantic similarity refers to the degree with which two words (two concepts) are related. For example, most human judges would agree that *paper* and *pencil* are more closely related than *car* and *toothbrush*. We use the term *semantic similarity* in this paper in a more general sense of *semantic relatedness* (two concepts can be related by their context of use without necessarily being similar).

There are three types of semantic similarity measures: dictionary-based (lexical taxonomy structure), corpus-based, and hybrid. Most of the dictionary-based measures use path length in WordNet – for example (Leacock and Chodorow, 1998), (Hirst and St-Onge, 1998). The corpus-based measures use some form of vector similarity. The cosine measure uses frequency counts in its vectors and cosine to compute similarity; the simpler methods use binary vectors and compute coefficients such as: Matching, Dice, Jaccard, and Overlap. Examples of hybrid measures, based on WordNet and small corpora, are: Resnik (1995), Jiang and Conrath (1997), Lin (1998). All dictionary-based measures have the disadvantage of limited coverage: they cannot deal with many proper names and new words that are not in the dictionary. For WordNet-based approaches, there is the additional issue that they tend to work well only for nouns because the noun hierarchy in WordNet is the most developed. Also, most of the WordNet-based measures do not work for words with different part-of-speech, with small exceptions such as the extended Lesk measure (Banerjee and Pedersen, 2003).

We did a pre-screening of the various semantic similarity measures in order to choose the one measure of each type (dictionary-based and corpus-based) that seemed most promising for our task of detecting semantic outliers in automatic speech transcripts. The dictionary-based approaches that we evaluated were: the WordNet-based measure by Leacock and Chodorow (1987), and one other dictionary-based measure that uses the Roget thesaurus. The Roget measure (Jarmasz and Szpakowicz, 2003) has the advantage that it works across part-of-speech. The corpus-based measures we evaluated were: (a) the cosine measure based on word co-occurrence vectors (Lesk, 1969), (b) a new method that computes the Pearson correlation coefficient of the co-occurrence vectors instead of the cosine, and (c) a measure based on point-wise mutual information. We computed the first two measures on the 100-million-words British National Corpus (BNC)[1], and the third one on a much larger-corpus of Web data (one terabyte) accessed through the Waterloo Multitext system (Clarke and Terra, 2003). The reason for using corpora of different sizes is that PMI is the only one of the three corpus-based approaches that scales up to a terabyte corpus.

We describe here in detail the PMI corpus-based measure, because it is the most important for this paper. The semantic similarity score between two words w_1 and w_2 is defined as the probability of seeing the two words together divided by the probability of each word separately: $PMI(w_1,w_2) = \log [P(w_1,w_2) / (P(w_1)\cdot P(w_2))] = \log [C(w_1,w_2)\cdot N / (C(w_1)\cdot C(w_2))]$, where $C(w_1,w_2)$, $C(w_1)$, $C(w_2)$ are frequency counts, and N is the total number of words in the corpus. Such counts can easily and efficiently be retrieved for a terabyte corpus using the Waterloo Multitext system.

In order to assess how well the semantic similarity measures correlate with human perception, we use the set of 30 word pairs of Miller and Charles (1991), and the 65 pairs of Rubenstein and Goodenough (1965). Both used humans to judge the similarity. The Miller and Charles pairs were a subset of the Rubenstein and Goodenough pairs. Note that both of those sets were limited to nouns that appeared in the Roget thesaurus, and they are therefore favorably biased towards dictionary-based approaches. Table 1 shows the correlation of 5 similarity measures for the Rubenstein and Goodenough (R&G) and Miller and Charles (M&C) dataset. Note that although there are many WordNet-based semantic similarity measures, we only show correlations for Leacock and Chodorow (L&C) because it was previously shown to be better correlated (Jarmasz and Szpakowicz, 2003). We do not show figures for hybrid measures either because the same study showed L&C to be better.

Table 1: Correlation between human assigned and various machine assigned semantic similarity scores.

	Dictionary-based		**Corpus-based**		
	L&C	**Roget**	**Cos.**	**Corr.**	**PMI**
M&C	0.821	0.878	0.406	0.438	0.759
R&G	0.852	0.818	0.472	0.517	0.746

We see that the WordNet-based L&C measure based (Leacock and Chodorow, 1998 and the Roget measure (Jarmasz and Szpakowicz, 2003) both achieve high correlations but the two vector corpus-based measures (Cosine and Pearson Correlation) achieve much lower correlation. The only corpus-based measure that does well is PMI, probably because of the much larger corpus.

[1] http://www.natcorp.ox.ac.uk/index.html

We decided to experiment with two of the measures (one corpus-based and one thesaurus based) for computing the semantic similarity of word pairs in Step 2 of the algorithm described in Section 3. The two measures are: PMI computed on the Waterloo terabyte corpus and the Roget-based measure. These two seem the most promising given the nature of our task and the correlation figures reported above.

6 Evaluation Measures

We use several evaluation measures to determine how well our algorithm works for identifying semantic outliers. As summarized in Table 2, the task of detecting recognition errors can be viewed as a classification task. For each word, the algorithm must predict whether or not that word was transcribed correctly.

Table 2: Recognition error detection can be seen as a classification task.

	Correctly transcribed (actual)	NOT Correctly transcribed (actual)
Correctly transcribed (predicted)	True Positive (TP)	False Positive (FP)
NOT Correctly transcribed (predicted)	False Negative (FN)	True Negative (TN)

Note that we decide if a word is actually correctly transcribed or not by using the alignment of an automatic transcript with the manual transcript. A standard evaluation tool (sclite[2]) computes WER by counting the number of substitutions, deletions, and insertions needed to align a reference transcript with a hypothesis file. It also marks the words that are correct in automatic transcript (the hypothesis file). The rest of the words are the actual recognition errors (the insertions or substitutions). The deletions – words that are absent from the automatic transcript – cannot be tagged by the confidence measure.

We define the following performance measures in order to evaluate the improvement of the filtered transcripts compared to the initial transcripts:

1. **Word error rate** in the initial transcript and in the filtered transcript. These measures can be computed with and without stopwords (for which our algorithm does not apply). Note that WER without stopwords could be slightly lower than traditional WER mostly because content words tend to be recognized more accurately than stopwords (Désilets *et al.* 2001). When filtering out semantic outliers, there will be gaps in the filtered transcript, therefore the general WER might not improve because it penalizes heavily the deletions.

2. **Content word error rate (cWER)**. This is the error rate in an automatic transcript (initial or filtered) from the point of view of the confidence measure, for the content words only. It penalizes the words in the automatic transcripts that should not be there, but not any missing words (no deletions are penalized). In the case of a transcript filtered by our algorithm, it excludes not only the stopwords, but also the filtered words. We computed cWER with sclite without penalizing for the gaps created by the filtered words.

3. **The percentage of lost good content words (%Lost)**. This is the percentage of correctly recognized content words which are lost in the process of filtering out recognition errors, defined as: %Lost = 100 * FN / (TP + FN). We could also compute the **percent of discarded words**, without regard if they should have been filtered out or not. D = (TN + FN) / (TP + FP + TN + FN).

4. **Precision (P)**, **Recall (R)** and **F-measure**. **Precision** is the proportion of truly correct words contained in the list of content words which the algorithm labeled as correct. **Recall** is the proportion of truly correct content words that the algorithm was able to retain. **F-measure** is the geometric mean of P and R and expresses a tradeoff between those two measures. P = TP / (TP + FP); R = TP / (TP + FN); F = 2PR / (P+R).

7 Results

We ran various configurations of the algorithm described in Section 4 on the 100 story sample from the TDT2 corpus. This section discusses the results of those experiments. We studied the Precision-Recall (P-R) curves for various configurations of our algorithm over the 100 stories, for the two types of transcripts: the BBN and Dragon datasets. Figures 1 and 2 show an example for each dataset. Each point on a P-R curve shows the Precision and Recall for one value of K in {0, 20, 40, 60, 80,

[2] http://www.nist.gov/speech/tools/

100, 120, 140, 160, 180, 200}. Points on the left correspond to aggressive filtering (high values of K), whereas points on the right correspond to lenient filtering (low values of K).

First, we looked at the relative merits of the two semantic similarity measures (PMI and Roget) for Step 2. Figures 1 and 2 plot the P-R curves for the All-PMI-AVG and All-Roget-AVG configurations. The graphs clearly indicate that PMI performs better, especially for the high WER Dragon dataset. So PMI was used in the rest of the experiments.

Next, we looked at the variants for setting up the neighborhood N(w) in Step 1 (All vs. Window). The three P-R curves for All-PMI-X and Window-PMI-X for all aggregation approaches X in {AVG, MAX, 3MAX} are not shown here because they were similar to the P-PMI curves from Figures 1 and 2, for the BBN dataset and for the Dragon dataset, respectively. The Window variant was marginally better for X=MAX on both datasets, as well as for X=3MAX on the BBN dataset. In all other cases, the Window and All variants performed approximately the same.

Next, we looked at the different schemes for aggregating the pair-wise similarity scores in Step 3 (AVG, MAX, 3MAX). By plotting the P-R curves for All-PMI-AVG, All-PMI-MAX, and All-PMI-3MAX for both datasets we obtained again curves similar to the P-PMI curves from Figures 1 and 2. It seemed that AVG performs slightly better for high Recall, the difference being more marked when there is no windowing or when we are working on the Dragon dataset. The 3MAX and MAX variants seemed to be slightly better at high Precision with acceptable Recall values, with 3MAX being always equal or very slightly better than MAX. In an audio gisting and browsing context Precision is more important than Recall, therefore we can choose 3MAX.

Having established Window-PMI-3MAX as one of the better configurations, we now look more closely at its performance.

Figures 3 and 4 show how the content word error rate (cWER), the percentage of lost good words (%Lost), and the F-measure vary as we apply more and more aggressive error filtering (by increasing K) to both datasets. We see that our semantic outlier filtering approach is able to significantly reduce the number of transcription errors, while losing some correct words. For example, with the

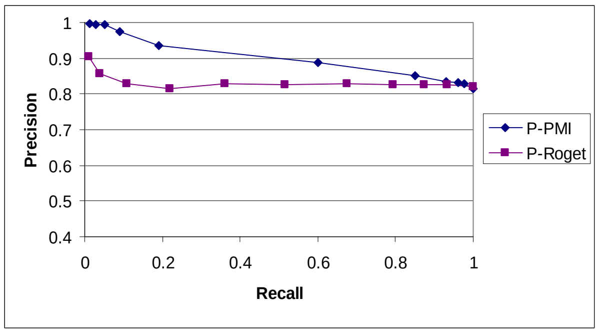

Fig 1: P-R curves of PMI vs. Roget (with All and AVG) on the BBN dataset. Each P-R point corresponds to a different value of the threshold K (high Recall for low values of K, high Precision for high values of K).

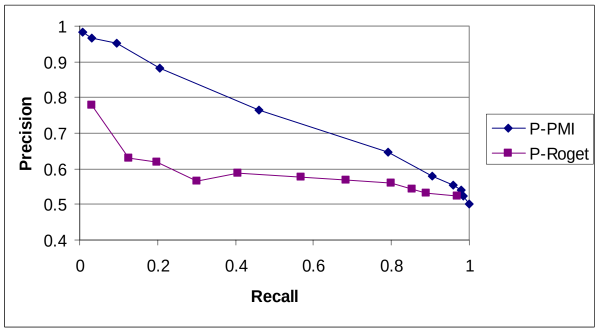

Fig 2: P-R curves of PMI vs. Roget (with All and AVG) on the Dragon dataset

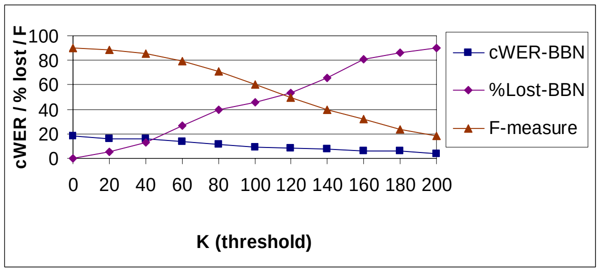

Fig.3. Content Words Error Rate (cWER), %Lost good keywords (%Lost) and F-measure as a function of the filtering level K for the Window-PMI-3MAXconfiguration on the BBN dataset.

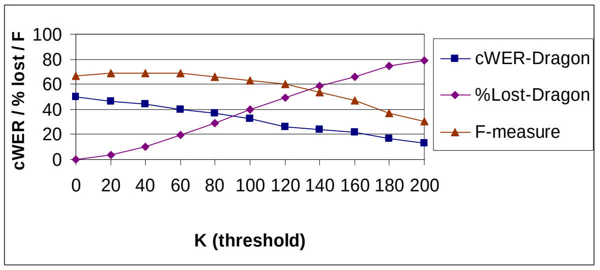

Fig.4. Content Words Error Rate (cWER), %Lost good keywords (%Lost) and F-measure as a function of the filtering level K for the Window-PMI-3MAX configuration on the Dragon dataset.

moderately accurate BBN dataset, we can reduce cWER by 50%, while losing 45% of the good content words (K=100). For the low accuracy Dragon dataset, we can reduce cWER by 50%, while losing 50% of the good content words (K=120). We can choose lower thresholds, for smaller reduction in cWER but smaller percent of lost good content words. Even small reductions in cWER are important, especially for less-than-broadcast conditions where WER is initially very high.

In general, we were not able to show an improvement in WER computed in a standard way (item 1 in Section 6), because of the high penalty due to deletions for both filtered semantic outliers and lost good content words. The percent of lost good words is admittedly too high, but this seems to be the case for speech error confidence measures (which do not remove the words tagged as incorrect). Also, for the purpose of audio browsing and gisting, we believe that fewer errors even with loss of content are preferable for intelligibility.

Comparing our results to those reported by Cox and Dasmahapatra (2000) our PMI-based measure seems to performs better than their LSA-based measure, judging by the shape of the Precision-Recall curves. (For example, at Precision=90%, they obtained Recall=12%, whereas we obtain 20%. At Precision=80%, they obtain Recall=50%, whereas we get Recall=100%.) Note however that their results and ours are not completely comparable since the experiments used different audio corpora (WSJCAM0 vs. TDT2), but those two corpora seem to exhibit similar initial WERs (the WER appears to be around 30% for WSJCAM0; the WER is 27.6% for our BBN dataset). Also, it is worth noting the LSA measure was computed based on a corpus that was very similar to the audio corpus used to evaluate the performance of the measure (both were Wall Street Journal corpora). If one was to evaluate this measure on audio from a completely different domain (ex: news in the scientific or technical domain), one would expect the performance to drop significantly. In contrast, our PMI measure was computed based on a general sample of the World Wide Web, which was not tailored to the audio corpus used to evaluate its performance. Therefore, our numbers are probably more representative of what would be experienced with audio corpora outside of the Wall Street Journal domain.

8 Conclusion and Future Work

We presented a basic method for filtering recognition errors of content words from automatic speech transcripts, by identifying semantic outliers. We described and evaluated several variants of the basic algorithm.

In future work, we plan to run our experiments on other datasets when they become available to us. In particular, we want to experiment with multi-topic audio documents where we expect more marked advantages for windowing and alternative aggregation schemes like MAX and 3MAX. We plan to explore ways to scale up other corpus-based semantic similarity measures to large terabyte corpora. We plan to explore more approaches to detecting semantic outliers, for example clustering or lexical chains (Hirst and St-Onge, 1997).

The most promising direction is to combine our method with confidence measures that use internal information from the ASR system (although the internal information is hard to obtain when using an ASR as a black box, and it could be recognizer-specific). A combination is likely to improve the performance, with the PMI-based measure contributing at the high-Precision end and the internal ASR measure contributing to the high-Recall end of the spectrum. To increase Recall we can also identify named entities and not filter them out. Some named entities could have high semantic similarity with the text if they are frequently mentioned in the same contexts in the Web corpus, but some names could be common to many contexts.

Another future direction will be to actually correct the errors instead of just filtering them out. For example, we might look at the top N speech recognizer hypotheses (for a fairly large N like 1000) and choose the one that maximizes semantic cohesion. A final direction for research is to conduct experiments with human subjects, to evaluate the degree to which filtered transcripts are better than unfiltered ones for tasks like browsing, gisting and searching audio clips.

Acknowledgments

We thank the following people: Peter Turney and his colleagues for useful feedback; Gerald Penn for feedback on earlier versions of this paper; Egidio Terra and Charlie Clarke for giving us permission to use the Multitext System, the NRC copy; Mario Jarmasz and Stan Szpakowicz for sharing their code for the Roget similarity measure; Aminul Islam for the correlation figures and the correlative measure. Our research is supported by the Natural Sciences and Engineering Research Council of Canada, University of Ottawa, IBM Toronto Centre for Advanced Studies, and the National Research Council.

Redundancy-based Correction of Automatically Extracted Facts

Roman Yangarber and **Lauri Jokipii**
Department of Computer Science
University of Helsinki, Finland
`first.last@cs.helsinki.fi`

Abstract

The accuracy of event extraction is limited by a number of complicating factors, with errors compounded at all sages inside the Information Extraction pipeline. In this paper, we present methods for recovering automatically from errors committed in the pipeline processing. Recovery is achieved via post-processing facts aggregated over a large collection of documents, and suggesting corrections based on evidence external to the document. A further improvement is derived from propagating multiple, *locally non-best* slot fills through the pipeline. Evaluation shows that the global analysis is over 10 times more likely to suggest valid corrections to the local-only analysis than it is to suggest erroneous ones. This yields a substantial overall gain, with no supervised training.

1 Introduction

Information Extraction (IE) is a technology for finding facts in plain text, and coding them in a logical representation, such as, e.g., a relational database. IE is typically viewed and implemented as a sequence of stages—a "pipeline":

1. Layout, tokenization, lexical analysis
2. Name recognition and classification
3. Shallow (commonly,) syntactic parsing
4. Resolution of co-reference among entities
5. Pattern-based event matching and role mapping
6. Normalization and output generation

While accuracy at the lowest levels can reach high 90's, as the stages advance, complexity increases and performance degrades considerably.

The problem of IE as a whole, as well each of the listed subproblems, has been studied intensively for well over a decade, in many flavors and varieties. Key observations about much state-of-the-art IE are:

a. IE is typically performed by a pipeline process;

b. Only one hypothesis is propagated through the pipeline for each fact—the "best guess" the system can make for each slot fill;

c. IE is performed in a document-by-document fashion, applying *a priori* knowledge locally to each document.

The *a priori* knowledge may be encoded in a set of rules, an automatically trained model, or a hybrid thereof. Information extracted from documents—which may be termed *a posteriori* knowledge—is usually not reused across document boundaries, because the extracted facts are imprecise, and are therefore not a reliable basis for future extraction.

Furthermore, locally non-best slot fills are not propagated through the pipeline, and are consequently not available downstream, nor for any global analysis.

In most systems, these stages are performed in sequence. The locally-best slot fills are passed from the "lower-" to the "higher-level" modules, without feedback. Improvements are usually sought (e.g., the ACE research programme, (ACE, 2004)) by boosting performance at the lower levels, to reap benefits in the subsequent stages, where fewer errors are propagated.

The point of departure for this paper is: the IE process is noisy and imprecise at the single-document level; this has been the case for some time, and though there is much active research in the area, the situation is not likely to change radically in the immediate future—rather, we can expect slow, incremental improvements over some years.

In our experiments, we approach the performance problem from the opposite end: start with the extracted results and see if the totality of *a posteriori* knowledge about the domain—knowledge generated by the same noisy process we are trying to improve—can help recover from errors that stem from locally insufficient *a priori* knowledge.

The aim of the research presented in this paper is to improve performance by aggregating related facts, which were extracted from a large document collection, and to examine to what extent the correctly extracted facts can help correct those that were extracted erroneously.

The rest of the paper is organized as follows. Section 2 contains a brief review of relevant prior work. Section 3 presents the experimental setup: the text corpus, the IE process, the extracted facts, and what aspects of the the extracted facts we try to improve in this paper. Section 4 presents the methods for improving the quality of the data using global analysis, starting with a naive, baseline method, and proceeding with several extensions. Each method is then evaluated, and the results are examined in section 5. In section 6, we present further extensions currently under research, followed by the conclusion.

2 Prior Work

As we stated in the introduction, typical IE systems consist of modules arranged in a cascade, or a pipeline. The modules themselves are be based on heuristic rules or automatically trained, there is an abundance of approaches in both camps (and everywhere in between,) to each of the pipeline stages listed in the introduction.

It is our view that to improve performance we ought to depart from the traditional linear, pipeline-style design. This view is shared by others in the research community; the potential benefits have previously been recognized in several contexts.

In (Nahm and Mooney, 2000a; Nahm and Mooney, 2000b), it was shown that learning rules from a fact base, extracted from a corpus of job postings for computer programmers, improves future extraction, even though the originally extracted facts themselves are far from error-free. The idea is to mine the data base for association rules, and then to integrate these rules into the extraction process.

The baseline system is obtained by supervised learning from a few hundred manually annotated examples. Then the IE system is applied to successively larger sets of unlabeled examples, and association rules are mined from the extracted facts. The resulting combined system (trained model plus association rules) showed an improvement in performance on a test set, which correlated with the size of the unlabeled corpus.

In work on improving (Chinese) named entity tagging, (Ji and Grishman, 2004; Ji and Grishman, 2005), show benefits to this component from integrating decisions made in later stages, viz. coreference, and relation extraction.[1]

Tighter coupling and integration between IE and KDD components for mutual benefit is advocated by (McCallum and Jensen, 2003), which present models based on CRFs and supervised training.

This work is related in spirit to the work presented in this paper, in its focus on leveraging cross-document information that information—though it is inherently noisy—to improve local decisions. We expect that the approach could be quite powerful when these ideas are used in combination, and our experiments seem to confirm this expectation.

3 Experimental Setup

In this section we describe the text corpus, the underlying IE process, the form of the extracted facts, and the specific problem under study—i.e., which aspects of these facts we first try to improve.

[1]Performance on English named entity tasks reaches mid to high 90's in many domains.

3.1 Corpus

We conducted experiments with redundancy-based auto-correction over a large database of facts extracted from the texts in ProMED-Mail, a mailing list which carries reports about outbreaks of infectious epidemics around the world and the efforts to contain them. This domain has been explored earlier; see, e.g., (Grishman et al., 2003) for an overview.

Our underlying IE system is described in (Yangarber et al., 2005). The system is a hybrid automatically- and manually-built pattern base for finding facts, an HMM-based name tagger, automatically compiled and manually verified domain-specific ontology, based in part on MeSH, (MeS, 2004), and a rule-based co-reference module, that uses the ontology.

The database is live on-line, and is continuously updated with new incoming reports; it can be accessed at `doremi.cs.helsinki.fi/plus/`.

Text reports have been collected by ProMED-Mail for over 10 years. The quality of reporting (and editing) has been rising over time, which is easy to observe in the text data. The distribution of the data, aggregated by month is shown in Figure 1, where one can see a steady increase in volume over time.[2]

3.2 Extracted Facts

We now describe the makeup of the data extracted from text by the IE process, with basic terminology.

Each document in the corpus, contains a single *report*, which may contain one or more *stories*. Story breaks are indicated by layout features, and are extracted by heuristic rules, tuned for this domain and corpus. When processing a multi-story report, the IE system treats each story as a separate document; no information is shared among stories, except that the text of the main headline of a multi-story report is available to each story. [3]

Since outbreaks may be described in complex ways, it is not obvious how to represent a single fact in this context. To break down this problem, we use the notion of an *incident*. Each story may contain

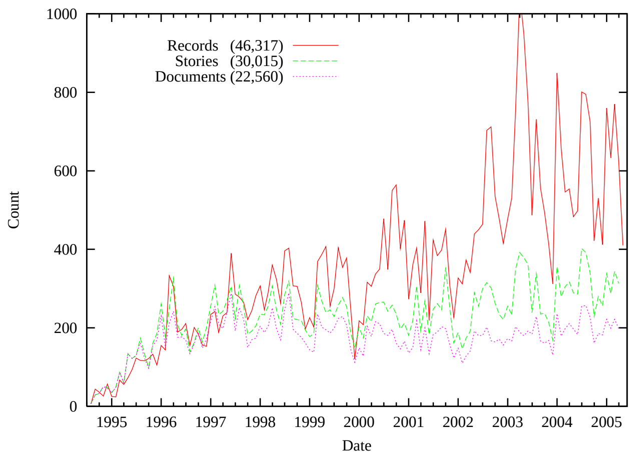

Figure 1: Distribution of data in ProMED-Mail

multiple outbreak-related incidents/facts.[4]

We analyze an outbreak as a series of incidents. The incidents may give "redundant" information about an outbreak, e.g., by covering overlapping time intervals or geographic areas. For example, a report may first state the number of cases within the last month, and then give the total for the entire year. We treat each of these statements as a separate incident; the containment relations among them are beyond the scope of our current goals.[5]

Thus each incident corresponds to a partial description of an outbreak, over a period of time and geographic area. This makes it easy to represent each incident/fact as a separate row in the table.

The key fields of the incident table are:

- Disease Name
- Location
- Date (start and end)

Where possible, the system also extracts information about the victims affected in the incident—their count, severity (affected or dead), and a descriptor (people, animals, etc.). The system also extracts bookkeeping information about each incident: locations of mentions of the key fields in the text, etc.

The system's performance is currently at 71.16 F-measure: 67% recall, 74% precision. This score is obtained by a MUC scorer (Douthat, 1998) on a 50-document test corpus, which was manually tagged with correct incidents with these slots. We have

[2]This is beneficial to the IE process, which operates better with formulaic, well-edited text.

[3]The format of the documents in the archive can be examined by browsing the source site `www.promedmail.org`.

[4]In this paper, we use the terms *fact*, *incident*, and *event* interchangeably.

[5]This problem is addressed in, e.g., (Huttunen et al., 2002).

no blind-test corpus at present, but prior experience suggests that we ought to expect about a 10% reduction in F-measure on unseen data; this is approximately borne out by our informal evaluations.

Further, the system attempts to "normalize" the key fields. An alias for a disease name (e.g., "bird flu") is mapped to a *canonical* name ("avian influenza.")[6] Date expressions are normalized to a standard format `yyyy.mm.dd`–`yyyy.mm.dd`.[7]

Note that the system may not be able to normalize some entities, which then remain un-normalized.

Such normalization is clearly helpful for searching, but it is not only a user-interface issue. Normalizing reduces sparseness of data; and since our intent is to aggregate related facts across a large fact base, excessive variation in the database fields would reduce the effectiveness of the proposed methods.

3.3 Experimental Focus: Location Normalization

A more complex problem arises out of the need to normalize location names. For each record, we normalize the location field—which may be a name of a small village or a larger area—by relating it to the name of the containing country; we also decided to map locations in the United States to the name of the containing state, (rather than the name of the country, "USA").[8] This mapping will be henceforth referred to as "location–state," for short. The ideas presented in the introduction are explored in the remainder of this paper in the context of correcting the location–state mapping.

Section 6 will touch upon our current work on extending the methodology to slots other than *state*. (Please see Section 5 for further justification of this choice for our initial experiments.)

To make the experiments interesting and fair, we kept the size of the gazetteer small. The *a priori* geographic knowledge base contains names of countries of the world (270), with aliases for several of them; a list of capitals and other selected major cities (300); a list of states in the USA and acronyms (50); major US cities (100); names of the (sub)continents (10), and oceans. In our current implementation, continents are treated semantically as "states" as well.[9]

The IE system operates in a local, document-by-document fashion. Upon encountering a location name that is not in its dictionaries, the system has two ways to map it to the state name. One way is by matching patterns over the immediate local context, ("Milan, Italy"). Failing that, it tries to find the corresponding state by positing an "underspecified" state name (as if referred to by a kind of special "pronoun") and mapping the location name to that. The reference resolution module then finds the most likely antecedent entity, of the semantic type "state/country," where likelihood is determined by its proximity to the mention of the location name.

Note that the IE system outputs only a single, best hypothesis for the *state* fill for each record.

3.4 The Data

The database currently contains about $46,317$ individual facts/incidents, extracted from $30,015$ stories, from $22,560$ reports (cf. Fig. 1). Each incident has a *location* and a *state* filler. We say a location name is "ambiguous" if it appears in the *location* slot of at least two records, which have different names in the *state* slot. The number of distinct "ambiguous" location names is $1,020$.

Note, this terminology is a bit sloppy: the fillers to which we refer as "ambiguous location names", may not be valid location names at all; they may simply be errors in the IE process. E.g., at the name classification stage, a disease name (especially if not in the disease dictionary) may be misclassified, and used as a filler for the *location* slot.

We further group together the *location* fills by stripping lower-case words that are not part of the proper name, from the front and the end of the fill. E.g., we group together "southern Mumbai" and "the Mumbai area," as referring to the same name.

After grouping and trimming insignificant words, the number of distinct names appearing in *location* fills is 600, which covers a total of 6583 records, or 14.2% of all extracted facts. As an estimate of the *potential* for erroneous mapping from locations to states, this is quite high, about 1 in 7 records.[10]

[6]This is done by means of a set of scenario-specific patterns and a dictionary of about 2500 disease names with aliases.

[7]Some date intervals may not have a starting date, e.g., if the text states "As of last Tuesday, the victim count is N..."

[8]This decision was made because otherwise records with state = USA strongly skew the data, and complicate learning.

[9]By the same token, both *Connecticut* and *USA* are "states."

[10]Of course, it can be higher as well, if the IE system con-

4 Experiments and Results

We now present the methods of correcting possible errors in the location–state relation. A method M tries to suggest a new value for the *state* fill for every incident $\mathbf{I}$ that contains an ambiguous *location* fill:

$$NewState(\mathbf{I}) = \arg \max_{s \in \mathcal{S}_M(\mathbf{I})} Score_M(s, \mathbf{I}) \quad (1)$$

where $\mathcal{S}_M(\mathbf{I})$ is a set of all candidate states considered by M for $\mathbf{I}$; $Score_M(s, \mathbf{I})$ is the scoring function specific to M. The method chooses the candidate state which maximizes the score.

For each method below, we discuss how $\mathcal{S}_M$ and $Score_M$ are constructed.

4.1 Baseline: Raw Majority

We begin with a simple recovery approach. We simply assume that the correct state for an ambiguous location name is the state most frequently associated with it in the database. We denote by $\mathcal{D}$ the set of all incidents in the database. For an incident $\mathbf{I} \in \mathcal{D}$, we write $l, s \sqsubset \mathbf{I}$ when location l, state s, etc., "belong" to $\mathbf{I}$, i.e., are extracted as fills in $\mathbf{I}$. In the baseline method, B, for each incident $\mathbf{I}$ where $l \sqsubset \mathbf{I}$ is one of the 600 ambiguous location names, we define:

$$\mathcal{S}_B(\mathbf{I}) = \{s' : \exists \mathbf{I}' \in \mathcal{D} \mid (l, s') \sqsubset \mathbf{I}'\}$$
$$Score_B(s', \mathbf{I}) = |\{\mathbf{I}' \in \mathcal{D} \mid (l, s') \sqsubset \mathbf{I}'\}|$$

i.e., s' is a candidate if it is a *state* fill in some incident whose *location* fill is also l; the score is the number of times the pair (l, s') appear together in some incident in $\mathcal{D}$. The majority winner is then suggested as the "correct" state, for *every* record containing l. By "majority" winner we mean the candidate with the *maximal* count, rather than a state with more than half of the votes. When the candidates tie for first place, no suggestions are made—although it is quite likely that some of the records carrying l will have incorrect *state* fills.

A manual evaluation of the performance of this method is shown in Table 1, the *Baseline* column.

The first row shows for how many records this method suggested a change from the original, IE-filled *state*. The baseline changed 858 incidents. This constitutes about 13% out of the maximum number of changeable records, 6583.

Thus, this number represents the volume of the potential gain or loss from the global analysis: the proportion of records that actually get modified.

The remaining records were unchanged, either because the majority winner coincides with the original IE-extracted state, or because there was a tie for the top score, so no decision could be made.

We manually verified a substantial sample of the modified records. When verifying the changes, we referred back to the text of the incident, and, when necessary, consulted further geographical sources to determine exactly whether the change was correct in each case.

For the baseline we had manually verified 27.7% of the changes. Of these, 68.5% were a clear gain: an incorrect state was changed to a correct state. 6.3% were a clear loss, a correct state lost to an incorrect one. This produces quite a high baseline, surprisingly difficult to beat.

The next two rows represent the "grey" areas. These are records which were difficult to judge, for one of two technical reasons. A: the "location" name was itself *erroneous*, in which case these redundancy-based approaches are not meaningful; or, B: the suggestion replaces an area by its sub-region or super-region, e.g., changing "Connecticut" to "USA", or "Europe" to "France."[11]

Although it is not strictly meaningful to judge whether these changes constitute a gain or a loss, we nonetheless tried to assess whether changing the state hurt the accuracy of *the incident*, since the incident may have a correct state even though its location is erroneous (case A); likewise, it may be correct to say that a given location is indeed a part of Connecticut, in which case changing it to USA loses information, and is a kind of loss.

That is the interpretation of the grey gain and loss instances. The final row, *no loss*, indicates the proportion of cases where an originally incorrect state name was changed to a new one, also incorrect.

sistently *always* maps some location name to the same wrong state; these cases are below the radar of our scheme, in which the starting point is the "ambiguous" locations.

[11]Note, that for some locations, which are not within any one state's boundary, a continent is a "correct state", for example, "the Amazon Region," or "Serengeti."

Records	*Baseline*		*DB-filtered*		*Confidence*		*Multi-candidate*	
Changed	13.0%	858/6583	8.7%	577/6583	9.7%	642/6583	**16.2**%	1072/6583
Verified	27.7%	238/858	38.6%	223/577	37.1%	238/642	26.5%	284/1072
Gain	68.5%	163/238	71.3%	159/223	80.3%	191/238	**76.4**%	217/284
Loss	6.3%	15/238	2.2%	5/223	1.3%	3/238	**3.5**%	10/284
Grey gain	10.9%	26/238	12.6%	28/223	11.8%	28/238	13.7%	39/284
Grey loss	6.7%	16/238	5.4%	12/223	0.0%	0/238	2.1%	6/284
No loss	7.6%	18/238	8.5%	19/223	6.7%	16/238	4.2%	12/284

Table 1: Performance of Correction Methods

4.2 Database Filtering

Next we examined a variant of baseline raw majority vote, noting that simply choosing the state most frequently associated with a location name is a bit naive: the location–state relation is not functional—i.e., some location names map to more than one state in reality. There are many locations which share the same name.[12]

To approach this more intelligently, we define:

$$\mathcal{S}_F(\mathbf{I}) = \mathcal{S}_B(\mathbf{I}) \cap StatesInStory(\mathbf{I})$$
$$Score_F(s', \mathbf{I}) = Score_B(s', \mathbf{I})$$

The baseline vote counting across the data base (DB) produced a ranked list of candidate states s' for the location $l \sqsubset \mathbf{I}$. We then filtered this list through $StatesInStory(\mathbf{I})$, the list of states mentioned in the story containing the incident $\mathbf{I}$. The filtered majority winner was selected as the suggested change.

For example, the name “Athens” may refer to the city in Greece, or to the city in Georgia (USA). Suppose that Greece is the raw majority winner. The baseline method will always tag all instances of Athens as being in Greece. However, in a story about Georgia, Greece will likely not be mentioned at all, so it is safe to rule it out. This helps a minority winner, when the majority is not present in the story.

Surprisingly, this method did not yield a substantial improvement over the baseline, (though it was more careful by changing fewer records). This may indicate that NWP is not an important source of errors here: though many truly ambiguous locations do exist, they do not account for many instances in this DB.

[12]We refer to this as the “New-World phenomenon” (NWP), due to its prevalence in the Americas: “Santa Cruz” occurs in several Latin American countries; locations named after saints are common. In the USA, city and county names often appear in multiple states—Winnebago County, Springfield; many cities are named after older European cities.

4.3 Confidence-Based Ranking

A more clear improvement over the baseline is obtained by taking the *local confidence* of the state–location association into account. For each record, we extend the IE analysis to produce a confidence value for the state. Confidence is computed by simple, document-local heuristics, as follows:

If the location and state are both within the span of text covered by the incident—text which was actually matched by a rule in the IE system,—or if the state is the *unique* state mentioned in the story, it gets a score of 2—the incident has high confidence in the state. Otherwise, if the state is outside the incident's span, but is inside the same sentence as the incident, and is also the unique state mentioned in that sentence, it gets a score of 1. Otherwise it receives a score of zero.

Given the confidence score for each (location l, state s) pair, the majority counting is based on the *cumulative confidence*, $conf_{state}$ (l, s) in the DB, rather than on the *cumulative count* of occurrences of this pair in the DB:

$$\mathcal{S}_C(\mathbf{I}) = \mathcal{S}_F(\mathbf{I})$$
$$Score_C(s', \mathbf{I}) = \sum_{\mathbf{I}' \in \mathcal{D} | (l, s') \sqsubset \mathbf{I}'} conf_{state}(\mathbf{I}')$$

Filtering through the story is also applied, as in the previous method. The resulting method favors more correct decisions, and fewer erroneous ones.

We should note here, that the notion of confidence of a fill (here, the state fill) is naturally extended to the notion of confidence of a *record*: For each of the three key fills—location, date, disease name—compute a confidence based on the same heuristics. Then we say that a record **I** has high confidence, if it has non-zero confidence in all three of the key fills. The notion of record confidence is used in Section 6.

4.4 Multi-Candidate Propagation

Finally, we tried propagating multiple candidate state hypotheses for each instance of an ambiguous location name l:

$$\mathcal{S}_+(\mathbf{I}) = \bigcup_{\mathbf{I}' \in \mathcal{D} | l \sqsubset \mathbf{I}'} StatesInStory(\mathbf{I}')$$

$$Score_+(s', \mathbf{I}) = \sum_{\mathbf{I}' \in \mathcal{D} | l \sqsubset \mathbf{I}'} prox(s', \mathbf{I}')$$

where the proximity is inversely proportional to the distance of s' from incident $\mathbf{I}'$, in the story of $\mathbf{I}'$:

$$prox(s, \mathbf{I}) = \begin{cases} \frac{1}{Z(\mathbf{I})} \cdot \frac{1}{\Delta(s, \mathbf{I}) + 1} & if\ s \sqsubset \mathbf{I} \\ 0 & otherwise \end{cases}$$

For an incident **I** mentioning location l, the IE system outputs the list of all states $\{s\}$ mentioned in the same story; we then rank each s according to the inverse of *distance* Δ: the number of sentences between **I** and s. $Z(\mathbf{I})$ is a normalization factor.

The proximity for each pair (l, s), is between 0 and 1. Rather than giving a full point to a single, locally-best guess among the s's, this point is shared proportionately among all competing s's. For example, if states s_0, s_1, s_5 are in the same sentence as **I**, one, and five sentences away, respectively, then $Z(\mathbf{I}) = 1 + \frac{1}{2} + \frac{1}{6} = \frac{5}{3}$, and $prox(s_0) = 1 \cdot \frac{3}{5} = \frac{3}{5}$, $prox(s_1) = \frac{1}{2} \cdot \frac{3}{5} = \frac{3}{10}$,and $prox(s_5) = \frac{1}{6} \cdot \frac{3}{5} = \frac{1}{10}$.

The score for each state s for the given l is then the sum of proximities of s to l across all stories.

The resulting performance is substantially better than the baseline, while the *number of changed* records is substantially higher than in the competing methods. This is due to the fact that this method allows for a much larger pool of candidates than the others, and assigns to them much smoother weights, virtually eliminating ties in the ranking among hypotheses.

5 Discussion

Among the four competing approaches presented above, the baseline performs surprisingly well. We should note that this research is not aimed specifically at improving geographic Named Entity resolution. It is the first in a series of experiments aiming to leverage redundancy across a large fact base extracted from text, to improve the quality of extracted data. We chose to experiment with this relation first because of its simplicity, and because the *state* field is a key field in our application.

For this reason, the *a priori* geographic knowledge base was intentionally not as extensive as it might have been, had we tried in earnest to match locations with corresponding states (e.g., by incorporating the CIA Factbook, or other gazetteer).

The intent here is to investigate how a relation can be improved by leveraging redundancy across a large body of records. The support we used for geographic name resolution was therefore deliberately modest, cf. Section 3.3.

It is quite feasible to enumerate the countries and the larger regions, since they number in the low hundreds, whereas there are many tens of thousands of cities, towns, villages, regions, districts, etc.

6 Current Work

Three parallel lines of current research are:

1. combining evidence from multiple features
2. applying redundancy-based correction to other fields in the database
3. back-propagation of corrected results, to repair components that induced incorrect information.

The results so far presented show that even a naive, intuitive approach can help correct local errors via global analysis. We are currently working on more complex extensions of these methods.

Each method exploits one main feature of the underlying data: the distance from candidate state to the mention of the location name. In the multi-candidate hypothesis method, this distance is exploited explicitly in the scoring function. In the other methods, it is used inside the co-reference module of the IE pipeline, to find the (single) locally-best state.

However, other textual features of the state candidate should contribute to establishing the relations to a location mention, besides the raw distance. For example, at a given distance, it is very important whether the state is mentioned before the location (more likely to be related) vs. after the location (less likely). Another important feature: is the state mentioned in the main story/report headline? If so, its score should be raised. It is quite common for documents to declaim the focal state only once in the headline, and never mention it again, instead mentioning other states, neighboring, or otherwise relevant to the story. The distance measure used alone may be insufficient in such cases.

How are these features to be combined? One path is to use some combination of features, such as a weighted sum, with parameters trained on a manually tagged data set. As we already have a reasonably sized set tagged for evaluation, we can split it into two, train the parameter on a larger portion, evaluate on a smaller one, and cross-validate.

We will be using this approach as a baseline. However, we aim to use a much larger set of data to train the parameters, without manually tagging large training sets.

The idea is to treat the set of incidents with high *record confidence*, Sec. 4.3, rather than manually tagged data, as ground truth. Again, there "confident" truth will not be completely error-free, but because error rates are lower among the confident records, we may be able to leverage global analysis to produce the desired effect: training parameters for more complex models—involving multiple features—for global re-ranking of decisions.

Conclusion

Our approach rests on the idea that evidence aggregated across documents should help resolve difficult problems at the level of a given document.

Our experiments confirm that aggregating global information about related facts, and propagating locally non-best analyses through the pipeline, provide powerful sources of additional evidence, which are able to reverse incorrect decisions, based only on local and *a priori* information.

The proposed approach requires no supervision or training of any kind. It does, however require a substantial collection of evidence across a large body of extracted records; this approach needs a "critical mass" of data to be effective. Although large volume of facts is usually not reported in classic IE experiments, obtaining high volume should be natural in principle.

Acknowledgement

We'd like to thank Winston Lin of New York University, who worked on an early version of these experiments.

Abstract

This paper presents a novel approach to combining different word alignments. We view word alignment as a pattern classification problem, where alignment combination is treated as a classifier ensemble, and alignment links are adorned with linguistic features. A neural network model is used to learn word alignments from the individual alignment systems. We show that our alignment combination approach yields a significant 20-34% relative error reduction over the best-known alignment combination technique on English-Spanish and English-Chinese data.

1 Introduction

Parallel texts are a valuable resource in natural language processing and essential for projecting knowledge from one language onto another. Word-level alignment is a critical component of a wide range of NLP applications, such as construction of bilingual lexicons (Melamed, 2000), word sense disambiguation (Diab and Resnik, 2002), projection of language resources (Yarowsky et al., 2001), and statistical machine translation. Although word-level aligners tend to perform well when there is *sufficient* training data, the quality decreases as the size of training data decreases. Even with large amounts of training data, statistical aligners have been shown to be susceptible to mis-aligning phrasal constructions (Dorr et al., 2002) due to many-to-many correspondences, morphological language distinctions, paraphrased and free translations, and a high percentage of function words (about 50% of the tokens in most texts).

This paper presents a novel approach to alignment combination, *NeurAlign*, that treats each alignment system as a black box and merges their outputs. We view word alignment as a pattern classification problem and treat alignment combination as a *classifier ensemble* (Hansen and Salamon, 1990; Wolpert, 1992). The ensemble-based approach was developed to select the best features of different learning algorithms, including those that may not produce a globally optimal solution (Minsky, 1991).

We use neural networks to implement the classifier-ensemble approach, as these have previously been shown to be effective for combining classifiers (Hansen and Salamon, 1990). Neural nets with 2 or more layers and non-linear activation functions are capable of learning any function of the feature space with arbitrarily small error. Neural nets have been shown to be effective with (1) high-dimensional input vectors, (2) relatively sparse data, and (3) noisy data with high within-class variability, all of which apply to the word alignment problem.

The rest of the paper is organized as follows: In Section 2, we describe previous work on improving word alignments and use of classifier ensembles in NLP. Section 3 gives a brief overview of neural networks. In Section 4, we present a new approach, *NeurAlign*, that learns how to combine individual word alignment systems. Section 5 describes our experimental design and the results on English-Spanish and English-Chinese. We demonstrate that NeurAlign yields significant improvements over the best-known alignment combination technique.

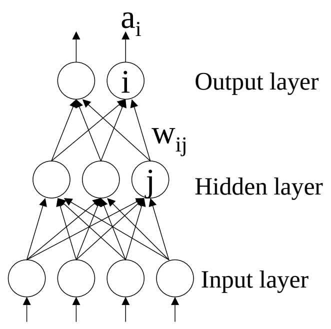

Figure 1: Multilayer Perceptron Overview

2 Related Work

Previous algorithms for improving word alignments have attempted to incorporate additional knowledge into their modeling. For example, Liu (2005) uses a log-linear combination of linguistic features. Additional linguistic knowledge can be in the form of part-of-speech tags. (Toutanova et al., 2002) or dependency relations (Cherry and Lin, 2003). Other approaches to improving alignment have combined alignment models, e.g., using a log-linear combination (Och and Ney, 2003) or mutually independent association clues (Tiedemann, 2003).

A simpler approach was developed by Ayan et al. (2004), where word alignment outputs are combined using a linear combination of feature weights assigned to the individual aligners. Our method is more general in that it uses a neural network model that is capable of learning nonlinear functions.

Classifier ensembles are used in several NLP applications. Some NLP applications for classifier ensembles are POS tagging (Brill and Wu, 1998; Abney et al., 1999), PP attachment (Abney et al., 1999), word sense disambiguation (Florian and Yarowsky, 2002), and parsing (Henderson and Brill, 2000).

The work reported in this paper is the first application of classifier ensembles to the word-alignment problem. We use a different methodology to combine classifiers that is based on *stacked generalization* (Wolpert, 1992), i.e., learning an additional model on the outputs of individual classifiers.

3 Neural Networks

A multi-layer perceptron (MLP) is a feed-forward neural network that consists of several units (neurons) that are connected to each other by weighted links. As illustrated in Figure 1, an MLP consists of one input layer, one or more hidden layers, and one output layer. The external input is presented to the input layer, propagated forward through the hidden layers and creates the output vector in the output layer. Each unit i in the network computes its output with respect to its net input $net_i = \sum_j w_{ij} a_j$, where j represents all units in the previous layer that are connected to the unit i. The output of unit i is computed by passing the net input through a non-linear activation function f, i.e. $a_i = f(net_i)$.

The most commonly used non-linear activation functions are the log sigmoid function $f(x) = \frac{1}{1+e^{-x}}$ or hyperbolic tangent sigmoid function $f(x) = \frac{1-e^{-2x}}{1+e^{-2x}}$. The latter has been shown to be more suitable for binary classification problems.

The critical question is the computation of weights associated with the links connecting the neurons. In this paper, we use the resilient backpropagation (RPROP) algorithm (Riedmiller and Braun, 1993), which is based on the gradient descent method, but converges faster and generalizes better.

4 NeurAlign Approach

We propose a new approach, *NeurAlign*, that learns how to combine individual word alignment systems. We treat each alignment system as a classifier and transform the combination problem into a classifier ensemble problem. Before describing the NeurAlign approach, we first introduce some terminology used in the description below.

Let $E = e_1, \ldots, e_t$ and $F = f_1, \ldots, f_s$ be two sentences in two different languages. An alignment link (i, j) corresponds to a translational equivalence between words e_i and f_j. Let A_k be an alignment between sentences E and F, where each element $a \in A_k$ is an alignment link (i, j). Let $\mathcal{A} = \{A_1, \ldots, A_l\}$ be a set of alignments between E and F. We refer to the true alignment as T, where each $a \in T$ is of the form (i, j). A *neighborhood* of an alignment link (i, j)—denoted by $N(i, j)$—consists of 8 possible alignment links in a 3×3 window with (i, j) in the center of the window. Each element of $N(i, j)$ is called a *neighboring link* of (i, j).

Our goal is to combine the information in $A_1, \ldots, A_l$ such that the resulting alignment is closer to T. A straightforward solution is to take the intersection or union of the individual alignments, or perform a majority voting for each possible alignment link (i, j). Here, we use an additional model to learn how to combine outputs of $A_1, \ldots, A_l$.

We decompose the task of combining word alignments into two steps: (1) Extract features; and (2) Learn a classifier from the transformed data. We describe each of these two steps in turn.

4.1 Extracting Features

Given sentences E and F, we create a (potential) alignment instance (i, j) for all possible word combinations. A crucial component of building a classifier is the selection of features to represent the data. The simplest approach is to treat each alignment-system output as a separate feature upon which we build a classifier. However, when only a few alignment systems are combined, this feature space is not sufficient to distinguish between instances. One of the strategies in the classification literature is to supply the input data to the set of features as well.

While combining word alignments, we use two types of features to describe each instance (i, j): (1) linguistic features and (2) alignment features. Linguistic features include POS tags of both words (e_i and f_j) and a dependency relation for one of the words (e_i). We generate POS tags using the MXPOST tagger (Ratnaparkhi, 1996) for English and Chinese, and Connexor for Spanish. Dependency relations are produced using a version of the Collins parser (Collins, 1997) that has been adapted for building dependencies.

Alignment features consist of features that are extracted from the outputs of individual alignment systems. For each alignment $A_k \in \mathcal{A}$, the following are some of the alignment features that can be used to describe an instance (i, j):

1. Whether (i, j) is an element of A_k or not
2. Translation probability $p(f_j|e_i)$ computed over A_k[1]
3. Fertility of (i.e., number of words in F that are aligned to) e_i in A_k
4. Fertility of (i.e., number of words in E that are aligned to) f_j in A_k
5. For each neighbor $(x, y) \in N(i, j)$, whether $(x, y) \in A_k$ or not (8 features in total)
6. For each neighbor $(x, y) \in N(i, j)$, translation probability $p(f_y|e_x)$ computed over A_k (8 features in total)

It is also possible to use variants, or combinations, of these features to reduce feature space.

Figure 2 shows an example of how we transform the outputs of 2 alignment systems, A_1 and A_2, for an alignment link (i, j) into data with some of the features above. We use -1 and 1 to represent the absence and existence of a link, respectively. The neighboring links are presented in row-by-row order.

A_1	f_{j-1}	f_j	f_{j+1}
e_{i-1}			
e_i	X	X	
e_{i+1}			X

A_2	f_{j-1}	f_j	f_{j+1}
e_{i-1}	X		
e_i			X
e_{i+1}			X

Features for the alignment link (*i* , *j*)	
pos(e_i) , pos(f_j)	Noun, Prep
rel(e_i)	Modifier
outputs of aligners	1 (for A_1), -1 (for A_2)
neighbors (A_1)	-1, -1, -1, **1**, -1, -1, -1, **1**
neighbors (A_2)	**1**, -1, -1, -1, **1**, -1, -1, **1**
neighbors ($A_1 \cup A_2$)	**1**, -1, -1, **1**, **1**, -1, -1, **1**
total neighbors	2 (for A_1), 3 (for A_2)
fertility(e_i)	2 (for A_1), 1 (for A_2)
fertility(f_j)	1 (for A_1), 0 (for A_2)

Figure 2: An Example of Transforming Alignments into Classification Data

For each sentence pair $E = e_1, \ldots, e_t$ and $F = f_1, \ldots, f_s$, we generate $s \times t$ instances to represent the sentence pair in the classification data.

Supervised learning requires the correct output, which here is the true alignment T. If an alignment link (i, j) is an element of T, then we set the correct output to 1, and to -1, otherwise.

4.2 Learning A Classifier

Once we transform the alignments into a set of instances with several features, the remaining task is to learn a classifier from this data. In the case of word alignment combination, there are important issues to consider for choosing an appropriate classifier. First, there is a very limited amount of manually annotated data. This may give rise to poor generalizations because it is very likely that unseen data include lots of cases that are not observed in the training data.

Second, the distribution of the data according to the classes is skewed. In a preliminary study on an English-Spanish data set, we found out that only 4% of the all word pairs are aligned to each other by humans, among a possible 158K word pairs. Moreover, only 60% of those aligned word pairs were

[1]The translation probabilities can be borrowed from the existing systems, if available. Otherwise, they can be generated from the outputs of individual alignment systems using likelihood estimates.

Table 1: Error Rates according to POS Tags for GIZA++ (E-to-S) (in percentages)

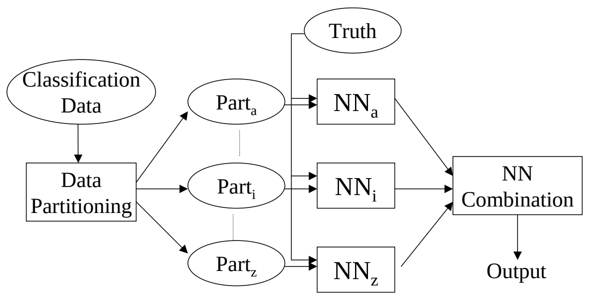

Figure 4: NeurAlign$_2$—Alignment Combination with Partitioning

also aligned by the individual alignment systems that were tested.

Finally, given the distribution of the data, it is difficult to find the right features to distinguish between instances. Thus, it is prudent to use as many features as possible and let the learning algorithm filter out the redundant features.

Below, we describe how neural nets are used at different levels to build a good classifier.

4.2.1 NeurAlign$_1$: Learning All At Once

Figure 3 illustrates how we combine alignments using all the training data at the same time (NeurAlign$_1$). First, the outputs of individual alignments systems and the original corpus (enriched with additional linguistic features) are passed to the feature extraction module. This module transforms the alignment problem into a classification problem by generating a training instance for every pair of words between the sentences in the original corpus. Each instance is represented by a set of features (described in Section 4.1). The new training data is passed to a neural net learner, which outputs whether an alignment link exists for each training instance.

4.2.2 NeurAlign$_2$: Multiple Neural Networks

The use of multiple neural networks (NeurAlign$_2$) enables the decomposition of a complex problem into smaller problems. *Local experts* are learned for each smaller problem and these are then merged. Following Tumer and Ghosh (1996), we apply spatial partitioning of training instances using proximity of patterns in the input space to reduce the complexity of the tasks assigned to individual classifiers.

We conducted a preliminary analysis on 100 randomly selected English-Spanish sentence pairs from a mixed corpus (UN + Bible + FBIS) to observe the distribution of errors according to POS tags in both languages. We examined the cases in which the individual alignment and the manual annotation were different—a total of 3,348 instances, where 1,320 of those are misclassified by GIZA++ (E-to-S).[2] We use a standard measure of error, i.e., the percentage of misclassified instances out of the total number of instances. Table 1 shows error rates (by percentage) according to POS tags for GIZA++ (E-to-S).[3]

Table 1 shows that the error rate is relatively low in cases where both words have the same POS tag. Except for verbs, the lowest error rate is obtained when both words have the same POS tag (the error rates on the diagonal). On the other hand, the error rates are high in several other cases, as much as 100%, e.g., when the Spanish word is a determiner or a preposition.[4] This suggests that dividing the training data according to POS tag, and training neural networks on each subset separately might be better than training on the entire data at once.

Figure 4 illustrates the combination approach with neural nets after partitioning the data into dis-

[2]For this analysis, we ignored the cases where both systems produced an output of -1 (i.e., the words are not aligned).

[3]Only POS pairs that occurred at least 10 times are shown.

[4]The same analysis was done for the other direction and resulted in similar distribution of error rates.

joint subsets (NeurAlign$_2$). Similar to NeurAlign$_1$, the outputs of individual alignment systems, as well as the original corpus, are passed to the feature extraction module. Then the training data is split into disjoint subsets using a subset of the available features for partitioning. We learn different neural nets for each partition, and then merge the outputs of the individual nets. The advantage of this is that it results in different generalizations for each partition and that it uses different subsets of the feature space for each net.

5 Experiments and Results

This section describes our experimental design, including evaluation metrics, data, and settings.

5.1 Evaluation Metrics

Let A be the set of alignment links for a set of sentences. We take S to be the set of sure alignment links and P be the set of probable alignment links (in the gold standard) for the same set of sentences. Precision (Pr), recall (Rc) and alignment error rate (AER) are defined as follows:

$$Pr = \frac{|A \cap P|}{|A|} \quad Rc = \frac{|A \cap S|}{|S|}$$
$$AER = 1 - \frac{|A \cap S| + |A \cap P|}{|A| + |S|}$$

A manually aligned corpus is used as our gold standard. For English-Spanish data, the manual annotation is done by a bilingual English-Spanish speaker. Every link in the English-Spanish gold standard is considered a sure alignment link (i.e., $P = S$).

For English-Chinese, we used 2002 NIST MT evaluation test set. Each sentence pair was aligned by two native Chinese speakers, who are fluent in English. Each alignment link appearing in both annotations was considered a sure link, and links appearing in only one set were judged as probable. The annotators were not aware of the specifics of our approach.

5.2 Evaluation Data and Settings

We evaluated NeurAlign$_1$ and NeurAlign$_2$, using 5-fold cross validation on two data sets:

1. A set of 199 English-Spanish sentence pairs (nearly 5K words on each side) from a mixed corpus (UN + Bible + FBIS).
2. A set of 491 English-Chinese sentence pairs (nearly 13K words on each side) from 2002 NIST MT evaluation test set.

We computed precision, recall and error rate on the entire set of sentence pairs for each data set.[5]

To evaluate NeurAlign, we used GIZA++ in both directions (E-to-F and F-to-E, where F is either Chinese (C) or Spanish (S)) as input and a *refined alignment* approach (Och and Ney, 2000) that uses a heuristic combination method called *grow-diag-final* (Koehn et al., 2003) for comparison. (We henceforth refer to the refined-alignment approach as "RA.")

For the English-Spanish experiments, GIZA++ was trained on 48K sentence pairs from a mixed corpus (UN + Bible + FBIS), with nearly 1.2M of words on each side, using 10 iterations of Model 1, 5 iterations of HMM, and 5 iterations of Model 4. For the English-Chinese experiments, we used 107K sentence pairs from FBIS corpus (nearly 4.1M English and 3.3M Chinese words) to train GIZA++, using 5 iterations of Model 1, 5 iterations of HMM, 3 iterations of Model 3, and 3 iterations of Model 4.

5.3 Neural Network Settings

In our experiments, we used a multi-layer perceptron (MLP) consisting of 1 input layer, 1 hidden layer, and 1 output layer. The hidden layer consists of 10 units, and the output layer consists of 1 unit. All units in the hidden layer are fully connected to the units in the input layer, and the output unit is fully connected to all the units in the hidden layer. We used hyperbolic tangent sigmoid function as the activation function for both layers.

One of the potential pitfalls is overfitting as the number of iterations increases. To address this, we used the *early stopping with validation set* method. In our experiments, we held out (randomly selected) 1/4 of the training set as the validation set.

Neural nets are sensitive to the initial weights. To overcome this, we performed 5 runs of learning for each training set. The final output for each training is obtained by a majority voting over 5 runs.

[5]The number of alignment links varies over each fold. Therefore, we chose to evaluate all data at once instead of evaluating on each fold and then averaging.

5.4 Results

This section describes the experiments on English-Spanish and English-Chinese data for testing the effects of feature selection, training on the entire data (NeurAlign$_1$) or on the partitioned data (NeurAlign$_2$), using two input alignments: GIZA++ (E-to-F) and GIZA++ (F-to-E). We used the following additional features, as well as the outputs of individual aligners, for an instance (i, j) (set of features 2–7 below are generated separately for each input alignment A_k):

1. $posE_i, posF_j, relE_i$: POS tags and dependency relation for e_i and f_j.
2. $neigh(i, j)$: 8 features indicating whether a neighboring link exists in A_k.
3. $fertE_i, fertF_j$: 2 features indicating the fertility of e_i and f_j in A_k.
4. $NC(i, j)$: Total number of existing links in $N(i, j)$ in A_k.
5. $TP(i, j)$: Translation probability $p(f_j|e_i)$ in A_k.
6. $NghTP(i, j)$: 8 features indicating the translation probability $p(f_y|e_x)$ for each $(x, y) \in N(i, j)$ in A_k.
7. $AvTP(i, j)$: Average translation probability of the neighbors of (i, j) in A_k.

We performed statistical significance tests using two-tailed paired t-tests. Unless otherwise indicated, the differences between NeurAlign and other alignment systems, as well as the differences among NeurAlign variations themselves, were statistically significant within the 95% confidence interval.

5.4.1 Results for English-Spanish

Table 2 summarizes the precision, recall and alignment error rate values for each of our two alignment system inputs plus the three alternative alignment-combination approaches. Note that the best performing aligner among these is the RA method, with an AER of 21.2%. (We include this in subsequent tables for ease of comparison.)

Alignments	**Pr**	**Rc**	**AER**
E-to-S	87.0	67.0	24.3
S-to-E	88.0	67.5	23.6
Intersection	**98.2**	59.6	25.9
Union	80.6	**74.9**	22.3
RA	83.8	74.4	**21.2**

Table 2: Results for GIZA++ Alignments and Their Simple Combinations

Feature Selection for Training All Data At Once: NeurAlign$_1$ Table 3 presents the results of training neural nets using the entire data (NeurAlign$_1$) with different subsets of the feature space. When we used POS tags and the dependency relation as features, NeurAlign$_1$ performs worse than RA. Using the neighboring links as the feature set gave slightly (not significantly) better results than RA. Using POS tags, dependency relations, and neighboring links also resulted in better performance than RA but the difference was not statistically significant.

When we used fertilities along with the POS tags and dependency relations, the AER was 20.0%—a significant relative error reduction of 5.7% over RA. Adding the neighboring links to the previous feature set resulted in an AER of 17.6%—a significant relative error reduction of 17% over RA.

Interestingly, when we removed POS tags and dependency relations from this feature set, there was no significant change in the AER, which indicates that the improvement is mainly due to the neighboring links. This supports our initial claim about the clustering of alignment links, i.e., when there is an alignment link, usually there is another link in its neighborhood. Finally, we tested the effects of using translation probabilities as part of the feature set, and found out that using translation probabilities did no better than the case where they were not used. We believe this happens because the translation probability $p(f_j|e_i)$ has a unique value for each pair of e_i and f_j; therefore it is not useful to distinguish between alignment links with the same words.

Feature Selection for Training on Partitioned Data: NeurAlign$_2$ In order to train on partitioned data (NeurAlign$_2$), we needed to establish appropriate features for partitioning the training data. Table 4 presents the evaluation results for NeurAlign$_1$ (i.e., no partitioning) and NeurAlign$_2$ with different features for partitioning (English POS tag, Spanish POS tag, and POS tags on both sides). For training on each partition, the feature space included POS tags (e.g., Spanish POS tag in the case where partitioning is based on English POS tag only), dependency relations, neighborhood features, and fertilities. We observed that partitioning based on POS tags on one side reduced the AER to 17.4% and

Features	**Pr**	**Rc**	**AER**
$posE_i, posF_j, relE_i$	90.6	67.7	22.5
$neigh(i,j)$	91.3	69.5	21.1
$posE_i, posF_j, relE_i,$ $neigh(i,j)$	**91.7**	70.2	20.5
$posE_i, posF_j, relE_i,$ $fertE_i, fertF_j$	91.4	71.1	20.0
$posE_i, posF_j, relE_i,$ $neigh(i,j), NC(i,j)$ $fertE_i, fertF_j$	89.5	**76.3**	**17.6**
$neigh(i,j), NC(i,j)$ $fertE_i, fertF_j$	89.7	75.7	17.9
$posE_i, posF_j, relE_i,$ $fertE_i, fertF_j,$ $neigh(i,j), NC(i,j),$ $TP(i,j), AvTP(i,j)$	90.0	75.7	17.9
RA	83.8	74.4	21.2

Table 3: Combination with Neural Networks: NeurAlign$_1$ (All-Data-At-Once)

17.1%, respectively. Using POS tags on *both* sides reduced the error rate to 16.9%—a significant relative error reduction of 5.6% over no partitioning. All four methods yielded statistically significant error reductions over RA—we will examine the fourth method in more detail below.

Alignment	**Pr**	**Rc**	**AER**
NeurAlign$_1$	89.7	75.7	17.9
NeurAlign$_2[posE_i]$	91.1	75.4	17.4
NeurAlign$_2[posF_j]$	91.2	**76.0**	17.1
NeurAlign$_2[posE_i, posF_j]$	**91.6**	**76.0**	**16.9**
RA	83.8	74.4	21.2

Table 4: Effects of Feature Selection for Partitioning

Once we determined that partitioning by POS tags on both sides brought about the biggest gain, we ran NeurAlign$_2$ using this partitioning, but with different feature sets. Table 5 shows the results of this experiment. Using dependency relations, word fertilities and translation probabilities (both for the link in question and the neighboring links) yielded a significantly lower AER (18.6%)—a relative error reduction of 12.3% over RA. When the feature set consisted of dependency relations, word fertilities, and neighborhood links, the AER was reduced to 16.9%—a 20.3% relative error reduction over RA. We also tested the effects of adding translation probabilities to this feature set, but as in the case of NeurAlign$_1$, this did not improve the alignments.

In the best case, NeurAlign$_2$ achieved substantial and significant reductions in AER over the input alignment systems: a 28.4% relative error reduction over S-to-E and a 30.5% relative error reduction over E-to-S. Compared to RA, NeurAlign$_2$ also achieved significantly better results over RA: relative improvements of 9.3% in precision, 2.2% in recall, and 20.3% in AER.

Features	**Pr**	**Rc**	**AER**
$relE_i, fertE_i, fertF_j,$ $TP(i,j), AvTP(i,j),$ $NghTP(i,j)$	**91.9**	73.0	18.6
$neigh(i,j)$	90.3	74.0	18.7
$relE_i, fertE_i, fertF_j,$ $neigh(i,j), NC(i,j)$	91.6	76.0	**16.9**
$relE_i, fertE_i, fertF_j,$ $neigh(i,j), NC(i,j),$ $TP(i,j), AvTP(i,j)$	91.4	**76.1**	**16.9**
RA	83.8	74.4	21.2

Table 5: Combination with Neural Networks: NeurAlign$_2$ (Partitioned According to POS tags)

5.4.2 Results for English-Chinese

The results of the input alignments to NeurAlign, i.e., GIZA++ alignments in two different directions, NeurAlign$_1$ (i.e., no partitioning) and variations of NeurAlign$_2$ with different features for partitioning (English POS tag, Chinese POS tag, and POS tags on both sides) are shown in Table 6. For comparison, we also include the results for RA in the table. For brevity, we include only the features resulting in the best configurations from the English-Spanish experiments, i.e., POS tags, dependency relations, word fertilities, and neighborhood links (the features in the third row of Table 5). The ground truth used during the training phase consisted of all the alignment links with equal weight.

Alignments	**Pr**	**Rc**	**AER**
E-to-C	70.4	68.3	30.7
C-to-E	66.0	69.8	32.2
NeurAlign$_1$	85.0	71.4	22.2
NeurAlign$_2[posE_i]$	85.7	74.6	20.0
NeurAlign$_2[posF_j]$	85.7	73.2	20.8
NeurAlign$_2[posE_i, posF_j]$	**86.3**	74.7	**19.7**
RA	61.9	**82.6**	29.7

Table 6: Results on English-Chinese Data

Without any partitioning, NeurAlign achieves an alignment error rate of 22.2%—a significant relative error reduction of 25.3% over RA. Partitioning the data according to POS tags results in significantly better results over no partitioning. When the data is partitioned according to both POS tags, NeurAlign reduces AER to 19.7%—a significant relative error reduction of 33.7% over RA. Compared to the input alignments, the best version of NeurAlign achieves a relative error reduction of 35.8% and 38.8%, respectively.

6 Conclusions

We presented NeurAlign, a novel approach to combining the outputs of different word alignment systems. Our approach treats individual alignment systems as black boxes, and transforms the individual alignments into a set of data with features that are borrowed from their outputs and additional linguistic features (such as POS tags and dependency relations). We use neural nets to learn the true alignments from these transformed data.

We show that using POS tags to partition the transformed data, and learning a different classifier for each partition is more effective than using the entire data at once. Our results indicate that NeurAlign yields a significant 28-39% relative error reduction over the best of the input alignment systems and a significant 20-34% relative error reduction over the best known alignment combination technique on English-Spanish and English-Chinese data.

We should note that NeurAlign is not a standalone word alignment system but a supervised learning approach to improve already existing alignment systems. A drawback of our approach is that it requires annotated data. However, our experiments have shown that significant improvements can be obtained using a small set of annotated data. We will do additional experiments to observe the effects of varying the size of the annotated data while learning neural nets. We are also planning to investigate whether NeurAlign helps when the individual aligners are trained using more data.

We will extend our combination approach to combine word alignment systems based on different models, and investigate the effectiveness of our technique on other language pairs. We also intend to evaluate the effectiveness of our improved alignment approach in the context of machine translation and cross-language projection of resources.

A Discriminative Matching Approach to Word Alignment

Berkeley, CA 94720

Abstract

We present a discriminative, large-margin approach to feature-based matching for word alignment. In this framework, pairs of word tokens receive a matching score, which is based on features of that pair, including measures of association between the words, distortion between their positions, similarity of the orthographic form, and so on. Even with only 100 labeled training examples and simple features which incorporate counts from a large unlabeled corpus, we achieve AER performance close to IBM Model 4, in much less time. Including Model 4 predictions as features, we achieve a relative AER reduction of 22% in over intersected Model 4 alignments.

1 Introduction

The standard approach to word alignment from sentence-aligned bitexts has been to construct models which generate sentences of one language from the other, then fitting those generative models with EM (Brown et al., 1990; Och and Ney, 2003). This approach has two primary advantages and two primary drawbacks. In its favor, generative models of alignment are well-suited for use in a noisy-channel translation system. In addition, they can be trained in an unsupervised fashion, though in practice they do require labeled validation alignments for tuning model hyper-parameters, such as null counts or smoothing amounts, which are crucial to producing alignments of good quality. A primary drawback of the generative approach to alignment is that, as in all generative models, explicitly incorporating arbitrary features of the input is difficult. For example, when considering whether to align two words in the IBM models (Brown et al., 1990), one cannot easily include information about such features as orthographic similarity (for detecting cognates), presence of the pair in various dictionaries, similarity of the frequency of the two words, choices made by other alignment systems on this sentence pair, and so on. While clever models can implicitly capture some of these information sources, it takes considerable work, and can make the resulting models quite complex. A second drawback of generative translation models is that, since they are learned with EM, they require extensive processing of large amounts of data to achieve good performance. While tools like GIZA++ (Och and Ney, 2003) do make it easier to build on the long history of the generative IBM approach, they also underscore how complex high-performance generative models can, and have, become.

In this paper, we present a discriminative approach to word alignment. Word alignment is cast as a maximum weighted matching problem (Cormen et al., 1990) in which each pair of words (e_j, f_k) in a sentence pair (e, f) is associated with a score $s_{jk}(e, f)$ reflecting the desirability of the alignment of that pair. The alignment for the sentence pair is then the highest scoring matching under some constraints, for example the requirement that matchings be one-to-one.

This view of alignment as graph matching is not, in itself, new: Melamed (2000) uses competitive linking to greedily construct matchings where the pair score is a measure of word-to-word association, and Matusov et al. (2004) find exact maximum matchings where the pair scores come from the alignment posteriors of generative models. Tiedemann (2003) proposes incorporating a variety of word association "clues" into a greedy linking algorithm.

What we contribute here is a principled approach for tractable and efficient learning of the alignment score $s_{jk}(e, f)$ as a function of arbitrary features of that token pair. This contribution opens up the possibility of doing the kind of feature engineering for alignment that has been so successful for other NLP tasks. We first present the algorithm for large margin estimation of the scoring function. We then show that our method can achieve AER rates comparable to unsymmetrized IBM Model 4, using extremely little labeled data (as few as 100 sentences) and a simple feature set. Remarkably, by including bi-directional IBM Model 4 predictions as features, we achieve an absolute AER of 5.4 on the English-French Hansards alignment task, a relative reduction of 22% in AER over intersected Model 4 alignments and, to our knowledge, the best AER result published on this task.

2 Algorithm

We model the alignment prediction task as a maximum weight bipartite matching problem, where nodes correspond to the words in the two sentences. For simplicity, we assume here that each word aligns to one or zero words in the other sentence. The edge weight s_{jk} represents the degree to which word j in one sentence can translate into the word k in the other sentence. Our goal is to find an alignment that maximizes the sum of edge scores. We represent a matching using a set of binary variables y_{jk} that are set to 1 if word j is assigned to word k in the other sentence, and 0 otherwise. The score of an assignment is the sum of edge scores: $s(\mathbf{y}) = \sum_{jk} s_{jk} y_{jk}$. The maximum weight bipartite matching problem, $\arg\max_{\mathbf{y}\in\mathcal{Y}} s(\mathbf{y})$, can be solved using well known combinatorial algorithms or the following linear program:

$$\begin{aligned} \max_{\mathbf{z}} \quad & \sum_{jk} s_{jk} z_{jk} && (1) \\ \text{s.t.} \quad & \sum_{j} z_{jk} \le 1, \quad \sum_{k} z_{jk} \le 1, \quad 0 \le z_{jk} \le 1, \end{aligned}$$

where the continuous variables z_{jk} correspond to the binary variables y_{jk}. This LP is guaranteed to have integral (and hence optimal) solutions for any scoring function $s(\mathbf{y})$ (Schrijver, 2003). Note that although the above LP can be used to compute alignments, combinatorial algorithms are generally more efficient. However, we use the LP to develop the learning algorithm below.

For a sentence pair $\mathbf{x}$, we denote position pairs by $\mathbf{x}_{jk}$ and their scores as s_{jk}. We let $s_{jk} = \mathbf{w}^\top \mathbf{f}(\mathbf{x}_{jk})$ for some user provided feature mapping $\mathbf{f}$ and abbreviate $\mathbf{w}^\top \mathbf{f}(\mathbf{x}, \mathbf{y}) = \sum_{jk} y_{jk} \mathbf{w}^\top \mathbf{f}(\mathbf{x}_{jk})$. We can include in the feature vector the identity of the two words, their relative positions in their respective sentences, their part-of-speech tags, their string similarity (for detecting cognates), and so on.

At this point, one can imagine estimating a linear matching model in multiple ways, including using conditional likelihood estimation, an averaged perceptron update (see which matchings are proposed and adjust the weights according to the difference between the guessed and target structures (Collins, 2002)), or in large-margin fashion. Conditional likelihood estimation using a log-linear model $P(\mathbf{y} \mid \mathbf{x}) = \frac{1}{Z_{\mathbf{w}}(\mathbf{x})} \exp\{\mathbf{w}^\top \mathbf{f}(\mathbf{x}, \mathbf{y})\}$ requires summing over all matchings to compute the normalization $Z_{\mathbf{w}}(\mathbf{x})$, which is #P-complete (Valiant, 1979). In our experiments, we therefore investigated the averaged perceptron in addition to the large-margin method outlined below.

2.1 Large-margin estimation

We follow the large-margin formulation of Taskar et al. (2005a). Our input is a set of training instances $\{(\mathbf{x}_i, \mathbf{y}_i)\}_{i=1}^{m}$, where each instance consists of a sentence pair $\mathbf{x}_i$ and a target alignment $\mathbf{y}_i$. We would like to find parameters $\mathbf{w}$ that predict correct alignments on the training data:

$$\mathbf{y}_i = \arg\max_{\bar{\mathbf{y}}_i \in \mathcal{Y}_i} \mathbf{w}^\top \mathbf{f}(\mathbf{x}_i, \bar{\mathbf{y}}_i), \quad \forall i,$$

where $\mathcal{Y}_i$ is the space of matchings appropriate for the sentence pair i.

In standard classification problems, we typically measure the error of prediction, $\ell(\mathbf{y}_i, \bar{\mathbf{y}}_i)$, using the simple 0-1 loss. In structured problems, where we are jointly predicting multiple variables, the loss is often more complex. While the F-measure is a natural loss function for this task, we instead chose a sensible surrogate that fits better in our framework: Hamming distance between $\mathbf{y}_i$ and $\bar{\mathbf{y}}_i$, which simply counts the number of edges predicted incorrectly.

We use an SVM-like hinge upper bound on the loss $\ell(\mathbf{y}_i, \bar{\mathbf{y}}_i)$, given by $\max_{\bar{\mathbf{y}}_i \in \mathcal{Y}_i}[\mathbf{w}^\top \mathbf{f}_i(\bar{\mathbf{y}}_i) + \ell_i(\bar{\mathbf{y}}_i) - \mathbf{w}^\top \mathbf{f}_i(\mathbf{y}_i)]$, where $\ell_i(\bar{\mathbf{y}}_i) = \ell(\mathbf{y}_i, \bar{\mathbf{y}}_i)$, and $\mathbf{f}_i(\bar{\mathbf{y}}_i) = \mathbf{f}(\mathbf{x}_i, \bar{\mathbf{y}}_i)$. Minimizing this upper bound encourages the true alignment $\mathbf{y}_i$ to be optimal with respect to $\mathbf{w}$ for each instance i:

$$\min_{||\mathbf{w}|| \le \gamma} \sum_i \max_{\bar{\mathbf{y}}_i \in \mathcal{Y}_i} [\mathbf{w}^\top \mathbf{f}_i(\bar{\mathbf{y}}_i) + \ell_i(\bar{\mathbf{y}}_i)] - \mathbf{w}^\top \mathbf{f}_i(\mathbf{y}_i),$$

where γ is a regularization parameter.

In this form, the estimation problem is a mixture of continuous optimization over $\mathbf{w}$ and combinatorial optimization over $\mathbf{y}_i$. In order to transform it into a more standard optimization problem, we need a way to efficiently handle the *loss-augmented inference,* $\max_{\bar{\mathbf{y}}_i \in \mathcal{Y}_i}[\mathbf{w}^\top \mathbf{f}_i(\bar{\mathbf{y}}_i) + \ell_i(\bar{\mathbf{y}}_i)]$. This optimization problem has precisely the same form as the prediction problem whose parameters we are trying to learn — $\max_{\bar{\mathbf{y}}_i \in \mathcal{Y}_i} \mathbf{w}^\top \mathbf{f}_i(\bar{\mathbf{y}}_i)$ — but with an additional term corresponding to the loss function. Our assumption that the loss function decomposes over the edges is crucial to solving this problem. In particular, we use weighted Hamming distance, which counts the number of variables in which a candidate solution $\bar{\mathbf{y}}_i$ differs from the target output $\mathbf{y}_i$, with different cost for false positives (c^+) and false negatives (c^-):

$$\ell_i(\bar{\mathbf{y}}_i) = \sum_{jk} [c^- y_{i,jk}(1 - \bar{y}_{i,jk}) + c^+ \bar{y}_{i,jk}(1 - y_{i,jk})]$$

$$= \sum_{jk} c^- y_{i,jk} + \sum_{jk} [c^+ - (c^- + c^+) y_{i,jk}] \bar{y}_{i,jk}.$$

The loss-augmented matching problem can then be written as an LP similar to Equation 1 (without the constant term $\sum_{jk} c^- y_{i,jk}$):

$$\max_{\mathbf{z}} \quad \sum_{jk} z_{i,jk} [\mathbf{w}^\top \mathbf{f}(\mathbf{x}_{i,jk}) + c^+ - (c^- + c^+) y_{i,jk}]$$

$$\text{s.t.} \quad \sum_j z_{i,jk} \le 1, \quad \sum_k z_{i,jk} \le 1, \quad 0 \le z_{i,jk} \le 1.$$

Hence, without any approximations, we have a continuous optimization problem instead of a combinatorial one:

$$\max_{\bar{\mathbf{y}}_i \in \mathcal{Y}_i} \mathbf{w}^\top \mathbf{f}_i(\bar{\mathbf{y}}_i) + \ell_i(\bar{\mathbf{y}}_i) = d_i + \max_{\mathbf{z}_i \in \mathcal{Z}_i} (\mathbf{w}^\top \mathbf{F}_i + \mathbf{c}_i)^\top \mathbf{z}_i,$$

where $d_i = \sum_{jk} c^- y_{i,jk}$ is the constant term, $\mathbf{F}_i$ is the appropriate matrix that has a column of features $\mathbf{f}(\mathbf{x}_{i,jk})$ for each edge jk, $\mathbf{c}_i$ is the vector of the loss terms $c^+ - (c^- + c^+) y_{i,jk}$ and finally $\mathcal{Z}_i = \{\mathbf{z}_i : \sum_j z_{i,jk} \le 1, \ \sum_k z_{i,jk} \le 1, \ 0 \le z_{i,jk} \le 1\}$.

Plugging this LP back into our estimation problem, we have

$$\min_{||\mathbf{w}|| \le \gamma} \max_{\mathbf{z} \in \mathcal{Z}} \sum_i \mathbf{w}^\top \mathbf{F}_i \mathbf{z}_i + \mathbf{c}_i^\top \mathbf{z}_i - \mathbf{w}^\top \mathbf{F}_i \mathbf{y}_i, \quad (2)$$

where $\mathbf{z} = \{\mathbf{z}_1, \ldots, \mathbf{z}_m\}$, $\mathcal{Z} = \mathcal{Z}_1 \times \ldots \times \mathcal{Z}_m$. Instead of the derivation in Taskar et al. (2005a), which produces a joint convex optimization problem using Lagrangian duality, here we tackle the problem in its natural saddle-point form.

2.2 The extragradient method

For saddle-point problems, a well-known solution strategy is the extragradient method (Korpelevich, 1976), which is closely related to projected-gradient methods.

The gradient of the objective in Equation 2 is given by: $\sum_i \mathbf{F}_i(\mathbf{z}_i - \mathbf{y}_i)$ (with respect to $\mathbf{w}$) and $\mathbf{F}_i^\top \mathbf{w} + \mathbf{c}_i$ (with respect to each $\mathbf{z}_i$). We denote the Euclidean projection of a vector onto $\mathcal{Z}_i$ as $P_{\mathcal{Z}_i}(\mathbf{v}) = \arg\min_{\mathbf{u} \in \mathcal{Z}_i} ||\mathbf{v} - \mathbf{u}||$ and projection onto the ball $||\mathbf{w}|| \le \gamma$ as $P_\gamma(\mathbf{w}) = \gamma \mathbf{w} / \max(\gamma, ||\mathbf{w}||)$.

An iteration of the extragradient method consists of two very simple steps, prediction:

$$\bar{\mathbf{w}}^{t+1} = P_\gamma(\mathbf{w}^t + \beta_k \sum_i \mathbf{F}_i(\mathbf{y}_i - \mathbf{z}_i^t));$$
$$\bar{\mathbf{z}}_i^{t+1} = P_{\mathcal{Z}_i}(\mathbf{z}_i^t + \beta_k(\mathbf{F}_i^\top \mathbf{w}^t + \mathbf{c}_i));$$

and correction:

$$\mathbf{w}^{t+1} = P_\gamma(\mathbf{w}^t + \beta_k \sum_i \mathbf{F}_i(\mathbf{y}_i - \bar{\mathbf{z}}_i^{t+1}));$$
$$\mathbf{z}_i^{t+1} = P_{\mathcal{Z}_i}(\mathbf{z}_i^t + \beta_k(\mathbf{F}_i^\top \bar{\mathbf{w}}^{t+1} + \mathbf{c}_i)),$$

where β_k are appropriately chosen step sizes. The method is guaranteed to converge linearly to a solution $\mathbf{w}^*, \mathbf{z}^*$ (Korpelevich, 1976; He and Liao, 2002; Taskar et al., 2005b). Please see www.cs.berkeley.edu/~taskar/extragradient.pdf for more details.

The key subroutine of the algorithm is Euclidean projection onto the feasible sets $\mathcal{Z}_i$. In case of word alignment, $\mathcal{Z}_i$ is the convex hull of bipartite matchings and the problem reduces to the much-studied minimum cost quadratic flow problem (Bertsekas et al., 1997). The projection problem $P_{\mathcal{Z}_i}(\mathbf{z}'_i)$ is given by

$$\begin{aligned} \min_{\mathbf{z}} \quad & \sum_{jk} \frac{1}{2}(z'_{i,jk} - z_{i,jk})^2 \\ \text{s.t.} \quad & \sum_j z_{i,jk} \leq 1, \quad \sum_k z_{i,jk} \leq 1, \quad 0 \leq z_{i,jk} \leq 1. \end{aligned}$$

We can now use a standard reduction of bipartite matching to min cost flow by introducing a source node connected to all the words in one sentence and a sink node connected to all the words in the other sentence, using edges of capacity 1 and cost 0. The original edges jk have a quadratic cost $\frac{1}{2}(z'_{i,jk} - z_{i,jk})^2$ and capacity 1. Now the minimum cost flow from the source to the sink computes projection of $\mathbf{z}'_i$ onto $\mathcal{Z}_i$ We use standard, publicly-available code for solving this problem (Guerriero and Tseng, 2002).

3 Experiments

We applied this matching algorithm to word-level alignment using the English-French Hansards data from the 2003 NAACL shared task (Mihalcea and Pedersen, 2003). This corpus consists of 1.1M automatically aligned sentences, and comes with a validation set of 39 sentence pairs and a test set of 447 sentences. The validation and test sentences have been hand-aligned (see Och and Ney (2003)) and are marked with both *sure* and *possible* alignments. Using these alignments, *alignment error rate* (AER) is calculated as:

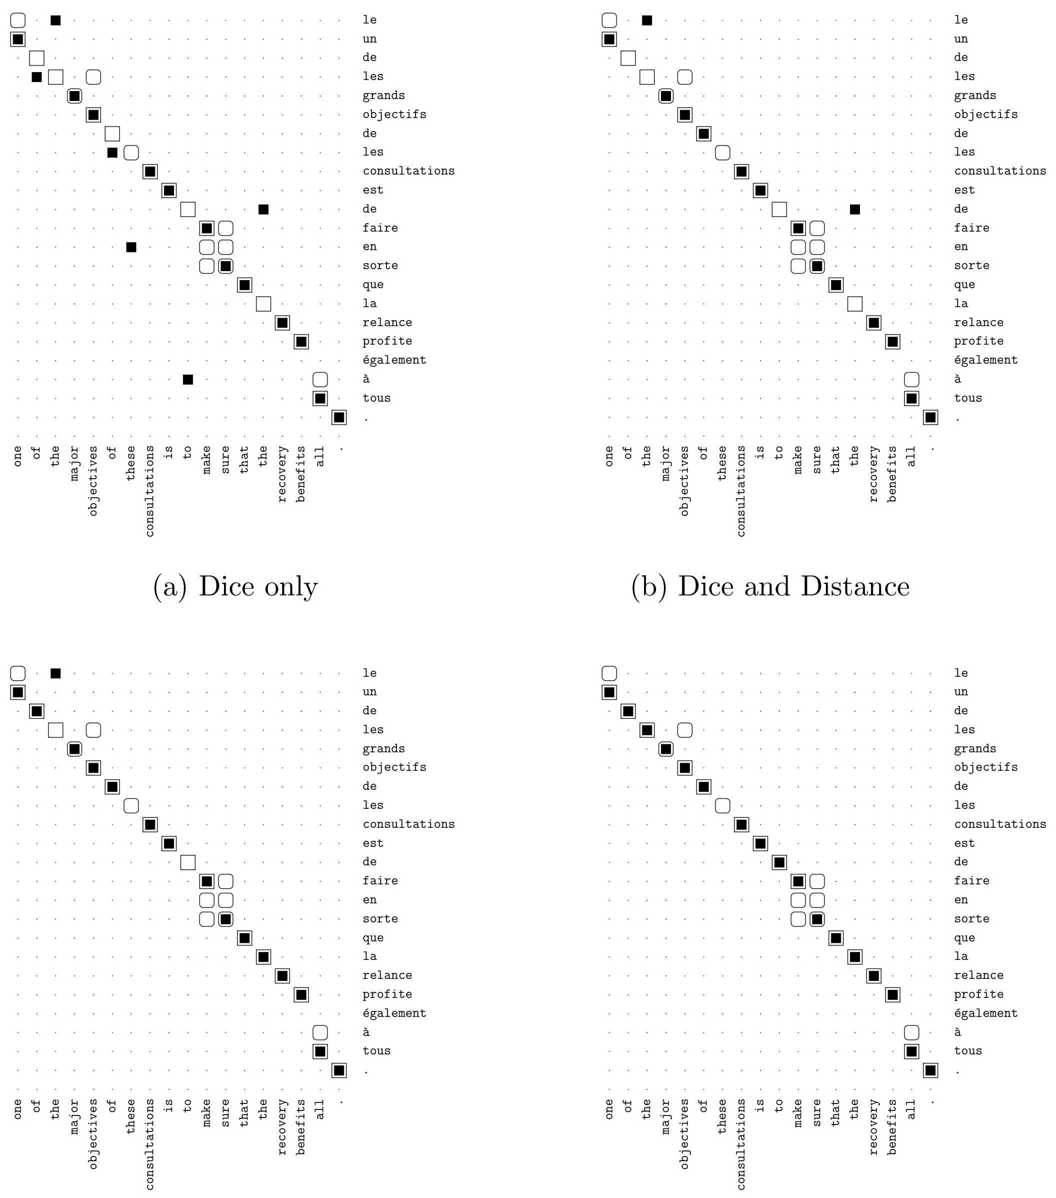
$$AER(A, S, P) = 1 - \frac{|A \cap S| + |A \cap P|}{|A| + |S|}$$

Here, A is a set of proposed index pairs, S is the sure gold pairs, and P is the possible gold pairs. For example, in Figure 1, proposed alignments are shown against gold alignments, with open squares for sure alignments, rounded open squares for possible alignments, and filled black squares for proposed alignments.

Since our method is a supervised algorithm, we need labeled examples. For the training data, we split the original test set into 100 training examples and 347 test examples. In all our experiments, we used a structured loss function $\ell(\mathbf{y}_i, \bar{\mathbf{y}}_i)$ that penalized false negatives 3 times more than false positives, where 3 was picked by testing several values on the validation set. Instead of selecting a regularization parameter γ and running to convergence, we used early stopping as a cheap regularization method, by setting γ to a very large value (10000) and running the algorithm for 500 iterations. We selected a stopping point using the validation set by simply picking the best iteration on the validation set in terms of AER (ignoring the initial ten iterations, which were very noisy in our experiments). All selected iterations turned out to be in the first 50 iterations, as the algorithm converged fairly rapidly.

3.1 Features and Results

Very broadly speaking, the classic IBM models of word-level translation exploit four primary sources of knowledge and constraint: association of words (all IBM models), competition between alignments (all models), zero- or first-order preferences of alignment positions (2,4+), and fertility (3+). We model all of these in some way,



(a) Dice only (b) Dice and Distance

(c) Dice, Distance, Orthographic, and BothShort (d) All features

Figure 1: Example alignments for each successive feature set.

except fertility.[1]

First, and, most importantly, we want to include information about word association; translation pairs are likely to co-occur together in a bitext. This information can be captured, among many other ways, using a feature whose value is the Dice coefficient (Dice, 1945):

$$Dice(e,f) = \frac{2C_{EF}(e,f)}{C_E(e)C_F(f)}$$

Here, C_E and C_F are counts of word occurrences in each language, while C_{EF} is the number of co-occurrences of the two words. With just this feature on a pair of word tokens (which depends only on their types), we can already make a stab

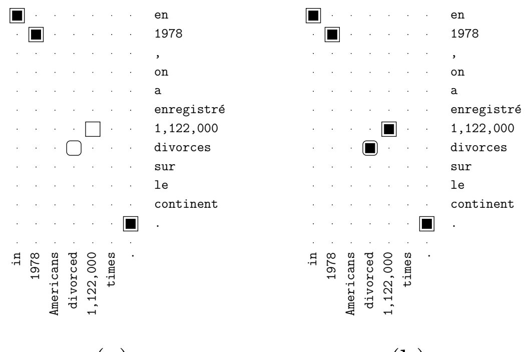
[1]In principle, we can model also model fertility, by allowing 0-k matches for each word rather than 0-1, and having bias features on each word. However, we did not explore this possibility.

at word alignment, aligning, say, each English word with the French word (or null) with the highest Dice value (see (Melamed, 2000)), simply as a matching-free heuristic model. With Dice counts taken from the 1.1M sentences, this gives and AER of 38.7 with English as the target, and 36.0 with French as the target (in line with the numbers from Och and Ney (2003)).

As observed in Melamed (2000), this use of Dice misses the crucial constraint of competition: a candidate source word with high association to a target word may be unavailable for alignment because some other target has an even better affinity for that source word. Melamed uses competitive linking to incorporate this constraint explicitly, while the IBM-style models get this effect via explaining-away effects in EM training. We can get something much like the combination of Dice and competitive linking by running with just one feature on each pair: the Dice value of that pair's words.[2] With just a Dice feature – meaning no learning is needed yet – we achieve an AER of 29.8, between the Dice with competitive linking result of 34.0 and Model 1 of 25.9 given in Och and Ney (2003). An example of the alignment at this stage is shown in Figure 1(a). Note that most errors lie off the diagonal, for example the often-correct *to-à* match.

IBM Model 2, as usually implemented, adds the preference of alignments to lie near the diagonal. Model 2 is driven by the product of a word-to-word measure and a (usually) Gaussian distribution which penalizes distortion from the diagonal. We can capture the same effect using features which reference the relative positions j and k of a pair (e_j, f_k). In addition to a Model 2-style quadratic feature referencing relative position, we threw in the following proximity features: absolute difference in relative position $abs(j/|e|-k/|f|)$, and the square and square root of this value. In addition, we used a conjunction feature of the dice coefficient times the proximity. Finally, we added a bias feature on each edge, which acts as a threshold that allows

[2]This isn't quite competitive linking, because we use a non-greedy matching.



(a) (b)

Figure 2: Example alignments showing the effects of orthographic cognate features. (a) Dice and Distance, (b) With Orthographic Features.

sparser, higher precision alignments. With these features, we got an AER of 15.5 (compare to 19.5 for Model 2 in (Och and Ney, 2003)). Note that we already have a capacity that Model 2 does not: we can learn a non-quadratic penalty with linear mixtures of our various components – this gives a similar effect to learning the variance of the Gaussian for Model 2, but is, at least in principle, more flexible.[3] These features fix the *to-à* error in Figure 1(a), giving the alignment in Figure 1(b).

On top of these features, we included other kinds of information, such as word-similarity features designed to capture cognate (and exact match) information. We added a feature for exact match of words, exact match ignoring accents, exact matching ignoring vowels, and fraction overlap of the longest common subsequence. Since these measures were only useful for long words, we also added a feature which indicates that both words in a pair are short. These orthographic and other features improved AER to 14.4. The running example now has the alignment in Figure 1(c), where one improvement may be attributable to the short pair feature – it has stopped proposing *the-de*, partially because the short pair feature downweights the score of that pair. A clearer example of these features making a difference is shown in Figure 2, where both the exact-match and character overlap fea-

[3]The learned response was in fact close to a Gaussian, but harsher near zero displacement.

tures are used.

One source of constraint which our model still does not explicitly capture is the first-order dependency between alignment positions, as in the HMM model (Vogel et al., 1996) and IBM models 4+. The *the-le* error in Figure 1(c) is symptomatic of this lack. In particular, it is a slightly better pair according to the Dice value than the correct *the-les*. However, the latter alignment has the advantage that *major-grands* follows it. To use this information source, we included a feature which gives the Dice value of the words following the pair.[4] We also added a word-frequency feature whose value is the absolute difference in log rank of the words, discouraging very common words from translating to very rare ones. Finally, we threw in bilexical features of the pairs of top 5 non-punctuation words in each language.[5] This helped by removing specific common errors like the residual tendency for French *de* to mistakenly align to English *the* (the two most common words). The resulting model produces the alignment in Figure 1(d). It has sorted out the *the-le* / *the-les* confusion, and is also able to guess *to-de*, which is not the most common translation for either word, but which is supported by the good Dice value on the following pair (*make-faire*).

With all these features, we got a final AER of 10.7, broadly similar to the 8.9 or 9.7 AERs of unsymmetrized IBM Model 4 trained on the same data that the Dice counts were taken from.[6] Of course, symmetrizing Model 4 by intersecting alignments from both directions does yield an improved AER of 6.9, so, while our model does do surprisingly well with cheaply obtained count-based features, Model 4 does still outperform it so far. However, our model can also easily incorporate the predictions of Model 4 as additional features. We therefore added three new features for each edge: the prediction of Model 4 in the English-French direction, the prediction in the French-English direction, and the intersection of the two predictions. With these powerful new features, our AER dropped dramatically to 5.4, a 22% improvement over the intersected Model 4 performance.

Model	AER
Dice (without matching)	38.7 / 36.0
Model 4 (E-F, F-E, intersected)	8.9 / 9.7/ 6.9
Discriminative Matching	
Dice Feature Only	29.8
+ Distance Features	15.5
+ Word Shape and Frequency	14.4
+ Common Words and Next-Dice	10.7
+ Model 4 Predictions	5.4

Figure 3: AER on the Hansards task.

Another way of doing the parameter estimation for this matching task would have been to use an averaged perceptron method, as in Collins (2002). In this method, we merely run our matching algorithm and update weights based on the difference between the predicted and target matchings. However, the performance of the average perceptron learner on the same feature set is much lower, only 8.1, not even breaking the AER of its best single feature (the intersected Model 4 predictions).

3.2 Scaling Experiments

We explored the scaling of our method by learning on a larger training set, which we created by using GIZA++ intersected bi-directional Model 4 alignments for the unlabeled sentence pairs. We then took the first 5K sentence pairs from these 1.1M Model 4 alignments. This gave us more training data, albeit with noisier labels. On a 3.4GHz Intel Xeon CPU, GIZA++ took 18 hours to align the 1.1M words, while our method learned its weights in between 6 minutes (100 training sentences) and three hours (5K sentences).

[4]It is important to note that while our matching algorithm has no first-order effects, the features can encode such effects in this way, or in better ways – e.g. using as features posteriors from the HMM model in the style of Matusov et al. (2004).

[5]The number of such features which can be learned depends on the number of training examples, and since some of our experiments used only a few dozen training examples we did not make heavy use of this feature.

[6]Note that the common word pair features affected common errors and therefore had a particularly large impact on AER.

4 Conclusions

We have presented a novel discriminative, large-margin method for learning word-alignment models on the basis of arbitrary features of word pairs. We have shown that our method is suitable for the common situation where a moderate number of good, fairly general features must be balanced on the basis of a small amount of labeled data. It is also likely that the method will be useful in conjunction with a large labeled alignment corpus (should such a set be created). We presented features capturing a few separate sources of information, producing alignments on the order of those given by unsymmetrized IBM Model 4 (using labeled training data of about the size others have used to tune generative models). In addition, when given bi-directional Model 4 predictions as features, our method provides a 22% AER reduction over intersected Model 4 predictions alone. The resulting 5.4 AER on the English-French Hansarks task is, to our knowledge, the best published AER figure for this training scenario (though since we use a subset of the test set, evaluations are not problem-free). Finally, our method scales to large numbers of training sentences and trains in minutes rather than hours or days for the higher-numbered IBM models, a particular advantage when not using features derived from those slower models.

A Discriminative Framework for Bilingual Word Alignment

Robert C. Moore

Abstract

Bilingual word alignment forms the foundation of most approaches to statistical machine translation. Current word alignment methods are predominantly based on generative models. In this paper, we demonstrate a discriminative approach to training simple word alignment models that are comparable in accuracy to the more complex generative models normally used. These models have the the advantages that they are easy to add features to and they allow fast optimization of model parameters using small amounts of annotated data.

1 Motivation

Bilingual word alignment is the first step of most current approaches to statistical machine translation. Although the best performing systems are “phrase-based” (e.g, Och and Ney, 2004), possible phrase translations are normally first extracted from word-aligned bilingual text segments. The standard approach to word alignment makes use of various combinations of five generative models developed at IBM by Brown et al. (1993), sometimes augmented by an HMM-based model or Och and Ney’s “Model 6” (Och and Ney, 2003). The best combinations of these models can produce high accuracy alignments, at least when trained on a large corpus of fairly direct translations in related languages.

These standard models are less than ideal, however, in a number of ways, two of which we address in this paper. First, although the standard models can theoretically be trained without supervision, in practice various parameters are introduced that should be optimized using annotated data. For, example, Och and Ney (2003) suggest supervised optimization of a number of parameters, including the probablity of jumping to the empty word in the HMM model, as well as smoothing parameters for the distortion probabilities and fertility probabilities of the more complex models. Since the values of these parameters affect the values of the translation, alignment, and fertility probabilities trained by EM, there is no effective way to optimize them other than to run the training procedure with a particular combination of values and evaluate the accuracy of the resulting alignments. Since evaluating each combination of parameter values in this way can take hours to days on a large training corpus, it seems safe to say that these parameters are rarely if ever truly jointly optimized for a particular alignment task.

The second problem we address is the difficulty of adding features to the standard generative models. Generative models require a generative “story” as to how the observed data is generated by an interrelated set of stochastic processes. For example, the generative story for IBM Models 1 and 2 and the HMM alignment model is that a target language translation of a given source language sentence is generated by first choosing a length for the target language sentence, then for each target sentence position choosing a source sentence word, and then choosing the corresponding target language word. When Brown et al. (1993) wanted to add a fertility component to create Models 3, 4, and 5, however, this generative story didn't fit any longer, because it does not include how many target language words to align to each source language word as a separate decision. To model this explicitly, they had to come up with a different generative story.

In this paper, we take a different approach to word alignment, based on discriminative training of a weighted linear combination of a small number of features. For a given parallel sentence pair, for each possible word alignment considered, we simply multiply the values of each of these features by a corresponding weight to give a score for that feature, and sum the features scores to give an overall score for the alignment. The possible alignment having the best overall score is selected as the word alignment for that sentence pair. Thus, for a sentence pair (e, f) we seek the alignment $\hat{a}$ such that

$$\hat{a} = \mathrm{argmax}_a \sum_{i=1}^{n} \lambda_i f_i(a, e, f)$$

where the f_i are features and the λ_i are weights.

We optimize the model weights using a modified version of averaged perceptron learning as described by Collins (2002). This is fast to train, because selecting the feature weights is the last step in building the model and the "online" nature of perceptron learning allows the parameter optimization to converge quickly. Furthermore, no generative story has to be invented to explain how the features generate the data, so new features can be easily added without having to change the overall structure of the model.

In theory, a disadvantage of a discrimintative approach compared to a generative approach is that it requires annotated data for training. In practice, however, effective discriminative models for word alignment require only a few parameters, which can be optimized on a set of annotated sentence pairs comparable in size to what is needed to tune the free parameters used in the generative approach. As we will show, a simple sequence of two such models can achieve alignment accuracy comparable to that of a combination of more complex standard models.

2 Discriminative Alignment Models

We develop two word alignment models, incorporating different word association features intended to indicate how likely two words or groups of words are to be mutual translations, plus additional features measuring how much word reordering is required by the alignment[1], and how many words are left unlinked. One of the models also includes a feature measuring how often one word is linked to several words.

Each of our feature scores have analogs in the IBM and HMM models. The association scores corresponds to word translation probabilities; the reordering scores correspond to distortion probabilities; the scores for words left unlinked corresponds to probabilities of words being linked to the null word; and the scores for one-to-many links correspond to fertility probabilities.

2.1 The Log-Likelihood-Based Model

In our first model, we use a log-likelihood-ratio (LLR) statistic as our measure of word association. We chose this statistic because it has previously been found to be effective for automatically constructing translation lexicons (e.g., Melamed, 2000). We compute LLR scores using the following formula presented by Moore (2004):

$$LLR(f, e) = \sum_{f? \in \{f, \neg f\}} \sum_{e? \in \{e, \neg e\}} C(f?, e?) \log \frac{p(f?|e?)}{p(f?)}$$

In this formula f and e mean that the words whose degree of association is being measured occur in the respective target and source sentences of an aligned sentence pair, $\neg f$ and $\neg e$ mean that the corresponding words do not occur in the respective sentences, $f?$ and $e?$ are variables ranging over these values, and $C(f?, e?)$ is the observed joint count for the values of $f?$ and $e?$. All the probabilities in the formula refer to maximum likelihood estimates. The LLR score for a pair of words is high if the words have either a strong positive association or a strong negative association. Since we expect translation pairs to be positively associated, we discard any negatively associated word pairs by requiring that $p(f, e) > p(f) \cdot p(e)$. To reduce the memory requirements of our algorithms we discard any word pairs whose LLR score is less than 1.0.

[1]We will use the term "alignment" to mean an overall word alignment of a sentence pair, and the term "link" to mean the alignment of a particular pair of words or small group of words.

In our first model, the value of the *word association feature* for an alignment is simply the sum of all the individual LLR scores for the word pairs linked by the alignment. The LLR-based model also includes the following features:

nonmonotonicity features It may be observed that in closely related languages, word alignments of sentences that are mutual translations tend to be approximately monotonic (i.e., corresponding words tend to be in nearly corresponding sentence positions). Even for distantly related languages, the number of crossing links is far less than chance, since phrases tend to be translated as contiguous chunks. To model these tendencies, we introduce two *nonmonotonicity features*.

To find the points of nonmonotonicity of a word alignment, we arbitrarily designate one of the languages as the source and the other as the target. We sort the word pairs in the alignment, first by source word position, and then by target word position. We then iterate through the sorted alignment, looking only at the target word positions. The points of nonmonotonicity in the alignment will be the places where there are backward jumps in this sequence of target word positions. For example, suppose we have the sorted alignment ((1,1)(2,4)(2,5)(3,2)(5,6)). The sequence of target word positions in this sorted alignment is (1,4,5,2,6); hence, there is one point of nonmonotonicity where target word position 2 follows target word position 5.

We still need to decide how to measure the degree of nonmonotonicity of an alignment. Two methods immediately suggest themselves. One is to sum the magnitudes of the backward jumps in the target word sequence; the other is to simply count the number of backward jumps. Rather than choose between them, we use both features.

the one-to-many feature It has often been observed that word alignment links tend to be one-to-one. Indeed, word alignment results can often be improved by restricting more general models to permit only one-to-one links. For example, Och and Ney (2003) found that the intersection of the alignments found training the IBM models in both directions always outperformed either direction alone in their experiments. Since the IBM models allow one-to-many links only in one direction, this intersection can contain only one-to-one links.

To model the tendency for links to be one-to-one, we define a *one-to-many feature* as the number of links connecting two words such that exactly one of them participates in at least one other link. We also define a *many-to-many feature* as the number of links that connect two words that both participate in other links. We don't use this directly in the model, but to cut down on the number of alignments we need to consider, we discard any alignments having a non-zero value of the many-to-many feature.

the unlinked word feature To control the number of words that get linked to something, we introduce an *unlinked word feature* that simply counts the total number of unlinked words in both sentences in an aligned sentence pair.

2.2 The Conditional-Link-Probability-Based Model

In this model we replace the LLR-based word association statistic with the logarithm of the estimated conditional probability of two words (or combinations of words) being linked, given that they co-occur in a pair of aligned sentences. These estimates are derived from the best alignments according to some other, simpler model. For example, if *former* occurs 1000 times in English sentences whose French translations contain *ancien*, and the simpler alignment model links them in 600 of those sentence pairs, we might estimate the conditional link probability (CLP) for this word pair as 0.6. We find it better, however, to adjust these probabilities by subtracting a small fixed discount from the link count:

$$LP_d(f,e) = \frac{links_1(f,e) - d}{cooc(f,e)}$$

$LP_d(f,e)$ represents the estimated conditional link probability for the words f and e, $links_1(f,e)$ is the number of times they are linked by the simpler alignment model, d is the discount, and $cooc(f,e)$ is the number of times they co-occur. This adjustment prevents assigning high probabilities to links between pairs of words that rarely co-occur.

An important difference between the LLR-based model and CLP-based model is that the LLR-based model considers each word-to-word link separately, but allows multiple links per word, as long as they lead to an alignment consisting only of one-to-one and one-to-many links (in either direction). In the CLP-based model, however, we allow conditional probabilities for both one-to-one and one-to-many clusters, but we require all clusters to be disjoint.

For example, we estimate the conditional probability of linking *not* to *ne...pas* by considering the number of sentence pairs in which *not* occurs in the English sentence and both *ne* and *pas* occur in the French sentence, compared to the number of times *not* is linked to both *ne* and *pas* in pairs of corresponding sentences. However, when we make this estimate in the CLP-based model, we do not count a link between *not* and *ne...pas* if the same instance of *not*, *ne*, or *pas* is linked to any other words.

The CLP-based model incorporates the same adtional features as the LLR-based model, except that it omits the one-to-many feature, since we assume that the one-to-one vs. one-to-many trade-off is already modeled in the conditional link probabilities for particular one-to-one and one-to-many clusters.

We have developed two versions of the CLP-based model, using two different estimates for the conditional link probabilities. One estimate of the conditional link probabilities comes from the LLR-based model described above, optimized on an annotated development set. The other estimate comes from a heuristic alignment model that we previously developed (Moore, 2005).[2] Space does not permit a full description of this heuristic model here, but in brief, it utilizes a series of greedy searches inspired by Melamed's competitive linking algorithm (2000), in which constraints limiting alignments to being one-to-one and monotonic are applied at different thresholds of the LLR score, with a final cutoff of the LLR score below which no alignments are made.

3 Alignment Search

While the discriminative models presented above are very simple to describe, finding the optimal alignment according to these models is non-trivial. Adding a link for a new pair of words can affect the nonmonotonicity scores, the one-to-many score, and the unlinked word score differently, depending on what other links are present in the alignment. Nevertheless, we have found a beam-search procedure that seems highly effective in finding good alignments when used with these models.

For each sentence pair, we create a list of association types and their corresponding scores, consisting of the associations for which we have determined a score and for which the words involved in the association type occur in the sentence pair.[3] We sort the resulting list of association types from best to worst according to their scores.

Next, we initialize a list of possible alignments with the empty alignment, assigning it a score equal to the number of words in the sentence pair multiplied by the unlinked word weight. We then iterate through our sorted list of association types from best to worst, creating new alignments that add links for all instances of the association type currently being considered to existing alignments, potentially keeping both the old and new alignments in our set of possible alignments.

Without pruning, we would soon be overwhelmed by a combinatorial explosion of alignments. The set of alignments is therefore pruned in two ways. First, we keep track at all times of the score of the best alignment we have seen so far, and any new alignment whose overall score is worse than the best score so far by more than a fixed difference D is immediately discarded. Second, for each instance of a particular alignment type, when we have completed creating modified versions of previous alignments to include that instance, we merge the set of new alignments that we have created into the set of previous alignments. When we do this merge, the resulting set of alignments is sorted by overall score, and only the N best alignments are kept, for a fixed N.

Some details of the search differ between the LLR-based model and the CLP-based model. One difference is how we add links to existing alignments. In both cases, if there are no existing links involving any of the words involved in the new link, we simply add it (keeping a copy of the original alignment, subject to pruning).

If there are existing links involving word instances also involved in the new link, the two mod-

[2]The conditional link probabilities used in the current work are those used in Method 4 of the earlier work. Full details are provided in the reference.

[3]By *association type* we mean a possible link between a pair of words, or, in the case of the CLP-based models, a possible one-to-many or many-to-one linkage of words.

els are treated differently. For the CLP-based model, each association score is for a cluster of words that must be disjoint from any other association cluster, so when we add links for a new cluster, we must remove any other links involving the same word instances. For the LLR-based model, we can add additional links without removing old ones, but the resulting alignment may be worse due to the degradation in the one-to-many score. We therefore add both an alignment that keeps all previous links, and an additional set of alignments, each of which omits one of the previous links involving one of the word instances involved in the new link.

The other difference in how the two models are treated is an extra pruning heuristic we use in the LLR-based model. In generating the list of association types to be used in aligning a given sentence pair, we use only association types which have the best association score for this sentence pair for one of the word types involved in the association. We initially explored limiting the number of associations considered for each word type simply as an efficiency heuristic, but we were surprised to discover that the most extreme form of such pruning actually reduced alignment error rate over any less restrictive form or not pruning on this basis at all.

4 Parameter Optimization

We optimize the feature weights using a modified version of averaged perceptron learning as described by Collins (2002). Starting with an initial set of feature weight values, perceptron learning iterates through the annotated training data multiple times, comparing, for each sentence pair, the best alignment a_{hyp} according to the current model with the reference alignment a_{ref}. At each sentence pair, the weight for each feature is is incremented by the difference between the value of the feature for the best alignment according to the model and the value of the feature for the reference alignment:

$$\lambda_i \leftarrow \lambda_i + (f_i(a_{ref}, e, f) - f_i(a_{hyp}, e, f))$$

The updated feature weights are used to compute a_{hyp} for the next sentence pair.

Iterating through the data continues until the weights stop changing, because $a_{ref} = a_{hyp}$ for each sentence pair, or until some other stopping condition is met. In the averaged perceptron, the feature weights for the final model are the average of the weight values over all the data rather than simply the values after the final sentence pair of the final iteration.

We make a few modifications to the procedure as described by Collins. First, we average the weight values over each pass through the data, rather than over all passes, as we found this led to faster convergence. After each pass of perceptron learning through the data, we make another pass through the data with feature weights fixed to their average values for the previous learning pass, to evaluate current performance of the model. We iterate this procedure until a local optimum is found.

Next, we used a fixed weight of 1.0 for the word-association feature, which we expect to be most important feature in the model. Allowing all weights to vary allows many equivalent sets of weights that differ only by a constant scale factor. Fixing one weight eliminates a spurious apparent degree of freedom. This necessitates, however, employing a version of perceptron learning that uses a learning rate parameter. As described by Collins, the perceptron update rule involves incrementing each weight by the difference in the feature values being compared. If the feature values are discrete, however, the minimum difference may be too large compared to the unweighted association score. We therefore multiply the feature value difference by a learning rate parameter η to allow smaller increments when needed:

$$\lambda_i \leftarrow \lambda_i + \eta(f_i(a_{ref}, e, f) - f_i(a_{hyp}, e, f))$$

For the CLP-based model, based on the typical feature values we expected to see, we guessed that 0.01 might be a good value for the learning rate parameter. That seemed to produce good results, so we did not attempt to further optimize the learning rate parameter for this model.

The situation with the LLR-based model was more complicated. Our previous experience using LLR scores in statistical NLP applications indicated that with large data sets, LLR values can get very high (upwards of 100000 for our 500000 sentence pair corpus), but small difference could be significant, which led us to believe that the same would be true of the weight values we were trying to learn. That meant that a learning rate small enough to let us converge on the desired weight values might take a very large number of iterations through the data to reach those values. We addressed this problem, by using a progression of learning rates, starting at 1000, reducing each successive weight by an order of magnitude, until we ended with a learning rate of 1.0. At each transition between learning rates, we re-initialized the weights to the optimum values found with the previous learning rate.

We experimented with one other idea for optimizing the weight values. Perceptron learning does not directly optimize error rate, but we have only a small number of parameters that we need to optimize. We therefore thought it might be helpful to apply a general optimization procedure directly to the error rate, starting from the best parameter values found by perceptron learning, using the N-best alignments found with these parameter values. We experimented with both the downhill simplex method (Press et al., 2002, Section 10.4) and Powell's method (Press et al., 2002, Section 10.5), but we obtained slightly better results with a more heuristic method designed to look past minor local minima. We found that using this approach on top of perceptron learning led to slightly lower error rates on the development set with the CLP-based model, but not with the LLR-base model, so we used it only with the former in our final evaluations.

5 Data and Methodology for Evaluation

We evaluated our models using data from the bilingual word alignment workshop held at HLT-NAACL 2003 (Mihalcea and Pedersen, 2003). We used a subset of the Canadian Hansards bilingual corpus supplied for the workshop, comprising 500,000 English-French sentences pairs, including 447 manually word-aligned sentence pairs designated as test data. The test data annotates particular pairs of words either as "sure" or "possible" links. Automatic sentence alignment of the training data was provided by Ulrich Germann, and the hand alignments of the words in the test data were created by Franz Och and Hermann Ney (Och and Ney, 2003).

Since our discriminative training approach requires a small amount of annotated data for parameter optimization, we split the test data set into two virtually equal subsets, by randomly ordering the test data pairs, and assigning alternate pairs from the random order to the two subsets. We used one of these subsets as a development set for parameter optimization, and held out the other for a final test set.

We report the performance of our alignment models in terms of precision, recall, and alignment error rate (AER) as defined by Och and Ney (2003):

$$\text{recall} = \frac{|A \cap S|}{|S|}$$

$$\text{precision} = \frac{|A \cap P|}{|A|}$$

$$\text{AER} = 1 - \frac{|A \cap P| + |A \cap S|}{|A| + |S|}$$

In these definitions, S denotes the set of alignments annotated as sure, P denotes the set of alignments annotated possible or sure, and A denotes the set of alignments produced by the method under test. Following standard practice in the field, we take AER, which is derived from F-measure, as the primary evaluation metric that we are attempting to optimize.

6 Experimental Results

We first trained the LLR-based model by perceptron learning, using an N-best value of 20 and an unbounded allowable score difference in the alignment search, using the development set as annotated training data. We then aligned all the sentences of length 100 or less in our 500,000 sentence pair corpus, using an N-best value of 20 and a maximum allowable score difference of 125000. We collected link counts and co-occurrence counts from these alignments for estimating conditional link probabilities. We trained CLP-based models from these counts for a range of values for the discount used in the conditional link probability estimation, finding a value of 0.4 to be a roughly optimal value of the discount parameter for the development set. We also trained a CLP-based model using the conditional link probabilities from the heuristic alignment model mentioned previously. In training both CLP-based models, we also used an N-best value of 20 and an unbounded allowable score difference in the alignment search.

We evaluated three models on the final test data: the LLR-based model (LLR) and the two CLP-based models, one with conditional link probabilities from

Alignment	Recall	Precision	AER
LLR	0.829	0.848	0.160
CLP_1	0.889	0.934	0.086
CLP_2	0.898	0.947	0.075

Table 1: Discriminative Model Results.

Alignment	Recall	Precision	AER
$\text{E} \rightarrow \text{F}$	0.870	0.890	0.118
$\text{F} \rightarrow \text{E}$	0.876	0.907	0.106
Union	0.929	0.845	0.124
Intersection	0.817	0.981	0.097
Refined	0.908	0.929	0.079

Table 2: IBM Model 4 Results.

the LLR-based model (CLP_1), and one with conditional link probabilities from the heuristic alignment model (CLP_2). All parameters were optimized on the development set. Recall, precision, and alignment error rates on the test set are shown in Table 1.

For comparison, we aligned our parallel corpus with IBM Model 4 using Och's Giza++ software package (Och and Ney, 2003).[4] We used the default configuration file included with the version of Giza++ that we used, which resulted in five iterations of Model 1, followed by five iterations of the HMM model, followed by five iterations of Model 4. We trained the models in both directions, English-to-French and French-to-English, and computed the union, intersection, and what Och and Ney (2003) call the "refined" combination of the two alignments. We evaluated the resulting alignments of the final test set, with the results shown in Table 2.

As these tables show, our discriminatively trained CLP-based models compare favorably to IBM Model 4 on this data set. The one with conditional link probabilities from the heuristic alignment model, CLP_2, performs slightly better than the best of the Model 4 combinations, and the one with conditional link probabilities from the LLR-based model, CLP_1, performs only slightly worse.

An interesting question is why CLP_2 outperformed CLP_1. CLP_1 is the more "principled" model, so one might have expected it to perform better. We believe the most likely explanation is the fact that CLP_2 received 403,195 link probabilities from the heuristic model, while CLP_1 received only 144,051 link probabilities from the LLR-based model. Hence CLP_2 was able to consider more possible links.

In light of our claims about the ease of optimizing the models, we should make some comments on the time need to train the parameters. Our current implementation of the alignment search is written in Perl, and is therefore quite slow. Alignment of our 500,000 sentence pair corpus with the LLR-based mode took over a day on a 2.8 GHz Pentium IV workstation. Nevertheless, the parameter optimization was still quite fast, since it took only a few iterations over our 224 sentence pair development set. With either the LLR-based or CLP-based models, one combined learning/evaluation pass of perceptron training always took less than two minutes, and it never took more that six passes to reach the local optimum we took to indicate convergence. Total training time was greater since we used multiple runs of perceptron learning with different learning rates for the LLR-based model and different conditional link probability discounts for CLP_1, but total training time for each model was around an hour.

7 Related Work

When the first version of this paper was submitted for review, we could honestly state, "We are not aware of any previous work on discriminative word alignment models." Callison-Burch et al. (2004) had investigated the use of small amounts of annotated data to help train the IBM and HMM models, but the models were still generative and were trained using maximum-likelihood methods.

Recently, however, three efforts nearly simultaneous with ours have made use of discriminative methods to train alignment models. Fraser and Marcu (2005) modify Model 4 to be a log-linear combination of 11 submodels (5 based on standard Model 4 parameters, and 6 based on additional features) and discriminatively optimize the submodel weights on each iteration of a Viterbi approximation to EM.

Liu et al. (2005) also develop a log-linear model, based on IBM Model 3. They train Model 3 using Giza++, and then use the Model 3 score of a possible alignment as a feature value in a discriminatively trained log-linear model, along with fea-

[4]Thanks to Chris Quirk for carrying out this alignment.

tures incorporating part-of-speech information, and whether the aligned words are given as translations in a bilingual dictionary. The log-linear model is trained by standard maximum-entropy methods.

Klein and Taskar (2005), in a tutorial on maximum margin methods for natural-language processing, described a weighted linear model incorporating association, position, and orthography features, with its parameters trained by a structured-support-vector-machine method. This model is in some respects very similar to our LLR-based model, using Dice coefficient association scores where we use LLR scores, and absolute position differences where we use nonmonotonicity measures.

8 Conclusions

The results of our work and other recent efforts on discriminatively trained alignment models show that results comparable to or better than those obtained with the IBM models are possible within a framework that makes it easy to add arbitrary additional features. After many years using the same small set of alignment models, we now have an easy way to experiment with a wide variety of knowledge sources to improve word-alignment accuracy.

Abstract

This paper presents a maximum entropy word alignment algorithm for Arabic-English based on *supervised* training data. We demonstrate that it is feasible to create training material for problems in machine translation and that a mixture of supervised and unsupervised methods yields superior performance. The probabilistic model used in the alignment directly models the link decisions. Significant improvement over traditional word alignment techniques is shown as well as improvement on several machine translation tests. Performance of the algorithm is contrasted with human annotation performance.

1 Introduction

Machine translation takes a source sequence,

$$S = [s_1 \ s_2 \ \dots \ s_K]$$

and generates a target sequence,

$$T = [t_1 \ t_2 \ \dots \ t_M]$$

that renders the meaning of the source sequence into the target sequence. Typically, algorithms operate on sentences. In the most general setup, one or more source words can generate 0, 1 or more target words. Current state of the art machine translation systems (Och, 2003) use phrasal (n-gram) features extracted automatically from parallel corpora. These phrases are extracted using word alignment algorithms that are trained on parallel corpora. Phrases, or phrasal features, represent a mapping of source sequences into a target sequences which are typically a few words long.

In this paper, we investigate the feasibility of training alignment algorithms based on supervised alignment data. Although there is a modest cost associated with annotating data, we show that a reduction of 40% relative in alignment error (AER) is possible over the GIZA++ aligner (Och and Ney, 2003).

Although there are a number of other applications for word alignment, for example in creating bilingual dictionaries, the primary application continues to be as a component in a machine translation system. We test our aligner on several machine translation tests and show encouraging improvements.

2 Related Work

Most of the prior work on word alignments has been done on parallel corpora where the alignment at the sentence level is also done automatically. The IBM models 1-5 (Brown et al., 1993) produce word alignments with increasing algorithmic complexity and performance. These IBM models and more recent refinements (Moore, 2004) as well as algorithms that bootstrap from these models like the HMM algorithm described in (Vogel et al., 1996) are unsupervised algorithms.

The relative success of these automatic techniques together with the human annotation cost has delayed the collection of supervised word-aligned corpora for more than a decade.

(Cherry and Lin, 2003) recently proposed a direct alignment formulation and state that it would be straightforward to estimate the parameters given a supervised alignment corpus. In this paper, we extend their work and show that with a small amount of annotated data, together with a modeling strategy and search algorithm yield significant gains in alignment F-measure.

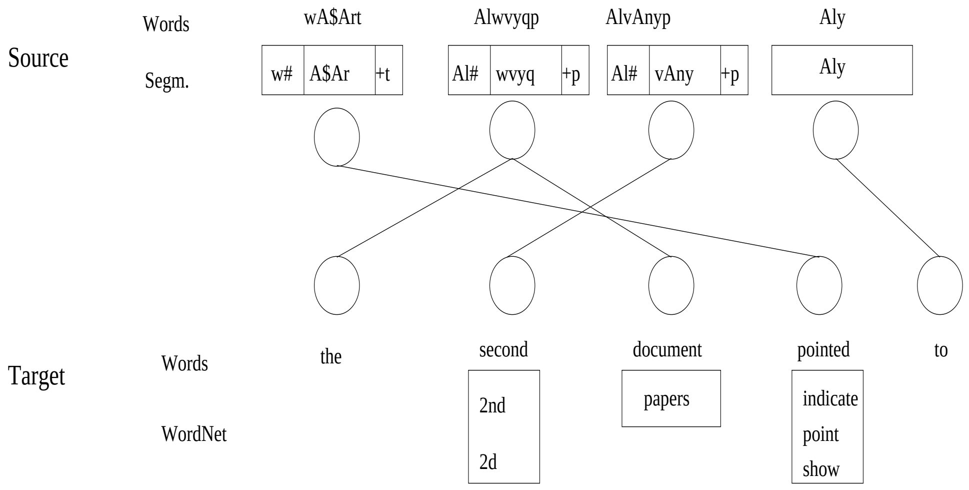

Figure 1: Alignment example.

3 Algorithm

In order to describe the algorithm, we will need to first describe the direct link model. Figure 1 shows two sequences where the top sequence is considered the source sequence and the bottom sequence the target sequence. Each sequence can have auxilliary information such as Arabic segmentation or English WordNet (Miller, 1990) information as shown. Given the source and target sequences, there are a number of different ways to link each target word to a source word. Each target word has a link l_i which indicates which source position it links to. The range of l_i is from 0 to K and there are M of these links. The source word position 0 is used to indicate NULL which we imagine gives rise to unaligned English words. In this paper, we refer to these words as being spontaneous. A valid link configuration has M links. Define $\mathcal{L}$ to be the set of all possible valid link configurations, and L to be a member of that set. We seek to maximize the alignment probability by finding the optimum link configuration L_{opt},

$$\begin{aligned} p(L_{\mathrm{opt}}|S,T) &= \arg\max_{L\in\mathcal{L}} p(L|S,T) \\ &= p(l_i^M|t_1^M, s_1^K) \\ &= \prod_{i=0}^{M} p(l_i|t_1^M, s_1^K, l_1^{i-1}). \end{aligned}$$

We factor this into a transition model and an observation model,

$$p(L|S,T) = \frac{1}{Z}\prod_{i=0}^{M} p(l_i|l_{i-1})^{\alpha} p(l_i|t_1^M, s_1^K, l_1^{i-1})^{1-\alpha}.$$

where Z is the normalizing constant.

We factor the model as above so that the transition model computation, which uses information available on the search hypotheses, is reduced during the search process. In the aligner presented here, α is always set to 0.5. Next we will describe the transition model, then the observation model and finally the experiments in alignment and machine translation.

In the IBM Model 1 aligner, the choice of the language to serve as states of the search algorithm is not prescribed, but practically the choice is important as it affects performance. To see this, note that in generative models an input word can only be aligned to a single state in the search. In our current situation, we are interested in aligning unsegmented Arabic words and typical words have a few affixes to indicate for example pronouns, definiteness, prepositions and conjunctions. In English these are separate words, and therefore to maximize performance the unsegmented Arabic words serve as states in the search algorithm and we align English words to these states.

3.1 Transition Model

The transition model tends to keep the alignments close together and penalizes alignments in which adjacent words in the target language come from very distant words in the source language. Also, we would like to penalize many English words coming from the same Arabic state; we call this the state visit penalty and will be described later. In this paper, we use a parametric form for the transition model,

$$p(l_i|l_{i-1}) = \frac{1}{Z(l_{i-1})}\left[\frac{1}{\mathrm{dist}(l_i, l_{i-1})} + \frac{1}{ns(l_i)}\right] \quad (1)$$

where $ns(i)$ represents the state visit penalty for state i, $Z(l_{i-1})$ is the normalization constant and

$$\mathrm{dist}(l_i, l_{i-1}) = \min(|l_i - l_{i-1}|, |l_i - f_i|) + a.$$

Here a is a penalty for a zero distance transition and is set to 1 in the experiments below. The min operator chooses the lowest cost transition distance either from the previous state or the frontier state, f_i, which is the right most state that has been visited (even though Arabic is normally displayed right to left, we make our Arabic state graphs from left to right). This is a language specific criteria and intended to model the adjective noun reversal between English and Arabic. Once the current noun phrase is completed, the next word often aligns to the state just beyond frontier state. As an example, in Figure 1, the verb 'pointed' aligns to the first Arabic word 'wA$Art', and aligning the 'to' to its Arabic counterpart 'Aly' would incur normally a distance of 3 but with the frontier notion it incurs only a penalty of 1 on the hypothesis that aligns the word 'second' to 'AlvAnyp'. In this alignment with the frontier notion, there are only distance 1 transitions, whereas the traditional shapes would incur a penalty of 2 for alignment of 'pointed' and a penalty of 3 for the word 'to'.

The state visit penalty, $ns(i)$ is the distance between the English words aligned to this state times the number of state visits[1]. This penalty controls the fertility of the Arabic words. To determine the English words that aligned to the Arabic position, the search path is traced back for each hypothesis and a sufficiently large beam is maintained so that alignments in the future can correct past alignment decisions. This penalty allows English determiners and prepositions to align to the Arabic content word while penalizing distant words from aligning to the state. In terms of alignment F-measure to be described below, the state visit penalty, if removed makes the performance degrade from F=87.8 to F=84.0 compared to removing the frontier notion which only degrades performance to F=86.9.

3.2 Observation Model

The observation model measures the linkage of the source and target using a set of feature functions defined on the words and their context. In Figure 1, an event is a single link from an English word to an Arabic state and the event space is the sentence pair. We use the maximum entropy formulation (e.g. (Berger et al., 1996)),

$$f = \psi(l_i)$$
$$h = \left[t_1^{i-1}, s_1^K\right]$$
$$p(f|h) = \frac{1}{Z(h)} \exp \sum_i \lambda_i \phi_i(h, f),$$

where Z(h) is the normalizing constant,

$$Z(h) = \sum_f \exp \sum_i \lambda_i \phi_i(h, f).$$

and $\phi_i(h, f)$ are binary valued feature functions. The function ψ selects the Arabic word at the position being linked or in the case of segmentation features, one of the segmentations of that position. We restrict the history context to select from the current English word and words to the left as well as the current word's WordNet (Miller, 1990) synset as required by the features defined below. As in (Cherry and Lin, 2003), the above functions simplify the conditioning portion, h by utilizing only the words and context involved in the link l_i. Training is done using the IIS technique (Della Pietra et al., 1995) and convergence often occurs in 3-10 iterations. The five types of features which are utilized in the system are described below.

Phrase to phrase (for example, idiomatic phrases) alignments are intepreted as each English word coming from each of the Arabic words.

3.2.1 Lexical Features

The lexical features are similar to the translation matrix of the IBM Model 1. However, there is a signficant out of vocabulary (OOV) issue in the model since training data is limited. All words that have a corpus frequency of 1 are left out of the model and classed into an unknown word class in order to explicitly model connecting unknown words. From the training data we obtain 50K lexical features, and applying the Arabic segmenter obtain another 17K lexical features of the form ϕ(English content word, Arabic stem).

3.2.2 Arabic Segmentation Features

An Arabic segmenter similar to (Lee et al., 2003) provides the segmentation features. A small dictionary is used (with 71 rules) to restrict the set of Arabic segments that can align to English stopwords, for example that 'the' aligns to 'Al#' and that 'for', 'in' and 'to' align to 'b#' and 'her' aligns with the suffix '+hA'. Segmentation features also help align unknown words, as stems might be seen in the training corpus with other prefixes or suffixes. Additionally, the ability to align the prefix and suffix accurately, tends to 'drag' the unknown stem to its English target.

[1]We are overloading the word 'state' to mean Arabic word position.

3.2.3 WordNet Features

WordNet features provide normalization on the English words. The feature is instantiated for nouns, adjectives, adverbs and verbs following their definitions in WordNet. If the Arabic word has a segmentation then the feature is ϕ(WordNet synset id, Arabic stem), otherwise it is ϕ(WordNet synset id, Arabic word). The feature ties together English synonyms and helps improve recall of the aligner.

3.2.4 Spelling Feature

The spelling feature is applied only on unknown words and is used to measure the string kernel distance(Lodhi et al., 2000) between romanized Arabic and English words. The feature is designed primarily to link unknown names. For example, 'Clinton' is written as 'klyntwn' in one of its romanized Arabic versions. In a sentence, measuring the string kernel distance shows a correlation between these names even though there is not much overlap between the characters. The feature has four possible values: nomatch, somematch, goodmatch, and exact.

3.2.5 Dynamic Features

Dynamic features are defined on the lattice of the search algorithm. These features fire when the previous source and target word pair are linked. For example, one such feature is 'b# in' and if on the hypothesis we have just linked this pair and the next English word is being aligned to the stem of the Arabic word where this prefix occurs, this feature fires and boosts the probability that the next words are aligned. The basic intuition behind this feature is that words inside prepositional phrases tend to align, which is similar to the dependency structure feature of (Cherry and Lin, 2003).

At training time, the lattice reduces to the single path provided by the annotation. Since this feature tends to suffer from the drag of function words, we insist that the next words that are being linked have at least one feature that applies. All word pairs linked in the training data have lexical features as described above, and if both source and target words are unknown they have a single feature for their link. Applying dynamic features on words that have at least one other feature prevents words which are completely unrelated from being linked because of a feature about the context of the words.

Two types of dynamic features are distinguished: (a) English word with Arabic prefix/suffix and (b) English word with Arabic stem.

4 Smoothing the Observation Model

Since the annotated training data for word alignment is limited and a much larger parallel corpus is available for other aligners, we smooth the observation probability with an IBM Model 1 estimate,

$$p(l_i|t_1^M, s_1^K) = \frac{1}{Z} p_{\mathrm{ME}}(l_i|t_1^M, s_1^K)^{\beta} p_{\mathrm{M1}}(s|t_i)^{1-\beta}.$$

where β is set to 0.9 in the experiments below. In the equation above, the s represents the Arabic word that is being linked from the English word t_i.

When β is set to 1.0 there is no smoothing performed and performance degrades to F=84.0 from the best system performance (F=87.8). When β is set to 0, the model uses only the IBM Model 1 distribution and the resulting aligner is similar to an HMM aligner with the transition shape discussed above and yields performance of F=73.2.

Anno. 1	96.5	92.4	91.7
Anno. 1'	95.2	—	93.2

Table 1: F-measure for human performance on word alignment for Arabic-English.

5 Search Algorithm

A beam search algorithm is utilized with the English words consumed in sequence and the Arabic word positions serving as states in the search process. In order to take advantage of the transition model described above, a large beam must be maintained. To see this, note that English words often repeat in a sentence and the models will tend to link the word to all Arabic positions which have the same Arabic content. In traditional algorithms, the Markov assumption is made and hypothesis are merged if they have the same history in the previous time step. However, here we maintain all hypotheses and merge only if the paths are same for 30 words which is the average sentence length.

6 Experimental Data

We have word aligned a portion of the Arabic Treebank (4300 sentences) and material from the LDC news sources (LDC, 2005) to obtain a total of 10.3K sentence pairs for training. As a test of alignment, we use the first 50 sentences of the MT03 Evaluation test set which has 1313 Arabic words and 1528 English words [2]. In terms of annotation guidelines, we use the following instructions: (a) Align determiners to their head nouns, (b) Alignments are done word by word unless the phrase is idiomatic in which case the entire phrase to phrase alignment was marked, (c) spontaneous words are marked as being part of a

[2]The test data is available by contacting the authors.

	1K	3K	5K	7K	9K	10.3K

Table 2: Varying Training data size.

phrase wherever possible but left unaligned if there is no evidence to link the word.

In order to measure alignment performance, we use the standard AER measure (Och and Ney, 2000) but consider all links as sure. This measure is then related to the F-measure which can be defined in terms of precision and recall as

Precision The number of correct word links over the total number of proposed links.

Recall The number of correct word links over the total number of links in the reference.

and the usual definition of the F-measure,

$$F = \frac{2PR}{(R + P)}$$

and define the alignment error as AER $= 1 - F$. In this paper, we report our results in terms of F-measure over aligned links. Note that links to the NULL state (unaligned English words) are not included in the F-measure. Systems are compared relative to the reduction in AER.

6.1 Annotator Agreement

We measure intra/inter-annotator agreement on the test set in order to determine the feasibility of human annotation of word links. These are shown in Table 1. In the table, the column for 'Annotator 1 Correction' is the first annotator correcting his own word alignments after a span of a year. After two weeks, the annotator (Annotator 1') was given the same material with all the links removed and asked to realign and we see that there is more discrepancy in resulting alignments. The differences are largely on the head concept where determiners are attached and the alignment of spontaneous words. The performance with a second annotator is in the same range as the reannotation by a single annotator.

7 Experiments

In order to evaluate the performance of the algorithm, we investigate the effect due to: (a) increasing the training data size, (b) additional feature types, and (c) comparable algorithms.

7.1 Training Data Size

We varied the training data size from 1K sentences to the complete set in Table 2. Each batch re-estimates the unknown word class by creating a vocabulary on the training set. The trend indicates a reasonable progression of performance and more data is required to determine the saturation point.

7.2 Feature Types

The results obtained by different feature sets are shown in Table 3. Each feature type was added incrementally (Add Feature column) to the line above to determine the effect of the individual feature types and then removed incrementally from the full system (Subtract Feature column) in order to see the final effect. The results indicate that lexical features are the most important type of feature; segmentation features further reduce the AER by 15.8%. The other features add small gains in performance which, although are not statistically significant for the alignment F-measure, are important in terms of feature extraction. Segmentation features discussed above result in both suffix and prefix features as well as stem features. In the Subtract column, for the segmentation feature, only the suffix and prefix features were removed. This result indicates that most of the alignment improvement from the segmentation feature comes in the form of new lexical features to link Arabic stems and English words.

7.3 Comparison to other alignment algorithms

In order to gauge the performance of the algorithm with respect to other alignment strategies, we provide results using GIZA++ and an HMM Max Posterior Algorithm (Ge, 2004). These algorithms, as well as the Model 1 smoothing for the MaxEnt aligner, are all trained on a corpus of 500K sentence pairs from the UN parallel corpus and the LDC news corpora released for 2005 (LDC, 2005). Note that these algorithms are unsupervised by design but we utilize them to have a baseline for comparing the performance of this supervised approach.

7.3.1 HMM Max Posterior Aligner

The maximum-posterior word alignments are obtained by finding the link configuration that maxi-

System	# of feats	Add Feature	Subtract Feature

Table 3: Alignment performance in terms of the feature types utilized.

	F-Measure
GIZA++	79.5
HMM	76.3
MaxEnt	87.8

Table 4: Alignment performance

mizes the posterior state probability. In contrast, in performing a Viterbi alignment, we compute the best state sequence given the observation. The maximum posterior computes the best state one at a time and iterates over all possible combinations. Once we find the maximum in the posterior probability matrix, we also know the corresponding state and observation which is nothing but the word pair (s_j, t_i). We will then align the pair and continue to find the next posterior maximum and align the resulting pair. At each iteration of the process, a word pair is aligned. The process is repeated until either every word in one (or both) language is aligned or no more maximum can be found, whichever happens first.

7.3.2 GIZA Alignment

In order to contrast our algorithm, we ran GIZA++ in the standard configuration which implies 5 iterations of IBM Model 1, HMM, Model 3 and Model 4. All parameters are left to their default values.

The results using the three different aligners is shown in Table 4. The reduction in AER over the GIZA++ system is 40.5% and over the HMM system is 48.5%. The Wilcoxon signed-rank test yields a probability of 0.39 for rejecting the GIZA++ alignment over the HMM alignment, whereas the MaxEnt algorithm should be rejected with a probability of 1.7e-6 over the HMM algorithm and similarly MaxEnt should be rejected with a probability of 0.9e-6 over the GIZA++ algorithm. These significance tests indicate that the MaxEnt algorithm presented above is significantly better than either GIZA++ or HMM.

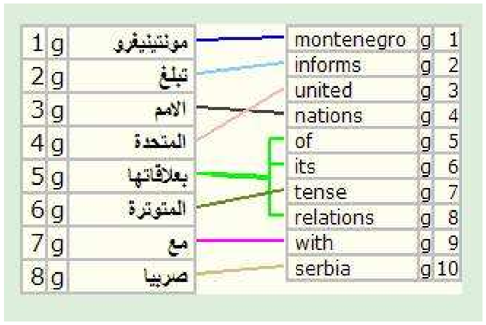

Figure 2: An alignment showing a split link from an Arabic word.

8 Phrase Extraction

Once an alignment is obtained, phrases which satisfy the inverse projection constraint are extracted (although earlier this constraint was called consistent alignments (Och et al., 1999)). This constraint enforces that a sequence of source words align to a sequence of target words as defined by the lowest and highest target index, and when the target words are projected back to the source language through the alignment, the original source sequence is retrieved. Examination of the hand alignment training data showed that this criteria is often violated for Arabic and English. Prepositional phrases with adjectives often require a split– for example, the alignment shown in Figure 2 has 'of its relations' aligned to a word in Arabic and 'tense' aligned to the next word. The inverse projection constraint fails in this case, and in the experiments below, we relax this constraint and generate features for single source words as long as the target phrase has a gap less than 2 English words. This relaxation allows a pair of adjectives to modify the head noun. In future work we explore the use of features with variables to be filled at decode time.

9 Translation Experiments

The experiments in machine translation are carried out on a phrase based decoder similar to the one de-

	MT03	MT04	MT05
GIZA++	0.454	—	—
HMM	0.459	0.419	0.456
MaxEnt	0.468	0.433	0.451
Combined	0.479	0.437	0.465
Significance	0.017	0.020	—

Table 5: Machine Translation Performance using the NIST 2005 Bleu scorer

scribed in (Tillmann and Ney, 2003). In order to contrast the performance of the extracted features, we compare the translation performance to (a) a system built from alignments proposed by an HMM Max Posterior Aligner, and (b) a system built from GIZA alignments. All other parameters of the decoder remain constant and only the feature set is changed for these experiments. As training data, we use the UN parallel corpus and the LDC news corpora released in 2005. Comparison should therefore be only made across systems reported here and not to earlier evaluations or other systems. The results are shown in Table 5.

Combination of the phrasal features from the HMM and MaxEnt alignments results in the 'Combined' system. The Combined system performs better in all cases; in MT03 and MT04 the MaxEnt derived features perform better than the HMM system. In MT05, there is a slight degradation which is not significant and the combination system still results in an improvement over either system. Since the MaxEnt aligner has access to a unique resource, every attempt was made to make that resource available to the other systems. Although GIZA++ and HMM can not directly utilize word aligned data, the training data for MaxEnt was converted to parallel sentences where each sentence has only the pair of linked words. The resulting numbers make both HMM and GIZA much closer in performance to the MaxEnt aligner but the results are better for comparing alignment methods.

10 Error Analysis and Discussion

The alignment errors made by the system can be attributed to

- English words that require multi-word Arabic states, for example (a) dates which are written in Arabic in more than one form 'kAnwn AlvAny / ynAyr' for 'january', and (b) compound words like 'rAm Allh' in English is 'Ramallah'.
- Rare translation of a common Arabic word as well as a common English word used as the translation for a rare Arabic word.
- Parallel corpora mismatch: training material for translation is processed at a document level and yet systems often operate at a sentence level. Human translators often use pronouns for earlier mentioned names although in the source language the name is repeated. Information which is sometimes repeated in the source in an earlier sentence is dropped in future sentences of the document. Document level features are required to allow the system to have information to leave these words unaligned.

Figure 3 shows a human alignment on the left and a machine output on the right. The columns next to the words indicate whether the alignments are 'good' or 'extra' which indicates that these words are aligned to the special NULL state. There are two examples of multi-word Arabic states shown: (a) for 'january', and (b) the English word 'agenda'. The system aligns 'the' before committee and it seems in this case its an annotation error. In this example the Arabic words lnAHyp, AltnZym, wAlAEdAd and Allwjsty are all unknown words in the vocabulary yet the system managed to link 3 out 4 words correctly.

While significant gains have been made in alignment performance, these gains have not directly translated to machine translation improvements. In fact, although the GIZA system is better than the HMM system at alignment, the machine translation result on MT03 indicates a slight degradation (although it is not statistically significant). The prime reason for this is that features extracted from the alignments are aggregated over the training corpus and this process helps good alignments to have significantly better counts than errors in alignment. Aligning rare words correctly should help performance but since their count is low it is not reflected in bleu scores.

11 Conclusion and Future Work

This paper presented a word aligner trained on annotated data. While the performance of the aligner is shown to be significantly better than other unsupervised algorithms, the utility of these alignments in machine translation is still an open subject although gains are shown in two of the test sets. Since features are extracted from a parallel corpus, most of the information relating to the specific sentence alignment is lost in the aggregation of features across sentences. Improvements in capturing sentence context could allow the machine translation system to use a rare but correct link appropriately.

Another significant result is that a small amount (5K sentences) of word-aligned data is sufficient for this algorithm since a provision is made to handle

A Large-Scale Exploration of Effective Global Features for a Joint Entity Detection and Tracking Model

Abstract

Entity detection and tracking (EDT) is the task of identifying textual mentions of real-world entities in documents, extending the named entity detection and coreference resolution task by considering mentions other than names (pronouns, definite descriptions, etc.). Like NE tagging and coreference resolution, most solutions to the EDT task separate out the mention detection aspect from the coreference aspect. By doing so, these solutions are limited to using only local features for learning. In contrast, by modeling both aspects of the EDT task simultaneously, we are able to learn using highly complex, non-local features. We develop a new joint EDT model and explore the utility of many features, demonstrating their effectiveness on this task.

1 Introduction

In many natural language applications, such as automatic document summarization, machine translation, question answering and information retrieval, it is advantageous to pre-process text documents to identify references to entities. An entity, loosely defined, is a person, location, organization or geo-political entity (GPE) that exists in the real world. Being able to identify references to real-world entities of these types is an important and difficult natural language processing problem. It involves finding text spans that correspond to an entity, identifying what *type of entity* it is (person, location, etc.), identifying what *type of mention* it is (name, nominal, pronoun, etc.) and finally identifying which *other* mentions in the document it corefers with. The difficulty lies in the fact that there are often many ambiguous ways to refer to the same entity. For example, consider the two sentences below:

$\underline{\text{Bill Clinton}}^{\text{NAM}}_{\text{PER}-1}$ gave a speech today to $\underline{\text{the Senate}}^{\text{NAM}}_{\text{ORG}-2}$. $\underline{\text{The President}}^{\text{NOM}}_{\text{PER}-1}$ outlined $\underline{\text{his}}^{\text{PRO}}_{\text{PER}-1}$ plan for budget reform to $\underline{\text{them}}^{\text{PRO}}_{\text{ORG}-2}$.

There are five entity *mentions* in these two sentences, each of which is underlined (the corresponding mention type and entity type appear as superscripts and subscripts, respectively, with coreference chains marked in the subscripts), but only two *entities*: { Bill Clinton, The president, his } and { the Senate, them }. The *mention detection* task is to identify the entity mentions and their types, without regard for the underlying entity sets, while *coreference resolution* groups a given mentions into sets.

Current state-of-the-art solutions to this problem split it into two parts: mention detection and coreference (Soon et al., 2001; Ng and Cardie, 2002; Florian et al., 2004). First, a model is run that attempts to identify each mention in a text and assign it a type (person, organization, etc.). Then, one holds these mentions fixed and attempts to identify which ones refer to the same entity. This is typically accomplished through some form of clustering, with clustering weights often tuned through some local learning procedure. This pipelining scheme has the significant drawback that the mention detection module cannot take advantage of information from the coreference module. Moreover, within the coreference task, performing learning and clustering as separate tasks makes learning rather ad-hoc.

In this paper, we build a model that solves the mention detection and coreference problems in a simultaneous, joint manner. By doing so, we are able to obtain an empirically superior system as well as integrate a large collection of features that one cannot consider in the standard pipelined approach. Our ability to perform this modeling is based on the *Learning as Search Optimization* framework, which we review in Section 2. In Section 3, we describe our joint EDT model in terms of the search procedure executed. In Section 4, we describe the features we employ in this model; these include the standard lexical, semantic (WordNet) and string matching features found in most other systems. We additionally consider many other feature types, most interestingly *count-based features*, which take into account the distribution of entities and mentions (and are not expressible in the binary classification method for coreference) and *knowledge-based features*, which exploit large corpora for learning name-to-nominal references. In Section 5, we present our experimental results. First, we compare our joint system with a pipelined version of the system, and show that joint inference leads to improved performance. Next, we perform an extensive feature comparison experiment to determine which features are most useful for the coreference task, showing that our newly introduced features provide useful new information. We conclude in Section 6.

2 Learning as Search Optimization

When one attempts to apply current, standard machine learning algorithms to problems with combinatorial structured outputs, the resulting algorithm implicitly assumes that it is possible to find the best structures for a given input (and some model parameters). Furthermore, most models require much more, either in the form of feature expectations for conditional likelihood-based methods (Lafferty et al., 2001) or local marginal distributions for margin-based methods (Taskar et al., 2003). In many cases—including EDT and coreference—this is a false assumption. Often, we are not able to find the *best* solution, but rather must employ an approximate search to find the best possible solution, given time and space constraints. The Learning as Search Optimization (LaSO) framework exploits this difficulty as an opportunity and seeks to find model parameters that are good *within the context of search.*

```
Algo Learn(problem, initial, enqueue, $\boldsymbol{w}$, $x$, $y$)
nodes ← MakeQueue(MakeNode(problem,initial))
while nodes is not empty do
  node ← RemoveFront(nodes)
  if none of nodes ∪ {node} is $y$-good or
      GoalTest(node) and node is not $y$-good then
      sibs ← siblings(node, $y$)
      $\boldsymbol{w}$ ← update($\boldsymbol{w}$, $x$, sibs, node ∪ nodes)
      nodes ← MakeQueue(sibs)
  else
      if GoalTest(node) then return $\boldsymbol{w}$
      next ← Operators(node)
      nodes ← enqueue(problem, nodes, next, $\boldsymbol{w}$)
  end if
end while
```

Figure 1: The generic search/learning algorithm.

More formally, following the LaSO framework, we assume that there is a set of input structures $\mathcal{X}$ and a set of output structures $\mathcal{Y}$ (in our case, elements $x \in \mathcal{X}$ will be documents and elements $y \in \mathcal{Y}$ will be documents marked up with mentions and their coreference sets). Additionally, we provide the structure of a search space $\mathcal{S}$ that results in elements of $\mathcal{Y}$ (we will discuss our choice for this component later in Section 3). The LaSO framework relies on a *monotonicity* assumption: given a structure $y \in \mathcal{Y}$ and a node n in the search space, we must be able to calculate whether it is *possible* for this node n to eventually lead to y (such nodes are called y-good).

LaSO parameterizes the search process with a weight vector $\boldsymbol{w} \in \mathbb{R}^D$, where weights correspond to features of search space nodes and inputs. Specifically, we write $\Phi : \mathcal{X} \times \mathcal{S} \to \mathbb{R}^D$ as a function that takes a pair of an input x and a node in the search space n and produces a vector of features. LaSO takes a standard search algorithm and modifies it to incorporate learning in an online manner to the algorithm shown in Figure 1. The key idea is to perform search as normal until a point at which it becomes impossible to reach the correct solution. When this happens, the weight vector $\boldsymbol{w}$ is updated in a corrective fashion. The algorithm relies on a parameter update formula; the two suggested by (Daumé III and Marcu, 2005) are a standard Perceptron-style update and an approximate large margin update of the sort proposed by (Gentile, 2001). In this work, we only use the large margin update, since in the original LaSO work, it consistently outperformed the simpler Perceptron updates. The update has the form given below:

$$\boldsymbol{w} \leftarrow \mathit{proj}\left(\boldsymbol{w} + Ck^{-1/2}\,\boldsymbol{\Delta}\right)$$

$$\boldsymbol{\Delta} = \mathit{proj}\left[\sum_{n \in sibs} \frac{\boldsymbol{\Phi}(x,n)}{|sibs|} - \sum_{n \in nodes} \frac{\boldsymbol{\Phi}(x,n)}{|nodes|}\right]$$

Where k is the update number, C is a tunable parameter and *proj* projects a vector into the unit sphere.

3 Joint EDT Model

The LaSO framework essentially requires us to specify two components: the search space (and corresponding operations) and the features. These two are inherently tied, since the features rely on the search space, but for the time being we will ignore the issue of the feature functions and focus on the search.

3.1 Search Space

We structure search in a left-to-right decoding framework: a hypothesis is a complete identification of the initial segment of a document. For instance, on a document with N words, a hypothesis that ends at position $0 < n < N$ is essentially what you would get if you took the full structured output and chopped it off at word n. In the example given in the introduction, one hypothesis might correspond to "Bill Clinton gave a" (which would be a y-good hypothesis), or to "Bill Clinton gave a" (which would not be a y-good hypothesis).

A hypothesis is expanded through the application of the search operations. In our case, the search procedure first chooses the number of words it is going to consume (for instance, to form the mention "Bill Clinton," it would need to consume two words). Then, it decides on an entity type and a mention type (or it opts to call this chunk not an entity (NAE), corresponding to non-underlined words). Finally, assuming it did not choose to form an NAE, it decides on which of the foregoing coreference chains this entity belongs to, or none (if it is the first mention of a new entity). All these decisions are made simultaneously, and the given hypothesis is then scored.

3.2 An Example

For concreteness, consider again the text given in the introduction. Suppose that we are at the word "them" and the hypothesis we are expanding is correct. That is, we have correctly identified "Bill Clinton" with entity type "person" and mention type "name;" that we have identified "the Senate" with entity type "organization" and mention type "name;" and that we have identified both "The President" and "his" as entities with entity type "person" and mention types "nominal" and "pronoun," respectively, and that "The President" points back to the chain ⟨Bill Clinton⟩ and that "his" points back to the chain ⟨Bill Clinton, The President⟩.

At this point of search, we have two choices for length: one or two (because there are only two words left: "them" and a period). A first hypothesis would be that the word "them" is NAE. A second hypothesis would be that "them" is a named person and is a new entity; a third hypothesis would be that "them" is a named person and is coreference with the "Bill Clinton" chain; a fourth hypothesis would be that "them" is a pronominal organization and is a new entity; next, "them" could be a pronominal organization that is coreferent with "the Senate"; and so on. Similar choices would be considered for the string "them ." when two words are selected.

3.3 Linkage Type

One significant issue that arises in the context of assigning a hypothesis to a coreference chain is how to compute features over that chain. As we will discuss in Section 4, the majority of our coreference-specific features are over *pairs* of chunks: the proposed new mention and an antecedent. However, since in general a proposed mention can have well more than one antecedent, we are left with a decision about how to combine this information.

The first, most obvious solution, is to essentially do nothing: simply compute the features over all pairs and add them up as usual. This method, however, intuitively has the potential for over-counting the effects of large chains. To compensate for this, one might advocate the use of an *average link* computation, where the score for a coreference chain is computed by averaging over its elements. One might also consider a *max link* or *min link* scenario, where one of the extrema is chosen as the value. Other research has suggested that a simple *last link*, where a mention is simply matched against the most recent mention in a chain might be appropriate, while *first link* might also be appropriate because the first mention of an entity tends to carry the most information.

In addition to these standard linkages, we also consider an *intelligent link* scenario, where the method of computing the link structure depends on the *mention type*. The intelligent link is computed as follow, based on the mention type of the current mention, m:

If m =**NAM then:** match *first* on NAM elements in the chain; if there are none, match against the *last* NOM element; otherwise, use *max link*.

If m =**NOM then:** match against the *max* NOM in the chain; otherwise, match against the most *last* NAM; otherwise, use *max link*.

If m =**PRO then:** use *average link* across all PRO or NAM; if there are none, use *max link*.

The construction of this methodology as guided by intuition (for instance, matching names against names is easy, and the first name tends to be the most complete) and subsequently tuned by experimentation on the development data. One might consider *learning* the best link method, and this may result in better performance, but we do not explore this option in this work. The initial results we present will be based on using intelligent link, but we will also compare the different linkage types explicitly.

4 Feature Functions

All the features we consider are of the form *base-feature* × *decision-feature*, where base features are functions of the input and decisions are functions of the hypothesis. For instance, a base feature might be something like "the current chunk contains the word 'Clinton"' and a decision feature might be something like "the current chunk is a named person."

4.1 Base Features

For pedagogical purposes and to facility model comparisons, we have separated the base features into eleven classes: lexical, syntactic, pattern-based, count-based, semantic, knowledge-based, class-based, list-based, inference-based, string match features and history-based features. We will deal with each of these in turn. Finally, we will discuss how these base features are combined into *meta-features* that are actually used for prediction.

Lexical features. The class of lexical features contains simply computable features of single words. This includes: the number of words in the current chunk; the unigrams (words) contained in this chunk; the bigrams; the two character prefixes and suffixes; the word stem; the case of the word, computed by regular expressions like those given by (Bikel et al., 1999); simple morphological features (number, person and tense when applicable); and, in the case of coreference, pairs of features between the current mention and an antecedent.

Syntactic features. The syntactic features are based on running an in-house state of the art part of speech tagger and syntactic chunker on the data. The words include unigrams and bigrams of part of speech as well as unigram chunk features. We have not used any parsing for this task.

Pattern-based features. We have included a whole slew of features based on lexical and part of speech patterns surrounding the current word. These include: eight hand-written patterns for identifying pleonastic "it" and "that" (as in "It is raining" or "It seems to be the case that ..."); identification of pluralization features on the previous and next head nouns (this is intended to help make decisions about entity types); the previous and next content verb (also intended to help with entity type identification); the possessor or possessee in the case of simple possessive constructions ("The president 's speech" would yield a feature of "president" on the word "speech", and vice-versa; this is indented to be a sort of weak sub-categorization principle); a similar feature but applied to the previous and next content verbs (again to provide a weak sort of subcategorization); and, for coreference, a list of part of speech and word sequence patterns that match up to four words between nearby mentions that are either highly indicative of coreference (e.g., "of," "said," "am" ", a") or highly indicative of non-coreference (e.g., "'s," "and," "in the," "and the"). This last set was generated by looking at intervening strings and finding the top twenty that had maximal mutual information with with class (coreferent or not coreferent) across the training data.

Count-based features. The count-based features apply only to the coreference task and attempt to capture regularities in the size and distribution of coreference chains. These include: the total number of entities detected thus far; the total number of mentions; the entity to mention ratio; the entity to word ratio; the mention to word ratio; the size of the hypothesized entity chain; the ratio of the number of mentions in the current entity chain to the total number of mentions; the number of intervening mentions between the current mention and the last one in our chain; the number of intervening mentions of the same type; the number of intervening sentence breaks; the Hobbs distance computed over syntactic chunks; and the "decayed density" of the hypothesized entity, which is computed as $\sum_{m=e} 0.5^{d(m)} / \sum_m 0.5^{d(m)}$, where m ranges over all previous mentions (constrained in the numerator to be in the same coreference chain as our mention) and $d(m)$ is the number of entities away this mention is. This feature is captures that some entities are referred to consistently across a document, while others are mentioned only for short segments, but it is relatively rare for an entity to be mentioned once at the beginning and then ignored again until the end.

Semantic features. The semantic features used are drawn from WordNet (Fellbaum, 1998). They include: the two most common synsets from WordNet for all the words in a chunk; all hypernyms of those synsets; for coreference, we also consider the distance in the WordNet graph between pairs of head words (defined to be the final word in the mention name) and whether one is a part of the other. Finally, we include the synset and hypernym information of the preceding and following verbs, again to model a sort of sub-categorization principle.

Knowledge-based features. Based on the hypothesis that many name to nominal coreference chains are best understood in terms of background knowledge (for instance, that "George W. Bush" is the "President"), we have attempted to take advantage of recent techniques from large scale data mining to extract lists of such pairs. In particular, we use the name/instance lists described by (Fleischman et al., 2003) and available on Fleischman's web page to generate features between names and nominals (this list contains $2m$ pairs mined from 15GBs of news data). Since this data set tends to focus mostly on person instances from news, we have additionally used similar data mined from a 138GB web corpus, for which more general "ISA" relations were mined (Ravichandran et al., 2005).

Class-based features. The class-based features we employ are designed to get around the sparsity of data problem while simultaneously providing new information about word usage. The first class-based feature we use is based on word classes derived from the web corpus mentioned earlier and computed as described by (Ravichandran et al., 2005). The second attempts to instill knowledge of collocations in the data; we use the technique described by (Dunning, 1993) to compute multi-word expressions and then mark words that are commonly used as such with a feature that expresses this fact.

List-based features. We have gathered a collection of about 40 lists of common places, organization, names, etc. These include the standard lists of names gathered from census data and baby name books, as well as standard gazetteer information listing countries, cities, islands, ports, provinces and states. We supplement these standard lists with lists of airport locations (gathered from the FAA) and company names (mined from the NASDAQ and NYSE web pages). We additionally include lists of semantically plural but syntactically singular words (e.g., "group") which were mined from a large corpus by looking for patterns such as ("members of the ..."). Finally, we use a list of persons, organizations and locations that were identified at least 100 times in a large corpus by the BBN IdentiFinder named entity tagger (Bikel et al., 1999).

These lists are used in three ways. First, we use simple list membership as a feature to improve detection performance. Second, for coreference, we look for word pairs that appear on the same list but are not identical (for instance, "Russia" and "England" appearing on the "country" list but not being identical hints that they are different entities). Finally, we look for pairs where one element in the pair is the head word from one mention and the other element in the pair is a list. This is intended to capture the notion that a word that appears on out "country list" is often coreferent with the word "country."

Inference-based features. The inference-based features are computed by attempting to infer an underlying semantic property of a given mention. In particular, we attempt to identify gender and semantic number (e.g., "group" is semantically plural although it is syntactically singular). To do so, we created a corpus of example mentions labels with number and gender, respectively. This data set was automatically extracted from our EDT data set by looking for words that corefer with pronouns for which we know the number or gender. For instance, a mention that corefers with "she" is known to be singular and female, while a mention that corefers with "they" is known to be plural. In about 5% of the cases, this was ambiguous – these cases were thrown out. We then used essentially the same features as described above to build a maximum entropy model for predicting number and gender. The predictions of this model are used both as features for detection as well as coreference (in the latter case, we check for matches). Additionally, we use several pre-existing classifiers as features. This are simple maximum entropy Markov models trained off of the MUC6 data, the MUC7 data and our ACE data.

String match features. We use the standard string match features that are described in every other coreference paper. These are: string match; substring match; string overlap; pronoun match; and normalized edit distance. In addition, we also use a string nationality match, which matches, for instance "Israel" and "Israeli," "Russia" and "Russian," "England" and "English," but not "Netherlands" and "Dutch." This is done by checking for common suffixes on nationalities and matching the first half of the of the words based on exact match. We additionally use a linguistically-motivated string edit distance, where the replacement costs are lower for vowels and other easily confusable characters. We also use the Jaro distance as an additional string distance metric. Finally, we attempt to match acronyms by looking at initial letters from the words in long chunks.

History-based features. Finally, for the detection phase of the task, we include features having to do with long-range dependencies between words. For instance, if at the beginning of the document we tagged the word "Arafat" as a person's name (perhaps because it followed "Mr." or "Palestinian leader"), and later in the document we again see the word "Arafat," we should be more likely to call this a person's name, again. Such features have previously been explored in the context of information extraction from meeting announcements using conditional random fields augmented with long-range links (Sutton and McCallum, 2004), but the LaSO framework makes no Markov assumption, so there is no extra effort required to include such features.

4.2 Decision Features

Our decision features are divided into three classes: simple, coreference and boundary features.

Simple. The simple decision features include: is this chunk tagged as an entity; what is its entity type; what is its entity subtype; what is its mention type; what is its entity type/mention type pair.

Coreference. The coreference decision features include: is this entity the start of a chain or continuing an existing chain; what is the entity type of this started (or continued) chain; what is the entity subtype of this started (or continued) chain; what is the mention type of this started chain; what is the mention type of this continued chain and the mention type of the most recent antecedent.

Boundary. The boundary decision features include: the second and third order Markov features over entity type, entity subtype and mention type; features appearing at the previous (and next) words within a window of three; the words that appear and the previous and next mention boundaries, specified also by entity type, entity subtype and mention type.

5 Experimental Results

5.1 Data

We use the official 2004 ACE training and test set for evaluation purposes; however, we exclude from the training set the Fisher conversations data, since this is very different from the other data sets and there is no Fisher data in the 2004 test set. This amounts to 392 training documents, consisting of $8.1k$ sentences and $160k$ words. There are a total of $24k$ mentions in the data corresponding to $10k$ entities (note that the data is not annotated for cross-document coreference, so instances of "Bill Clinton" appearing in two different documents are counted as two different entities). Roughly half of the entities are people, a fifth are organizations, a fifth are GPEs and the remaining are mostly locations or facilities. The test data is 192 documents, $3.5k$ sentences and $64k$ words, with $10k$ mentions to $4.5k$ entities. In all cases, we use a beam of 16 for training and test, and ignore features that occur fewer than five times in the training data.

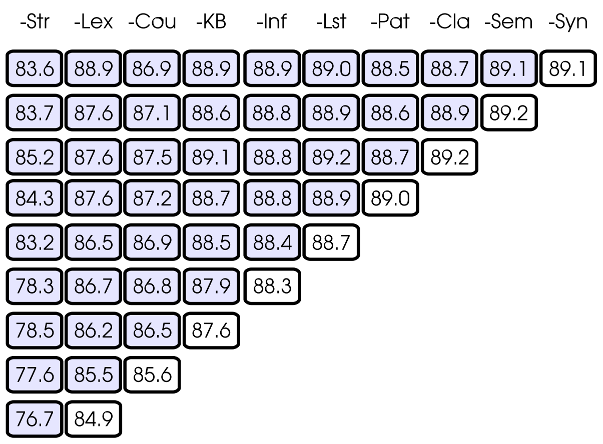
5.2 Evaluation Metrics

There are many evaluation metrics possible for this data. We will use as our primary measure of quality the ACE metric. This is computed, roughly, by first matching system mentions with reference mentions, then using those to match system entities with reference entities. There are costs, once this matching is complete, for type errors, false alarms and misses, which are combined together to give an ACE score, ranging from 0 to 100, with 100 being perfect (we use v.10 of the ACE evaluation script).

5.3 Joint versus Pipelined

We compare the performance of the joint system with the pipelined system. For the pipelined system, to build the mention detection module, we use the same technique as for the full system, but simply don't include in the hypotheses the coreference chain information (essentially treating each mention as if it were in its own chain). For the stand-alone coreference system, we assume that the correct mentions and types are always given, and simply hypothesize the chain (though still in a left-to-right manner).[1] Run as such, the joint model achieves an ACE score of 79.4 and the pipelined model achieves an ACE score of 78.1, a reasonably substantial improvement for performing both task simultaneously. We have also computed the performance of these two systems, ignoring the coreference scores (this is done by considering each mention to be its own entity and recomputing the ACE score). In this case, the joint model, ignoring its coreference output, achieves an ACE score of 85.6 and the pipelined model achieves a score of 85.3. The joint model does marginally better, but it is unlikely to be statistically significant. In the 2004 ACE evaluation, the best three performing systems achieved scores of 79.9, 79.7 and 78.2; it is unlikely that our system is significantly worse than these.

[1]One subtle difficulty with the joint model has to do with the online nature of the learning algorithm: at the beginning of training, the model is guessing randomly at what words are entities and what words are not entities. Because of the large number of initial errors made in this part of the task, the weights learned by the coreference model are initially very noisy. We experimented with two methods for compensating for this effect. The first was to give the mention identification model as "head start": it was run for one full pass through the training data, ignoring the coreference aspect and the following iterations were then trained jointly. The second method was to only update the coreference weights when the mention was identified correctly. On development data, the second was more efficient and outperformed the first by 0.6 ACE score, so we use this for the experiments reported in this section.



-Str	-Lex	-Cou	-KB	-Inf	-Lst	-Pat	-Cla	-Sem	-Syn
83.6	88.9	86.9	88.9	88.9	89.0	88.5	88.7	89.1	89.1
83.7	87.6	87.1	88.6	88.8	88.9	88.6	88.9	89.2	
85.2	87.6	87.5	89.1	88.8	89.2	88.7	89.2		
84.3	87.6	87.2	88.7	88.8	88.9	89.0			
83.2	86.5	86.9	88.5	88.4	88.7				
78.3	86.7	86.8	87.9	88.3					
78.5	86.2	86.5	87.6						
77.6	85.5	85.6							
76.7	84.9

5.4 Feature Comparison for Coreference

In this section, we analyze the effects of the different base feature types on coreference performance. We use a model with perfect mentions, entity types and mention types (with the exception of pronouns: we do not assume we know pronoun types, since this gives away too much information), and measure the performance of the coreference system. When run with the full feature set, the model achieves an ACE score of 89.1 and when run with no added features beyond simple biases, it achieves 65.4. The best performing system in the 2004 ACE competition achieved a score of 91.5 on this task; the next best system scored 88.2, which puts us squarely in the middle of these two (though, likely not statistically significantly different). Moreover, the best performing system took advantage of additional data that they labeled in house.

To compute feature performance, we begin with all feature types and iteratively remove them one-by-one so that we get the best performance (we do not include the "history" features, since these are not relevant to the coreference task). The results are shown in Figure 2. Across the top line, we list the ten feature classes. The first row of results shows the performance of the system after removing just one feature class. In this case, removing lexical features reduces performance to 88.9, while removing string-match features reduces performance to 83.6. The non-shaded box (in this case, syntactic features) shows the feature set that can be removed with the least penalty in performance. The second row repeats this, after removing syntactic features.

As we can see from this figure, we can freely remove syntax, semantics and classes with little decrease in performance. From that point, patterns are dropped, followed by lists and inference, each with a performance drop of about 0.4 or 0.5. Removing the knowledge based features results in a large drop from 87.6 down to 85.6 and removing count-based features drops the performance another 0.7 points. Based on this, we can easily conclude that the most important feature classes to the coreference problem are, in order, string matching features, lexical features, count features and knowledge-based features, the latter two of which are novel to this work.

5.5 Linkage Types

As stated in the previous section, the coreference-only task with intelligent link achieves an ACE score of 89.1. The next best score is with min link (88.7) followed by average link with a score of 88.1. There is then a rather large drop with max link to 86.2, followed by another drop for last link to 83.5 and first link performs the poorest, scoring 81.5.

6 Discussion

In this paper, we have applied the *Learning as Search Optimization (LaSO)* framework to the entity detection and tracking task. The framework is an excellent choice for this problem, due to the fact that many relevant features for the coreference task (and even for the mention detection task) are highly non-local. This non-locality makes models like Markov networks intractable, and LaSO provides an excellent framework for tackling this problem. We have introduced a large set of new, useful features for this task, most specifically the use of knowledge-based features for helping with the name-to-nominal problem, which has led to a substantial improvement in performance. We have shown that performing joint learning for mention detection and coreference results in a better performing model that pipelined learning. We have also provided a comparison of the contributions of our various feature classes and compared different linkage types for coreference chains. In the process, we have developed an efficient model that is competitive with the best ACE systems.

Despite these successes, our model is not perfect: the largest source of error is with pronouns. This is masked by the fact that the ACE metric weights pronouns low, but a solution to the EDT problem should handle pronouns well. We intend to explore more complex features for resolving pronouns, and to incorporate these features into our current model. We also intend to explore more complex models for automatically extracting knowledge from data that can help with this task and applying this technique to a real application, such as summarization.

Novelty Detection: The TREC Experience

Ian Soboroff and **Donna Harman**
National Institute of Standards and Technology
Gaithersburg, MD

Abstract

A challenge for search systems is to detect not only when an item is relevant to the user's information need, but also when it contains something new which the user has not seen before. In the TREC novelty track, the task was to highlight sentences containing relevant and new information in a short, topical document stream. This is analogous to highlighting key parts of a document for another person to read, and this kind of output can be useful as input to a summarization system. Search topics involved both news events and reported opinions on hot-button subjects. When people performed this task, they tended to select small blocks of consecutive sentences, whereas current systems identified many relevant and novel passages. We also found that opinions are much harder to track than events.

1 Introduction

The problem of novelty detection has long been a significant one for retrieval systems. The "selective dissemination of information" (SDI) paradigm assumed that the people wanted to be able to track new information relating to known topics as their primary search task. While most SDI and information filtering systems have focused on similarity to a topical profile (Robertson, 2002) or to a community of users with a shared interest (Belkin and Croft, 1992), recent efforts (Carbonell and Goldstein, 1998; Allan et al., 2000; Kumaran et al., 2003) have looked at the retrieval of specifically *novel* information.

The TREC novelty track experiments were conducted from 2002 to 2004 (Harman, 2002; Soboroff and Harman, 2003; Soboroff, 2004). The basic task was defined as follows: given a topic and an ordered set of documents related to that topic, segmented into sentences, return those sentences that are both relevant to the topic and novel given what has already been seen previously in that document set. This task models an application where a user is skimming a set of documents, and the system highlights new, on-topic information.

There are two problems that participants must solve in this task. The first is identifying relevant sentences, which is essentially a passage retrieval task. Sentence retrieval differs from document retrieval because there is much less text to work with, and identifying a relevant sentence may involve examining the sentence in the context of those surrounding it. The sentence was specified as the unit of retrieval in order to standardize the task across a variety of passage retrieval approaches, as well as to simplify the evaluation.

The second problem is that of identifying those relevant sentences that contain new information. The operational definition of "new" here is information that has not appeared previously in this topic's set of documents. In other words, we allow the system to assume that the user is most concerned about finding new information in this particular set of documents, and is tolerant of reading information he already knows because of his background knowledge. Since each sentence adds to the user's knowledge, and later sentences are to be retrieved only if they contain new information, novelty retrieval resembles a filtering task.

Novelty is an inherently difficult phenomenon to operationalize. Document-level novelty detection, while intuitive, is rarely useful because nearly every document contains something new, particularly when the domain is news. Hence, our decision to use sentences as the unit of retrieval. Moreover, determining ground truth for a novelty detection task is more difficult than for topical relevance, because one is forced not only to face the idiosyncratic nature of relevance, but also to rely all the more on the memory and organizational skills of the assessor, who must try and remember everything he has read. We wanted to determine if people could accomplish this task to any reasonable level of agreement, as well as to see what computational approaches best solve this problem.

2 Input Data

The first year of the novelty track (Harman, 2002) was a trial run in several ways. First, this was a new task for the community and participating groups had no training data or experience. But second, it was unclear how humans would perform this task and therefore creating the "truth" data was in itself a large experiment. NIST decided to minimize the cost by using 50 old topics from TRECs 6, 7, and 8.

The truth data was created by asking NIST assessors (the humans performing this task) to identify the set of relevant sentences from each relevant document and then from that set of relevant sentences, mark those that were novel. Specifically, the assessors were instructed to identify a list of sentences that were:

1. relevant to the question or request made in the description section of the topic,
2. their relevance was independent of any surrounding sentences,
3. they provided new information that had not been found in any previously picked sentences.

Most of the NIST assessors who worked on this task were not the ones who created the original topics, nor had they selected the relevant documents. This turned out to be a major problem. The assessors' judgments for the topics were remarkable in that only a median of 2% of the sentences were judged to be relevant, despite the documents themselves being relevant. As a consequence, nearly every relevant sentence (median of 93%) was declared novel. This was due in large part to assessor disagreement as to relevancy, but also that fact that this was a new task to the assessors. Additionally, there was an encouragement not to select consecutive sentences, because the goal was to identify relevant and novel sentences minimally, rather than to try and capture coherent blocks of text which could stand alone. Unfortunately, this last instruction only served to confuse the assessors. Data from 2002 has not been included in the rest of this paper, nor are groups encouraged to use that data for further experiments because of these problems.

In the second year of the novelty track (Soboroff and Harman, 2003), the assessors created their own new topics on the AQUAINT collection of three contemporaneous newswires. For each topic, the assessor composed the topic and selected twenty-five relevant documents by searching the collection. Once selected, the documents were ordered chronologically, and the assessor marked the relevant sentences and those relevant sentences that were novel. No instruction or limitation was given to the assessors concerning selection of consecutive sentences, although they were told that they did not need to choose an otherwise irrelevant sentence in order to resolve a pronoun reference in a relevant sentence. Each topic was independently judged by two different assessors, the topic author and a "secondary" assessor, so that the effects of different human judgments could be measured. The judgments of the primary assessor were used as ground truth for evaluation, and the secondary assessor's judgments were taken to represent a ceiling for system performance in this task.

Another new feature of the 2003 data set was a division of the topics into two types. Twenty-eight of the fifty topics concerned events such as the bombing at the 1996 Olympics in Atlanta, while the remaining topics focused on opinions about controversial subjects such as cloning, gun control, and same-sex marriages. The topic type was indicated in the topic description by a `<toptype>` tag.

This pattern was repeated for TREC 2004 (Soboroff, 2004), with fifty new topics (twenty-five events and twenty-five opinion) created in a similar manner and with the same document collection. For 2004, assessors also labeled some documents as irrelevant, and irrelevant documents up through the first twenty-five relevant documents were included in the document sets distributed to the participants. These irrelevant documents were included to increase the "noise" in the data set. However, the assessors only judged sentences in the relevant documents, since, by the TREC standard of relevance, a document is considered relevant if it contains any relevant information.

3 Task Definition

There were four tasks in the novelty track:

Task 1. Given the set of documents for the topic, identify all relevant and novel sentences.

Task 2. Given the relevant sentences in all documents, identify all novel sentences.

Task 3. Given the relevant and novel sentences in the first 5 documents **only**, find the relevant and novel sentences in the remaining documents. Note that since some documents are irrelevant, there *may not be* any relevant or novel sentences in the first 5 documents for some topics.

Task 4. Given the relevant sentences from all documents, and the novel sentences from the first 5 documents, find the novel sentences in the remaining documents.

These four tasks allowed the participants to test their approaches to novelty detection given different levels of training: none, partial, or complete relevance information, and none or partial novelty information.

The test data for a topic consisted of the topic statement, the set of sentence-segmented documents, and the chronological order for those documents. For tasks 2-4, training data in the form of relevant and novel "sentence qrels" were also given. The data was released and results were submitted in stages to limit "leakage" of training data between tasks. Depending on the task, the system was to output the identifiers of sentences which the system determined to contain relevant and/or novel relevant information.

4 Evaluation

Because novelty track runs report their relevant and novel sentences as an unranked set, traditional measures of ranked retrieval effectiveness such as mean average precision can't be used. One alternative is to use set-based recall and precision. Let M be the number of matched sentences, i.e., the number of sentences selected by both the assessor and the system, A be the number of sentences selected by the assessor, and S be the number of sentences selected by the system. Then sentence set recall is $R = M/A$ and precision is $P = M/S$.

However, set-based recall and precision do not average well, especially when the assessor set sizes A vary widely across topics. Consider the following example as an illustration of the problems. One topic has hundreds of relevant sentences and the system retrieves 1 relevant sentence. The second topic has 1 relevant sentence and the system retrieves hundreds of sentences. The average for both recall and precision over these two topics is approximately .5 (the scores on the first topic are 1.0 for precision and essentially 0.0 for recall, and the scores for the second topic are the reverse), even though the system did precisely the wrong thing. While most real systems wouldn't exhibit this extreme behavior, the fact remains that set recall and set precision averaged over a set of topics is not a robust diagnostic indicator

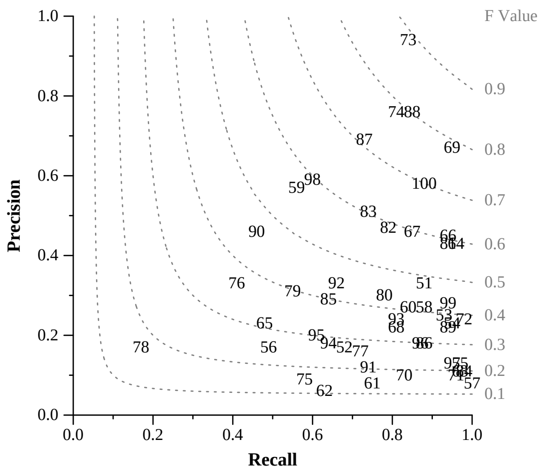

Figure 1: The F measure, plotted according to its precision and recall components. The lines show contours at intervals of 0.1 points of F. The black numbers are per-topic scores for one TREC system.

of system performance. There is also the problem of how to define precision when the system returns no sentences ($S = 0$). Leaving that topic out of the evaluation for that run would mean that different systems would be evaluated over different numbers of topics. The standard procedure is to define precision to be 0 when $S = 0$.

To avoid these problems, the primary measure used in the novelty track was the F measure. The F measure (which is itself derived from van Rijsbergen's E measure (van Rijsbergen, 1979)) is a function of set recall and precision, together with a parameter β which determines the relative importance of recall and precision:

$$F = \frac{(\beta^2 + 1)PR}{\beta^2 P + R}$$

A β value of 1, indicating equal weight, is used in the novelty track:

$$\mathrm{F}_{\beta=1} = \frac{2PR}{P + R}$$

Alternatively, this can be formulated as

$$\mathrm{F}_{\beta=1} = \frac{2 \times (\text{\# relevant retrieved})}{(\text{\# retrieved}) + (\text{\# relevant})}$$

For any choice of β, F lies in the range $[0, 1]$, and the average of the F measure is meaningful even when the judgment sets sizes vary widely. For example, the F measure in the scenario above is essentially 0, an intuitively appropriate score for such behavior. Using the F measure also deals with the problem of what to do when the system returns no sentences since recall is 0 and the F measure is legitimately 0 regardless of what precision is defined to be.

Note, however, that two runs with equal F scores do not indicate equal precision and recall. The contour lines in Figure 1 illustrate the shape of the F measure in recall-precision space. An F score of 0.5, for example, can describe a range of precision and recall scores. Figure 1 also shows the per-topic scores for a particular TREC run. It is easy to see that topics 98, 83, 82, and 67 exhibit a wide range of performance, but all have an F score of close to 0.6. Thus, two runs with equal F scores may be performing quite differently, and a difference in F scores can be due to changes in precision, recall, or both. In practice, if F is used, precision and recall should also be examined, and we do so in the analysis which follows.

5 Analysis

5.1 Analysis of truth data

Since the novelty task requires systems to automatically select the same sentences that were selected manually by the assessors, it is important to analyze the characteristics of the manually-created truth data in order to better understand the system results. Note that the novelty task is both a passage retrieval task, i.e., retrieve relevant sentences, and a novelty task, i.e., retrieve only relevant sentences that contain new information.

In terms of the passage retrieval part, the TREC novelty track was the first major investigation into how users select relevant parts of documents. This leads to several obvious questions, such as what percentage of the sentences are selected as relevant, and do these sentences tend to be adjacent/consecutive? Additionally, what kinds of variation appear, both across users and across topics. Table 1 shows the median percentage of sentences that were selected as relevant, and what percentage of these sentences were consecutive. Since each topic was judged by two assessors, it also shows the percentage of sentences selected by assessor 1 (the "official" assessor used in scoring) that were also selected by assessor 2. The table gives these percentages for all topics and also broken out into the two types of topics (events and opinions).

First, the table shows a large variation across the two years. The group in 2003 selected more relevant sentences (almost 40% of the sentences were selected as relevant), and in particular selected many consecutive sentences (over 90% of the relevant sentences were adjacent). The median length of a string of consecutive sentences was 2; the mean was 4.252 sentences. The following year, a different group of assessors selected only about half as many relevant sentences (20%), with fewer consecutive sentences. This variation across years may reflect the group of assessors in that the 2004 set were TREC "veterans" and were more likely to be very selective in terms of what was considered relevant.

The table also shows a variation across topics, in particular between topics asking about events versus those asking about opinions. The event topics, for both years, had more relevant sentences, and more consecutive sentences (this effect is more apparent in 2004).

Agreement between assessors on which sentences were relevant was fairly close to what is seen in document relevance tasks. There was slightly more agreement in 2003, but there were also many more relevant sentences so the likelihood of a match was higher. There is more agreement on events than on opinions, partially for the same reason, but also because there is generally less agreement on what constitutes an opinion. These medians hide a wide range of judging behavior across the assessors, particularly in 2003.

The final two rows of data in the table show the medians for novelty. There are similar patterns to those seen in the relevant sentence data, with the 2003 assessors clearly being more liberal in judging. However, the pattern is reversed for topic types, with more sentences being considered relevant and novel for the opinion topics than for the event topics. The agreement on novelty is less than on relevance, particularly in 2004 where there were smaller numbers of novel and relevant sentences selected.

Another way to look at agreement is with the kappa statistic (Cohen, 1960). Kappa computes whether two assessors disagree, with a correction for "chance agreement" which we would expect to occur randomly. Kappa is often interpreted as the degree of agreement between assessors, although this interpretation is not well-defined and varies from field to field (Di Eugenio, 2000). For relevant sentences across all topics in the 2004 data set, the kappa value is 0.549, indicating statistically significant agreement between the assessors but a rather low-to-moderate degree of agreement by most scales of interpretation. Given that agreement is usually not very high for relevance judgments (Voorhees, 1998), this is as expected.

5.2 Analysis of participants results

Most groups participating in the 2004 novelty track employed a common approach, namely to measure relevance as similarity to the topic and novelty as

		2003	2004
Relevant	all topics	0.39	0.20
	events only	0.47	0.25
	opinions only	0.38	0.15
Consecutive	all topics	0.91	0.70
	events only	0.93	0.85
	opinions only	0.91	0.65
Relevant agreement	all topics	0.69	0.60
	events only	0.82	0.68
	opinions only	0.63	0.50
Novelty	all topics	0.68	0.40
	events only	0.61	0.38
	opinions only	0.73	0.42
Novelty agreement	all topics	0.56	0.35
	events only	0.65	0.45
	opinions only	0.48	0.29

Table 1: Median fraction of sentences which were relevant and novel, fraction of consecutive relevant sentences, and proportion of agreement by the secondary assessor.

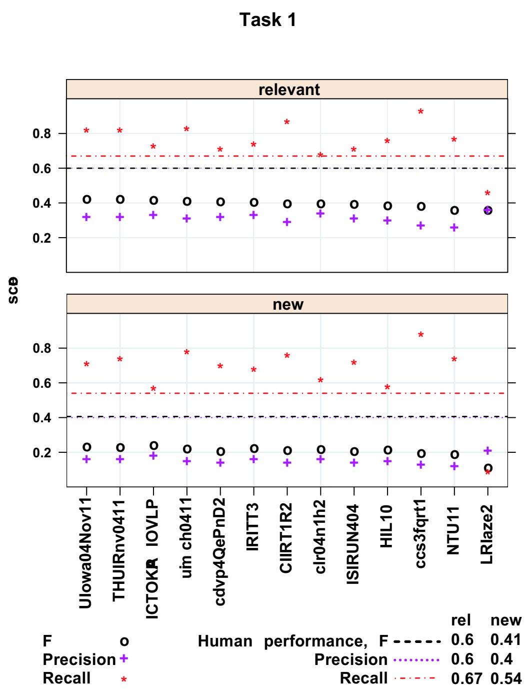

Figure 2: Task 1 precision, recall, and F scores for the top run from each group in TREC 2004

dissimilarity to past sentences. On top of this framework the participants used a wide assortment of methods which may be broadly categorized into statistical and linguistic methods. Statistical methods included using traditional retrieval models such as tf.idf and Okapi coupled with a threshold for retrieving a relevant or novel sentence, expansion of the topic and/or document sentences using dictionaries or corpus-based methods, and using named entities as features. Some groups also used machine learning algorithms such as SVMs in parts of their detection process. Semantic methods included deep parsing, matching discourse entities, looking for particular verbs and verb phrases in opinion topics, coreference resolution, normalization of named entities, and in one case manual construction of ontology's for topic-specific concepts.

Figure 2 shows the Task 1 results for the top run from each group in TREC 2004. Groups employing statistical approaches include UIowa, CIIR, UMich, and CDVP. Groups employing more linguistic methods include CLR, CCS, and LRI. THU and ICT took a sort of kitchen-sink approach where each of their runs in each task tried different techniques, mostly statistical.

The F scores for both relevance and novelty retrieval are fairly uniform, and they are dominated by the precision component. The top scoring systems by F score are largely statistical in nature; for example, see (Abdul-Jaleel et al., 2004) (CIIR) and (Eichmann et al., 2004) (UIowa). CLR (Litkowski, 2004) and LRI (Amrani et al., 2004), which use much stronger linguistic processing, achieve the highest precision at the expense of recall. Overall, precision is quite low and recall is high, implying that most systems are erring in favor of retrieving many sentences.

A closer comparison of the runs among themselves and to the truth data confirms this hypothesis. While the 2004 assessors were rather selective in choosing relevant and novel sentences, often selecting just a handful of sentences from each document, the systems were not. The systems retrieved an average of 49.5% of all sentences per topic as relevant, compared to 19.2% chosen by the assessor. Furthermore, the runs chose 41% of all sentences (79% of their own relevant sentences) as novel, compared to the assessor who selected only 8.4%. While these numbers are a very coarse average that ignores differences between the topics and between the documents in each set, it is a fair summary of the data. Most of the systems called nearly every sentence relevant and novel. By comparison, the person attempting this task (the second assessor, scored as a run and shown as horizontal lines in Figure 2) was much more effective than the systems.

The lowest scoring run in this set, LRIaze2, actually has the highest precision for both relevant and novel sentences. The linguistics-driven approach of this group included standardizing acronyms, building a named-entity lexicon, deep parsing, resolving coreferences, and matching concepts to manually-built, topic-specific ontologies (Amrani et al., 2004). A close examination of this run's pattern shows that they retrieved very few sentences, in line with the amounts chosen by the assessor. They were not often the correct sentences, which accounts for the low recall, but by not retrieving too many false alarms, they managed to achieve a high precision.

Our hypothesis here is that the statistical systems, which are essentially using algorithms designed for document retrieval, approached the sentences with an overly-broad term model. The majority of the documents in the data set are relevant, and so many of the topic terms are present throughout the documents. However, the assessor was often looking for a finer-grained level of information than what exists at the document level. For example, topic N51 is concerned with Augusto Pinochet's arrest in London. High-quality content terms such as Pinochet, Chile, dictator, torture, etc appear in nearly every sentence, but the key relevant ones — which are very few — are those which specifically talk about the arrest. Most systems flagged nearly every sentence as relevant, when the topic was much narrower than the documents themselves.

One explanation for this may be in how thresholds were learned for this task. Since task 1 provides no data beyond the topic statement and the documents themselves, it is possible that systems were tuned to the 2003 data set where there are more relevant sentences. However, this isn't the whole story, since the difference in relevant sentences between 2003 and 2004 is not so huge that it can explain the rates of retrieval seen here. Additionally, in task 3 some topic-specific training data was provided, and yet the effectiveness of the systems was essentially the same.

Of those systems that tried a more fine-grained approach, it appears that it is complicated to learn exactly which sentences contain the relevant information. For example, nearly every system had trouble identifying relevant opinion sentences. One might expect that those systems which analyzed sentence structure more closely would have done better here, but there is essentially no difference. Identifying relevant information at the sentence level is a very hard problem.

We see very similar results for novel sentence retrieval. Rather than looking at task 1, where systems retrieved novel from their own selection of relevant sentences, it's better to look at runs in task 2 (Figure 3). Since in this task the systems are given all relevant sentences and just search for novelty, the baseline performance for comparison is just labeling all the sentences as novel. Most systems, surprisingly including the LRI run, essentially do retrieve nearly every sentence as novel. The horizontal lines show the baseline performance; the baseline recall is 1.0 and is at the top of the Y axis. All the runs except clr04n2 are just above this baseline, with cdvp4NTerFr1 and novcolrcl the most discriminating.

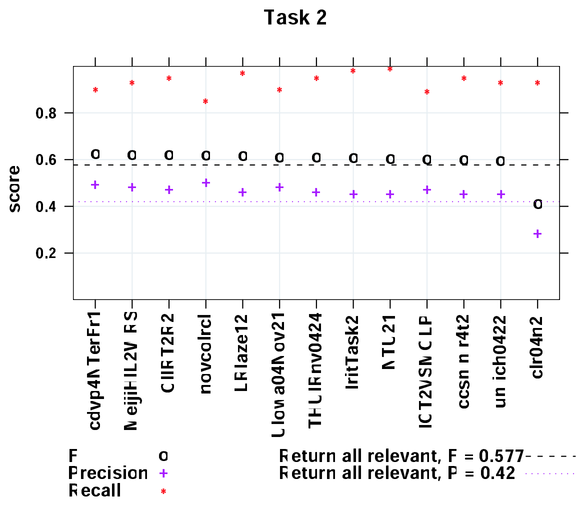

Figure 3: Task 2 scores for the top run from each group in TREC 2004

The approach of Dublin City University (cdvp4NTerFr1) is essentially to set a threshold on the tf.idf value of the unique words in the given sentence, but their other methods which incorporate the history of unique terms and the difference in sentence frequencies between the current and past sentences perform comparably (Blott et al., 2004). Similarly, Columbia University (novcolrcl) focuses on previously unseen words in the current sentence as the main evidence of novelty (Schiffman and McKeown, 2004). As opposed to the ad hoc threshold in the DCU system, Columbia employs a hill-climbing approach to learning the threshold. This particular run is optimized for recall; another optimized for precision achieved the highest precision of all task 2 runs, but with very low recall. In general, we conclude that most systems achieving high scores in novelty detection are recall-oriented and as a result still provide the user with too much information.

As was mentioned above, opinion topics proved much harder than events. Every system but one did better on event topics than on opinions in task 1

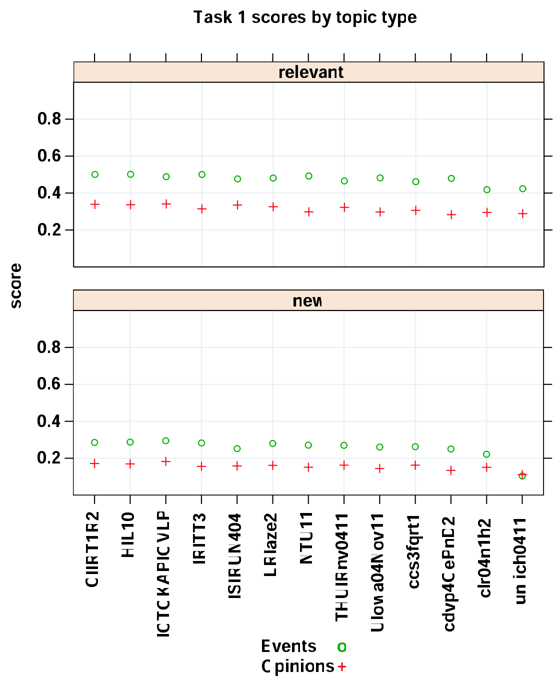

Figure 4: F scores for event and opinion topics in task 1.

(Figure 4). In task 2, where all relevant sentences were provided, many runs do as well or better on opinion topics than events. Thus, the complexity for opinions is more in finding which sentences contain them, than determining which opinions are novel.

6 Conclusion

The novelty track in TREC examined a particular kind of novelty detection, that is, finding novel, on-topic sentences within documents that the user is reading. Both statistical and linguistic techniques, as well as filtering and learning approaches can be applied to detecting novel relevant information within documents, but nevertheless it is a hard problem for several reasons. First, because the unit of interest is a sentence, there is not a lot of data in each unit on which to base the decision. When the document as a whole is relevant, techniques designed for document retrieval seem unable to make fine distinctions about which sentences within the document contain the relevant information. Initial threshold setting is critical and difficult.

When we examined human performance on this task, it is clear that users do make very fine distinctions. Looking particularly at the 2004 set of relevant and novel sentences, less than 20% of the sentences in relevant documents were marked as relevant, and only 40% of those (or 8% of the total sentences) were marked as both relevant and novel.

The TREC novelty data sets themselves support some interesting uses outside of the novelty track. Whereas the data from 2002 is clearly flawed and should not be used, the data from 2003 and 2004 can be regarded as valid samples of user input in terms of relevant sentence selection, and further reduction of those sentences to those presenting new information. One obvious use is in the passage retrieval arena, e.g., using the relevant sentences for testing passage retrieval, either at the single sentence level or using the consecutive sentences to test when to retrieve multiple sentences. A second use is for summarization, where the relevant AND novel sentences can serve as the truth data for the extraction phase (and then compressed in some manner). Other uses of the data include manual analysis of user behavior when processing documents in response to a question, or looking further into the user agreement issues, particularly in the summarization area.

The novelty data is also unique in that it deliberately contains a mix of topics on events and on opinions regarding controversial subjects. The opinions topics are quite different in this regard than other TREC topics, which have historically focused on events or narrative information on a subject or person. This exploration has been an interesting and fruitful one. By mixing the two topic types within each task, we see that identifying opinions within documents is hard, even with training data, while detecting new opinions (given relevance) seems analogous to detecting new information about an event.

Abstract

Biography creation requires the identification of important events in the life of the individual in question. While there are events such as birth and death that apply to everyone, most of the other activities tend to be occupation-specific. Hence, occupation gives important clues as to which activities should be included in the biography. We present techniques for automatically identifying which *important* events apply to the general population, which ones are occupation-specific, and which ones are person-specific. We use the extracted information as features for a multi-class SVM classifier, which is then used to automatically identify the occupation of a previously unseen individual. We present experiments involving 189 individuals from ten occupations, and we show that our approach accurately identifies general and occupation-specific activities and assigns unseen individuals to the correct occupations. Finally, we present evidence that our technique can lead to efficient and effective biography generation relying only on statistical techniques.

1 Introduction

Natural language processing (NLP) applications such as summarization and question-answering (QA) systems are designed to reduce the amount of time necessary for finding information of interest. Summarization systems produce a condensed version of the generally important information presented in the input, while QA systems target specific information according to a certain question.

Recently there has been increased interest in creating systems which combine summarization and QA and can give long answers to definition, biography, opinion and other question types. Such systems use general summarization techniques and at the same time take advantage of the fact that the selected information is not *generally* important but should be targeted towards answering the user's request. This idea is exploited in DUC 2004,[1] where one of the tasks is to create a summary targeting an answer to the "Who is X?" question. The systems that showed the highest performance for this task, combine traditional summarization techniques and also have modules developed specifically for creating summaries containing biographical information. Using a set of biographical facts proved to be useful to answer questions other than "What is X?" (Prager et al., 2004).

To extract biographical facts it is useful to understand the nature of different human activities. Biographical activities such as birth, death, living somewhere are applicable to all people, while each occupation is associated with its own set of activities.

In this work we suggest a novel unsupervised approach for automatic extraction of general biographical activities and activities typical for people of a particular occupation. To extract such activities we use *atomic events* (Filatova and Hatzivassiloglou, 2003) and statistical algorithms based on Markov Chains. Before creating a biography of a person as a representative of some occupation it is necessary to find out the occupation of this person; to do this we use SVM classification with activities as features.

In Section 2 we describe the current approaches for biography creation. In Section 3 we give an overview of atomic events and formulate our approach towards extracting occupation-specific activities. In Section 4 we describe mathematical models we use to identify activities typical for different occupations. In Section 5 we describe an SVM classification procedure for assigning people to the appropriate occupations. Finally, Section 6 summarizes the results and suggests a plan for future work.

[*]Part of this work was conducted while Elena Filatova was a summer intern at the IBM T. J. Watson Research Center.

[1]Document Understanding Conferences are a testbed for evaluating summarization systems

2 Related work

The systems participating in DUC 2004 create summaries which could be used as answers to the question "Who is X?". These systems use a wide variety of techniques. Blair-Goldensohn et al. (2004a) treat "Who is X?" as a definition question and use the DefScriber system (Blair-Goldensohn et al., 2004b). Biryukov et al. (2005) use Topic Signatures (Lin and Hovy, 2000) constructed around the person's name. Zhou et al. (2004) use nine features which are likely to be used in biography texts: bio (biographical facts), fame, personality, social, education, nationality, scandal, personal, work. Using manual annotation of 130 biographies they learn the textual patterns corresponding to these nine features.

Biographical information can be used to answer not only "Who is X?" questions. Prager et al. (2004) use biographical information within their QA-by-Dossier-with-Constraints system, which checks whether the possible answer satisfies the constraints for the person about whom the question is asked. For example, a natural constraint for artists, composers and writers is that all their works are produced in the span of time between the dates of birth and death.

Biographies vary greatly in length, genre and the presented information. Biographies of the same person in encyclopedias and yellow press magazines might contain different information. Encyclopedic biographies contain dates of birth and death, the most important achievements of people, while yellow press magazines tend to describe less important, usually scandalous facts of someone's life.

In this work we assume that most biographies can be broken into two main parts: biographical facts (the person's place and date of birth, where the person lived); and activities typically associated with the person's occupation (e.g., singers sing, explorers travel to study new lands, artists create paintings). Existing research shows that knowing the persons's occupation is helpful for detecting information which should be used in the biography (Schiffman et al., 2001; Duboue and McKeown, 2003).

3 Automatic extraction of activities typical for different occupations

3.1 Data

We created our own set of people belonging to various occupations as we were aware of no set diverse enough to analyze activities of people belonging to different occupations. We could not use the list of people whose biographies were created for DUC 2004 task: as the input documents for this task were contemporary newswire articles, more than a half of the 50 people used there were politicians.

We therefore performed what might be considered a pilot study. We chose 10 occupations and 20 practitioners of each. We understood that 10 occupations would not cover every person mentioned in a news corpus, but that was not critical to our study.

As described later, we sought documents for each chosen person. Since no documents were found for some of the individuals, these people were eliminated from the experiments; 189 survived. We ended up with the following sets of collections:

a. 20 artists	f. 20 mathematicians
b. 18 athletes	g. 19 physicists
c. 20 composers	h. 20 politicians
d. 15 dancers	i. 20 singers
e. 17 explorers	j. 20 writers

We found that for some occupations human annotators agree upon its representatives however different they are. For example, to whatever school an artist belongs (impressionism, surrealism) he/she is usually addressed as an *artist*. The situation with *politicians* is different. They are often referred to not as politicians but according to the post held (president, prime-minister). Choosing an appropriate occupation title becomes crucial at the document retrieval stage as this title is used to query the search engine.

Our goals for the occupation list are that it satisfies the following criteria:

- it is diverse and covers a substantial variety of occupations from arts, sciences and other aspects of human activities;
- it contains some occupations which are closely related between each other and might be later merged into one superclass, for example, mathematicians and physicists;
- it contains occupations that are very different and it is almost impossible to specify activities which are routinely performed in two occupations, for example, singers and explorers.

To get the lists of people belonging to each particular occupation we use WordNet 2.0 (Fellbaum, 1998) (e.g., hyponyms for *composer* contain a list of composers). We also use "Google Sets" interface,[2] it was previously successfully used to find people belonging to the same occupation (Prager et al., 2004).

We retrieve documents from four corpora: AQUAINT, TREC, part of World Book and part of

[2]`http://labs.google.com/sets`

Encyclopedia Britannica. For document retrieval we use IBM's JuruXML search engine (Carmel et al., 2001) which allows one to index terms along with any associated named entity class labels. Queries to JuruXML may include tagged terms, which will only match similarly tagged instances in the index. We use ⟨person⟩ and ⟨role⟩ tags in the queries to perform word sense disambiguation of two types: to differentiate a person from, for example, a location with the same name (e.g., Newton - a physicist and Newton - a town in Massachusetts); and to differentiate two different people with the same name belonging to different occupations (e.g., Louis Armstrong a singer and Lance Armstrong an athlete). The second issue can be partially avoided by submitting full name of a person but it reduces the amount of documents retrieved about this person dramatically. Thus, we retrieve all the documents about people by submitting the query "*⟨person⟩Name⟨/person⟩ ⟨role⟩Occupation⟨/role⟩*".

The number of documents retrieved varied from one, for the query "*⟨person⟩Cauchy⟨/person⟩ ⟨role⟩mathematician⟨/role⟩*," to up to 8,144, for "*⟨person⟩Clinton⟨/person⟩ ⟨role⟩politician⟨/role⟩*." To counteract misbalance in the data we relied on the $tf.idf$ ranking of JuruXML to sort the matching documents. The top ten such documents were kept (or all of them if fewer than ten were returned).

3.2 Extracting occupation-specific activities

To automatically discover general and occupation-specific activities we use a modified version of atomic events (Filatova and Hatzivassiloglou, 2003). Atomic events are triplets consisting of two named entities and a verb which labels the relation between these two named entities. We extract 189 lists of atomic events according to the following procedure:

1. For each person analyze the corresponding collection of documents retrieved for this person.
2. From every sentence containing the name of the person under analysis extract all the pairs of named entities, one of the elements of which is the name of this person.
3. For every such pair of named entities extract all verbs, excluding modal and auxiliary verbs, that appear in-between them.
4. Count how many times each triplet containing two named entities and a verb in-between appears in the collection of documents describing the person under analysis.

First Named Entity	Verb	Second Named Entity
Columbus/PERSON	died/VBN	1506/DATE
Columbus/PERSON	sailed/VBD	India/PLACE

Table 1: A sample of atomic events extracted for the collection of documents about Christopher Columbus

First Named Entity	Verb	Second Named Entity
Vespucci/PERSON	explored/VBD	S. America/PLACE
Bering/PERSON	explored/VBD	Aleutian/PLACE

Table 2: A sample of atomic events extracted for the collection of documents about Christopher Columbus

The NE tagger we use is a derivative of that described in (Prager et al., to appear). It tags named entities of about 100 types. Some of the marked types are very specific, like ZIPCODE and ROYALTY. To avoid overfitting we choose six high-level types for atomic events' extraction: PERSON, PLACE, DATE, WHOLENO, ORG and ROLE. In contrast to the original atomic event scores we keep simple counts for the triplets as later we combine triplets extracted for different people. Table 1 contains examples from the list of atomic events extracted for Columbus.

3.3 Generalized atomic events

Our goal is to collect information about activities general for all people and about activities specific for some occupations. Thus, we are interested in the semantic information reflected in the atomic events but not in the exact named entities. We analyze not the atomic events themselves but the generalized versions of the extracted atomic events. For example, here are two sentences about explorers:

> Vespucci explored the shores of South America.
> Vitus Bering explored Aleutian Islands.

The corresponding atomic events extracted for these sentences are presented in Table 2. Clearly, these atomic events capture information about the same type of activity, namely that explorers explore some locations. What makes these atomic events different is the exact names of the explorers and the locations a particular explorer explored. We can unify these atomic events by omitting the exact named entities and leaving only their types. The resulting atomic events we call *generalized atomic events*. The atomic events presented in Table 2 can be converged to the following generalized atomic event:

NAME/PERSON - explored/VBD - PLACE

In the generalized atomic events we distinguish two types of named entities with the tag PERSON: those which refer to the person under analysis (from now on they are marked as NAME/PERSON) and all the rest (marked as PERSON). Thus, we separate the person whose occupation we want to identify from the people who are linked to this person through some activities. This generalization technique is similar to the one used by Yangarber(2003) for semantic patterns discovery for information extraction.

Filatova and Hatzivassiloglou (2003) showed that atomic events capture the most important relations described in the input and assign to them good-quality labels. In this work we show that generalized atomic events can be used for capturing the activities performed by people of different occupations.

To select occupation-related activities we merge lists of atomic events corresponding to the people of the same occupation. Hence, we get ten lists of generalized atomic events corresponding to the ten occupations under analysis. The count of each generalized atomic event is equal to the sum of the counts of all the atomic events which are merged into this generalized atomic event.

4 Getting occupation-related activities

We assume that the activities important for an occupation are linked to the named entities important for this occupation and vice versa, the named entities important for this occupation are linked to the representatives of this occupation through the important activities. Formulated like this, the problem of identifying the actions important for an occupation can be solved using the methodology suggested (pre-Google) by Kleinberg (1998) for ranking web-sites, where a search engine counts "inbound and outbound links to identify central sites in a community." The major idea of this technique is based on the assumption that good hubs contain links to good authorities and that links to good authorities are listed within good hubs. Treating activity verbs as hubs and named entity tags as authorities we map the problem of discovering activities closely related to a specific occupation to the problem of ranking the reliability of web-pages for the submitted query.

To rank the importance of activities for a particular occupation we define a bipartite graph $G = \{N, V, E\}$, where V are the verb nodes (activities), N are the nodes corresponding to the named entity types linked to V verbs, and E are the arcs connecting the named entity types and the activities. A part of such a bipartite graph created for the *explorers* occupation is presented in Figure 1.

Following this procedure we create bipartite graphs for every occupation. Each of the created ten bipartite graphs contains m named entity types on one side and k verbs (activities) on the other side.[3]

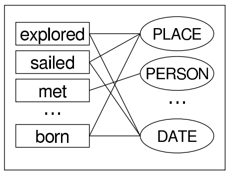

Figure 1: Bipartite graph for a set of generalized atomic events corresponding to *explorers* occupation

Dancer	Physicist	Singer

blessed/VBN	helped/VBD	made/VBD
perform/VB	named/VBN	became/VBD

Table 3: Top ten activities for four occupations: dancers, physicists and singers

We define $P_{N \to V}$ as a $m \times k$ stochastic transition matrix from named entities to verbs, with elements[4]

$$P_{N \to V}[i,j] \equiv p_{n_i,v_j} = (1-c)\frac{f(n_i \to v_j)}{\sum_{v \in V} f(n_i \to v)} + c \quad (1)$$

where f is equal to the sum of the counts of all the generalized atomic events containing this link for the occupation under analysis. In the same way we define $P_{V \to N}$ $k \times m$ row-stochastic transition matrix from verbs to named entities. Using $P_{V \to N}$ and $P_{N \to V}$, we can define the transition matrix:

$$P_{V \to V} = P_{V \to N} \cdot P_{N \to V} \quad (2)$$

that can be used for scoring the verbs according to how important they are for the current occupation. Due to the construction rules, this matrix is stochastic.According to Markov Chain Theory (Kemeny and Snell, 1960) for a square stochastic matrix it is possible to find a steady state which corresponds to the eigenvector for the eigenvalue equal to 1. Any square stochastic matrix has 1 among its eigenvalues. The same way the eigenvector corresponding to the steady state for web-pages ranks these pages, the eigenvector corresponding to the steady state of transition matrix (2) ranks how tightly the activities

[3]Variables m and k are unique for every occupation

[4]To avoid data sparseness we use a smoothing factor $c = 0.01$.

Table 4: Top ten activities common for all the eleven occupations.

are linked to the occupation under consideration. The size of this matrix depends on the variety of the verbs in all forms used in the generalized atomic events for the representatives of this occupation and varies from 800 for physicists up to 2100 for politicians in our data.

Table 3 contains top ten activities for three occupations: dancers, physicists and singers. These activities are listed in the sorted order, the ones on top of the table have the highest scores in the respective eigenvectors corresponding to the eigenvalues of 1.

The activities presented in Table 3 can be divided into three types:

1. those which are occupation-specific, such as *danced* and *perform* for dancers, *discovered* for physicists, *singing* and *sang* for singers;
2. those which are likely to be used in any biography, such as *born*, *died*, *became*;
3. other, which are mostly general purpose verbs, such as *been*, *made*.

For our classification we rely mainly on the first type of the activities. To extract the activities of the second type we create $P_{V \rightarrow V}$ a transition matrix for the combined set for all the generalized atomic events created for all the ten occupations. This matrix is also stochastic and by calculating the eigenvector corresponding to its steady state we can identify those activities which are tightly linked to any person irrespectively of his/her occupation and thus reflect general biographical information. Table 4 contains top ten activities for this matrix.

In Section 5 we show that the lists of occupation-related and general activities are reliable features for classifying people according to their occupations.

5 Classification

In this section we describe people classification according to their occupations. For our classification experiments we use a multi-class SVM classifier.[5] As we have 189 data-points corresponding to ten classes we use leave-one-out cross validation which allows us to use the maximal possible amount of data for training. We experiment with two sets of features: one set consists only of the verbs corresponding to the occupation-specific activities (Section 5.1); the other set consists of the complete triplets for the generalized atomic events (Section 5.2).

5.1 SVM classification using only verbs

To get verb features for multi-class SVM classification we use ten occupation-related lists of activities with activities sorted according to the eigenvector corresponding to the steady state.

The verb-only algorithm is as follows:

V1 Get the sorted list of activities (verbs) for every occupation (ten lists). These activities are the major features on which SVM relies to assign an occupation to a person.

V2 Get the sorted list of activities for all occupations merged together. These activities are used in Step V4 to remove from the list of classification features those activities which are general and not helpful for identifying the occupation of a person.

V3 Get top 15% of the activities from each of the ten lists.

V4 From the ten occupation-specific lists remove those activities which are also present in the list of general activities.

V5 Merge ten occupation-related lists into one list and remove from this list all the activities that appear in more than 2 occupations.

By leaving at Step 3 some percentage of the activities (verbs) instead of an absolute amount, we take into account the fact that the number of activities used to describe different occupations varies from occupation to occupation (for example, 1794 activities are used in the atomic events for composers, and 800 - for physicists). As the activities get scores according to the steady state vectors, the activities with high scores are the ones which are most likely to be used for the description of a person of the current occupation. The activities with low values are too specific and are likely to be used in only a few descriptions of people of this occupation. For example, we know that Alexander Borodin was both a composer and a chemist: we do not want to keep those specific verbs which describe his activities as a chemist in the list of the activities describing composers.

In Step 4 we remove from our final list those activities that are typical for all humans and thus cannot

[5] `http://www.cs.cornell.edu/People/tj/svm_light/svm_multiclass.html`

			SVM classification				Probing		Random
			Verbs		Atomic Events				
Occupation	Amount of Representatives	Average Amount of Documents	Amount	Ratio	Amount	Ratio	Amount	Ratio	
Artists	20	10.0	9	0.450	15	0.750	14	0.700	0.106

Average				0.480		0.663		0.677	

Table 5: Performance of different classification methods.

be used to distinguish among different occupations. In Step 5 we make our activities as specific as possible: For example, there will be some intersection in activities among mathematicians and physicists, and such activities cannot be helpful for differentiation between these occupations.

The final activities list is used as the list of features for SVM classification. Then we assign values to these features for every person: if the activity from the features list is used as a connector for the extracted atomic events, then this feature receives the value of 1, if there is no atomic event using this activity as a connector then this feature is assigned 0. We use binary values for our features instead of the atomic event counts because the reliability of the scores for the atomic events extracted for different people varies greatly. For some people we retrieve 10 documents with many biographical facts about those people, for other people we retrieve 2 or 3documents which only mentione the people queried.

Removal of some of the features is reinforced by the (Koller and Sahami, 1997) work on feature selection for document classification. It indicates that keeping only a small fraction of the available features improves the classification performance. The optimal number of features is still to be determined.

We train our classifier and evaluate its performance using leave-one-out cross validation. Out of 189 people, eight are not assigned any features. This is because all the atomic events extracted for these 8 people are either too general or too specific. As these 8 people do not have any features to assign them to the most likely occupation, they are misclassified to the default occupation (artists). Six of these eight are mathematicians, one is a dancer, one is a physicist. Absence of verbal features can be explained by a small number of the documents retrieved for these people. Table 5 shows how many documents are analyzed per person on average for each occupation. Due to the nature of our document collections, the smallest number of documents analyzed was for mathematicians and physicists: current newswire texts do not contain much information about scientists, and those parts of encyclopedias which we had at our disposal only contained information for some of the scientists. Out of the remaining 181 people, only 90 are classified correctly. As the distribution of people across occupations is not even, Table 5 contains two numbers for each occupation: the absolute number and the ratio of people classified correctly for this occupation.

We believe that the performance of SVM classification based solely on the activities is so poor because it does not take into account the information that many activities which are expressed with the help of the same verb are surrounded by different types of arguments for different occupations. For example, Henri Matisse is classified as a dancer based on the frequent co-occurrence with the *dance* activity, which is understandable as one of his most famous paintings is "Dance". Or, the *explored* activity is among the top activities for several occupations: writers, composers, explorers; but only for the explorers this activity is linked to the PLACE named entity tag. Though the classification based solely on verbs gives quite poor results we consider it to be a valid starting classification as usually activities are associated with the verbs corresponding to these activities.

5.2 SVM classification using atomic events

To create generalized atomic event features for multiclass SVM classification we use the sorted lists of activities for the ten occupations and the general list of activities. The activities are sorted according to the values they get from the eigenvector corresponding to the steady state.

AE1 Same as step V1 above.
AE2 Same as step V2 above.

AE3 For the top 15% of the activities from the ten occupation-specific lists get all the generalized atomic events containing those activities.

AE4 For the top 15% of the activities typical for all the occupation (Step AE2) get all the generalized atomic events containing those activities.

AE5 From the ten occupation-related lists (Step AE3) remove those generalized atomic events which are also present in the list of general generalized atomic events (Step AE4).

AE6 Merge the ten occupation-related lists into one and remove from it all the generalized atomic events that appear in more than 2 occupations.

Out of 189 people, nine are not assigned any features. This again is because all the atomic events extracted for these 9 people were either too general or too specific. The people who do not get any event features are the same as those who do not get any verb features plus one physicist. Out of the remaining 180 people, 124 people are classified into the appropriate occupations. Table 5 shows that generalized atomic events are more reliable for occupation classification than plain activities extracted from these generalized atomic events. Thus, it can be concluded that structured information captured by atomic events is valuable and reliable. For example, using atomic events Matisse was correctly classified as an artist. According to the t-test the performance of the classification based on atomic events is significantly better ($p < 0.05$) than the performance of the classification based solely on activities.

We would like to note, that after closer analysis some of the cases of misclassification can be considered as correct assignments as a person could excel in different occupations. For example, in our corpus Paul McCartney is defined as a singer while classifying him as a composer is a valid results as well.

5.3 Other types of classification

The task of classifying people according to their occupations is new and to our knowledge there is no existing baseline we could compare our results with. Nevertheless, we decided to adapt for comparison two classification techniques used for other tasks: random assignment of an occupation and probing.

Random occupation assignment. As the distribution of people among the occupations is not even we cannot give one exact probability of assigning a correct occupation to a particular person. Instead, we calculate such random probabilities for each occupation. The results are presented in Table 5.

Random assignment gives a very low baseline which we easily outperform, which is why we use another classification based on probing to estimate how good our results are. Classification based on probing is considered to be the state-of-the-art classification method for such tasks as hidden web classification (Ipeirotis et al., 2003) and answer verification (Magnini et al., 2002).

Probing. First, we get the counts of how many documents are retrieved for the queries containing only the titles of the occupations (e.g., "⟨*role*⟩ *mathematician* ⟨*/role*⟩", "⟨*role*⟩ *artist* ⟨*/role*⟩", etc.). Then, we get the counts for the queries containing all possible combinations of people's names and occupations' titles. (for example, "⟨*role*⟩ *mathematician* ⟨*/role*⟩ ⟨*person*⟩ *Picasso*⟨*/person*⟩", "⟨*role*⟩ *artist* ⟨*/role*⟩ ⟨*person*⟩ *Picasso* ⟨*/person*⟩", etc.). Finally, we divide the counts for the queries submitted for the occupation plus person by the count for the corresponding occupation query. The maximum of all the ratios for the person gives the occupation for this person.

$$Occupation_j = max_{for\ all\ i,j} \frac{count_{occupation_i,\ person_j}}{count_{occupation_i}} \quad (3)$$

According to Table 5 SVM, classification based on atomic events outperforms probing classification for six occupations out of ten, for one occupation (*explorers*) the results for SVM classification and probing are the same and for three occupations probing classification outperforms SVM classification. One of the cases where probing classification outperforms SVM classification is *mathematicians*, where nine mathematicians have no features in SVM classification and thus, do not have any better than random chance to be classified correctly.

Thus, our SVM classification of people according to their occupations based on atomic events has performance comparable to probing-based classification. This is significant since in those tasks for which it has been used so far, probing classification outperforms other methods and is considered to be the state-of-the-art (Ipeirotis et al., 2003; Magnini et al., 2002).

5.4 Using classification extracted features

Though we do not dramatically outperform probing, our methodology has one crucial advantage. We use classification not as a primary task but as an evaluation testbed to show that the lists of generalized atomic events created for every occupation and for general biographies indeed capture the major activities performed by people of the respective occupa-

tions and can be used for biography generation. For example, the generalized atomic events which are used for the description of representatives within all the ten occupations and are excluded from the list of features for SVM classification as too general, contain verbs such as *born/VBN*, *died/VBD* linked to the DATE and PLACE named entity tags or *became/VBD* linked to the ROLE named entity tag. Table 6, on the other hand, contains occupation-specific generalized atomic events. These generalized atomic events have high scores within the respective occupations, are used as features for SVM classification and have non-zero values in the feature sets which correctly classified people into the appropriate occupations.

6 Conclusions and future work

We reported results on extracting human activities which can be used for classifying people according to their occupations. We introduced a novel representation for describing human activities (generalized atomic events). SVM classification using generalized atomic events as features gives results comparable to other state-of-the-art classification techniques. We are currently looking at ways of identifying other types of activities which are neither general no occupation-specific but rather person-specific. We observed that those generalized atomic events which have high scores for a particular person but are not used in the description of any other person are good candidates to point out person-specific information. We believe that the usage of generalized atomic events can enable significant new techniques for a number of natural language processing tasks. One direction is to use the generalized atomic events typical for all the occupations as an initial representation for the auxiliary biography-related questions. Another direction is to use generalized atomic events for biography generation.

Using Names and Topics for New Event Detection

Abstract

New Event Detection (NED) involves monitoring chronologically-ordered news streams to automatically detect the stories that report on new events. We compare two stories by finding three cosine similarities based on names, topics and the full text. These additional comparisons suggest treating the NED problem as a binary classification problem with the comparison scores serving as features. The classifier models we learned show statistically significant improvement over the baseline vector space model system on all the collections we tested, including the latest TDT5 collection.

The presence of automatic speech recognizer (ASR) output of broadcast news in news streams can reduce performance and render our named entity recognition based approaches ineffective. We provide a solution to this problem achieving statistically significant improvements.

1 Introduction

The instant and automatic detection of new events is very useful in situations where novel information needs to be detected from a real-time stream of rapidly growing data. These real-life situations occur in scenarios like financial markets, news analyses, and intelligence gathering. In this paper we focus on creating a system to immediately identify stories reporting new events in a stream of news - a daunting task for a human analyst given the enormous volume of data coming in from various sources.

The Topic Detection and Tracking (TDT) program, a DARPA funded initiative, seeks to develop technologies that search, organize and structure multilingual news-oriented textual materials from a variety of broadcast news media. One of the tasks in this program, New Event Detection (NED), involves constant monitoring of streams of news stories to identify the first story reporting topics of interest. A *topic* is defined as "a seminal event or activity, along with directly related events and activities" (Allan, 2002). An earthquake at a particular place is an example of a topic. The first story on this topic is the story that first carries the report on the earthquake's occurrence. The other stories that make up the topic are those discussing the death toll, the rescue efforts, the reactions from different parts of the world, scientific discussions, the commercial impact and so on. A good NED system would be one that correctly identifies the article that reports the earthquake's occurrence as the first story.

NED is a hard problem. For example, to distinguish stories about earthquakes in two different places, a vector space model system would rely on a tf-idf weighting scheme that will bring out the difference by weighting the locations higher. More often then not, this doesn't happen as the differences are buried in the mass of terms in common between stories describing earthquakes and their aftermath. In this paper we reduce the dependence on tf-idf weighting by showing the utility of creating three distinct representations of each story based on named entities. This allows us to view NED as a binary classification problem - i.e., each story has to be classified into one of two categories - *old* or *new*, based on features extracted using the three different representations.

The paper starts by summarizing the previous work on NED in Section 2. In Section 3, we explain the rationale behind our intuition. Section 4 describes the experimental setup, data pre-processing, and our baseline NED system. We then briefly describe the evaluation methodology for NED in Section 5. Model creation and the results of applying these models to test data are detailed in Section 6. In the same section, we describe the effect on performance if the manually transcribed version of broadcast news is replaced with ASR output. Since its hard to recognize named entities from ASR data, performance expectedly deteriorates. We follow a novel approach to work around the problem resulting in statistically significant improvement in performance. The results are analyzed in Section 7. We wrap up with conclusions and future work in Section 8.

2 Previous Research

Previous approaches to NED have concentrated on developing similarity metrics or better document representations or both. A summer workshop on topic-based novelty detection held at Johns Hopkins University extensively studied the NED problem. Similarity metrics, effect of named entities, pre-processing of data, and language and Hidden Markov Models were explored (Allan et al., 1999). Combinations of NED systems were also discussed. In the context of this paper, selective re-weighting of named entities didn't bring about expected improvement.

Improving NED by better comparison of stories was the focus of following papers. In an approach to solve on-line NED, when a new document was encountered it was processed immediately to extract features and build up a query representation of the document's content (Papka and Allan, 1998). The document's initial threshold was determined by evaluating it with the query. If the document did not trigger any previous query by exceeding this particular threshold, it was marked as a new event. Unlike the previous paper, good improvements on TDT benchmarks were shown by extending a basic incremental TF-IDF model to include source-specific models, similarity score normalization techniques, and segmentation of documents (Brants et al., 2003).

Other researchers have attempted to build better document models. A combination of evidence derived from two distinct representations of a document's content was used to create a new representation for each story (Stokes and Carthy, 2001). While one of the representations was the usual free text vector, the other made use of lexical chains (created using WordNet) to obtain the most prevalent topics discussed in the document. The two vectors were combined in a linear fashion and a marginal increase in effectiveness was observed.

NED approaches that rely on exploiting existing news tracking technology were proved to inevitably exhibit poor performance (Allan et al., 2000). Given tracking error rates, the lower and upper bounds on NED error rates were derived mathematically. These values were found to be good approximations of the true NED system error rates. Since tracking and filtering using full-text similarity comparison approaches were not likely to make the sort of improvements that are necessary for high-quality NED results, the paper concluded that an alternate approach to NED was required. This led to a series of research efforts that concentrated on building multi-stage NED algorithms and new ways to combine evidence from different sources.

In the topic-conditioned novelty detection approach, documents were classified into broad topics and NED was performed within these categories (Yang et al., 2002). Additionally, named entities were re-weighted relative to the normal words for each topic, and a stop list was created for each topic. The experiments were done on a corpus different from the TDT corpus and, apparently didn't scale well to the TDT setting.

The DOREMI research group treated named entities like *people* and *locations* preferentially and developed a new similarity measure that utilized the semantics classes they came up with (Makkonen et al., 2002). They explored various definitions of the NED task and tested their system accordingly. More recently, they utilized a perceptron to learn a weight function on the similarities between different semantic classes to obtain a final confidence score for each story (Makkonen et al., 2004).

The TDT group at UMass introduced multiple document models for each news story and modified similarity metrics by splitting up stories into only named entities and only terms other than named entities (Kumaran and Allan, 2004). They observed that certain categories of news were better tackled using only named entities, while using only topic terms for the others helped.

In approaches similar to named entity tagging, part-of-speech tagging (Farahat et al., 2003) has also been successfully used to improve NED.

Papers in the TDT2003 and TDT2004 workshops validated the hypothesis that ensemble single-feature classifiers based on majority voting exhibited better performance than single classifiers working with a number of features on the NED task (Braun and Kaneshiro, 2003; Braun and Kaneshiro, 2004). Examples of features they used are cosine similarity, text tiling output and temporally-weighted tf-idf.

Probabilistic models for online clustering of documents, with a mechanism for handling creation of new clusters have been developed. Each cluster was assumed to correspond to a topic. Experimental results did not show any improvement over baseline systems (Zhang et al., 2005).

3 Features for NED

Pinning down the character of new stories is a tough process. New events don't follow any periodic cycle, can occur at any instant, can involve only one particular type of named entity (people, places, organizations etc.) or a combination, can be reported in any language, and can be reported as a story of any length by any source[1]. Apart from the source, date, and time of publication or broadcast of each news story, the TDT corpora do not contain any other clues like placement in the webpage, the number of sources reporting the same news and so on. Given all these factors, we decided that the best features to use would be those that were not particular to the story in question only, but those that measure differences between the story and those it is compared with.

[1]It could be argued that articles from a source, say *NYTimes*, are much longer than news stories from *CNN*, and hence the length of stories is a good candidate for use as a feature. However, when there is no pattern that indicates that either of the two sources reports new stories preferentially, the use of length as a feature is moot.

Category-specific rules that modified the baseline confidence score assigned to each story have been developed (Kumaran and Allan, 2004). The modification was based on additional evidence in the form of overlap of named entities and topic terms (terms in the document not identified as named entities) with the closest story reported by a baseline system. We decided to use these three scores: namely the baseline confidence score, named entity overlap, and topic-term overlap as features. The named entities considered were *Event*, *Geopolitical Entity*, *Language*, *Location*, *Nationality*, *Organization*, *Person*, *Cardinal*, *Ordinal*, *Date*, and *Time*. These named entities were detected in stories using BBN IdentiFinder^{TM}(Bikel et al., 1999). Irrespective of their type, all named entities were pooled together to form a single named entity vector.

The intuition behind using these features is that we believe every event is characterized by a set of people, places, organizations, etc. (named entities), and a set of terms that describe the event. While the former can be described as the *who*, *where*, and *when* aspects of an event, the latter relates to the *what* aspect. If two stories were on the same topic, they would share both named entities as well as topic terms. If they were on different, but similar, topics, then either named entities or topic terms will match but not both.

We illustrate the above intuition with examples. Terms in **bold face** are named entities common to both stories, while those in *italics* are topic terms in common. We start with an example showing that for old stories both the named entities as well as topic terms overlap with a story on the same topic.

Story 1. : Story on a topic already reported

While in **Croatia** today, **Pope John Paul II** called on the *international community* to *help* end the fighting in the Yugoslavia's **Kosovo** province.

Story 2. : Story on the same topic

Pope John Paul II is urging the *international community* to quickly *help* the ethnic Albanians in **Kosovo**. He spoke in the coastal city of Split, where he ended a three-day visit to **Croatia**.

Story 1 is an old story about Pope John Paul II's visit to Yugoslavia. Story 2 was the first story on the topic and it shares both named entities likes **Pope John Paul II** and **Croatia** and also topic terms like *international community* and *help*.

Our next example shows that for new stories, either the named entities or topic terms match with an earlier story.

Story 3. : Topic not seen before

Turkey has sent 10,000 troops to its southern border with Syria amid growing tensions between the two neighbors, newspapers reported Thursday. Defense Minister **Ismet Sezgin** denied any troop movement along the border, but said **Turkey's** patience was running out. **Turkey** accuses Syria of harboring Turkish Kurdish rebels fighting for autonomy in **Turkey's** southeast; it says rebel leader Abdullah Ocalan lives in Damascus.

Story 4. : Closest Story due to Named Entities

A senior **Turkish** government official called Monday for closer military cooperation with neighboring Bulgaria. After talks with President Petar Stoyanov at the end of his four-day visit, Turkish Deputy Premier and National Defense Minister **Ismet Sezgin** expressed satisfaction with the progress of bilateral relations and the hope that Bulgarian-**Turkish** military cooperation will be promoted.

Story 3 is a new story about the rising tensions between Turkey and Syria. The closest story as reported by a (baseline) basic vector space model NED system using cosine similarity is Story 4, a story about Turkish-Bulgarian relations. The named entities **Turkey** and **Ismet Sezgin** caused this match. We see that none of the topic terms match. However, the system reported with a high confidence score that Story 3 is old. This is because of the matching of high IDF-valued named entities. Determining that the topic terms didn't match would have helped the system avoid this mistake.

4 Experimental Setup and Baseline

We used the TDT2, TDT3, TDT4, and TDT5 corpora for our experiments. They contain a mix of broadcast news (*bn*) and newswire (*nwt*) stories. Only the English stories in the multi-lingual collections were considered for the NED task. The broadcast news material is provided in the form of an audio sampled data signal, a manual transcription of the audio signal (*bn-man*), and a transcription created using an automatic speech recognizer (*bn-asr*).

We used version 3.0 of the open source Lemur system[2] to tokenize the data, remove stop words, stem and create document vectors. We used the 418 stopwords included in the stop list used by InQuery (Callan et al., 1992), and the Krovetz-stemmer algorithm implementation provided as part of Lemur.

Documents were represented as term vectors with incremental TF-IDF weighting (Brants et al., 2003; Yang et al., 1998). We used the cosine similarity metric to judge the similarity of a story *S* with those seen in the past.

$$Sim(S,X) = \frac{\sum_w weight(w,S) * weight(w,X)}{\sqrt{\sum_w weight(w,S)^2}\sqrt{\sum_w weight(w,X)^2}} \quad (1)$$

where

$$\begin{aligned} weight(w,d) &= tf * idf \\ tf &= \log(termfrequency + 1.0) \\ idf &= \frac{\log((docCount+1)}{(documentfreq+0.5)} \end{aligned}$$

The maximum similarity of the story *S* with stories seen in the past was taken as the confidence score that *S* was old. This constituted our baseline system.

We extracted three features for each incoming story *S*. The first was the confidence score reported by the baseline system. The second and third features were the cosine similarity between only the named entities in *S* and *X* and the cosine similarity between only the topic terms in *S* and *X*. We trained a Support Vector Machine (SVM) (Burges, 1998) classifier on these features. We chose to use SVMs as they are considered state-of-the-art for text classification purposes (Mladeni et al., 2004), and provide us with options to consider both linear and nonlinear decision boundaries. To develop SVM models we used SVM^{Light}(Joachims, 1999), which is an implementation of SVMs in C. SVM^{Light} is an implementation of Vapnik's Support Vector Machine (Vapnik, 1995).

For training, we used the TDT3 and TDT4 corpora. There were 115 and 70 topics respectively giving us a total of 185 positive examples (new stories)

[2] `http://www.lemurproject.org`

and 7800 negative examples (old stories). We balanced the number of positive and negative examples by oversampling the minority class until there were equal number of positive and negative training instances. Testing was done on the TDT2 and TDT5 corpora (96 and 126 topics resp.).

5 NED Evaluation

The official TDT evaluation requires a NED system to assign a confidence score between 0 (new) and 1 (old) to every story upon its arrival in the time-ordered news stream. This assignment of scores is done either immediately upon arrival or after a fixed look-ahead window of stories. To evaluate performance, the stories are sorted according to their scores, and a threshold sweep is performed. All stories with scores above the threshold are declared *old*, while those below it are considered *new*. At each threshold value, the misses and false alarms are identified, and a cost C_{det} is calculated as follows.

$$C_{det} = C_{miss} * P_{miss} * P_{target} + C_{FA} * P_{FA} * P_{non-target}$$

where C_{Miss} and C_{FA} are the costs of a Miss and a False Alarm, respectively, P_{Miss} and P_{FA} are the conditional probabilities of a Miss and a False Alarm, respectively, and P_{target} and $P_{non-target}$ are the a priori target probabilities ($P_{non-target}$ = 1 - P_{target}).

The threshold that results in the least cost is selected as the optimum one. Different NED systems are compared based on their minimum cost. In other words, the **lower** the C_{det} score reported by a system on test data, the **better** the system.

6 Results

Our first set of experiments were performed on data consisting of newswire text and manual transcription of broadcast news (*nwt+bn-man*). We used the features mentioned in Section 3 to build SVM models in the classification mode. We experimented with linear, polynomial, and RBF kernels. The output from the SVM classifiers was normalized to fall within the range zero and one.

We found that using certain kernels improved performance over the baseline system significantly. The results for both corpora, TDT2 and TDT5, were consistently and significantly improved by using the classification models. The 2004 NED evaluations conducted by the National Institute of Standards and Technology was on the TDT5 collection. The large size of the collection and existence of a large number of topics with a single story made the task very challenging. The best system fielded by the participating sites was the baseline system used here. Table 1 summarizes the results we obtained.

Kernel Type	TDT2 (*nwt+bn-man*)	TDT5 (*nwt*)
Baseline System	0.585	0.701
Linear Kernel	0.548	0.696
Poly. of deg. 1	0.548	0.696
Poly. of deg. 2	0.543	0.688
Poly. of deg. 3	0.545	0.684
Poly. of deg. 4	0.535	0.694
Poly. of deg. 5	0.533	0.688
Poly. of deg. 6	0.534	0.693
RBF with γ = 1	**0.540**	**0.661**
RBF with γ = 5	0.530	0.699

Table 1: Summary of the results of using SVM classifi er models for NED on the TDT2 and TDT5 collections. The numbers are the minimum cost (C_{det}) values (lower is better). The sign test, with α = 0.05, was performed to compare the baseline system with only a classifi er using RBF kernels with γ = 1. For both collections, the improvements were found to be statistically signifi cant (shown in bold). While there are better performing kernels for TDT2, we chose to perform signifi cance tests for only one kernel to show that signifi cant improvement over the baseline can be obtained using a single kernel across different test collections.

All statistical significance testing was done using the sign test. We counted the number of topics for which using the SVM classifier improved over the baseline (in terms of detecting more previously undetected new and old stories), and also the number of topics for which using the SVM classifier actually converted originally correct decisions into wrong ones. These were used as input for the sign test. The test were used to check whether improvement in performance using the classifier-based system was spread across a significant number of topics, and not confined to a few. Table 2 gives some examples of topics and the associated improvements in detecting them.

Topic ID	Number of old stories	Num. detected by baseline system	Num. detected by SVM classifier	Improvement (Higher the better)
55105	420	407	403	-4
55010	21	21	20	-1
55023	5	5	4	-1
55089	226	226	225	-1
55125	120	114	120	6
55107	331	327	331	7

Table 2: Examples of improvements due to using the SVM classifier on a per-topic basis. Shown here are the four topics each in which the greatest degradation and improvements in performance were seen. The topics vary in size. The SVM classifier resulted in overall (statistically significant, refer Table 1) improvement as it corrected more errors than introduced them.

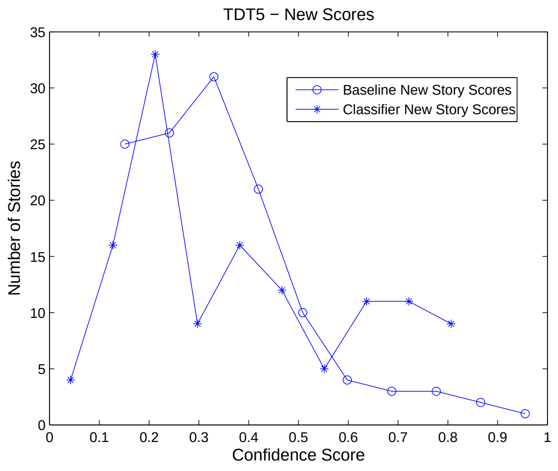

Figure 1: Distribution of new story scores for the baseline and SVM model systems.

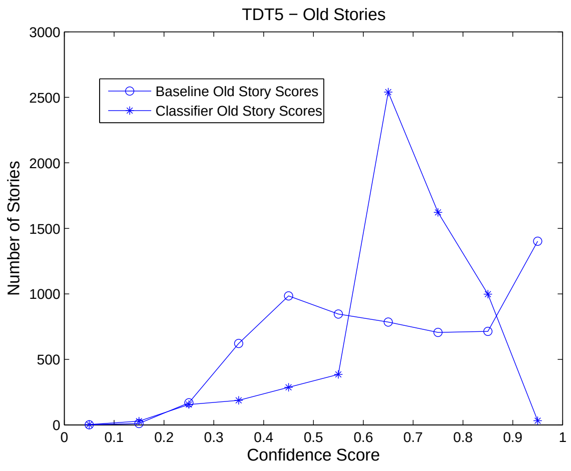

Figure 2: Distribution of old story scores for the baseline and SVM model systems.

7 Analysis

The main goal of our effort was to come up with a way to correctly identify new stories based on features we thought characterized them. To understand what we had actually achieved by using these models, we studied the distribution of the confidence scores assigned to new and old stories for the baseline and a classifier-based NED system for the TDT5 collection (Figures 1 and 2 respectively).

We observe that the scores for a small fraction of new stories that were initially missed (between scores 0.8 and 1) are decreased by the model-based NED system while a larger fraction (between scores 0.1 and 0.4) is also decreased by a small amount. However, the major impact of using SVM model-based NED systems appears to be in detecting old stories. We observe that the scores of a significant number of old stories (between scores 0.2 and 0.55) have been increased to be closer to one. This had the effect of increasing the score difference between old and new stories, and hence improved classification accuracy as measured by the minimum cost.

We investigated the relative importance of the three features by looking that the linear kernel SVM model. While the original cosine similarity metric *CS* remained the prominent feature, the contribution of the third feature *non-NE-CS* was slightly more than if not equal to the contribution of named entities *NE-CS* (Table 3). This explains why simple re-weighting of named entities alone (Allan et al., 1999) doesn't suffice to improved performance.

Feature	*CS*	*NE-CS*	*non-NE-CS*
Weight	5.4	1.58	1.83

Table 3: Weights assigned to features by the linear kernel SVM.

If this method of harnessing named entities and topic terms were indeed so effective, then we should have been able to detect every old story in every topic. However, analysis reveals that this approach makes an assumption about the way stories in a topic are related. Not all topics are *dense*, with both named entities and topic terms threading the stories together. Examples of such topics are natural disaster topics. While the first story might report on the actual calamity and the region it affected, successive stories might report on individual survivor tales. These stories might be connected to the original story of the topic by as tenuous a link as only the name of the calamity, or the place. Such topic structures are very common in newswire. Hence our approach will fail in such topics with loosely connected stories. Much more advanced processing of story content is required in such cases. Mistakes made by the named entity recognizer also impede performance.

Given that its impractical to expect manual transcriptions of all broadcast news, we tested our baseline and classifier systems on a version of TDT2 with newswire stories and ASR output of the broadcast news (*nwt*+*bn*-*asr*). TDT5 was left out as it doesn't have any broadcast news. As shown in Table 4, the baseline system performed significantly worse when manual transcription was replaced with ASR output. The classifier systems did even worse than the *nwt* +*bn*-*asr* baseline result. An analysis of the named entities extracted revealed that the accuracy was very poor - worse than extraction from *bn*-*man* documents. This was primarily because the version of IdentiFinder (IdentiFinder-*man*) we used was by default trained on *nwt*.

To alleviate this problem we re-trained IdentiFinder using a simulated ASR corpus with named entities identified correctly. Since the amount of training data required was huge, we obtained the training data from the *bn*-*man* version of TDT3. We ran IdentiFinder-*man* on the *bn*-*man* version of TDT3 and tagged the named entities. We then removed punctuation and converted all the text to uppercase to simulate ASR to a limited degree. We re-trained IdentiFinder on this simulated ASR corpus and used it to tag named entities in only the *bn*-*asr* stories in TDT2. We retained the use of IdentiFinder-*man* for the *nwt* stories. The same three features were then extracted and we re-ran the classifiers. The results are shown in Table 4 in the column titled IdentiFinder-*asr*.

Kernel Type	TDT2 (*nwt*+*bn*-*asr*)	
Baseline System	0.640	
	IdentiFinder-*man*	IdentiFinder-*asr*
Linear Kernel	0.653	**0.608**
Poly. of deg. 1	0.654	0.608
Poly. of deg. 2	0.658	0.619
Poly. of deg. 3	0.659	0.616
Poly. of deg. 4	0.671	0.632
Poly. of deg. 5	0.676	0.640
Poly. of deg. 6	0.682	0.652
RBF with γ = 1	0.649	0.636
RBF with γ = 5	0.668	0.679

Table 4: The baseline system was the same used for the *nwt*+*bn*-*man* collection. We find that using a linear kernel for the procedure using IdentiFinder-*asr* to tag named entities results in statistically significant improvement.

8 Conclusions and Future Work

We have shown the applicability of machine learning classification techniques to solve the NED problem. Significant improvements were made over the baseline systems on all the corpora tested on. The features we engineered made extensive use of named entities, and reinforced the importance and need to effectively harness their utility to solve problems in TDT. NED requires not only detection and reporting of new events, but also suppression of stories that report old events. From the study of the distributions of scores assigned to stories by the baseline and SVM model systems, we can see that we now do a better job of detecting old stories (reducing false alarms). Thus we believe that attacking the problem as "*old story detection*" might be a better and more fruitful approach. We have shown the effects of ASR output in the news stream, and demonstrated a procedure to alleviate the problem.

A classifier with RBF kernel with γ set to one exhibited the best performance. The reason for this superior performance over other kernels needs to be investigated. Engineering of better features is also a definite priority. In the future NED can also be extended to other interesting domains like scientific literature to detect the emerge of new topics and interests.

Abstract

We propose a generalized bootstrapping algorithm in which categories are described by relevant seed features. Our method introduces two unsupervised steps that improve the initial categorization step of the bootstrapping scheme: (i) using Latent Semantic space to obtain a generalized similarity measure between instances and features, and (ii) the Gaussian Mixture algorithm, to obtain uniform classification probabilities for unlabeled examples. The algorithm was evaluated on two Text Categorization tasks and obtained state-of-the-art performance using only the category names as initial seeds.

1 Introduction

Supervised classification is the task of assigning category labels, taken from a predefined set of categories (classes), to instances in a data set. Within the classical supervised learning paradigm, the task is approached by providing a learning algorithm with a training data set of manually labeled examples. In practice it is not always easy to apply this schema to NLP tasks. For example supervised systems for Text Categorization (TC) require a large amount of hand labeled texts, while in many applicative cases it is quite difficult to collect the required amounts of hand labeled data. Unlabeled text collections, on the other hand, are in general easily available.

An alternative approach is to provide the necessary supervision by means of sets of “seeds” of intuitively relevant features. Adopting terminology from computability theory, we refer to the standard example-based supervision mode as *Extensional Learning* (EL), as classes are being specified by means of examples of their elements (their *extension*). Feature-based supervision is referred to as *Intensional Learning* (IL), as features may often be perceived as describing the *intension* of a category, such as providing the name or prominent key terms for a category in text categorization.

The IL approach reflects on classical rule-based classification methods, where the user is expected to specify exact classification rules that operate in the feature space. Within the machine learning paradigm, IL has been incorporated as a technique for bootstrapping an extensional learning algorithm, as in (Yarowsky, 1995; Collins and Singer, 1999; Liu et al., 2004). This way the user does not need to specify exact classification rules (and feature weights), but rather perform a somewhat simpler task of specifying few typical seed features for the category. Given the list of seed features, the bootstrapping scheme consists of (i) preliminary unsupervised categorization of the unlabeled data set based on the seed features, and (ii) training an (extensional) supervised classifier using the automatic classification labels of step (i) as the training data (the second step is possibly reiterated, such as by an Expectation-Maximization schema). The core part of IL bootstrapping is step (i), i.e. the initial unsupervised classification of the unlabeled dataset. This step was often approached by relatively simple methods, which are doomed to obtain mediocre quality. Even so, it is hoped that the second step of supervised training would be robust enough to the noise in the initial training set.

The goal of this paper is to investigate additional principled unsupervised mechanisms within the initial classification step, applied to the text categorization. In particular, (a) utilizing a Latent Semantic Space to obtain better similarity assessments between seeds and examples, and (b) applying a Gaussian Mixture (GM) algorithm, which provides a principled unsupervised estimation of classification probability. As shown in our experiments, incorporating these steps consistently improved the accuracy of the initial categorization step, which in turn yielded a better final classifier thanks to the more accurate training set. Most importantly, we obtained comparable or better performance than previous IL methods using *only* the category names as the seed features; other IL methods required collecting a larger number of seed terms, which turns out to be a somewhat tricky task.

Interesting results were revealed when comparing our IL method to a state-of-the-art extensional classifier, trained on manually labeled documents. The EL classifier required 70 (Reuters dataset) or 160 (Newsgroup dataset) documents per category to achieve the same performance that IL obtained using only the category names. These results suggest that IL may provide an appealing cost-effective alternative when sub-optimal accuracy suffices, or when it is too costly or impractical to obtain sufficient labeled training. Optimal combination of extensional and intensional supervision is raised as a challenging topic for future research.

2 Bootstrapping for Text Categorization

The TC task is to assign category labels to documents. In the IL setting, a category C_i is described by providing a set of relevant features, termed an *intensional description* (ID), $id_{c_i} \subseteq V$, where V is the vocabulary. In addition a training corpus $T = \{t_1, t_2, \dots t_n\}$ of *unlabeled* texts is provided. Evaluation is performed on a separate test corpus of labeled documents, to which standard evaluation metrics can be applied.

The approach of categorizing texts based on lists of keywords has been attempted rather rarely in the literature (McCallum and Nigam, 1999; Ko and Seo, 2000; Liu et al., 2004; Ko and Seo, 2004). Several names have been proposed for it – such as *TC by bootstrapping with keywords*, *unsupervised TC*, *TC by labelling words* – where the proposed methods fall (mostly) within the IL settings described here[1].

It is possible to recognize a common structure of these works, based on a typical bootstrap schema (Yarowsky, 1995; Collins and Singer, 1999):

Step 1: *Initial unsupervised categorization.* This step was approached by applying some similarity criterion between the initial category seed and each unlabeled document. Similarity may be determined as a binary criterion, considering each seed keyword as a classification rule (McCallum and Nigam, 1999), or by applying an IR style vector similarity measure. The result of this step is an initial categorization of (a subset of) the unlabeled documents. In (Ko and Seo, 2004) term similarity techniques were exploited to expand the set of seed keywords, in order to improve the quality of the initial categorization.

Step 2: *Train a supervised classifier on the initially categorized set.* The output of Step 1 is exploited to train an (extensional) supervised classifier. Different learning algorithms have been tested, including SVM, Naive Bayes, Nearest Neighbors, and Rocchio. Some works (McCallum and Nigam, 1999; Liu et al., 2004) performed an additional Expectation Maximization algorithm over the training data, but reported rather small incremental improvements that do not seem to justify the additional effort.

(McCallum and Nigam, 1999) reported categorization results close to human agreement on the same task. (Liu et al., 2004) and (Ko and Seo, 2004) contrasted their word-based TC algorithm with the performance of an extensional supervised algorithm, achieving comparable results, while in general somewhat lower. It should be noted that it has been more difficult to define a common evaluation framework for comparing IL algorithms for TC, due to the subjective selection of seed IDs and to the lack of common IL test sets (see Section 4).

[1]The major exception is the work in (Ko and Seo, 2004), which largely follows the IL scheme but then makes use of labeled data to perform a chi-square based feature selection before starting the bootstrap process. This clearly falls outside the IL setting, making their results incomparable to other IL methods.

3 Incorporating Unsupervised Learning into Bootstrap Schema

In this section we show how the core Step 1 of the IL scheme – the initial categorization – can be boosted by two unsupervised techniques. These techniques fit the IL setting and address major constraints of it. The first is exploiting a generalized similarity metric between category seeds (IDs) and instances, which is defined in a Latent Semantic space. Applying such unsupervised similarity enables to enhance the amount of information that is exploited from each seed feature, aiming to reduce the number of needed seeds. The second technique applies the unsupervised Gaussian Mixture algorithm, which maps similarity scores to a principled classification probability value. This step enables to obtain a uniform scale of classification scores across all categories, which is typically obtained only through calibration over labeled examples in extensional learning.

3.1 Similarity in Latent Semantic Space

As explained above, Step 1 of the IL scheme assesses a degree of "match" between the seed terms and a classified document. It is possible first to follow the intuitively appealing and principled approach of (Liu et al., 2004), in which IDs (category seeds) and instances are represented by vectors in a usual IR-style Vector Space Model (VSM), and similarity is measured by the cosine function:

$$\mathbf{sim}_{vsm}(id_{c_i}, t_j) = \cos(\vec{id}_{c_i}, \vec{t_j}) \qquad (1)$$

where $\vec{id}_{c_i} \in \mathbf{R}^{|V|}$ and $\vec{t_j} \in \mathbf{R}^{|V|}$ are the vectorial representations in the space $\mathbf{R}^{|V|}$ respectively of the category ID id_{c_i} and the instance t_j, and V is the set of all the features (the vocabulary).

However, representing seeds and instances in a standard feature space is severely affected in the IL setting by feature sparseness. In general IDs are composed by short lists of features, possibly just a single feature. Due to data sparseness, most instances do not contain any feature in common with any category's ID, which makes the seeds irrelevant for most instances (documents in the text categorization case). Furthermore, applying direct matching only for a few seed terms is often too crude, as it ignores the identity of the other terms in the document.

The above problems may be reduced by considering some form of similarity in the feature space, as it enables to compare additional document terms with the original seeds. As mentioned in Section 2, (Ko and Seo, 2004) expanded explicitly the original category IDs with more terms, using a concrete query expansion scheme. We preferred using a generalized similarity measure based on representing features and instances a Latent Semantic (LSI) space (Deerwester et al., 1990). The dimensions of the Latent Semantic space are the most explicative principal components of the feature-by-instance matrix that describes the unlabeled data set. In LSI both coherent features (i.e. features that often co-occur in the same instances) and coherent instances (i.e. instances that share coherent features) are represented by similar vectors in the reduced dimensionality space. As a result, a document would be considered similar to a category ID if the seed terms and the document terms tend to co-occur overall in the given corpus.

The Latent Semantic Vectors for IDs and documents were calculated by an empirically effective variation (self-reference omitted for anonymity) of the *pseudo-document* methodology to fold-in documents, originally suggested in (Berry, 1992). The similarity function $\mathbf{sim}_{lsi}$ is computed by the cosine metric, following formula 1, where $\vec{id}_{c_i}$ and $\vec{t_j}$ are replaced by their Latent Semantic vectors. As will be shown in section 4.2, using such non sparse representation allows to drastically reduce the number of seeds while improving significantly the recall of the initial categorization step.

3.2 The Gaussian Mixture Algorithm and the initial classification step

Once having a similarity function between category IDs and instances, a simple strategy is to base the classification decision (of Step 1) directly on the obtained similarity values (as in (Liu et al., 2004), for example). Typically, IL works adopt in Step 1 a single-label classification approach, and classify each instance (document) to only one category. The chosen category is the one whose ID is most similar to the classified instance amongst all categories, which does not require any threshold tuning over labeled examples. The subsequent training in Step 2 yields a standard EL classifier, which can then be used to assign multiple categories to a document.

Using directly the output of the similarity function for classification is problematic, because the obtained scales of similarity values vary substantially across different categories. The variability in similarity value ranges is caused by variations in the number of seed terms per category and the levels of their generality and ambiguity. As a consequence, choosing the class with the highest absolute similarity value to the instance often leads to selecting a category whose similarity values tend to be generally higher, while another category could have been more similar to the classified instance if normalized similarity values were used.

As a solution we propose using an algorithm based on unsupervised estimation of Gaussian Mixtures (GM), which differentiates relevant and non-relevant category information using statistics from unlabeled instances. We recall that mixture models have been widely used in pattern recognition and statistics to approximate probability distributions. In particular, a well-known nonparametric method for density estimation is the so-called Kernel Method (Silverman, 1986), which approximates an unknow density with a mixture of kernel functions, such as gaussians functions. Under mild regularity conditions of the unknown density function, it can be shown that mixtures of gaussians converge, in a statistical sense, to *any* distribution.

More formally, let $t_i \in T$ be an instance described by a vector of features $\vec{t_i} \in \mathbf{R}^{|V|}$ and let $id_{c_i} \subset V$ be the ID of category C_i; let $\mathbf{sim}(id_{c_i}, t_j) \in \mathbf{R}$ be a similarity function among instances and IDs, with the only expectation that it monotonically increases according to the "closeness" of id_{c_i} and t_j (see Section 3.1).

For each category C_i, GM induces a mapping from the similarity scores between its ID and any instance t_j, $\mathbf{sim}(id_{c_i}, t_j)$, into the probability of C_i given the text t_j, $P(C_i|t_j)$. To achieve this goal GM performs the following operations: (i) it computes the set $\mathcal{S}_i = \{\mathbf{sim}(id_{c_i}, t_j)|t_j \in T\}$ of the similarity scores between the ID id_{c_i} of the category C_i and all the instances t_j in the unlabeled training set T; (ii) it induces from the empirical distribution of values in $\mathcal{S}_i$ a Gaussian Mixture distribution which is composed of two "hypothetic" distributions $\mathcal{C}_i$ and $\overline{\mathcal{C}_i}$, which are assumed to describe respectively the distributions of similarity scores for positive and negative examples; and (iii) it estimates the conditional probability $P(C_i|\mathbf{sim}(id_{c_i}, t_j))$ by applying the Bayes theorem on the distributions $\mathcal{C}_i$ and $\overline{\mathcal{C}}_i$. These steps are explained in more detail below.

The core idea of the algorithm is in step (ii). Since we do not have labeled training examples we can only obtain the set $\mathcal{S}_i$ which includes the similarity scores for all examples together, both positive and negative. We assume, however, that similarity scores that correspond to positive examples are drawn from one distribution, $P(\mathbf{sim}(id_{c_i}, t_j)|C_i)$, while the similarity scores that correspond to negative examples are drawn from another distribution, $P(\mathbf{sim}(id_{c_i}, t_j)|\overline{C_i})$. The observed distribution of similarity values in $\mathcal{S}_i$ is thus assumed to be a mixture of the above two distributions, which are recovered by the GM estimation.

Figure 1 illustrates the mapping induced by GM from the empirical mixture distribution: dotted lines describe the Probability Density Functions (PDFs) estimated by GM for $\mathcal{C}_i$, $\overline{\mathcal{C}_i}$, and their mixture from the empirical distribution ($\mathcal{S}_i$) (in step (ii)). The continuous line is the mapping induced in step (iii) of the algorithm from similarity scores between instances and IDs (x axis) to the probability of the instance to belong to the category (y axis).

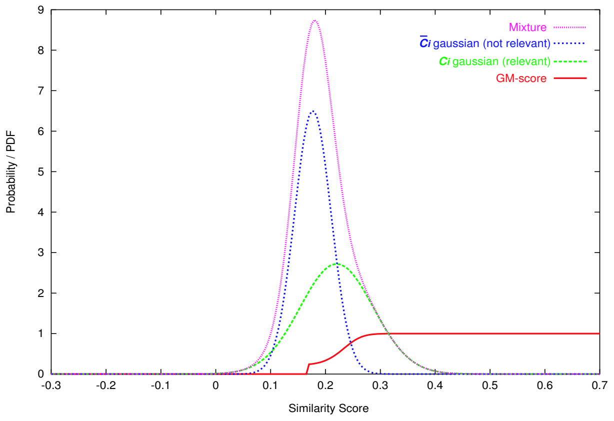

Figure 1: Mapping induced by GM for the category *rec.motorcycles* in the 20newsgroups data set.

The probabilistic mapping estimated in step (iii) for a category C_i given an instance t_j is computed by applying Bayes rule:

$$\begin{aligned} P(C_i|t_j) &= P(C_i|\mathrm{sim}(id_{c_i}, t_j)) = \\ &= \frac{P(\mathrm{sim}(id_{c_i}, t_j)|C_i)P(C_i)}{P(\mathrm{sim}(id_{c_i}, t_j)|C_i)P(C_i) + P(\mathrm{sim}(C_i, t_j)|\overline{C_i})P(\overline{C_i})} \end{aligned} \quad (2)$$

where $P(\mathbf{sim}(id_{c_i}, t_j)|C_i)$ is the value of the PDF of $\mathcal{C}_i$ at the point $\mathbf{sim}(id_{c_i}, t_j)$, $P(\mathbf{sim}(id_{c_i}, t_j)|\overline{C_i})$ is the value of the PDF of $\overline{\mathcal{C}_i}$ at the same point, $P(C_i)$ is the area of the distribution

$\mathcal{C}_i$ and $P(\overline{C_i})$ is the area of the distribution $\overline{\mathcal{C}_i}$. The mean and variance parameters of the two distributions $\mathcal{C}_i$ and $\overline{\mathcal{C}_i}$, used to evaluate equation 2, are estimated by the rather simple application of the Expectation Maximization (EM) algorithm for Gaussian Mixtures, as summarized in (Gliozzo et al., 2004).

Finally, following the single-labeled categorization setting of Step 1 in the IL scheme, the most likely category is assigned to each instance, that is, $argmax_{C_i} P(C_i|t_j)$.

3.3 Summary of the Bootstrapping Algorithm

step 1.a: Latent Semantic Space. Instances and Intensional Descriptions of categories (the seeds) are represented by vectors in Latent Semantic space. As an option, the algorithm can work with the classical Vector Space Model using the original feature space. Similarity scores between IDs and instances are computed by the Cosine measure.

step 1.b: GM. The mapping functions $P(C_i|t_j)$ for each category, conditioned on instances t_j, are induced by the GM algorithm. To that end, an Expectation Maximization algorithm estimates the parameters of the two component distributions of the observed mixture, which correspond to the distributions of similarity values for positive and negative examples. As an option, the GM mapping can be avoided.

step 1.c: Categorization. Each instance is classified to the most probable category - $argmax_{C_i} P(C_i|t_j)$.

step 2: Bootstrapping an extensional classifier. An EL classifier (SVM) is trained on the set of labeled instances resulting from step 1.c.

4 Evaluation

4.1 Intensional Text Categorization Datasets

Even though some typical data sets have been used in the TC literature (Sebastiani, 2002), the datasets used for IL learning were not standard. Often there is not sufficient clarity regarding details such as the exact version of the corpus used and the training/test splitting. Furthermore, the choice of categories was often not standard: (Ko and Seo, 2004) omitted 4 categories from the 20-Newsgroup dataset, while (Liu et al., 2004) evaluated their method on 4 separate subsets of the 20-Newsgroups, each containing only 4-5 categories. Such issues make it rather difficult to compare thoroughly different techniques, yet we have conducted several comparisons in Subsection 4.5 below. In the remainder of this Subsection we clearly state the corpora used in our experiments and the pre-processing steps performed on them.

20newsgroups. The 20 Newsgroups data set is a collection of newsgroup documents, partitioned (nearly) evenly across 20 different newsgroups. As suggested in the dataset Web site[2], we used the "bydate" version: the corpus (18941 documents) is sorted by date and divided in advance into a training (60%) set and a chronologically following test set (40%) (so there is no randomness in train/test set selection), it does not include cross-posts (duplicates), and (more importantly) does not include non-textual newsgroup-identifying headers which often help classification (Xref, Newsgroups, Path, Followup-To, Date).

We will first report results using *initial seeds* for the category ID's, which were selected using only the words in the category names, with some trivial transformations (i.e. `cryptography#n` for the category `sci.crypt`, `x-windows#n` for the category `comp.windows.x`). We also tried to avoid "overlapping" seeds, i.e. for the categories `rec.sport.baseball` and `rec.sport.hockey` the seeds are only {`baseball#n`} and {`hockey#n`} respectively and not {`sport#n, baseball#n`} and {`sport#n, hockey#n`}[3].

Reuters-10. We used the top 10 categories (Reuters-10) in the *Reuters-21578* collection Aptè split[4]. The complete Reuters collection includes 12,902 documents for 90 categories, with a fixed splitting between training and test data (70/30%). Both the Aptè and Aptè-10 splits are often used in TC tasks, as surveyed in (Sebastiani, 2002). To obtain the Reuters-10

[2]The collection is available at `www.ai.mit.edu/people/jrennie/20Newsgroups`.

[3]One could propose as a guideline for seed selection those seeds that maximize their distances in the LSI vector space model. On this perspective the LSI vectors built from {`sport#n, baseball#n`} and {`sport#n, hockey#n`} are closer than the vectors that represent {`baseball#n`} and {`hockey#n`}. It may be noticed that this is a reason for the slight initial performance decrease in the learning curve in Figure 2 below.

[4]available at `http://kdd.ics.uci.edu/databases/-reuters21578/reuters21578.html`).

Aptè split we selected the 10 most frequent categories: `Earn`, `Acquisition`, `Money-fx`, `Grain`, `Crude`, `Trade`, `Interest`, `Ship`, `Wheat` and `Corn`. The final data set includes 9296 documents. The initial seeds are only the words appearing in the category names.

Pre-processing. In both data sets we tagged the texts for part-of-speech and represented the documents by the frequency of each pos-tagged lemma, considering only nouns, verbs, adjectives, and adverbs. We induced the Latent Semantic Space from the training part[5] and consider the first 400 dimensions.

4.2 The impact of LSI similarity and GM on IL performance

In this section we evaluate the incremental impact of LSI similarity and the GM algorithm on IL performance. When avoiding both techniques the algorithm uses the simple cosine-based method over the original feature space, which can be considered as a baseline (similar to the method of (Liu et al., 2004)). We report first results using only the names of the categories as initial seeds.

Table 1 displays the F1 measure for the 20newsgroups and Reuters data sets, with and without LSI and with and without GM. The performance figures show the incremental benefit of both LSI and GM. In particular, when starting with just initial seeds and do not exploit the LSI similarity mechanism, then the performance is heavily penalized.

As mentioned above, the bootstrapping step of the algorithm (Step 2) exploits the initially classified instances to train a supervised text categorization classifier based on Support Vector Machines. It is worthwhile noting that the increment of performance after bootstrapping is generally higher when GM and LSI are incorporated, thanks to the higher quality of the initial categorization which was used for training.

4.3 Learning curves for the number of seeds

This experiment evaluates accuracy change as a function of the number of initial seeds. The experiment was performed for the 20 newsgroups corpus using both the LSI and the Classical vector space model. Additional seeds, beyond the category names, were identified by two lexicographers. For each category, the lexicographers were provided with a list of 100 seeds produced by the LSI similarity function applied to the category name (one list of 100 candidate terms for each category). From these lists the lexicographers selected the words that were judged as significantly related to the respective category, picking a mean of 40 seeds per category.

As seen in Figure 2, the learning curve using LSI vector space model dramatically outperforms the one using classical vector space. As can be expected, when using the original vector space (no generalization) the curve improves quickly with a few more terms. More surprisingly, with LSI similarity the best performance is obtained using the minimal initial seeds of the category names, while adding more seeds degrades performance. This might suggest that category names tend to be highly

[5] From a machine learning point of view, we could run the LSA on the full corpus (i.e. training and test), the LSA being a completely unsupervised technique (i.e. it does not take into account the data annotation). However, from an applicative point of view it is much more sensible to have the LSA built on the training part only. If we run the LSA on the full corpus, the performance figures increase in about 4 points.

indicative for the intensional meaning of the category, and therefore adding more terms introduces additional noise. Further research is needed to find out whether other methods for selecting additional seed terms might yield incremental improvements. The current results, though, emphasize the benefit of utilizing LSI and GM. These techniques obtain state-of-the-art performance (see comparisons in Section 4.5) using only the category names as seeds, allowing us to skip the quite tricky phase of collecting manually a larger number of seeds.

4.4 Extensional vs. Intensional Learning

A major point of comparison between IL and EL is the amount of supervision effort required to obtain a certain level of performance. To this end we trained a supervised classifier based on Support Vector Machines, and draw its learning curves as a function of percentage of the training set size (Figure 3). In the case of 20newsgroups, to achieve the 65% F1 performance of IL the supervised settings requires about 3200 documents (about 160 texts per category), while our IL method requires only the category name. Reuters-10 is an easier corpus, therefore EL achieves rather rapidly a high performance. But even here using just the category name is equal on average to labeling 70 documents per-category (700 in total). These results suggest that IL may provide an appealing cost-effective alternative in practical settings when sub-optimal accuracy suffices, or when it is too costly or impractical to obtain sufficient amounts of labeled training sets.

It should also be stressed that when using the complete labeled training corpus state-of-the-art EL outperforms our best IL performance. This result deviates from the flavor of previous IL literature, which reported almost comparable performance relative to EL. As mentioned earlier, the method of (Ko and Seo, 2004) (as we understand it) utilizes labeled examples for feature selection, and therefore cannot be compared with our strict IL setting. As for the results in (Liu et al., 2004), we conjecture that their comparable performance for IL and EL may not be sufficiently general, for several reasons: the easier classification task (4 subsets of 20-Newsgroups of 4-5 categories each); the use of the usually weaker Naive-Bayes as the EL device; the use of clustering as an aid for selecting the seed terms from the 20-Newsgroup subsets, which might not scale up well when applied to a large number of categories of varying size.

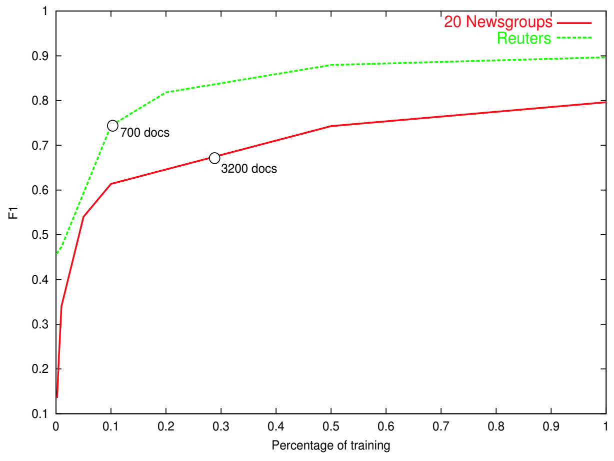

Figure 3: *Extensional* learning curves on as percentage of the training set.

4.5 Comparisons with other algorithms

As mentioned earlier it is not easy to conduct a thorough comparison with other algorithms in the literature. Most IL data sets used for training and evaluation are either not available (McCallum and Nigam, 1999) or are composed by somewhat arbitrary subsets of a standard data set. Another crucial aspect is the particular choice of the seed terms selected to compose an ID, which affects significantly the overall performance of the algorithm.

As a baseline system, we implemented a rule based approach in the spirit of (McCallum and Nigam, 1999). It is based on two steps. First, all the documents in the unlabeled training corpus containing at least one word in common with one and only one category ID are assigned to the respective class. Second, a supervised classifier based on SVM is trained on the labeled examples. Finally, the supervised classifier is used to perform the final categorization step on the test corpus. Table 2 reports the F1 measure of our replication of this method, using the category name as seed, which is substantially lower than the performance of the method we presented in this paper.

	Reuters	*20 Newsgroups*
	0.34	0.30
+ *bootstrap*	0.42	0.47

Table 2: Rule-based baseline performance

We also tried to replicate two of the non-standard data sets used in (Liu et al., 2004)[6]. Table 3 displays the performance of our approach in comparison to the results reported in (Liu et al., 2004). Following the evaluation metric adopted in that paper we report here accuracy instead of F1. For each data set (Liu et al., 2004) reported several results varying the number of seed words (from 5 to 30), as well as varying some heuristic thresholds, so in the table we report their best results. Notably, our method obtained comparable accuracy by using just the category name as ID for each class instead of multiple seed terms. This result suggests that our method enables to avoid the somewhat fuzzy process of collecting manually a substantial number of additional seed words.

	Our	*IDs per cat.*	*Liu et al.*	*IDs per cat.*
REC	0.94	1	0.95	5
TALK	0.80	1	0.80	20

Table 3: Accuracy on 4 “REC” and 4 “TALK” newsgroups categories

5 Conclusions

We presented a general bootstrapping algorithm for Intensional Learning. The algorithm can be applied to any categorization problem in which categories are described by initial sets of discriminative features and an unlabeled training data set is provided. Our algorithm utilizes a generalized similarity measure based on Latent Semantic Spaces and a Gaussian Mixture algorithm as a principled method to scale similarity scores into probabilities. Both techniques address inherent limitations of the IL setting, and leverage unsupervised information from an unlabeled corpus.

We applied and evaluated our algorithm on some text categorization tasks and showed the contribution of the two techniques. In particular, we obtain, for the first time, competitive performance using only the category names as initial seeds. This minimal information per category, when exploited by the IL algorithm, is shown to be equivalent to labeling about 70-160 training documents per-category for state of the art extensional learning. Future work is needed to investigate optimal procedures for collecting seed features and to find out whether additional seeds might still contribute to better performance. Furthermore, it may be very interesting to explore optimal combinations of intensional and extensional supervision, provided by the user in the forms of seed features *and* labeled examples.

[6]We used sequential splitting (70/30) rather than random splitting and did not apply any feature selection. This setting might be somewhat more difficult than the original one.

Speeding up Training with Tree Kernels for Node Relation Labeling

Abstract

We present a method for speeding up the calculation of tree kernels during training. The calculation of tree kernels is still heavy even with efficient dynamic programming (DP) procedures. Our method maps trees into a small feature space where the inner product, which can be calculated much faster, yields the same value as the tree kernel for *most* tree pairs. The training is sped up by using the DP procedure only for the exceptional pairs. We describe an algorithm that detects such exceptional pairs and converts trees into vectors in a feature space. We propose tree kernels on *marked labeled ordered trees* and show that the training of SVMs for semantic role labeling using these kernels can be sped up by a factor of several tens.

1 Introduction

Many NLP tasks such as parse selection and tagging can be posed as the classification of labeled ordered trees. Several tree kernels have been proposed for building accurate kernel-based classifiers (Collins and Duffy, 2001; Kashima and Koyanagi, 2002). They have the following form in common.

$$K(T_1, T_2) = \sum_{S_i} W(S_i) \cdot \#_{S_i}(T_1) \cdot \#_{S_i}(T_2), \quad (1)$$

where S_i is a possible subtree, $\#_{S_i}(T_j)$ is the number of times S_i is *included* in T_j, and $W(S_i)$ is the weight of S_i. That is, tree kernels are inner products in a subtree feature space where a tree is mapped to vector $V(T_j) = \left(\sqrt{W(S_i)}\#_{S_i}(T_j)\right)_i$. With tree kernels we can take global structures into account, while alleviating overfitting with kernel-based learning methods such as support vector machines (SVMs) (Vapnik, 1995).

Previous studies (Collins and Duffy, 2001; Kashima and Koyanagi, 2002) showed that although it is difficult to explicitly calculate the inner product in Eq. (1) because we need to consider an exponential number of possible subtrees, the tree kernels can be computed in $O(|T_1||T_2|)$ time by using dynamic programming (DP) procedures. However, these DP procedures are time-consuming in practice.

In this paper, we present a method for speeding up the training with tree kernels. Our target application is *node relation labeling*, which includes NLP tasks such as semantic role labeling (SRL) (Gildea and Jurafsky, 2002; Moschitti, 2004; Hacioglu et al., 2004). For this purpose, we designed kernels on *marked labeled ordered trees* and derived $O(|T_1||T_2|)$ procedures. However, the lengthy training due to the cost of kernel calculation prevented us from assessing the performance of these kernels and motivated us to make the training practically fast.

Our speed-up method is based on the observation that very few pairs in the training set have a great many common subtrees (we call such pairs *malicious* pairs) and most pairs have a very small number of common subtrees. This leads to a drastic variance in kernel values, e.g., when $W(S_i) = 1$. We thus call this property of data *unbalanced similarity*. Fast calculation based on the inner product is possible for non-malicious pairs since we can convert the trees into vectors in a space of a small subset of all subtrees. We can speed up the training by using the DP procedure only for the rare malicious pairs.

We developed the FREQTM algorithm, a modification of the FREQT algorithm (Asai et al., 2002), to detect the malicious pairs and efficiently convert trees into vectors by enumerating only the subtrees actually needed (feature subtrees). The experiments demonstrated that our method makes the training of SVMs for the SRL task faster by a factor of several tens, and that it enables the performance of the kernels to be assessed in detail.

2 Kernels for Labeled Ordered Trees

The tree kernels proposed so far differ in how subtree inclusion is defined. For instance, Kashima and Koyanagi (2002) used the following definition.

DEFINITION 2.1 *S is included in T iff there exists a one-to-one function ψ from a node of S to a node of T such that (i) $pa(\psi(n_i)) = \psi(pa(n_i))$ ($pa(n_i)$ returns the parent of node n_i), (ii) $\psi(n_i) \succeq \psi(n_j)$ iff $n_i \succeq n_j$ ($n_i \succeq n_j$ means that n_i is an elder sibling of n_j), and (iii) $l(\psi(n_i)) = l(n_i)$ ($l(n_i)$ returns the label of n_i).*

We refer to the tree kernel based on this definition as K_{lo}. Collins and Duffy (2001) used a more restrictive definition where the preservation of CFG productions, i.e., $nc(\psi(n_i)) = nc(n_i)$ if $nc(n_i) > 0$ ($nc(n_i)$ is the number of children of n_i), is required in addition to the requirements in Definition 2.1. We refer to the tree kernel based on this definition as K_c.

It is pointed that extremely unbalanced kernel values cause overfitting. Therefore, Collins and Duffy (2001) used $W(S_i) = \lambda^{(\text{\# of productions in } S_i)}$, and Kashima and Koyanagi (2002) used $W(S_i) = \lambda^{|S_i|}$, where λ ($0 \leq \lambda \leq 1$) is a factor to alleviate the unbalance by penalizing large subtrees.

To calculate the tree kernels efficiently, Collins and Duffy (2001) presented an $O(|T_1||T_2|)$ DP procedure for K_c. Kashima and Koyanagi (2002) presented one for K_{lo}. The point of these procedures is that Eq. (1) can be transformed:

$$K(T_1, T_2) = \sum_{n_1 \in T_1} \sum_{n_2 \in T_2} C(n_1, n_2),$$
$$C(n_1, n_2) \equiv \textstyle\sum_{S_i} W(S_i) \cdot \#_{S_i}(T_1 \vartriangle n_1) \cdot \#_{S_i}(T_2 \vartriangle n_2),$$

where $\#_{S_i}(T_j \vartriangle n_k)$ is the number of times S_i is included in T_j with $\psi(root(S_i)) = n_k$. $C(n_1, n_2)$ can then be calculated recursively from those of the children of n_1 and n_2.

3 Kernels for Marked Labeled Ordered Trees for Node Relation Labeling

3.1 Node Relation Labeling

The node relation labeling finds relations among nodes in a tree. Figure 1 illustrates the concept of node relation labeling with the SRL task as an example. A0, A1, and AM-LOC are the semantic roles

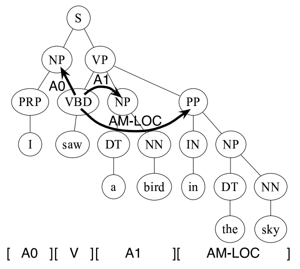

Figure 1: Node relation labeling.

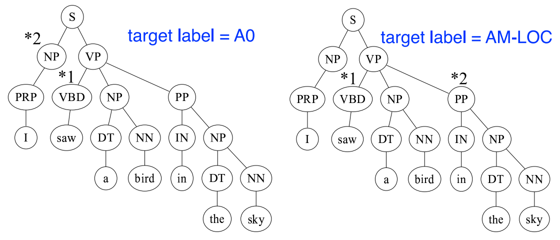

Figure 2: Semantic roles encoded by marked labeled ordered trees.

of the arguments of the verb "see (saw)". We represent an argument by the node that is the highest in the parse tree among the nodes that exactly cover the words in the argument. The node for the verb is determined similarly. For example, the node labeled "PP" represents the AM-LOC argument "in the sky", and the node labeled "VBD" represents the verb "see (saw)". We assume that there is a two-node relation labeled with the semantic role (represented by the arrow in the figure) between the verb node and the argument node.

3.2 Kernels on Marked Labeled Ordered Trees

We define a marked labeled ordered tree as a labeled ordered tree in which each node has a mark in addition to a label. We use $m(n_i)$ to denote the mark of node n_i. If n_i has no mark, $m(n_i)$ returns the special mark no-mark. We also use the function $marked(n_i)$, which returns $true$ iff $m(n_i)$ is not no-mark. We can encode a k-node relation by using k distinct marks. Figure 2 shows how the semantic roles illustrated in Figure 1 can be encoded using marked labeled ordered trees. We used the mark *1 to represent the verb node and *2 to represent the argument node.

The node relation labeling task can be posed as the classification of marked trees that returns $+1$ when the marks encode the correct relation and -1

Algorithm 3.1: KERNELLOMARK(T_1, T_2)

```
(nodes are ordered by the post-order traversal)
for $n_1 \leftarrow 1$ to $|T_1|$ do
  for $n_2 \leftarrow 1$ to $|T_2|$ do —————— (A)
    if $lm(n_1) \neq lm(n_2)$ then
      $C(n_1, n_2) \leftarrow 0$  $C^r(n_1, n_2) \leftarrow 0$
    else if $n_1$ and $n_2$ are leaf nodes then
      $C(n_1, n_2) \leftarrow \lambda$
      if $marked(n_1)$ and $marked(n_2)$ then
        $C^r(n_1, n_2) \leftarrow \lambda$  else $C^r(n_1, n_2) \leftarrow 0$
    else
      $S(0, j) \leftarrow 1$  $S(i, 0) \leftarrow 1$
      if $marked(n_1)$ and $marked(n_2)$ then
        $S^r(0, j) \leftarrow 1$  $S^r(i, 0) \leftarrow 1$
      else $S^r(0, j) \leftarrow 0$  $S^r(i, 0) \leftarrow 0$
      for $i \leftarrow 1$ to $nc(n_1)$ do
        for $j \leftarrow 1$ to $nc(n_2)$ do
          $S(i, j) \leftarrow$
            $S(i-1, j) + S(i, j-1) - S(i-1, j-1)$
            $+S(i-1, j-1) \cdot C(ch_i(n_1), ch_j(n_2))$
          $S^r(i, j) \leftarrow$ —————— (B)
            $S^r(i-1, j) + S^r(i, j-1) - S^r(i-1, j-1)$
            $+S^r(i-1, j-1) \cdot C(ch_i(n_1), ch_j(n_2))$
            $+S(i-1, j-1) \cdot C^r(ch_i(n_1), ch_j(n_2))$
            $-S^r(i-1, j-1) \cdot C^r(ch_i(n_1), ch_j(n_2))$
      $C(n_1, n_2) \leftarrow \lambda \cdot S(nc(n_1), nc(n_2))$
      $C^r(n_1, n_2) \leftarrow \lambda \cdot S^r(nc(n_1), nc(n_2))$
return $(\sum_{n_1=1}^{|T_1|} \sum_{n_2=1}^{|T_2|} C^r(n_1, n_2))$
```

otherwise. To enable such classification, we need tree kernels that take into account the node marks. We thus propose mark-aware tree kernels formulated as follows.

$$K(T_1, T_2) = \sum_{S_i : marked(S_i)} W(S_i) \cdot \#_{S_i}(T_1) \cdot \#_{S_i}(T_2),$$

where $marked(S_i)$ returns $true$ iff $marked(n_i) = true$ for at least one node in tree S_i. In these kernels, we require $m(\psi(n_i)) = m(n_i)$ in addition to $l(\psi(n_i)) = l(n_i)$ for subtree S_i to be regarded as included in tree T_j. In other words, these kernels treat $lm(n_i) \equiv (l(n_i), m(n_i))$ as the new label of node n_i and sum only over subtrees that have at least one marked node. We refer to the marked version of K_{lo} as K_{lo}^r and the marked version of K_c as K_c^r.

We can derive $O(|T_1||T_2|)$ DP procedures for the above kernels as well. Algorithm 3.1 shows the DP procedure for K_{lo}^r, which is derived by extending the DP procedure for K_{lo} (Kashima and Koyanagi, 2002). The key is the use of $C^r(n_1, n_2)$, which stores the sum over only marked subtrees, and its recursive calculation using $C(n_1, n_2)$ and $C^r(n_1, n_2)$ **(B)**. An $O(|T_1||T_2|)$ procedure for K_c^r can also be derived by extending (Collins and Duffy, 2001).

Table 1: Malicious and non-malicious pairs in the 1k data (3,136 trees) used in Sec. 5.2. We used $K(T_i, T_j) = 10^4$ with $\lambda = 1$ as the threshold for maliciousness. (A): pairs (i, i). (B): pairs from the same sentence except (i, i). (C): pairs from different sentences. Some malicious pairs are from different but similar sentences, which are difficult to detect.

		K_{lo}^r		K_c^r	
		# pairs	avg. $K(T_i, T_j)$	# of pairs	avg. $K(T_i, T_j)$
$\geq 10^4$	(A)	3,121	1.17×10^{52}	3,052	2.49×10^{32}
	(B)	7,548	7.24×10^{48}	876	1.26×10^{32}
	(C)	6,510	6.80×10^{9}	28	1.82×10^{4}

	(B)	4,864	2.90×10^{2}	11,536	1.27×10^{2}
	(C)	9,812,438	1.82×10^{1}	9,818,920	1.84×10^{-1}

4 Fast Training with Tree Kernels

4.1 Basic Idea

As mentioned, we define two types of tree pairs: malicious and non-malicious pairs. Table 1 shows how these two types of pairs are distributed in an actual training set. There is a clear distinction between malicious and non-malicious pairs, and we can exploit this property to speed up the training.

We define subset $\mathcal{F} = \{F_i\}$ (*feature subtrees*), which includes only the subtrees that appear as a common included subtree in the non-malicious pairs. We convert a tree to feature vector $V(T_j) = \left(\sqrt{W(F_i)}\#_{F_i}(T_j)\right)_i$ using only $\mathcal{F}$. Then we use a procedure that chooses the DP procedure or the inner product procedure depending on maliciousness:

$$K(T_i, T_j) = \begin{cases} K(T_i, T_j) \text{ (DP)} & \text{if } (i, j) \text{ is malicious.} \\ \langle V(T_i), V(T_j) \rangle & \text{otherwise} \end{cases}$$

This procedure returns the same value as the original calculation. Naively, if $|V(T_i)|$ (the number of feature subtrees such that $\#_{F_i}(T_i) \neq 0$) is small enough, we can expect a speed-up because the cost of calculating the inner product is $O(|V(T_i)| + |V(T_j)|)$. However, since $|V(T_i)|$ might increase as the training set becomes larger, we need a way to scale the speed-up to large data. In most kernel-based methods, such as SVMs, we actually need to calculate the kernel values with all the training examples for a given example T_i: $KS(T_i) = \{K(T_i, T_1), \ldots, K(T_i, T_L)\}$, where L is the number of training examples. Using *occurrence pattern* $OP(F_i) = \{(k, \#_{F_i}(T_k)) | \#_{F_i}(T_k) \neq 0\}$ pre-

  for each $F_i \in \mathcal{F}^1$ do SEARCH($F_i$, true )――――――-(PC)
  for each $F_i \in \mathcal{F}^1$ do SEARCH($F_i$, false )
  $\mathcal{M} \leftarrow \mathcal{M} \cup \{(i,i) | 1 \leq i \leq l\}$
  return ($\underline{\mathcal{M}}$, $\{V(T_i)\}$, $\underline{\{W(f_i)\}}$)
```

Table 2: Functions in FREQTM.

- $occ(F_i)$ returns occurrence list of F_i whose element (j, n) indicates that F_i appears in T_j and that n (of T_j) is the node added to generated F_i in T_j by the RME (n works as the position of F_i in T_j).
- $sup(F_i)$ returns the IDs of distinct trees in $occ(F_i)$.
- $malicious(F_i)$ returns $true$ iff all pairs in $sup(F_i)$ are already registered in the set of malicious pairs, $\mathcal{M}$. (Currently, this returns $false$ if $|sup(F_i)| > M$ where M is the maximum support size of the malicious subtrees so far. We will remove this check since we found that it did not affect efficiency so much.)
- $RME(F_i, T_j, n)$ is a set of subtrees generated by RMEs of F_i in T_j (permitted when previously expanded node to generate F_i is n).

pared beforehand, we can calculate $KS(T_i)$ efficiently (Algorithm 4.1). A similar technique was used in (Kudo and Matsumoto, 2003a) to speed up the calculation of inner products.

We can show that the per-pair cost of Algorithm 4.1 is $O(c_1 Q + r_m c_2 |T_i||T_j|)$, where Q is the average number of common feature subtrees in a tree pair, r_m is the rate of malicious pairs, c_1 and c_2 are the constant factors for vector operations and DP operations. This cost is independent of the number of training examples. We expect from our observations that both Q and r_m are very small and that $c_1 \ll c_2$.

4.2 Feature Subtree Enumeration with Malicious Pair Detection

To detect malicious pairs and enumerate feature subtrees $\mathcal{F}$ (and to convert each tree to a feature vector), we developed an algorithm based on the FREQT algorithm (Asai et al., 2002). The FREQT algorithm can efficiently enumerate subtrees that are included (Definition 2.1) in more than a pre-specified number of trees in the training examples by generating candidate subtrees using *right most expansions* (*RMEs*). FREQT-based algorithms have recently been used in methods that treat subtrees as features (Kudo and Matsumoto, 2004; Kudo and Matsumoto, 2003b).

To develop the algorithm, we made the definition of maliciousness more search-oriented since it is costly to check for maliciousness based on the exact number of common subtrees or the kernel values (i.e., by using the DP procedure for all L^2 pairs). Whatever definition we use, the correctness is preserved as long as we do not fail to enumerate the subtrees that appear in the pairs we consider non-malicious. First, we consider pairs (i, i) to always be malicious. Then, we use a FREQT search that enumerates the subtrees that are included in at least two trees as a basis. Next, we modify FREQT so that it stops the search if candidate subtree F_i is too large (larger than size D, e.g., 20), and we regard the pairs of the trees where F_i appears as malicious because having a large subtree in common implies having a possibly exponential number of subtrees of that subtree in common. Although this test is heuristic and conservative in that it ignores the shape and marks of a tree, it works fine empirically.

Algorithm 4.2 is our algorithm, which we call FREQTM. The differences from FREQT are underlined. Table 2 summarizes the functions used. To make the search efficient, pruning is performed as follows (see also Figure 3). The basic idea behind is that if $malicious(F_i)$ is $true$ then $malicious(F_k)$ is also $true$ for F_k that is expanded from F_i by an

RME since $sup(F_k) \subseteq sup(F_i)$. This means we do not need to enumerate F_i nor any descendant of F_i.

- **(P)** Once $|F_i| \geq D$ and the malicious pairs are registered, we stop searching further.
- **(P1)** If the search from F_k (expanded from F_i) found a malicious subtree and if $|sup(F_i)| = |sup(F_k)|$, we stop the search from any other subtree F_m (expanded from F_i) since we can prove that $malicious(F_m) = true$ without actually testing it (proof omitted).
- **(P2)** If $malicious(F_k) = true$, we prune the search from F_k. To prune even when $malicious(F_k)$ becomes $true$ as a result of succeeding searches, we first run a search only for detecting malicious pairs (see **(PC)**).
- **(S)** We stop searching when the occurrence list becomes too long (larger than threshold R) since it causes a severe search slowdown.

Note that we use a depth-first version of FREQT as a basis to first find the largest subtrees and to detect malicious pairs at early points in the search. Enumeration of unnecessary subtrees is avoided because the registration of subtrees is performed at the post-order position **(F)**. The conversion to vectors is performed by assigning an ID to subtree F_i when registering it at **(F)** and distributing the ID to all the examples in $occ(F_i)$. Finally, D should be large enough to make r_m sufficiently small but should not be so large that too many feature subtrees are enumerated.

We expect that the cost of FREQTM is offset by the faster training, especially when training on the same data is repeatedly performed as in the tuning of hyperparameters.

For K_c^{τ}, we use a similar search procedure. However, the RME is modified so that all the children of a CFG production are expanded at once. Although the modification is not trivial, we omit the explanation due to space limitations.

4.3 Feature Compression

Additionally, we use a simple but effective feature compression technique to boost speed-up. The idea is simple: feature subtrees F_i and F_j can be treated as one feature f_k, with weight $W(f_k) = W(F_i) + W(F_j)$ if $OP(F_i) = OP(F_j)$. This drastically reduces the number of features. Although this is similar to finding closed and maximal subtrees (Chi et al., 2004), it is easy to implement since we need only the occurrence pattern, $OP(F_i)$, which is easily obtained from $occ(F_i)$ in the FREQTM search.

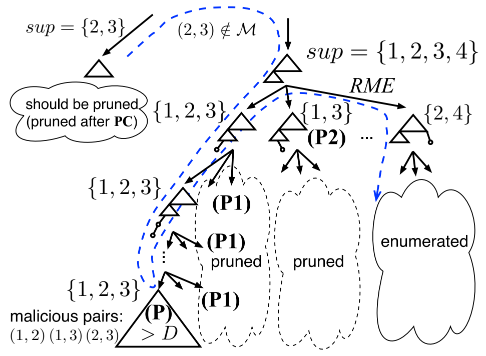

Figure 3: Pruning in FREQTM.

4.4 Alternative Methods

Vishwanathan and Smola (2004) presented the $O(|T_1| + |T_2|)$ procedure that exploits suffix trees to speed up the calculation of tree kernels. However, it can be applied to only a few types of subtrees that can be represented as a contiguous part in a string representation of a tree. Therefore, neither K_{lo}^{τ} nor K_c^{τ} can be sped up by using this procedure.

Another method is to change an inner loop, such as **(B)** in Algorithm 3.1, so that it iterates only over nodes in T_2 that have $l(n_1)$. We use this as the baseline for comparison, since we found that this is about two times faster than the standard implementation. [1]

4.5 Remaining Problem

Note that the method described here cannot speed up classification, since the converted vectors are valid only for calculating the kernels between trees in the training set. However, when we classify the same trees repeatedly, we can convert the trees in the training set and the classified trees at the same time and use the obtained vectors for classification.

5 Evaluation

We first evaluated the speed-up by our method for the semantic role labeling (SRL) task. We then demonstrated that the speed-up method enables a detailed comparison of K_{lo}^{τ} and K_c^{τ} for the SRL task.

[1]For K_c^{τ}, it might be possible to speed up comparisons in the algorithm by assigning IDs for CFG rules. We leave this for future work since it complicates implementation.

Table 3: Conversion statistics and speed-up for semantic role A2.

	K^r_{lo}					K^r_c				
size (# positive examples)	1,000	2,000	4,000	8,000	12,000	1,000	2,000	4,000	8,000	12,000

5.1 Setting

We used the data set provided for the CoNLL05 SRL shared task (Carreras and Màrquez, 2005). We used only the training part and divided it into our training, development, and testing sets (23,899, 7,966, and 7,967 sentences, respectively). As the tree structure, we used the output of Collins' parser (with WSJ-style non-terminals) provided with the data set. We also used POS tags by inserting the nodes labeled by POS tags above the word nodes. The average number of nodes in a tree was about 82. We ignored any arguments (and verbs) that did not match any node in the tree (the rate of such cases was about 3.5%). [2] The words were lowercased.

We used TinySVM[3] as the implementation of SVM and added our tree kernels, K^r_{lo} and K^r_c. We implemented FREQTM based on the implementation of FREQT by Kudo.[4] We normalized the kernel values: $K(T_i, T_j)/\sqrt{K(T_i, T_i) \times K(T_j, T_j)}$. Note that this normalization barely affected the training time since we can calculate $K(T_i, T_i)$ beforehand.

We assumed two-step labeling where we first find the argument node and then we determine the label by using a binary classifier for each semantic role. In this experiment, we focused on the performance for the classifiers in the latter step. We used the marked labeled ordered tree that encoded the target role as a positive example and the trees that encoded other roles of the verb in the same sentence as negative examples. We trained and evaluated the classifiers using the examples generated as above. [5]

[2]This was caused by parse errors, which can be solved by using more accurate parsers, and by bracketing inconsistencies between parser outputs and SRL annotations (e.g., phrasal verbs), many of which can be avoided by using heuristic transformers.

[3]http://chasen.org/˜taku/software/TinySVM

[4]http://chasen.org/˜taku/software/freqt

[5]The evaluation is slightly easier since the classifier for role X is evaluated only on the examples generated from the sentences that contain a verb that has X as a role.

5.2 Training Speed-up

We calculated the statistics for the conversion by FREQTM and measured the speed-up in SVM training for semantic role A2, for various numbers of training examples. For FREQTM, we used $D = 20$ and $R = 20$. For SVM training, we used convergence tolerance 0.001 (-e option in TinySVM), soft margin cost $C = 1.0 \times 10^3$ (-c), maximum number of iterations 10^5, kernel cache size 512 MB (-m), and decay factor $\lambda = 0.2$ for the weight of each subtree. We compared the time with our fast method (Algorithm 4.1) with that with the DP procedure with the node lookup described in Section 4.4. Note that these two methods yield almost identical SVM models (there are very slight differences due to the numerical computation). The time was measured using a computer with 2.4-GHz Opterons.

Table 3 shows the results for K^r_{lo} and K^r_c. The proposed method made the SVM training substantially faster for both K^r_{lo} and K^r_c. As we expected, the speed-up factor did not decrease even though $|V|$ increased as the amount of data increased. Note that FREQTM actually detected non-trivial malicious pairs such as those from very similar sentences in addition to trivial ones, e.g., (i, i). FREQTM conversion was much faster and the converted feature vectors were much shorter for K^r_c, presumably because K^r_c restricts the subtrees more.

The compression technique described in Section 4.3 greatly reduced the number of features. Without this compression, the storage requirement would be impractical. It also boosted the speed-up. For example, the training time with K^r_{lo} for the size 1,000 data in Table 3 was 86.32 seconds without compression. This means that the compression boosted the

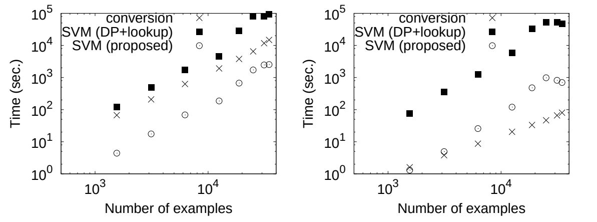

Figure 4: Scaling of conversion time and SVM training time. Left: K_{lo}^{r}. Right: K_{c}^{r}

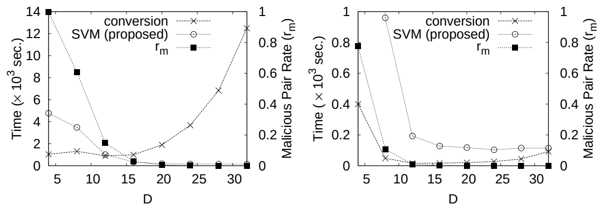

Figure 5: Relation between D and conversion time, SVM training time, and r_m. Left: K_{lo}^{r}. Right: K_{c}^{r}

speed-up by a factor of more than 5.

The cost of FREQTM is much smaller than that of SVM training with DP. Therefore, our method is beneficial even if we train the SVM only once.

To see how our method scales to large amounts of data, we plotted the time for the conversion and the SVM training w.r.t. data size on a log-log scale. As shown in Figure 4, the scaling factor was about 1.7 for the conversion time, 2.1 for SVM training with DP, and 2.0 for the proposed SVM training for K_{lo}^{r}. For K_{c}^{r}, the factors were about 1.3, 2.1, and 2.0, respectively. Regardless of the method, the cost of SVM training was about $O(L^2)$, as reported in the literature. Although FREQTM also has a super-linear cost, it is smaller than that of SVM training. Therefore, the cost of SVM training will become a problem before the cost of FREQTM does.

As we mentioned, the choice of D is a trade-off. Figure 5 shows the relationships between D and the time of conversion by FREQTM, the time of SVM training using the converted vectors, and the rate of malicious pairs, r_m. We can see that the choice of D is more important in the case of K_{lo} and that $D = 20$ used in our evaluation is not a bad choice.

5.3 Semantic Role Labeling

We assessed the performance of K_{lo}^{r} and K_{c}^{r} for semantic roles A1, A2, AM-ADV, and AM-LOC using our fast training method. We tuned soft margin cost C and λ by using the development set (we used the technique described in Section 4.5 to enable fast classification of the development set). We experimented with two training set sizes (4,000 and 8,000). For each λ (0.1, 0.15, 0.2, 0.25, and 0.30), we tested 40 different values of C ($C \in [2 \ldots 10^3]$ for size 4,000 and $C \in [0.5 \ldots 10^3]$ for size 8,000), and we evaluated the accuracy of the best setting for the test set.[6] Fast training is crucial since the performance differs substantially depending on the values of these hyperparameters. Table 4 shows the results. The accuracies are shown by F_1. We can see that K_{lo}^{r} outperformed K_{c}^{r} in all cases, presumably because K_{c}^{r} allows only too restrictive subtrees and therefore causes data sparseness. In addition, as one would expect, larger training sets are beneficial.

6 Discussion

The proposed speed-up method can also be applied to labeled ordered trees (e.g., for parse selection). However, the speed-up might be smaller since without node marks the number of subtrees increases while the DP procedure becomes simpler. On the other hand, the FREQTM conversion for marked labeled ordered trees might be made faster by exploiting the mark information for pruning. Although our method is not a complete solution in a classification setting, it might be in a clustering setting (in a sense it is training only). However, it is an open question whether unbalanced similarity, which is the key to our speed-up, is ubiquitous in NLP tasks and under what conditions our method scales better than the SVMs or other kernel-based methods.

Several studies claim that learning using tree kernels and other convolution kernels tends to overfit and propose selecting or restricting features (Cumby and Roth, 2003; Suzuki et al., 2004; Kudo and Matsumoto, 2004). Sometimes, the classification becomes faster as a result (Suzuki et al., 2004; Kudo and Matsumoto, 2004). We do not disagree with these studies. The fact that small λ values resulted in the highest accuracy in our experiment implies that too large subtrees are not so useful. However, since this tendency depends on the task, we need to assess the performance of full tree kernels for comparison. In this sense, our method is of great importance.

Node relation labeling is a generalization of node

[6]We used 10^6 as the maximum number of iterations.

Table 4: Comparison between K^r_{lo} and K^r_c.

		training set size = 4,000			training set size = 8,000

marking where we determine the mark (tag) of a node. Kashima and Koyanagi (2002) dealt with this task by inserting the node representing the mark above the node to be tagged and classifying the transformed tree using SVMs with tree kernels such as K_{lo}. For the SRL task, Moschitti (2004) applied the tree kernel (K_c) to tree fragments that are heuristically extracted to reflect the role of interest. For relation extraction, Culotta and Sorensen (2004) proposed a tree kernel that operates on only the smallest tree fragment including two entities for which a relation is assigned. Our kernels on marked labeled ordered trees differ in what subtrees are permitted. Although comparisons are needed, we think our kernels are intuitive and general.

There are many possible structures for which tree kernels can be defined. Shen et al. (2003) proposed a tree kernel for LTAG derivation trees to focus only on linguistically meaningful structures. Culotta and Sorensen (2004) proposed a tree kernel for dependency trees. An important future task is to find suitable structures for each task (the SRL task in our case). Our speed-up method will be beneficial as long as there is unbalanced similarity.

7 Conclusion

We have presented a method for speeding up the training with tree kernels. Using the SRL task, we demonstrated that our speed-up method made the training substantially faster.

Abstract

In order to promote the study of automatic summarization and translation, we need an accurate automatic evaluation method that is close to human evaluation. In this paper, we present an evaluation method that is based on convolution kernels that measure the similarities between texts considering their substructures. We conducted an experiment using automatic summarization evaluation data developed for Text Summarization Challenge 3 (TSC-3). A comparison with conventional techniques shows that our method correlates more closely with human evaluations and is more robust.

1 Introduction

Automatic summarization, machine translation, and paraphrasing have attracted much attention recently. These tasks include text-to-text language generation. Evaluation workshops are held in the U.S. and Japan, e.g., the Document Understanding Conference (DUC)[1], NIST Machine Translation Evaluation[2] as part of the TIDES project, the Text Summarization Challenge (TSC)[3] of the NTCIR project, and the International Workshop on Spoken Language Translation (IWSLT)[4].

These evaluation workshops employ human evaluations, which are essential in terms of achieving high quality evaluations results. However, human evaluations require a huge effort and the cost is considerable. Moreover, we cannot automatically evaluate a new system even if we use the corpora built for these workshops, and we cannot conduct re-evaluation experiments.

To cope with this situation, there is a particular need to establish a high quality automatic evaluation method. Once this is done, we can expect great progress to be made on natural language generation.

In this paper, we propose a novel automatic evaluation method for natural language generation technologies. Our method is based on the Extended String Subsequence Kernel (ESK) (Hirao et al., 2004b) which is a kind of convolution kernel (Collins and Duffy, 2001). ESK allows us to calculate the similarities between a pair of texts taking account of word sequences, their word sense sequences and their combinations.

We conducted an experimental evaluation using automatic summarization evaluation data developed for TSC-3 (Hirao et al., 2004a). The results of the comparison with ROUGE-N (Lin and Hovy, 2003; Lin, 2004a; Lin, 2004b), ROUGE-S(U) (Lin, 2004b; Lin and Och, 2004) and ROUGE-L (Lin, 2004a; Lin, 2004b) show that our method correlates more closely with human evaluations and is more robust.

2 Related Work

Automatic evaluation methods for automatic summarization and machine translation are grouped into two classes. One is the longest common subsequence (LCS) based approach (Hori et al., 2003; Lin, 2004a; Lin, 2004b; Lin and Och, 2004). The other is the N-gram based approach (Papineni et al.,

2002; Lin and Hovy, 2003; Lin, 2004a; Lin, 2004b; Soricut and Brill, 2004).

Hori et. al (2003) proposed an automatic evaluation method for speech summarization based on word recognition accuracy. They reported that their method is superior to BLEU (Papineni et al., 2002) in terms of the correlation between human assessment and automatic evaluation. Lin (2004a; 2004b) and Lin and Och (2004) proposed an LCS-based automatic evaluation measure called ROUGE-L. They applied ROUGE-L to the evaluation of summarization and machine translation. The results showed that the LCS-based measure is comparable to N-gram-based automatic evaluation methods. However, these methods tend to be strongly influenced by word order.

Various N-gram-based methods have been proposed since BLEU, which is now widely used for the evaluation of machine translation. Lin et al. (2003) proposed a recall-oriented measure, ROUGE-N, whereas BLEU is precision-oriented. They reported that ROUGE-N performed well as regards automatic summarization. In particular, ROUGE-1, *i.e.*, unigram matching, provides the best correlation with human evaluation. Soricut et. al (2004) proposed a unified measure. They integrated a precision-oriented measure with a recall-oriented measure by using an extension of the harmonic mean formula. It performs well in evaluations of machine translation, automatic summarization, and question answering.

However, N-gram based methods have a critical problem; they cannot consider co-occurrences with gaps, although the LCS-based method can deal with them. Therefore, Lin and Och (2004) introduced skip-bigram statistics for the evaluation of machine translation. However, they did not consider longer skip-n-grams such as skip-trigrams. Moreover, their method does not distinguish between bigrams and skip-bigrams.

3 Kernel-based Automatic Evaluation

The above N-gram-based methods correlated closely with human evaluations. However, we think some skip-n-grams (n$\geq$3) are useful. In this paper, we employ the Extended String Subsequence Kernel (ESK), which considers both n-grams and skip-n-grams. In addition, the ESK allows us to add word senses to each word. The use of word senses enables flexible matching even when paraphrasing is used.

The ESK is a kind of convolution kernel (Collins and Duffy, 2001). Convolution kernels have recently attracted attention as a novel similarity measure in natural language processing.

3.1 ESK

The ESK is an extension of the String Subsequence Kernel (SSK) (Lodhi et al., 2002) and the Word Sequence Kernel (WSK) (Cancedda et al., 2003).

The ESK receives two node sequences as inputs and maps each of them into a high-dimensional vector space. The kernel's value is simply the inner product of the two vectors in the vector space. In order to discount long-skip-n-grams, the decay parameter λ is introduced.

We explain the computation of the ESK's value whose inputs are the sentences (S1 and S2) shown below. In the example, word senses are shown in braces.

S1 Becoming a cosmonaut:$\{$*SPACEMAN*$\}$ is my great dream:$\{$*DREAM*$\}$

S2 Becoming an astronaut:$\{$*SPACEMAN*$\}$ is my ambition:$\{$*DREAM*$\}$

In this case, "cosmonaut" and "astronaut" share the same sense $\{$*SPACEMAN*$\}$ and "ambition" and "dream" also share the same sense $\{$*DREAM*$\}$. We can use WordNet for English and *Goitaikei* (Ikehara et al., 1997) for Japanese.

Table 1 shows the subsequences derived from S1 and S2 and its weights. Note that the subsequence length is two or less. From the table, there are fifteen subsequences[5] that are common to S1 and S2. Therefore, $\mathrm{ESK}^{d=2}(\mathrm{S1},\mathrm{S2}) = 7 + \lambda + 2\lambda^2 + \lambda^3 + \lambda^4 + \lambda^5 + \lambda^6 + \lambda^9$. For reference, there are three unigrams, one bigram, zero trigrams and three skip-bigrams common to S1 and S2.

Formally, the ESK is defined as follows. T and U are node sequences.

$$\mathrm{ESK}^d(T,U) = \sum_{m=1}^{d} \sum_{t_i \in T} \sum_{u_j \in U} K_m(t_i,u_j) \tag{1}$$

$$K_m(t_i,u_j) = \begin{cases} val(t_i,u_j) & \text{if} \quad m=1 \\ K'_{m-1}(t_i,u_j)\cdot val(t_i,u_j) & \text{otherwise} \end{cases} \tag{2}$$

Here, d is the upper bound of the subsequence length and $K'_m(t_i,u_j)$ is defined as follows. t_i is the i-th node of T. u_j is the j-th node of U. The function $val(s,t)$ returns the number of attributes common to given nodes s and t.

$$K'_m(t_i,u_j) = \begin{cases} 0 \quad \text{if} \quad j=1 \\ \lambda K'_m(t_i,u_{j-1}) + K''_m(t_i,u_{j-1}) & \text{otherwise} \end{cases} \tag{3}$$

$K''_m(t_i,u_j)$ is defined as follows:

$$K''_m(t_i,u_j) = \begin{cases} 0 \quad \text{if} \quad i=1 \\ \lambda K''_m(t_{i-1},u_j) + K_m(t_{i-1},u_j). \end{cases} \tag{4}$$

[5]Bold subsequences in Table 1.

Finally, we define the similarity measure between T and U by normalizing ESK. This similarity can be regarded as an extension of the cosine measure.

$$\mathrm{Sim}^d_{\mathrm{esk}}(T,U) = \frac{\mathrm{ESK}^d(T,U)}{\sqrt{\mathrm{ESK}^d(T,T)\mathrm{ESK}^d(U,U)}}. \tag{5}$$

3.2 Automatic Evaluation based on ESK

Suppose, $\mathcal{C}$ is a system output, which consists of ℓ sentences, and $\mathcal{R}$ is a human written reference, which consists of m sentences. c_i is a sentence in $\mathcal{C}$, and r_j is a sentence in $\mathcal{R}$. We define two scoring functions for automatic evaluation. First, we define a precision-oriented measure as follows:

$$P^d_{\mathrm{esk}}(\mathcal{C},\mathcal{R}) = \frac{1}{\ell}\sum_{i=1}^{\ell} \max_{1\le j\le m} \mathrm{Sim}^d_{\mathrm{esk}}(c_i,r_j) \tag{6}$$

Symmetrically, we define a recall-oriented measure as follows:

$$R^d_{\mathrm{esk}}(\mathcal{C},\mathcal{R}) = \frac{1}{m}\sum_{j=1}^{m} \max_{1\le i\le \ell} \mathrm{Sim}^d_{\mathrm{esk}}(c_i,r_j) \tag{7}$$

Finally, we define a unified measure, *i.e.*, F-measure, as follows:

$$F^d_{\mathrm{esk}}(\mathcal{C},\mathcal{R}) = \frac{(1+\beta^2)\times R_{\mathrm{esk}}(\mathcal{C},\mathcal{R})\times P_{\mathrm{esk}}(\mathcal{C},\mathcal{R})}{R_{\mathrm{esk}}(\mathcal{C},\mathcal{R})+\beta^2\times P_{\mathrm{esk}}(\mathcal{C},\mathcal{R})} \tag{8}$$

β is a cost parameter for R_{esk} and P_{esk}. β's value is selected depending on the evaluation task. Since summary should not miss important information given in the human reference, recall is more important than precision. Therefore,a large β will yield good results.

3.3 Extension for Multiple References

When multiple human references (correct answers) are available, we define a simple function for multiple references as follows:

$$F^{\mathrm{mean}}_{\mathrm{esk}}(\mathcal{C},R) = \frac{1}{n}\sum_{i=1}^{n} F_{\mathrm{esk}}(\mathcal{C},\mathcal{R}_i), \tag{9}$$

Here, equation (9) gives the average score. R indicates a set of references; $R = \{\mathcal{R}_1,\cdots,\mathcal{R}_n\}$.

4 Experimental Evaluation

To confirm and discuss the effectiveness of our method, we conducted an experimental evaluation using TSC-3 multiple document summarization evaluation data and our additional data.

4.1 Task and Evaluation Metrics in TSC-3

The task of TSC-3 is multiple document summarization. Participants were given a set of documents about a certain event and required to generate two different length summaries for the entire document set. The lengths were about 5% and 10% of the total number of characters in the document set, respectively. Thirty document sets were provided for the official run evaluation. There were ten participant systems; one provided by the TSC organizers as a baseline system.

The evaluation metric follows DUC's SEE evaluation scheme (Harman and Over, 2004). For each document set, one human subject makes a reference summary and uses it as a basis for evaluating ten system outputs. This human evaluation procedure consists of the following steps:

Step 1 For each reference sentence $r_j(\in \mathcal{R})$, repeat Steps 2 and 3.

Step 2 For r_j, the human assessor finds the most relevant sentence set S from the system output.

Step 3 The assessor assigns a score, $e(r_j, S)$, $0, 0.1, \cdots, 1.0$. 1.0 means perfect. in terms of how much of the content of r_j can be reproduced by using only sentences in S.

Step 4 Finally, the evaluation score of output $\mathcal{C}$ for reference $\mathcal{R}$ is defined $H(\mathcal{R}, \mathcal{C}) = \sum_j e(r_j, S)/|\mathcal{R}|$.

The final score of a system is calculated by applying the above procedure and normalized by the number of topics, *i.e.*, $\sum_{t=1}^{30} H(\mathcal{R}_t, \mathcal{C}_t)/30$. When multiple references $R(=\{\mathcal{R}1, \cdots, \mathcal{R}_n\})$ are available, the scores are given as follows: $H^{\text{mean}}(R, \mathcal{C}) = \sum_k H(\mathcal{R}_k, \mathcal{C})/|R|$.

4.2 Variation of Human Assessors

In TSC-3's official run evaluation, system outputs were compared with one human written reference summary for each topic. There were five topic sets and five human assessors (A-E in Table 2) for each topic set.

Before we use the one human written reference summary as the gold-standard-reference, to examine variations among human assessors, we prepared two additional human summaries for each topic sets.

Table 2: The relationship between topics and reference summary creators, *i.e.*, human assessors. $S(A)$ indicates a subject A's evaluation score for all systems for corresponding topics.

topic-ID	$\mathcal{D}_1$	$\mathcal{D}_2$	$\mathcal{D}_3$	$\mathcal{D}_{avg}$
1 - 6	S(A)	S(E)	S(C)	mean(S(A),S(E),S(C))
7 - 12	S(B)	S(A)	S(D)	mean(S(B),S(A),S(D))
13 - 18	S(C)	S(B)	S(E)	mean(S(C),S(B),S(E))
19 - 24	S(D)	S(C)	S(A)	mean(S(D),S(C),S(A))
25 - 30	S(E)	S(D)	S(B)	mean(S(E),S(D),S(B))

Table 3: Correlations between human judgments.

	correlation coefficient (r)				rank correlation coefficient (ρ)			
short								
	$\mathcal{D}_1$	$\mathcal{D}_2$	$\mathcal{D}_3$	$\mathcal{D}_{\text{avg}}$	$\mathcal{D}_1$	$\mathcal{D}_2$	$\mathcal{D}_3$	$\mathcal{D}_{\text{avg}}$
$\mathcal{D}_1$	1.00	.968	.902	.988	1.00	.976	.697	.988
$\mathcal{D}_2$	–	1.00	.910	.996	–	1.00	.733	.988
$\mathcal{D}_3$	–	–	1.00	.914	–	–	1.00	.758
$\mathcal{D}_{\text{avg}}$	–	–	–	1.00	–	–	–	1.00
long								
	$\mathcal{D}_1$	$\mathcal{D}_2$	$\mathcal{D}_3$	$\mathcal{D}_{\text{avg}}$	$\mathcal{D}_1$	$\mathcal{D}_2$	$\mathcal{D}_3$	$\mathcal{D}_{\text{avg}}$
$\mathcal{D}_1$	1.00	.908	.822	.964	1.00	.964	.939	.964
$\mathcal{D}_2$	–	1.00	.963	.987	–	1.00	.952	1.00
$\mathcal{D}_3$	–	–	1.00	.931	–	–	1.00	.932
$\mathcal{D}_{\text{avg}}$	–	–	–	1.00	–	–	–	1.00

Therefore, we obtained three reference summaries and evaluation results for each topic sets (Table 2).

Moreover, we prepared unified evaluation results of three human judgment as $\mathcal{D}_{\text{avg}}$, which is calculated as the average of three human scores.

The relationship between topics and human assessors is shown in Table 2. For example, subject B generates summaries and evaluates all systems for topics 7-12, 13-18 and 25-30 on $\mathcal{D}_1$, $\mathcal{D}_2$, and $\mathcal{D}_3$ respectively. Note that each human subject, A to E, was a retired professional journalist; that is, they shared a common background.

Table 3 shows the Pearson's correlation coefficient (r) and Spearman's rank correlation coefficient ρ for the human subjects. The results show that every pair has a high correlation. Therefore, changing the human subject has little influence as regards creating references and evaluating system summaries. The evaluation by human subjects is stable. This result agrees with DUC's additional evaluation results (Harman and Over, 2004). However, the behavior of the correlations between humans with different backgrounds is uncertain. The correlation might be fragile if we introduce a human subject whose background is different from the others.

4.3 Compared Automatic Evaluation Methods

We compared our method with ROUGE-N and ROUGE-L described below. We used only content words to calculate the ROUGE scores because the correlation coefficient decreased if we did not remove functional words.

WSK-based method

We use WSK instead of ESK in equation (6)-(8).

ROUGE-N

ROUGE-N is an N-gram-based evaluation measure defined as follows (Lin, 2004b):

$$\text{ROUGE-N}(\mathcal{C},\mathcal{R})=\frac{\sum_{\mathcal{S}\in\mathcal{R}}\sum_{\text{gram}_\text{N}\in\mathcal{S}}\text{Count}_\text{match}(\text{gram}_\text{N})}{\sum_{\mathcal{S}\in\mathcal{R}}\sum_{\text{gram}_\text{N}\in\mathcal{S}}\text{Count}(\text{gram}_\text{N})} \quad (10)$$

Here, $\text{Count}(\text{gram}_\text{N})$ is the number of an N-gram and $\text{Count}_\text{match}(\text{gram}_\text{N})$ denotes the number of n-gram co-occurrences in a system output and the reference.

ROUGE-S

ROUGE-S is an extension of ROUGE-2 defined as follows (Lin, 2004b):

$$\text{ROUGE-S}(\mathcal{C},\mathcal{R})=\frac{(1+\beta^2)\times R_\text{skip2}(\mathcal{C},\mathcal{R})\times P_\text{skip2}(\mathcal{C},\mathcal{R})}{R_\text{skip2}(\mathcal{C},\mathcal{R})+\beta^2 P_\text{skip2}(\mathcal{C},\mathcal{R})} \quad (11)$$

Where R_skip2 and P_skip2 are defined as follows:

$$\text{R}_\text{skip2}(\mathcal{C},\mathcal{R})=\frac{\text{Skip2}(\mathcal{C},\mathcal{R})}{\text{\# of skip bigram} \in \mathcal{R}} \quad (12)$$

$$\text{P}_\text{skip2}(\mathcal{C},\mathcal{R})=\frac{\text{Skip2}(\mathcal{C},\mathcal{R})}{\text{\# of skip bigram} \in \mathcal{C}} \quad (13)$$

Here, function Skip2 returns the number of skip-bi-grams that are common to $\mathcal{R}$ and $\mathcal{C}$.

ROUGE-SU

ROUGE-SU is an extension of ROUGE-S, which includes unigrams as a feature defined as follows (Lin, 2004b):

$$\text{ROUGE-SU}(\mathcal{C},\mathcal{R})=\frac{(1+\beta^2)\times R_\text{su}(\mathcal{C},\mathcal{R})\times P_\text{su}(\mathcal{C},\mathcal{R})}{R_\text{su}(\mathcal{C},\mathcal{R})+\beta^2 P_\text{su}(\mathcal{C},\mathcal{R})} \quad (14)$$

Where R_su and P_su are defined as follows:

$$\text{R}_\text{su}(\mathcal{C},\mathcal{R})=\frac{\text{SU}(\mathcal{C},\mathcal{R})}{\text{(\# of skip bigrams + \# of unigrams)} \in \mathcal{R}} \quad (15)$$

$$\text{P}_\text{su}(\mathcal{C},\mathcal{R})=\frac{\text{SU}(\mathcal{C},\mathcal{R})}{\text{(\# of skip bigrams + \# of unigrams)} \in \mathcal{C}} \quad (16)$$

Here, function SU returns the number of skip-bi-grams and unigrams that are common to $\mathcal{R}$ and $\mathcal{C}$.

ROUGE-L

ROUGE-L is an LCS-based evaluation measure defined as follows (Lin, 2004b):

$$\text{ROUGE-L}(\mathcal{C},\mathcal{R})=\frac{(1+\beta^2)\times R_\text{lcs}(\mathcal{C},\mathcal{R})\times P_\text{lcs}(\mathcal{C},\mathcal{R})}{R_\text{lcs}(\mathcal{C},\mathcal{R})+\beta^2 P_\text{lcs}(\mathcal{C},\mathcal{R})} \quad (17)$$

where R_lcs and P_lcs are defined as follows:

$$R_\text{lcs}(\mathcal{C},\mathcal{R})=\frac{1}{u}\sum_{r_i\in\mathcal{R}}\text{LCS}_\cup(r_i,\mathcal{C}) \quad (18)$$

$$P_\text{lcs}(\mathcal{C},\mathcal{R})=\frac{1}{v}\sum_{r_i\in\mathcal{R}}\text{LCS}_\cup(r_i,\mathcal{C}) \quad (19)$$

Here, $\text{LCS}_\cup(r_i,\mathcal{C})$ is the LCS score of the union longest common subsequence between reference sentences r_i and $\mathcal{C}$. u and v are the number of words contained in $\mathcal{R}$, and $\mathcal{C}$, respectively.

The multiple reference version of ROUGE-N S, SU or L, RN^mean, RS^mean, RSU^mean, RL^mean can be defined in accordance with equation (9).

4.4 Evaluation Measures

We evaluate automatic evaluation methods by using Pearson's correlation coefficient (r) and Spearman's rank correlation coefficient (ρ). Since we have ten systems, we make a vector $\mathbf{x}=(x_1,x_2,\cdots,x_i,\cdots,x_{10})$ from the results of an automatic evaluation. Here, $x_i=1/30\sum_{t=1}^{30} f(\mathcal{R}_t,\mathcal{C}_{i,t})$. $\mathcal{R}_t$ indicates a reference for the t-th topic. f indicates an automatic evaluation function such as F_esk, F_wsk, ROUGE-N, ROUGE-S, ROUGE-SU and ROUGE-L. Next, we make another vector $\mathbf{y}=(y_1,y_2,\cdots,y_i,\cdots,y_{10})$ from the human evaluation results. Here, $y_i=1/30\sum_{t=1}^{30} H(\mathcal{R}_t,\mathcal{C}_{i,t})$. Finally, we compute r and ρ between $\mathbf{x}$ and $\mathbf{y}$[6].

4.5 Evaluation Results and Discussions

Table 4 shows the evaluation results obtained by using Pearson's correlation coefficient r. Table 5 shows the evaluation results obtained with Spearman's rank correlation coefficient ρ. The ta-

[6]When using multiple references, functions f and H for making vectors $\mathbf{x}$ and $\mathbf{y}$ are substituted for f^mean and H^mean, respectively.

Table 4: Results obtained with Pearson's correlation coefficient."stop" indicates with stop word exclusion, "case" indicates w/o stop word exclusion.

bles show results obtained with and without stop word exclusion for the entire ROUGE family. For ROUGE-S and ROUGE-SU, we use three variations following (Lin, 2004b): the maximum skip distances are 4, 9 and infinity [7]. In addition, we examine $\beta = 2 \text{and} 3$ for the ESK-based and WSK-based methods. The decay parameter λ for F_{esk} and F_{wsk} is set at 0.5. We will discuss these parameter values in Section 4.6.

From the tables, ROUGE-N's r and ρ decrease monotonically with N when we exclude stop words. In most cases, the performance is improved by including stop words for N ($\geq$2). There is a large difference between ROUGE-1 and ROUGE-4. The ROUGE-S family is comparable to the ROUGE-SU family and their performance is close to ROUGE-1 without stop words and ROUGE-2 with stop words. ROUGE-L is better than both ROUGE-3 and ROUGE-4 but worse than ROUGE-1 or ROUGE-2.

On the other hand, F_{esk}'s correlation coefficients (r) do not change very much with respect to d. Even if d is set at 4, we can obtain good correlations. The behavior of rank correlation coefficients (ρ) is similar to the above. The difference between the ROUGE family and our method is particularly large for long summaries. By setting $d{=}2$, our method gives the good results. The optimal β is varied in the data sets. However, the difference between $\beta = 2$ and $\beta{=}3$ is small.

For ρ, our method outperforms the ROUGE family except for $\mathcal{D}_1$. By contrast, we can see $d{=}3$ or $d{=}4$ provided the best results. The differences between our method and the ROUGE family are larger than for r.

For both r and ρ, when multiple references are available, our method outperforms the ROUGE family.

Although ROUGE-1 sometimes provides better results than our method for short summaries, it has a critical problem; ROUGE-1 disregards word sequences making it easy to cheat. For instance, we can easily obtain a high ROUGE-1 score by using a sequence of high Inverse Document Frequency (IDF) words. Such a summary is incomprehensible and meaningless but we obtain a good ROUGE-1 score comparable to those of the top TSC-3 systems. By contrast, it is difficult to cheat other members of the ROUGE family or our method.

Our evaluation results imply that F_{esk} is robust

[7]We use β=1,2, and 3. However there are little difference among correlation coefficient regardless of β because the number of the words in reference and the number of the words in system output are almost the same.

Table 5: Results obtained with Spearman's correlation coefficient. "stop" indicates with stop word exclusion, "case" indicates w/o stop word exclusion.

	short								long

Table 6: Best scores for each data set.

Pearson's Correlation Coefficient

Length	$\mathcal{D}_1$	$\mathcal{D}_2$	$\mathcal{D}_3$	$\mathcal{D}_{\rm avg}$
short	.945	.946	.933	.967
(d, λ, β)	(2,0.7,2)	(2,0.7,4)	(2,0.1,3)	(2,0.7,3)
long	.941	.962	.971	.972
(d, λ, β)	(2,0.6,2)	(2,0.6,3)	(2,0.7,2)	(2,0.8,2)

Spearman's Rank Correlation Coefficient

Length	$\mathcal{D}_1$	$\mathcal{D}_2$	$\mathcal{D}_3$	$\mathcal{D}_{\rm avg}$
short	.964	.915	.915	.988
(d, λ, β)	(3,0.9,4)	(2,0.3,4)	(3,0.5,3)	(4,0.7,4)
long	.855	.927	.915	.939
(d, λ, β)	(2,0.8,4)	(3,0.5,2)	(2,0.5,4)	(2,0.8,3)

for d and length of summary and correlates closely with human evaluation results. Moreover, it includes no trivial way of obtaining a good score. These are significant advantages over ROUGE family. In addition, our method outperformed the WSK-based method in most cases. This result confirms the effectiveness of semantic information and the significant advantage of the ESK.

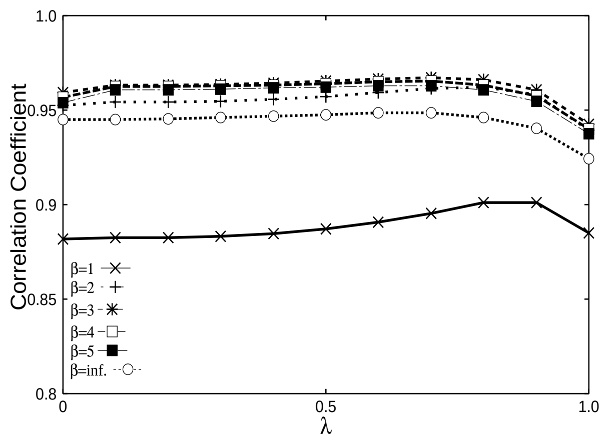
4.6 Effects of Parameters

Our method has three parameters, d, λ, and β. In this section, we discuss the effects of these parameters. Figure 1 shows r and ρ for various λ and β values with respect to $\mathcal{D}_{\rm avg}$. Note that we set d at 2 in the figure because the tendency is similar when we use other values, namely $d(=3 \text{ or } 4)$. From Fig. 1, we can see that $\beta{=}1$ is not good. With automatic summarization, 'precision' is not necessarily a good evaluation measure because highly redundant summaries may obtain a very high precision. On the other hand, 'recall' is not good when a system's output is redundant. Therefore, equal treatment of 'precision' and 'recall' does not give a good evaluation measure. The figure shows that $\beta{=}2, 3$ and 5 are good for r and $\beta{=}3, 4, 5$ and infinity are good for ρ.

Moreover, we can see a significant differences between $\lambda = 1$ and others from the figure. This implies an advantage of our method compared to ROUGE-S and ROUGE-SU, which cannot handle decay factor for skip-n-grams.

From Fig. 1, we can see that ρ is more sensitive to β than r. Here, $\beta{=}3, 4, 5$ and infinity obtained the best results. $\beta{=}1$ was again the worst. This result indicates that we have to determine the parameter value properly for different tasks. λ does not greatly affect the correlation for $d{=}3, 4, 5$ and infinity as regards the middle range.

Table 6 show the best results when we examined all parameter combinations. In the brackets, we show the best settings of these parameter combinations. For r, $d{=}\ 2$ provides the best result and middle range λ and $\beta{=}2$ or 3 are good in most cases. On the other hand, the best settings for ρ vary with



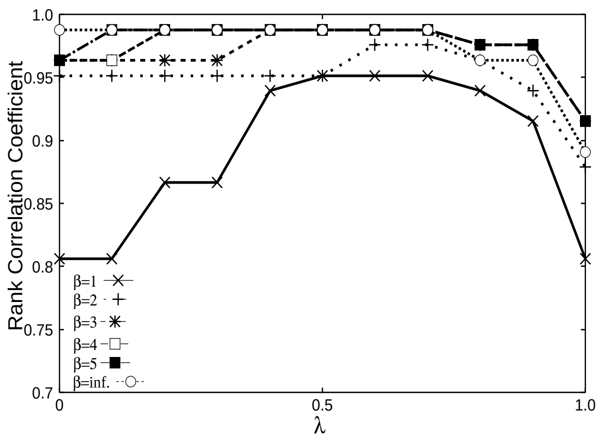


Figure 1: Correlation coefficients for various values of β and λ on $\mathcal{D}_{\text{avg}}$.

the data set. $d=2$ is not always good for ρ.

In short, we can see that the decay parameter for skips is significant and long skip-n-grams are effective especially ρ.

These results show that our method has an advantage over the ROUGE family. In addition, our method is robust and sufficiently good even if close attention is not paid to the parameters.

5 Conclusion

In this paper, we described an automatic evaluation method based on the ESK, which is a method for measuring the similarities between texts based on sequences of words and word senses. Our experiments showed that our method is comparable to ROUGE family for short summaries and outperforms it for long summaries. In order to prove that our method is language independent, we will conduct an experimental evaluation by using DUC's evaluation data. We believe that our method will also be useful for other natural language generation tasks. We are now planning to apply our method to an evaluation of machine translation.

Abstract

We approached the problem as *learning how to order documents* by estimated relevance with respect to a user query. Our *support vector machines* based classifier learns from the relevance judgments available with the standard test collections and generalizes to *new, previously unseen queries*. For this, we have designed a representation scheme, which is based on the *discrete* representation of the local (*lw*) and global (*gw*) weighting functions, thus is capable of reproducing and enhancing the properties of such popular ranking functions as *tf.idf*, *BM25* or those based on language models. Our tests with the standard test collections have demonstrated the capability of our approach to *achieve the performance of the best known scoring functions* solely from the labeled examples and without taking advantage of knowing those functions or their important properties or parameters.

1. Introduction

Our work is motivated by the objective to bring closer numerous achievements in the domains of machine learning and classification to the classical task of ad-hoc information retrieval (IR), which is ordering documents by the estimated degree of relevance to a given query. Although used with striking success for text categorization, classification-based approaches (e.g. those based on support vector machines, Joachims, 2001) have been relatively abandoned when trying to improve ad hoc retrieval in favor of empirical (e.g. vector space, Salton & McGill, 1983) or generative (e.g. language models; Zhai & Lafferty 2001; Song & Croft; 1999), which produce a ranking function that gives each document a score, rather than trying to learn a classifier that would help to discriminate between relevant and irrelevant documents and order them accordingly. A generative model needs to make assumptions that the query and document words are sampled from the same underlying distributions and that the distributions have certain forms, which entail specific smoothing techniques (e.g. popular Dirichlet-prior). A discriminative (classifier-based) model, on the other side, does not need to make any assumptions about the forms of the underlying distributions or the criteria for the relevance but instead, learns to predict to which class a certain pattern (document) belongs to based on the labeled training examples. Thus, an important advantage of a discriminative approach for the information retrieval task, is its ability to explicitly utilize the relevance judgments existing with standard test collections in order to train the IR algorithms and possibly enhance retrieval accuracy for the new (unseen) queries.

Cohen, Shapire and Singer (1999) noted the differences between ordering and classification and presented a two-stage model to learn ordering. The first stage learns a classifier for preference relations between objects using any suitable learning mechanism (e.g. support vector machines; Vapnik, 1998). The second stage converts preference relations into a rank order. Although the conversion may be NP complete in a general case, they presented efficient approximations. We limited our first study reported here to linear classifiers, in which conversion can be performed by simple ordering according to the score of each document. However, approaching the problem as "learning how to order things" allowed us to design our sampling and training mechanisms in a novel and, we believe, more powerful way.

Our classifier learns how to compare every pair of documents with respect to a given query, based on the relevance indicating features that the documents may have. As it is commonly done in information retrieval, the features are derived from the word overlap between the query and documents. According to Nallapati (2004), the earliest formulation of the classic IR problem as a classification (discrimination) problem was suggested by Robertson and Sparck Jones (1976), however performed well only when the relevance judgments were available for the same query but not generalizing well to new queries. Fuhr and Buckley (1991) used polynomial regression to estimate the coefficients in a linear scoring function combining such well-known features as a weighted term frequency, document length and query length. They tested their "description-oriented" approach on the standard small-scale collections (Cranfield, NPL, INSPEC, CISI, CACM) to achieve the relative change in the average precision ranging from -17%

to + 33% depending on the collection tested and the implementation parameters. Gey (1994) applied logistic regression in a similar setting with the following results: Cranfield +12%, CACM +7.9%, CISI -4.4%, however he did not test them on new (unseen by the algorithm) queries, hypothesizing that splitting documents into training and testing collections would not be possible since “a large number of queries is necessary in order to train for a decent logistic regression approach to document retrieval.” Instead, he applied a regression trained on Cranfield to CISI collection but with a negative effect.

Recently, the approaches based on learning have reported several important breakthroughs. Fan et al. (2004) applied genetic programming in order to learn how to combine various terms into the optimal ranking function that outperformed the popular Okapi formula on robust retrieval test collection. Nallapati (2004) made a strong argument in favor of discriminative models and trained an SVM-based classifier to combine 6 different components (terms) from the popular ranking functions (such as tf.idf and language models) to achieve better than the language model performance in 2 out of 16 test cases (figure 3 in Nallapati, 2004), not statistically distinguishable in 8 cases and only 80% of the best performance in 6 cases. There have been studies using past relevance judgements to optimize retrieval. For example, Joachims (2002) applied Support Vector Machines to learn linear ranking function from user click-throughs while interfacing with a search engine.

In this study, we have developed a representation scheme, which is based on the discretization of the *global* (corpus statistics) and *local* (document statistics) weighting of term overlaps between queries and documents. We have empirically shown that this representation is flexible enough to learn the properties of the popular ranking functions: tf.idf, BM25 and the language models. The major difference of our work from Fan et al. (2004) or Nallapati (2004) or works on fusion (e.g. Vogt & Cottrell, 1999) is that *we did not try to combine several known ranking functions (or their separate terms) into one, but rather we learn the weighting functions directly through discretization.*

Discretization allows representing a continuous function by a set of values at certain points. These values are learned by a machine learning technique to optimize certain criteria, e.g. average precision.

Another important motivation behind using *discretization* was to design a representation with high dimensionality of features in order to combine our representation scheme with Support Vector Machines (SVM) (Vapnik, 1998), which are known to work well with a large number of features. SVM contains a large class of neural nets, radial margin separation (RBF) nets, and polynomial classifiers as special cases. They have been delivering superior performance in classification tasks in general domains, e.g. in face recognition (Hearst, 1998), and in text categorization (Joachims, 2001).

Another important distinction of this work from the prior research is that we train our classifier not to predict the absolute relevance of a document *d* with respect to a query *q*, but rather to predict which of the two documents *d1, d2* is more relevant to the query *q*. The motivation for this distinction was that all the popular evaluation metrics in information retrieval (e.g. average precision) are based on document ranking rather than classification accuracy. This affected our specially designed sampling procedure which we empirically discovered to be crucial for successful learning.

We have also empirically established that our combination of the representation scheme, learning mechanism and sampling allows learning from the past relevance judgments in order to successfully generalize to the new (unseen) queries. When the representation was created without any knowledge of the top ranking functions and their parameters, *our approach reached the known top performance solely through the learning process*. When our representation was taking advantage of functions that are known to perform well and their parameters, the resulting combination was *able to slightly exceed the top performance on large test collections*. The next section formalizes our Discretization Based Learning (DBL) approach to Information Retrieval, followed by empirical results and conclusions.

2. Formalization Of Our Approach

2.1 Query and Document Representation

We limit our representation to the so called *lw.gw* *class*: $R(q, d) = \sum_{t \subset q} L(tf(t,d), d)G(t)$,

where *L*, local weighting, is the function of the number of occurrences of the term in the document *tf*, possibly combined with the other document statistics, e.g. word length. *G(t)*, global weighting, can be any collection level statistic of the term. For example, in the classical *tf.idf* formula *L(tf, d) = tf / |d|*, where *tf* is the number of occurrences of the term *t* in the document, |*d*| is the length of the document vector and *G(t) = log (N / df(t))*, where *df(t)* is the total number of documents in the collection that have term *t* and *N* is the total number of documents.

Without loss of generality it may also be extended to handle a number of occurrences of the term in the query, but we omit it here in our formalization for simplicity. *Lw.gw* class includes the BM25 Okapi ranking function which performs well on TREC collections (Robertson et al., 1996). It can be shown that many of the recently introduced language models fall into that category as well, specifically the best performing in TREC ad hoc tests Dirichlet smoothing, Jelinek Mercer smoothing, and Absolute Discounting approaches can be represented that way (see equation 6 and table I in Zhai & Lafferty, 2001). An *lw.gw* representation of Jelinek Mercer smoothing was used in Nallapati (2004). It has been known for a long time that the shapes of the global and local weighting functions can *dramatically affect the precision* in standard test collections because it in fact determines the difference between such formulas as *tf.idf*, *bm25* and language models. *However, we are not aware of any attempts to learn those shapes directly from the labeled examples, which we performed in this study.*

2.2 Intuition behind the discretization-based learning

The intuition behind discretization approach is to represent a function by values at the finite number of points. Then, the optimal shape of the function can be learned by using one of the machine learning techniques. Our discretization based learning (DBL) approach to information retrieval learns how important each class of an occurrence of a query term in a document. For example, in some very "primitive" DBL approach, we can define two classes: Class S ("strong"), containing all multiple occurrences of a rare query term (e.g. "discretization") in a document and Class W ("weak"), containing all single occurrences of a frequent term (e.g. "information"). Then, the machine learning technique should discover that the occurrences of Class S are much stronger indicators of relevance than the occurrences of Class W. In the DBL implementation presented in this paper, each occurrence of a query term is assigned to a class (called *bin*) based on the term document frequency in the collection (*df*) and the number of occurrences within the document (*tf*). The bin determines the weight of the contribution of each occurrence of the query term in the ranking score. Thus, the relevance score is just the weighted sum of the numbers of occurrences within each bin. The other way of looking at it is that the score is produced by a linear classifier, where the total number of occurrences within each bin serves as the feature value. *By learning the optimal weights, a linear classifier effectively learns the optimal shapes of the global (gw) and local (lw) weighting functions. By learning the discrimination properties of each bin, rather than separate word terms, DBL method allows generalization to new queries.*

2.3 Discretizing global weighting

We discretized the shape of the G*(t)* function by assigning each term to its global weighting bin *g*, which is an integer number in the *[1, |B|]* range, |*B*| is the total number of global weighting bins. The assignment of the term *t* to its global weighting bin *g(t)* is performed on the log linear scale according to the document frequency *df* of the term:

$$g(t) = \{|B|(1 - \frac{\log(df(t))}{\log(N)})\} \qquad (1)$$

where *N* is the total number of documents, {.} stands for rounding down to the nearest integer. The logarithmic scale allows more even term distribution among bins than simple linear assignment, which is desirable for more efficient learning. It is motivated by a typical histogram of *df(t)* distribution, which looks much more uniform in a logarithmic scale. It is important to note that it does not have anything to do with the *log* function in the classical *idf* weighting and that the formula for *g(t)* does not produce any weights but only assigns each term occurrence to a specific bin based on the term document frequency. The weights are later trained and effectively define any shape of global weighting, including such simple functions tried in the prior heuristic explorations as logarithm, square root, reciprocal and others.

2.4 Discretizing local weighting

Similarly to the global weighting, we assigned each occurrence of a term to its local weighting bin *l*, but this time by simply capping *tf* at the total number of local weighting bins |*L*|:

$$l\,(tf(t,d), d) = min(\,tf\,(t,d), |L|)\,) \qquad (1a)$$

Let's note that this particular representation does not really need rounding since *tf* is already a positive integer. However, in a more general case, *tf* can be normalized by document length (as is done in BM25 and language models) and thus local weighting would become a continuous function. It is important to note that our discrete representation does not ignore the occurrences above |*L*| but simply treats them the same way as *tf* = |*L*|. The intuition behind capping is that increasing *tf* above certain value (|L|) would not typically indicate the higher relevance of the document. Typically, a certain number of occurrences is enough to indicate the presence of the relevant passage. Please note again that this bin assignment does not assign any heuristic weights to the term occurrences.

2.5 Final discretized ranking function

The bin assignments based on *tf* and *df* specified in sections 2.3 and 2.4 are straightforward and do not involve any significant "feature engineering." Each occurrence of a query term in a document corresponds to a local/global bin combination *(g, l)*. Each *(g,l)* combination determines a feature in a vector representing a document-query pair ***f****(d, q)* and is denoted below as *f(d, q) [g , l]* . The dimensionality of the feature space is |*L*| x |*B*|. E.g. for 8 local weighting bins and 10 global weighting bins we would deal with the vector size of 80. A feature vector ***f****(d, q)* represents each document *d* with respect to query *q*. The value of each feature in the vector is just the number of the term occurrences assigned to the pair of bins *(g, l):*

$$f\,(d,q)\,[g\,,l] \;=\; \sum_{t \subset q,\, g(t)=g,\, l(t,d)=l} 1 \qquad (2)$$

Since our features capture local (tf) and global (df) term occurrence information, in order to represent a ranking function, we can simply use the dot product between the feature vector and the vector of learned optimal weights **w**:

R(q, d) = **w** * ***f*** *(d, q).*

Ideally, the learning mechanism should assign higher weights to the more important bin combinations (e.g. multiple occurrence of a rare term) and low weights to the less important combinations (e.g. single occurrence of a common term). The exact learned values determine the optimal shape of global and local weighting.

We still can make the representation more powerful by considering the learned weights *w[g, l]* not the replacements but rather the adjustments to some other chosen global *G (t)* and local *L (t, d)* weighting functions:

$$f(d, q)[g, l] = \sum_{t \subset q,\, g(t)=g,\, l(tf(t,d),d)=l} L(t,d)G(t) \qquad (2a)$$

We define the specific choice of global *G()* and local *L()* weighting functions as *starting ranking function (SRF)*. When all the bin weights *w[g, l]* are set to *1*, our ranking function is the same as its *SRF*. The learning process finds the optimal values for *w[g, l]* for the collection of training queries and their relevance judgments, thus adjusting the important shapes of the global and local weighting to achieve better accuracy. *SRF* can be chosen from one of the known to perform well ranking functions (e.g. *tf.idf* or *BM25* or based on language models) to take advantage of the fact that those formulas and their optimal parameters on the standard test collections are known for the researchers. Alternatively, we can set *SRF* to the constant value (e.g. *1* in formula 2), thus not taking advantage of any of the prior empirical investigations and to see if our framework is able to learn reasonable (or even top-notch) performance purely from labeled examples. Below, we describe our experiments with each approach.

Since the score is linear with respect to the feature values, we can train the weights **w** as a linear classifier that predicts the preference relation between pairs of documents with respect to the given query. Document *d1* is more likely to be relevant (has a higher score) than document *d2* iff ***f****(d1, q)* * ***w*** > ***f****(d1, q)* * ***w***. An important advantage of using a linear classifier is that rank ordering of documents according to the learned pairwise preferences can be simply performed by ordering according to the linear score. Please refer to Cohen et al. (1999) for the ordering algorithms in a more general non linear case.

We chose support vector machines (SVM) for training the classifier weights *w[g, l]* since they are known to work well with large numbers of features, ranging in our experiments from 8 to 512, depending on the number of bins. For our empirical tests, we used the SVMLight package freely available for academic research from Joachims (2001). We preserved the default parameters coming with version V6.01. Although SVMLight package allows learning ranking, we opted for training it as a classifier to retain more control over sampling, which we found crucial for successful learning, as described in the section below.

2.6 Sampling

Since we were training a classifier to predict preference relations, but not the absolute value of relevance, we trained on the differences between feature vectors. Thus, for each selected (sampled) pair of documents (*dr, di*), such that *dr* is a relevant document and *di* is irrelevant, the classifier was presented with a positive example created from the vector of differences of features $\boldsymbol{f_p} = \boldsymbol{f}(q, dr) - \boldsymbol{f}(q, di)$, and also with the negative example as the inverse of it: $\boldsymbol{f_n} = \boldsymbol{f}(q, di) - \boldsymbol{f}(q, dr)$. This approach also balances positive and negative examples.

We also informally experimented with training on absolute relevance judgments, similar to the prior work mentioned in the Introduction but obtained much worse results. We explain it by the fact that relative judgments (pairwise comparisons) are more generalizable to new queries than absolute judgments (relevant/irrelevant). This may explain prior difficulties with applying discriminative approaches mentioned in our Introduction.

Since presenting all pairs to the training mechanism would be overwhelming, we performed pseudo-random sampling of documents by the following intuitive consideration. Since it is more efficient to present the classifier with the pairs from the documents that are likely to more strongly affect the performance metric (average precision), we first pre-ordered the retrieved documents by any of the reasonably well-performing scoring function (e.g. *tf.idf*) and limited the sample of documents to the top *1000*. Then, for each query, each known relevant document *dr* from that subset was selected and "paired" with a certain number of randomly selected irrelevant documents. This number was linearly decreasing with the position of the relevant document in the pre-order. Thus, the higher the document was positioned in the pre-order, the more times it was selected for pairing (training). This placed more emphasis at correctly classifying the more important document pairs in the average precision computation. Again, without the correct emphasis during sampling the obtained results were much weaker. However, the choice of the ranking function to perform pre-order was found to be not important: virtually the same results were obtained using *tf.idf* or bm25 or language models.

3. Empirical Evaluation

3.1 Empirical setup

We used the TREC, Disks 1 and 2, collections to test our framework. We used topics 101-150 for training and 151-200 for testing and vice-versa. For indexing, we used the Lemur package (Kraaij et al., 2003), with the default set of parameters, and no stop word removal or stemming. Although those procedures are generally beneficial for accuracy, it is also known that they do not significantly interfere with testing various ranking functions and thus are omitted in many studies to allow easier replication.

We used only topic titles for queries, as it is commonly done in experiments, e.g. in Nallapati (2004). We used the most popular average (non-interpolated) precision as our performance metric, computed by the script included with the Lemur toolkit (later verified by trec_eval). The characteristics of the collection after indexing are shown in Table 1. We also reproduced results similar to the reported below on the Disk 3 collection and topics 101-150, but did not include them in this paper due to size limitations.

Collection	TREC Disks 1 and 2
Number of documents	741,863
Number of terms	325,059,876
Number of unique terms	697,610
Average doc. length	438
Topics	101-200

Table 1. The characteristics of the test collection: TREC Disks 1,2

3.2 The baseline

In this study, we were interested exclusively in the improvements due to learning, thus still staying within the "bag of words" paradigm. Although many enhancements can be easily combined within our framework, we limited our search for the baseline performance to "bag of words" techniques to avoid unfair comparison. We used the results reported in Nallapati (2004) as guidance and verified that the best performing language model on this test collection was the one based on the Dirichlet smoothing with $\mu = 1900$. Our average precision was lower (*0.205* vs. *0.256*), most likely due to the different indexing parameters, stemming or using a different stopword list. By experimenting with the other ranking functions and their parameters, we noticed that the implementation of *BM25,* available in Lemur, provided almost identical performance (*0.204*). Its ranking function is $BM25(tf, df) = tf / (tf + K^* (1 - b + b * |d| / |d|_a) * \log (N / (df + .5))$, where $|d|$ is the document word length and $|d|_a$ is its average across all documents. The optimal parameter values were close to the default $K = 1.0$ and $b = .5$. We noticed that the query term frequency components could be ignored without any noticeable loss of precision. This may be because the TREC topic titles are short and the words are very rarely repeated in the queries. Since the difference between this ranking function and the optimal from the available language models was negligible we selected the former as both our baseline and also as the starting ranking function (SRF) in our experiments. For simplicity, we call it simply *BM25* throughout our paper.

3.3 Discretization accuracy

Before testing the learning mechanism, we verified that the loss due to discretization is minimal and thus the approach is capable of capturing global and local weighting. For this, we discretized our baseline BM25 formula replacing each score contribution of the occurrence of a term $G(t)L(t,d) = BM25(t, d)$ with its average across all other occurrences within the same bin combination *[g, l]*, which is determined by the formulas 1 and 1a. We discovered that for the $|B| \times |L| = 8 \times 8$ configuration, the loss in average precision did not exceed *2%* (relatively). This demonstrates that the *G(t)L(t,d)* ranking functions can be discretized (replaced by values at certain points) at this level of granularity without losing much accuracy. We also verified that the weights *w[g, l]* can affect the performance significantly: when we set them to random numbers in the [0,1] range, the performance dropped by 50% relatively to the baseline.

3.4 Ability to achieve top performance from scratch

First, we were curious to see if our framework can learn reasonable performance without taking advantage of our knowledge of the top ranking functions and their parameters. For this, we set our starting ranking function (SRF) to a constant value, thus using only the minimum out of the empirical knowledge and theoretical models developed by information retrieval researchers during several decades: specifically only the fact that relevance can be predicted by tf and df

Table 2 shows performance for the 16 x 8 combination of bins. It can be seen that our approach has reached 90-100% of the top performance (baseline) solely through the learning process. The *original* performance is the one obtained by assigning all the classifier weights to 1. It can be seen that the topics 151-200 are more amenable for the technique that is why they show better recovery when used as a test set even when the training set 101-150 recovers only 90%. In order to evaluate if more training data can help, we also ran tests using 90 topics for training and the remaining 10 for testing. We ran 10 tests each time using 10 different sequential topics for testing and averaged our results. In this case, *the averaged performance was completely restored to the baseline level* with the mean difference in precision across test queries +0.5% and 1% standard deviation of the mean.

151-200	.179	.174	+1.8 (+/- 1.0)	.210	.204	+3.2 (+/- 1.3)

Table 3. Surpassing the baseline performance. 8 x 8 bin design.

numbers of bins. Learning on 101-150 and testing on 151-200.

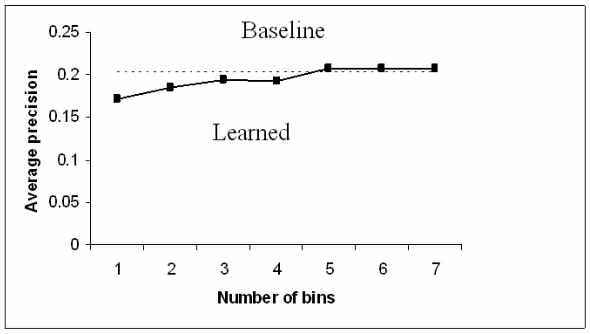

Figure 2. Learning global weighting for various numbers of bins. Learning on 101-150 and testing on 151-200.

We believe this is a remarkable result considering the difficulties that the prior learning based approaches had with the classical information retrieval task. We attribute our success to both higher flexibility and generalizability of our discrete representation. We also varied the number of bins to evaluate the effect of granularity of representation. Figures 1 and 2 demonstrate that 8 bins suffice for both global and local weighting. Higher numbers did not result in noticeable improvements.

When the same set was used for training and testing the result obviously overestimates the learning capability of the framework. However, it also gives the upper bound of performance of a discretized *gw.lw* combination assuming that the loss due to discretization is negligible which can be easily attained by using sufficiently large number of bins. *Thus, the results indicate that gw.lw, which includes practically all the popular "bag of words" ranking formulas such as tf.idf, BM25 or language models, has almost reached its upper limit and other classes of representations and ranking formulas need to be explored to attempt greater improvements.*

Figure 2. Learning global weighting for various numbers of bins. Learning on 101-150 and testing on 151-200.

3.5 Ability to surpass top performance

In order to test whether our approach can exceed the baseline performance we set *BM25* to be our starting ranking function (SRF). Thus, in this case:

$G(t) = \log (N / (df + .5))$ (6)

$L(tf, d) = tf / (tf + K * (1 - b + b * |d| / |d|_a)$

Table 3 shows performance for the 8 by 8 bin design. Although the improvement is relatively small (2-3%) it is still statistically significant at the level of alpha < 0.1, when the paired t-test was performed. The value in "*% change*" column shows the mean % improvement across all the queries and its standard deviation. It may differ from the % change of the mean performance since there is wide variability in the performance across queries but smaller variability in the improvement.

We believe even such a small improvement is remarkable considering the amount of attention the researches have paid to optimizing the ranking functions for this specific data set which has been available for more than seven years. A number of recent studies reported comparable improvements on the same test collection by using more elaborate modeling or richer representations. Of course the improvement due to the techniques such as those based on n-grams, document structures, natural language processing or query expansion can possibly achieve even better results. However in this study we deliberately limited our focus to the "bags of words."

3.6 Shape of optimal local weighting

Figure 3 shows the optimal shape of the local weighting function *L(tf)* learned on entire set of 100 topics and plotted against their counterparts of *BM25(t, d) = tf / (tf + 1)* and *tf.idf(t, d) = tf* for comparison. For plotting purposes, we assumed that the document length was equal to its average. The values were linearly scaled to meet at the *tf = 8* point. It is easy to observe that the behavior of the optimal function is much closer to BM25 than to *tf.idf*, which explains the good performance of the former on this test set.

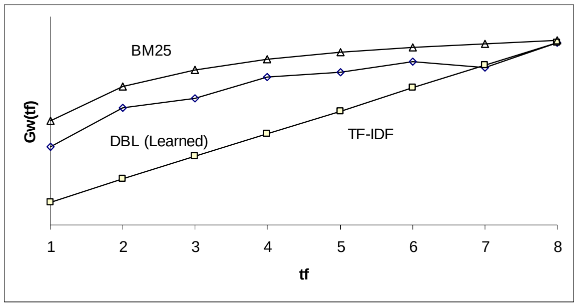

Figure 3. Learned optimal shape of local weighting.

3.7 Shape of optimal global weighting

Figure 4 shows the optimal shape of the global weighting function *G(t)* learned on the entire set of 100 topics with $|B| = 32$ plotted in logarithmic scale against the popular *idf* weighting used in both *tf.idf* and BM25. The lower end of the X-axis (*log10 df < 2*) corresponds to very infrequent terms, so the learned weights may not be very informative since the classifier encounters fewer occurrences of them and their impact on the overall accuracy is small. In the mid range (5,000 – 10,000), the optimal weights are higher than idf, which indicates that the latter has an overly steep shape to discount high frequency terms. A more detailed interpretation of the optimal shape may require further investigation.

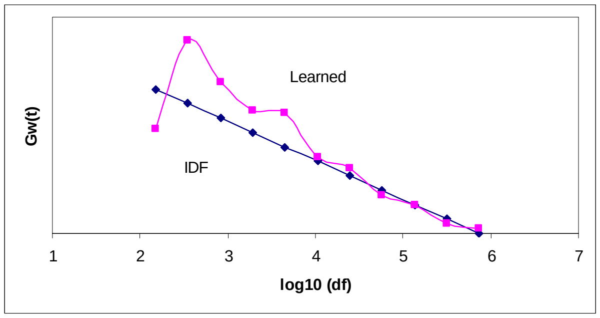

Figure 4. Learned optimal shape of global weighting G(t).

4. Conclusions

We explored learning how to rank documents with respect to a given query using linear Support Vector Machines and discretization-based representation. Our approach represents a family of discriminative approaches, currently studied much less than heuristic (*tf.idf*, *bm25*) or generative approaches (language models). Our experiments indicate that *learning from relevant judgments available with the standard test collections and generalizing to new queries is not only feasible but can be a source of improvement.* When tested with a popular standard collection, our approach achieved the performance of the best well-known techniques (BM25 and language models), which have been developed as a result of extensive past experiments and elaborate theoretical modeling. When combined with the best performing ranking functions, our approach added a small (2-3%), but statistically significant, improvement.

Although practical significance of this study may be limited at the moment since it does not demonstrate a dramatic increase in retrieval performance in large test collections, we believe our findings have important theoretical contributions since they indicate that the power of discriminative approach is comparable to the best known analytical or heuristic apporaches. This work also lays the foundation for extending the discriminative approach to "richer" representations, such as those using word n-grams, grammatical relations between words, and the structure of documents.

Our results also indicate that *gw.lw* family, which includes practically all the popular "bag of words" ranking formulas such as tf.idf, BM25 or language models, has almost reached its upper limit and other classes of representations and ranking formulas need to be explored in order to accomplish significant performance break-troughs.

Of course, using only few test cases (topics sets and collections) is a limitation of this current study, which we are going to address in our future research. We view our approach as a complement, rather than competitive, to the analytical approaches such as language models. Our approach can be also used as an explorative tool in order to identify important relevance-indicating features, which can be later modeled analytically. We believe that our work and the ones referred in this paper may bring many of the achievements made in a more general area of classification and machine learning closer to the task of rank ordered information retrieval, thus making retrieval engines more helpful in reducing the information overload and meeting people's needs.

Abstract

We describe stochastic models of local phrase movement that can be incorporated into a Statistical Machine Translation (SMT) system. These models provide properly formulated, non-deficient, probability distributions over reordered phrase sequences. They are implemented by Weighted Finite State Transducers. We describe EM-style parameter re-estimation procedures based on phrase alignment under the complete translation model incorporating reordering. Our experiments show that the reordering model yields substantial improvements in translation performance on Arabic-to-English and Chinese-to-English MT tasks. We also show that the procedure scales as the bitext size is increased.

1 Introduction

Word and Phrase Reordering is a crucial component of Statistical Machine Translation (SMT) systems. However allowing reordering in translation is computationally expensive and in some cases even provably NP-complete (Knight, 1999). Therefore any translation scheme that incorporates reordering must necessarily balance model complexity against the ability to realize the model without approximation. In this paper our goal is to formulate models of local phrase reordering in such a way that they can be embedded inside a generative phrase-based model of translation (Kumar et al., 2005). Although this model of reordering is somewhat limited and cannot capture all possible phrase movement, it forms a proper parameterized probability distribution over reorderings of phrase sequences. We show that with this model it is possible to perform Maximum A Posteriori (MAP) decoding (with pruning) and Expectation Maximization (EM) style re-estimation of model parameters over large bitext collections.

We now discuss prior work on word and phrase reordering in translation. We focus on SMT systems that do not require phrases to form syntactic constituents.

The IBM translation models (Brown et al., 1993) describe word reordering via a distortion model defined over word positions within sentence pairs. The Alignment Template Model (Och et al., 1999) uses phrases rather than words as the basis for translation, and defines movement at the level of phrases. Phrase reordering is modeled as a first order Markov process with a single parameter that controls the degree of movement.

Our current work is inspired by the block (phrase-pair) orientation model introduced by Tillmann (2004) in which reordering allows neighboring blocks to swap. This is described as a sequence of orientations (left, right, neutral) relative to the monotone block order. Model parameters are block-specific and estimated over word aligned trained bitext using simple heuristics.

Other researchers (Vogel, 2003; Zens and Ney, 2003; Zens et al., 2004) have reported performance gains in translation by allowing deviations from monotone word and phrase order. In these cases,

Figure 1: TTM generative translation process; here, $I = 9, K = 5, R = 7, J = 9$.

reordering is not governed by an explicit probabilistic model over reordered phrases; a language model is employed to select the translation hypothesis. We also note the prior work of Wu (1996), closely related to Tillmann's model.

2 The WFST Reordering Model

The Translation Template Model (TTM) is a generative model of phrase-based translation (Brown et al., 1993). Bitext is described via a stochastic process that generates source (English) sentences and transforms them into target (French) sentences (Fig 1 and Eqn 1).

$$\begin{aligned}
&P(f_1^J, v_1^R, d_0^K, c_0^K, y_1^K, x_1^K, u_1^K, K, e_1^I) = \\
&\quad P(e_1^I)\cdot \\
&\qquad \textit{Source Language Model} \;\; G \\
&\quad P(u_1^K, K|e_1^I)\cdot \\
&\qquad \textit{Source Phrase Segmentation} \;\; W \\
&\quad P(x_1^K|u_1^K, K, e_1^I)\cdot \\
&\qquad \textit{Phrase Translation and Reordering} \;\; R \\
&\quad P(v_1^R, d_0^K, c_0^K, y_1^K|x_1^K, u_1^K, K, e_1^I)\cdot \\
&\qquad \textit{Target Phrase Insertion} \;\; \Phi \\
&\quad P(f_1^J|v_1^R, d_0^K, c_0^K, y_1^K, x_1^K, u_1^K, K, e_1^I) \\
&\qquad \textit{Target Phrase Segmentation} \;\; \Omega
\end{aligned} \tag{1}$$

The TTM relies on a Phrase-Pair Inventory (PPI) consisting of target language phrases and their source language translations. Translation is modeled via component distributions realized as WFSTs (Fig 1 and Eqn 1) : Source Language Model (G), Source Phrase Segmentation (W), Phrase Translation and Reordering (R), Target Phrase Insertion (Φ), and Target Phrase Segmentation (Ω) (Kumar et al., 2005).

TTM Reordering Previously, the TTM was formulated with reordering prior to translation; here, we perform reordering of phrase sequences following translation. Reordering prior to translation was found to be memory intensive and unwieldy (Kumar et al., 2005). In contrast, we will show that the current model can be used for both phrase alignment and translation.

2.1 The Phrase Reordering Model

We now describe two WFSTs that allow local reordering within phrase sequences. The simplest allows swapping of adjacent phrases. The second allows phrase movement within a three phrase window. Our formulation ensures that the overall model provides a proper parameterized probability distribution over reordered phrase sequences; we emphasize that the resulting distribution is not degenerate.

Phrase reordering (Fig 2) takes as its input a French phrase sequence in English phrase order $x_1, x_2, ..., x_K$. This is then reordered into French phrase order $y_1, y_2, ..., y_K$. Note that words within phrases are not affected.

We make the following conditional independence assumption:

$$P(y_1^K|x_1^K, u_1^K, K, e_1^I) = P(y_1^K|x_1^K, u_1^K). \tag{2}$$

Given an input phrase sequence x_1^K we now associate a unique *jump sequence* b_1^K with each permissible output phrase sequence y_1^K. The jump b_k measures the displacement of the k^{th} phrase x_k, i.e.

$$x_k \rightarrow y_{k+b_k}, k \in \{1, 2, ..., K\}. \tag{3}$$

The jump sequence b_1^K is constructed such that y_1^K is a permutation of x_1^K. This is enforced by constructing all models so that $\sum_{k=1}^K b_k = 0$.

We now redefine the model in terms of the jump sequence

$$\begin{aligned}
&P(y_1^K|x_1^K, u_1^K) \\
&= \begin{cases} P(b_1^K|x_1^K, u_1^K) & y_{k+b_k} = x_k \; \forall k \\ 0 & \text{otherwise}, \end{cases}
\end{aligned} \tag{4}$$

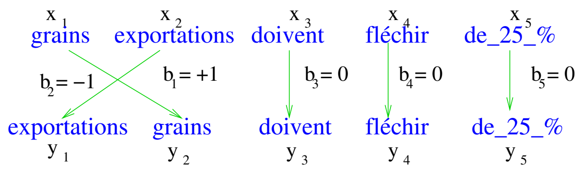

Figure 2: Phrase reordering and jump sequence.

where y_1^K is determined by x_1^K and b_1^K.

Each jump b_k depends on the phrase-pair (x_k, u_k) and preceding jumps b_1^{k-1}

$$P(b_1^K|x_1^K, u_1^K) = \prod_{k=1}^{K} P(b_k|x_k, u_k, \phi_{k-1}), \quad (5)$$

where ϕ_{k-1} is an equivalence classification (state) of the jump sequence b_1^{k-1}.

The jump sequence b_1^K can be described by a deterministic finite state machine. $\phi(b_1^{k-1})$ is the state arrived at by b_1^{k-1}; we will use ϕ_{k-1} to denote $\phi(b_1^{k-1})$.

We will investigate phrase reordering by restricting the maximum allowable jump to 1 phrase and to 2 phrases; we will refer to these reordering models as MJ-1 and MJ-2. In the first case, $b_k \in \{0, +1, -1\}$ while in the second case, $b_k \in \{0, +1, -1, +2, -2\}$.

2.2 Reordering WFST for MJ-1

We first present the Finite State Machine of the phrase reordering process (Fig 3) which has two equivalence classes (FSM states) for any given history b_1^{k-1}; $\phi(b_1^{k-1}) \in \{1, 2\}$. A jump of $+1$ has to be followed by a jump of -1, and 1 is the start and end state; this ensures $\sum_{k=1}^{K} b_k = 0$.

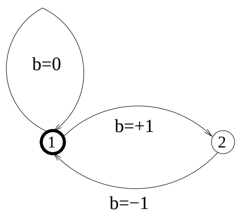

Figure 3: Phrase reordering process for MJ-1.

Under this restriction, the probability of the jump b_k (Eqn 5) can be simplified as

$$P(b_k|x_k, u_k, \phi(b_1^{k-1})) = \quad (6)$$
$$\begin{cases} \beta_1(x_k, u_k) & b_k = +1, \phi_{k-1} = 1 \\ 1 - \beta_1(x_k, u_k) & b_k = 0, \phi_{k-1} = 1 \\ 1 & b_k = -1, \phi_{k-1} = 2. \end{cases}$$

There is a single parameter jump probability $\beta_1(x, u) = P(b = +1|x, u)$ associated with each phrase-pair (x, u) in the phrase-pair inventory. This is the probability that the phrase-pair (x, u) appears out of order in the transformed phrase sequence.

We now describe the MJ-1 WFST. In the presentation, we use upper-case letters to denote the English phrases (u_k) and lower-case letters to denote the French phrases (x_k and y_k).

The PPI for this example is given in Table 1.

English	French	Parameters	
u	x	$P(x\|u)$	$\beta_1(x, u)$
A	a	0.5	0.2
A	d	0.5	0.2
B	b	1.0	0.4
C	c	1.0	0.3
D	d	1.0	0.8

Table 1: Example phrase-pair inventory with translation and reordering probabilities.

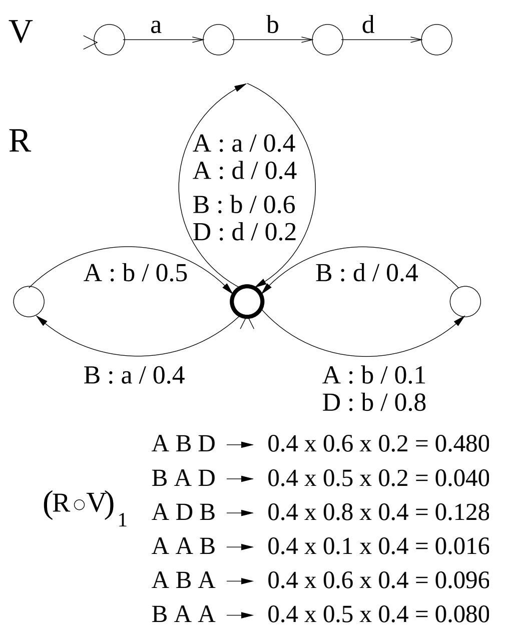
The input to the WFST (Fig 4) is a lattice of French phrase sequences derived from the French sentence to be translated. The outputs are the corresponding English phrase sequences. Note that the reordering is performed on the English side.

The WFST is constructed by adding a self-loop for each French phrase in the input lattice, and a 2-arc path for every pair of adjacent French phrases in the lattice. The WFST incorporates the translation model $P(x|u)$ and the reordering model $P(b|x, u)$. The score on a self-loop with labels (u, x) is $P(x|u) \times (1 - \beta_1(x, u))$; on a 2-arc path with labels (u_1, x_1) and (u_2, x_2), the score on the 1st arc is $P(x_2|u_1) \times \beta_1(x_2, u_1)$ and on the 2nd arc is $P(x_1|u_2)$.

In this example, the input to this transducer is a single French phrase sequence $V : a, b, c$. We perform the WFST composition $R \circ V$, project the result on the input labels, and remove the epsilons to form the acceptor $(R \circ V)_1$ which contains the six English phrase sequences (Fig 4).

Translation Given a French sentence, a lattice of translations is obtained using the weighted finite state composition: $\mathcal{T} = G \circ W \circ R \circ \Phi \circ \Omega \circ T$. The most-likely translation is obtained as the path with the highest probability in $\mathcal{T}$.

Alignment Given a sentence-pair (E, F), a lattice of phrase alignments is obtained by the finite state composition: $\mathcal{B} = S \circ W \circ R \circ \Phi \circ \Omega \circ T$, where



A B D → 0.4 x 0.6 x 0.2 = 0.480
B A D → 0.4 x 0.5 x 0.2 = 0.040
A D B → 0.4 x 0.8 x 0.4 = 0.128
A A B → 0.4 x 0.1 x 0.4 = 0.016
A B A → 0.4 x 0.6 x 0.4 = 0.096
B A A → 0.4 x 0.5 x 0.4 = 0.080

Figure 4: WFST for the MJ-1 model.

S is an acceptor for the English sentence E, and T is an acceptor for the French sentence F. The Viterbi alignment is found as the path with the highest probability in $\mathcal{B}$. The WFST composition gives the word-to-word alignments between the sentences. However, to obtain the phrase alignments, we need to construct additional FSTs not described here.

2.3 Reordering WFST for MJ-2

MJ-2 reordering restricts the maximum allowable jump to 2 phrases and also insists that the reordering take place within a window of 3 phrases. This latter condition implies that for an input sequence $\{a, b, c, d\}$, we disallow the three output sequences: $\{b, d, a, c;\ c, a, d, b;\ c, d, a, b;\}$. In the MJ-2 finite state machine, a given history b_1^{k-1} can lead to one of the six states in Fig 5.

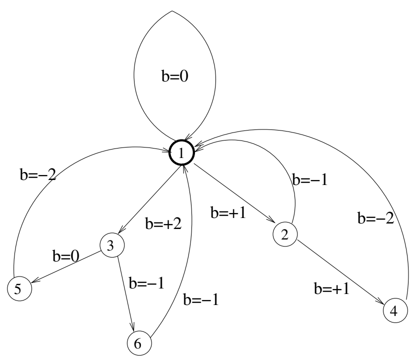


Figure 5: Phrase reordering process for MJ-2.

The jump probability of Eqn 5 becomes

$$P(b_k|x_k, u_k, \phi_{k-1}) =$$

$$\begin{cases} \beta_1(x_k, u_k) & b_k = 1, \phi_{k-1} = 1 \\ \beta_2(x_k, u_k) & b_k = 2, \phi_{k-1} = 1 \\ \begin{cases} 1 - \beta_1(x_k, u_k) \\ \quad -\beta_2(x_k, u_k) \end{cases} & b_k = 0, \phi_{k-1} = 1 \end{cases} \tag{7}$$

$$\begin{cases} \beta_1(x_k, u_k) & b_k = 1, \phi_{k-1} = 2 \\ 1 - \beta_1(x_k, u_k) & b_k = -1, \phi_{k-1} = 2 \end{cases} \tag{8}$$

$$\begin{cases} 0.5 & b_k = 0, \phi_{k-1} = 3 \\ 0.5 & b_k = -1, \phi_{k-1} = 3. \end{cases} \tag{9}$$

$$\begin{cases} 1 & b_k = -2, \phi_{k-1} = 4 \end{cases} \tag{10}$$

$$\begin{cases} 1 & b_k = -2, \phi_{k-1} = 5 \end{cases} \tag{11}$$

$$\begin{cases} 1 & b_k = -1, \phi_{k-1} = 6 \end{cases} \tag{12}$$

We note that the distributions (Eqns 7 and 8) are based on two parameters $\beta_1(x, u)$ and $\beta_2(x, u)$ for each phrase-pair (x, u).

Suppose the input is a phrase sequence a, b, c, the MJ-2 model (Fig 5) allows 6 possible reorderings: $a, b, c; a, c, b; b, a, c; b, c, a; c, a, b; c, b, a$. The distribution Eqn 9 ensures that the sequences b, c, a and c, b, a are assigned equal probability. The distributions in Eqns 10-12 ensure that the maximum jump is 2 phrases and the reordering happens within a window of 3 phrases. By insisting that the process start and end at state 1 (Fig 5), we ensure that the model is not deficient. A WFST implementing the MJ-2 model can be easily constructed for both phrase alignment and translation, following the construction described for the MJ-1 model.

3 Estimation of the Reordering Models

The Translation Template Model relies on an inventory of target language phrases and their source language translations. Our goal is to estimate the reordering model parameters $P(b|x, u)$ for each phrase-pair (x, u) in this inventory. However, when translating a given test set, only a subset of the phrase-pairs is needed. Although there may be an advantage in estimating the model parameters under an inventory that covers all the training bitext, we fix the phrase-pair inventory to cover only the phrases on the test set. Estimation of the reordering model parameters over the training bitext is then performed under this test-set specific inventory.

We employ the EM algorithm to obtain Maximum Likelihood (ML) estimates of the reordering model parameters. Applying EM to the MJ-1 reordering model gives the following ML parameter estimates for each phrase-pair (u, x).

$$\hat{\beta}_1(x,u) = \frac{C_{x,u}(0,+1)}{C_{x,u}(0,+1) + C_{x,u}(0,0)}. \quad (13)$$

$C_{x,u}(\phi, b)$ is defined for $\phi = 1, 2$ and $b = -1, 0, +1$. Any permissible phrase alignment of a sentence pair corresponds to a b_1^K sequence, which in turn specifies a ϕ_1^K sequence. $C_{x,u}(\phi, b)$ is the expected number of times the phrase-pair x, u is aligned with a jump of b phrases when the jump history is ϕ. We do not use full EM but a Viterbi training procedure that obtains the counts for the best (Viterbi) alignments. If a phrase-pair (x, u) is never seen in the Viterbi alignments, we back-off to a flat parameter $\beta_1(x, u) = 0.05$.

The ML parameter estimates for the MJ-2 model are given in Table 2, with $C_{x,u}(\phi, b)$ defined similarly. In our training scenario, we use WFST operations to obtain Viterbi phrase alignments of the training bitext where the initial reordering model parameters ($\beta_0(x, u)$) are set to a uniform value of 0.05. The counts $C_{x,u}(s, b)$ are then obtained over the phrase alignments. Finally the ML estimates of the parameters are computed using Eqn 13 (MJ-1) or Eqn 14 (MJ-2). We will refer to the Viterbi trained models as MJ-1 VT and MJ-2 VT. Table 3 shows the MJ-1 VT parameters for some example phrase-pairs in the Arabic-English (A-E) task.

Table 3: MJ-1 parameters for A-E phrase-pairs.

To validate alignment under a PPI, we measure performance of the TTM word alignments on French-English (500 sent-pairs) and Chinese-English (124 sent-pairs) (Table 4). As desired, the Alignment Recall (AR) and Alignment Error Rate (AER) improve modestly while Alignment Precision (AP) remains constant. This suggests that the models allow more words to be aligned and thus improve the recall; MJ-2 gives a further improvement in AR and AER relative to MJ-1. Alignment precision depends on the quality of the word alignments within the phrase-pairs and does not change much by allowing phrase reordering. This experiment validates the estimation procedure based on the phrase alignments; however, we do not advocate the use of TTM as an alternate word alignment technique.

Reordering	Metrics (%)

4 Translation Experiments

We perform our translation experiments on the large data track of the NIST Arabic-to-English (A-E) and Chinese-to-English (C-E) MT tasks; we report results on the NIST 2002, 2003, and 2004 evaluation test sets [1].

4.1 Exploratory Experiments

In these experiments the training data is restricted to FBIS bitext in C-E and the news bitexts in A-E. The bitext consists of chunk pairs aligned at sentence and sub-sentence level (Deng et al., 2004). In A-E, the training bitext consists of 3.8M English words, 3.2M Arabic words and 137K chunk pairs. In C-E, the training bitext consists of 11.7M English words, 8.9M Chinese words and 674K chunk pairs.

Our Chinese text processing consists of word segmentation (using the LDC segmenter) followed by grouping of numbers. For Arabic our text processing consisted of a modified Buckwalter analysis (LDC2002L49) followed by post processing to separate conjunctions, prepostions and pronouns, and Al-/w- deletion. The English text is processed using a simple tokenizer based on the text processing utility available in the the NIST MT-eval toolkit.

The Language Model (LM) training data consists of approximately 400M words of English text derived from Xinhua and AFP (English Gigaword), the English side of FBIS, the UN and A-E News texts, and the online archives of The People's Daily.

Table 5 gives the performance of the MJ-1 and MJ-2 reordering models when translation is performed using a 4-gram LM. We report performance on the 02, 03, 04 test sets and the combined test set

[1] `http://www.nist.gov/speech/tests/mt/`

(ALL=02+03+04). For the combined set (ALL), we also show the 95% BLEU confidence interval computed using bootstrap resampling (Och, 2003).

Row 1 gives the performance when no reordering model is used. The next two rows show the influence of the MJ-1 reordering model; in row 2, a flat probability of $\beta_1(x,u) = 0.05$ is used for all phrase-pairs; in row 3, a reordering probability is estimated for each phrase-pair using Viterbi Training (Eqn 13). The last two rows show the effect of the MJ-2 reordering model; row 4 uses flat probabilities ($\beta_1(x,u) = 0.05, \beta_2(x,u) = 0.01$) for all phrase-pairs; row 5 applies reordering probabilities estimating with Viterbi Training for each phrase-pair (Table 2).

On both language-pairs, we observe that reordering yields significant improvements. The gains from phrase reordering are much higher on A-E relative to C-E; this could be related to the fact that the word order differences between English and Arabic are much higher than the differences between English and Chinese. MJ-1 VT outperforms flat MJ-1 showing that there is value in estimating the reordering parameters from bitext. Finally, the MJ-2 VT model performs better than the flat MJ-2 model, but only marginally better than the MJ-1 VT model. Therefore estimation does improve the MJ-2 model but allowing reordering beyond a window of 1 phrase is not useful when translating either Arabic or Chinese into English in this framework.

The flat MJ-1 model outperforms the no-reordering case and the flat MJ-2 model is better than the flat MJ-1 model; we hypothesize that phrase reordering increases search space of translations that allows the language model to select a higher quality hypothesis. This suggests that these models of phrase reordering actually require strong language models to be effective. We now investigate the interaction between language models and reordering.

Our goal here is to measure translation performance of reordering models over variable span n-gram LMs (Table 6). We observe that both MJ-1 and MJ-2 models yield higher improvements under higher order LMs: e.g. on A-E, gains under 3g (3.6 BLEU points on MJ-1, 0.2 points on MJ-2) are higher than the gains with 2g (2.4 BLEU points on MJ-1, 0.1 points on MJ-2).

MJ-2 VT	23.5	40.6	42.0	16.0	26.1	26.8

Table 6: Reordering with variable span n-gram LMs on Eval02+03+04 set.

We now measure performance of the reordering models across the three test set genres used in the NIST 2004 evaluation: news, editorials, and speeches. On A-E, MJ-1 and MJ-2 yield larger improvements on News relative to the other genres; on C-E, the gains are larger on Speeches and Editorials relative to News. We hypothesize that the Phrase-Pair Inventory, reordering models and language models could all have been biased away from the test set due to the training data. There may also be less movement across these other genres.

Table 8: Translation Performance on Large Bitexts.

4.2 Scaling to Large Bitext Training Sets

We here describe the integration of the phrase reordering model in an MT system trained on large bitexts. The text processing and language models have been described in § 4.1. Alignment Models are trained on all available bitext (7.6M chunk pairs/207.4M English words/175.7M Chinese words on C-E and 5.1M chunk pairs/132.6M English words/123.0M Arabic words on A-E), and word alignments are obtained over the bitext. Phrase-pairs are then extracted from the word alignments (Koehn et al., 2003). MJ-1 model parameters are estimated over all bitext on A-E and over the non-UN bitext on C-E. Finally we use Minimum Error Training (MET) (Och, 2003) to train log-linear scaling factors that are applied to the WFSTs in Equation 1. 04news (04n) is used as the MET training set.

Table 8 reports the performance of the system. Row 1 gives the performance without phrase reordering and Row 2 shows the effect of the MJ-1 VT model. The MJ-1 VT model is used in an initial decoding pass with the four-gram LM to generate translation lattices. These lattices are then rescored under parameters obtained using MET (MET-basic), and 1000-best lists are generated. The 1000-best lists are augmented with IBM Model-1 (Brown et al., 1993) scores and then rescored with a second set of MET parameters. Rows 3 and 4 show the performance of the MET-basic and MET-IBM1 models.

We observe that the maximum likelihood phrase reordering model (MJ-1 VT) yields significantly improved translation performance relative to the monotone phrase order translation baseline. This confirms the translation performance improvements found over smaller training bitexts.

We also find additional gains by applying MET to optimize the scaling parameters that are applied to the WFST component distributions within the TTM (Equation 1). In this procedure, the scale factor applied to the MJ-1 VT Phrase Translation and Reordering component is estimated along with scale factors applied to the other model components; in other words, the ML-estimated phrase reordering model itself is not affected by MET, but the likelihood that it assigns to a phrase sequence is scaled by a single, discriminatively optimized weight. The improvements from MET (see rows MET-Basic and MET- IBM1) demonstrate that the MJ-1 VT reordering models can be incorporated within a discriminative optimized translation system incorporating a variety of models and estimation procedures.

5 Discussion

In this paper we have described local phrase reordering models developed for use in statistical machine translation. The models are carefully formulated so that they can be implemented as WFSTs, and we show how the models can be incorporated into the Translation Template Model to perform phrase alignment and translation using standard WFST operations. Previous approaches to WFST-based reordering (Knight and Al-Onaizan, 1998; Kumar and Byrne, 2003; Tsukada and Nagata, 2004) constructed permutation acceptors whose state spaces grow exponentially with the length of the sentence to be translated. As a result, these acceptors have to be pruned heavily for use in translation. In contrast, our models of local phrase movement do not grow explosively and do not require any pruning or approximation in their construction. In other related work, Bangalore and Ricardi (2001) have trained WFSTs for modeling reordering within translation; their WFST parses word sequences into trees containing reordering information, which are then checked for well-formed brackets. Unlike this approach, our model formulation does not use a tree representation and also ensures that the output sequences are valid permutations of input phrase sequences; we emphasize again that the probability distribution induced over reordered phrase sequences is not degenerate.

Our reordering models do resemble those of (Tillmann, 2004; Tillmann and Zhang, 2005) in that we treat the reordering as a sequence of jumps relative to the original phrase sequence, and that the likelihood of the reordering is assigned through phrase-pair specific parameterized models. We note that our implementation allows phrase reordering beyond simply a 1-phrase window, as was done by Tillmann. More importantly, our model implements a generative model of phrase reordering which can be incorporated directly into a generative model of the overall translation process. This allows us to perform 'embedded' EM-style parameter estimation, in which the parameters of the phrase reordering model are estimated using statistics gathered under the complete model that will actually be used in translation. We believe that this estimation of model parameters directly from phrase alignments obtained under the phrase translation model is a novel contribution; prior approaches derived the parameters of the reordering models from word aligned bitext, e.g. within the phrase pair extraction procedure.

We have shown that these models yield improvements in alignment and translation performance on Arabic-English and Chinese-English tasks, and that the reordering model can be integrated into large evaluation systems. Our experiments show that discriminative training procedures such Minimum Error Training also yield additive improvements by tuning TTM systems which incorporate ML-trained reordering models. This is essential for integrating our reordering model inside an evaluation system, where a variety of techniques are applied simultaneously.

The MJ-1 and MJ-2 models are extremely simple models of phrase reordering. Despite their simplicity, these models provide large improvements in BLEU score when incorporated into a monotone phrase order translation system. Moreover, they can be used to produced translation lattices for use by more sophisticated reordering models that allow longer phrase order movement. Future work will build on these simple structures to produce more powerful models of word and phrase movement in translation.

Abstract

HMM-based models are developed for the alignment of words and phrases in bitext. The models are formulated so that alignment and parameter estimation can be performed efficiently. We find that Chinese-English word alignment performance is comparable to that of IBM Model-4 even over large training bitexts. Phrase pairs extracted from word alignments generated under the model can also be used for phrase-based translation, and in Chinese to English and Arabic to English translation, performance is comparable to systems based on Model-4 alignments. Direct phrase pair induction under the model is described and shown to improve translation performance.

1 Introduction

Describing word alignment is one of the fundamental goals of Statistical Machine Translation (SMT). Alignment specifies how word order changes when a sentence is translated into another language, and given a sentence and its translation, alignment specifies translation at the word level. It is straightforward to extend word alignment to phrase alignment: two phrases align if their words align.

Deriving phrase pairs from word alignments is now widely used in phrase-based SMT. Parameters of a statistical word alignment model are estimated from bitext, and the model is used to generate word alignments over the same bitext. Phrase pairs are extracted from the aligned bitext and used in the SMT system. With this approach the quality of the underlying word alignments can have a strong influence on phrase-based SMT system performance. The common practice therefore is to extract phrase pairs from the best attainable word alignments. Currently, Model-4 alignments (Brown and others, 1993) as produced by GIZA++ (Och and Ney, 2000) are often the best that can be obtained, especially with large bitexts.

Despite its modeling power and widespread use, Model-4 has shortcomings. Its formulation is such that maximum likelihood parameter estimation and bitext alignment are implemented by approximate, hill-climbing, methods. Consequently parameter estimation can be slow, memory intensive, and difficult to parallelize. It is also difficult to compute statistics under Model-4. This limits its usefulness for modeling tasks other than the generation of word alignments.

We describe an HMM alignment model developed as an alternative to Model-4. In the word alignment and phrase-based translation experiments to be presented, its performance is comparable or improved relative to Model-4. Practically, we can train the model by the Forward-Backward algorithm, and by parallelizing estimation, we can control memory usage, reduce the time needed for training, and increase the bitext used for training. We can also compute statistics under the model in ways not practical with Model-4, and we show the value of this in the extraction of phrase pairs from bitext.

2 HMM Word and Phrase Alignment

Our goal is to develop a generative probabilistic model of Word-to-Phrase (WtoP) alignment. We start with an l-word source sentence $\mathbf{e} = e_1^l$, and an

m-word target sentence $\mathbf{f} = f_1^m$, which is realized as a sequence of K phrases: $\mathbf{f} = v_1^K$.

Each phrase is generated as a translation of one source word, which is determined by the alignment sequence a_1^K: $e_{a_k} \rightarrow v_k$. The length of each phrase is specified by the process ϕ_1^K, which is constrained so that $\sum_{k=1}^K \phi_k = m$.

We also allow target phrases to be inserted, i.e. to be generated by a NULL source word. For this, we define a binary hallucination sequence h_1^K : if $h_k = 0$, then NULL $\rightarrow v_k$; if $h_k = 1$ then $e_{a_k} \rightarrow v_k$.

With all these quantities gathered into an alignment $\mathbf{a} = (\phi_1^K, a_1^K, h_1^K, K)$, the modeling objective is to realize the conditional distribution $P(\mathbf{f}, \mathbf{a}|\mathbf{e})$. With the assumption that $P(\mathbf{f}, \mathbf{a}|\mathbf{e}) = 0$ if $\mathbf{f} \neq v_1^K$, we write $P(\mathbf{f}, \mathbf{a}|\mathbf{e}) = P(v_1^K, K, a_1^K, h_1^K, \phi_1^K|\mathbf{e})$ and

$$\begin{aligned} &P(v_1^K, K, a_1^K, h_1^K, \phi_1^K|\mathbf{e}) \\ &\quad = \epsilon(m|l) \times P(K|m, \mathbf{e}) \\ &\qquad \times P(a_1^K, \phi_1^K, h_1^K|K, m, \mathbf{e}) \\ &\qquad\quad \times P(v_1^K|a_1^K, h_1^K, \phi_1^K, K, m, \mathbf{e}) \end{aligned}$$

We now describe the component distributions.

Sentence Length $\epsilon(m|l)$ determines the target sentence length. It is not needed during alignment, where sentence lengths are known, and is ignored.

Phrase Count $P(K|m, \mathbf{e})$ specifies the number of target phrases. We use a simple, single parameter distribution, with $\eta = 8.0$ throughout

$$P(K|m, \mathbf{e}) = P(K|m, l) \propto \eta^K$$

Word-to-Phrase Alignment Alignment is a Markov process that specifies the lengths of phrases and their alignment with source words

$$\begin{aligned} &P(a_1^K, h_1^K, \phi_1^K|K, m, \mathbf{e}) \\ &= \prod_{k=1}^K P(a_k, h_k, \phi_k|a_{k-1}, \phi_{k-1}, \mathbf{e}) \\ &= \prod_{k=1}^K p(a_k|a_{k-1}, h_k; l)\, d(h_k)\, n(\phi_k; e_{a_k}) \end{aligned}$$

The actual word-to-phrase alignment (a_k) is a first-order Markov process, as in HMM-based word-to-word alignment (Vogel et al., 1996). It necessarily depends on the hallucination variable

$$\begin{aligned} &p(a_j|a_{j-1}, h_j; l) \\ &\quad = \begin{cases} 1 & a_j = a_{j-1},\ h_j = 0 \\ 0 & a_j \neq a_{j-1},\ h_j = 0 \\ a(a_j|a_{j-1}; l) & h_j = 1 \end{cases} \end{aligned}$$

This formulation allows target phrases to be inserted without disrupting the Markov dependencies of phrases aligned to actual source words.

The phrase length model $n(\phi; e)$ gives the probability that a word e produces a phrase with ϕ words in the target language; $n(\phi; e)$ is defined for $\phi = 1, \cdots, N$. The hallucination process is a simple i.i.d. process, where $d(0) = p_0$, and $d(1) = 1 - p_0$.

Word-to-Phrase Translation The translation of words to phrases is given as

$$P(v_1^K|a_1^K, h_1^K, \phi_1^K, K, m, \mathbf{e}) = \prod_{k=1}^K p(v_k|e_{a_k}, h_k, \phi_k)$$

We introduce the notation $v_k = v_k[1], \ldots, v_k[\phi_k]$ and a dummy variable x_k (for phrase insertion) :

$$x_k = \begin{cases} e_{a_k} & h_k = 1 \\ \text{NULL} & h_k = 0 \end{cases}$$

We define two models of word-to-phrase translation. This simplest is based on context-independent word-to-word translation

$$p(v_k|e_{a_k}, h_k, \phi_k) = \prod_{j=1}^{\phi_k} t(v_k[j] \,|\, x_k)$$

We also define a model that captures foreign word context with *bigram translation probabilities*

$$\begin{aligned} &p(v_k|e_{a_k}, h_k, \phi_k) \\ &\quad = t(v_k[1] \,|\, x_k) \prod_{j=2}^{\phi_k} t_2(v_k[j] \,|\, v_k[j-1], x_k) \end{aligned}$$

Here, $t(f|e)$ is the usual context independent word-to-word translation probability. The bigram translation probability $t_2(f|f', e)$ specifies the likelihood that target word f is to follow f' in a phrase generated by source word e.

2.1 Properties of the Model and Prior Work

The formulation of the WtoP alignment model was motivated by both the HMM word alignment model (Vogel et al., 1996) and IBM Model-4 with the goal of building on the strengths of each.

The relationship with the word-to-word HMM alignment model is straightforward. For example, constraining the phrase length component $n(\phi; e)$ to permit only phrases of one word would give a word-to-word HMM alignment model. The extensions introduced are the phrase count, and the phrase length models, and the bigram translation distribution. The hallucination process is motivated by the use of NULL alignments into Markov alignment models as done by (Och and Ney, 2003).

The phrase length model is motivated by Toutanova et al. (2002) who introduced 'stay' probabilities in HMM alignment as an alternative to word fertility. By comparison, Word-to-Phrase HMM alignment models contain detailed models of state occupancy, motivated by the IBM fertility model, which are more powerful than a single staying parameter. In fact, the WtoP model is a segmental Hidden Markov Model (Ostendorf et al., 1996), in which states emit observation sequences.

Comparison with Model-4 is less straightforward. The main features of Model-4 are NULL source words, source word fertility, and the distortion model. The WtoP alignment model includes the first two of these. However distortion, which allows hypothesized words to be distributed throughout the target sentence, is difficult to incorporate into a model that supports efficient DP-based search. We preserve efficiency in the WtoP model by insisting that target words form connected phrases; this is not as general as Model-4 distortion. This weakness is somewhat offset by a more powerful (Markov) alignment process as well as by the phrase count distribution. Despite these differences, the WtoP alignment model and Model-4 allow similar alignments. For example, in Fig. 1, Model-4 would allow f_1, f_3, and f_4 to be generated by e_1 with a fertility of 3. Under the WtoP model, e_1 could generate f_1 and $f_3 f_4$ with phrase lengths 1 and 2, respectively: source words can generate more than one phrase.

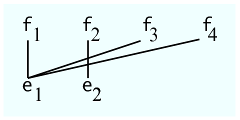

Figure 1: Word-to-Word and Word-to-Phrase Links

This alignment could also be generated via four single word foreign phrases. The balance between word-to-word and word-to-phrase alignments is set by the phrase count distribution parameter η. As η increases, alignments with shorter phrases are favored, and for very large η the model allows only word-to-word alignments (see Fig. 2). Although the WtoP alignment model is more complex than the word-to-word HMM alignment model, the Baum-Welch and Viterbi algorithms can still be used. Word-to-word alignments are generated by the Viterbi algorithm: $\hat{\mathbf{a}} = \operatorname{argmax}_{\mathbf{a}} P(\mathbf{f}, \mathbf{a}|\mathbf{e})$; if $e_{a_k} \rightarrow v_k$, e_{a_k} is linked to all the words in v_k.

The bigram translation probability relies on word context, known to be helpful in translation (Berger et al., 1996), to improve the identification of target phrases. As an example, f is the Chinese word for "world trade center". Table 1 shows how the likelihood of the correct English phrase is improved with bigram translation probabilities; this example is from the C→E, N=4 system of Table 2.

Model	unigram	bigram
$P(\text{world}\|f)$	0.06	0.06
$P(\text{trade}\|\text{world}, f)$	0.06	0.99
$P(\text{center}\|\text{trade}, f)$	0.06	0.99
$P(\text{world trade center}\|f, 3)$	0.0002	0.0588

Table 1: Context in Bigram Phrase Translation.

There are of course much prior work in translation that incorporates phrases. Sumita et al. (2004) develop a model of phrase-to-phrase alignment, which while based on HMM alignment process, appears to be deficient. Marcu and Wong (2002) propose a model to learn lexical correspondences at the phrase level. To our knowledge, ours is the first non-syntactic model of bitext alignment (as opposed to translation) that links words and phrases.

3 Embedded Alignment Model Estimation

We now discuss estimation of the WtoP model parameters by the EM algorithm. Since the WtoP model can be treated as an HMM with a very complex state space, it is straightforward to apply Baum-

Welch parameter estimation. We show the forward recursion as an example.

Given a sentence pair (e_1^l, f_1^m), the forward probability $\alpha_j(i, \phi)$ is defined as the probability of generating the first j target words with the added condition that the target words $f_{j-\phi+1}^j$ form a phrase aligned to source word e_i. It can be calculated recursively (omitting the hallucination process, for simplicity) as

$$\alpha_j(i,\phi) = \Big\{ \sum_{i',\phi'} \alpha_{j-\phi}(i',\phi') a(i|i',l) \Big\} \cdot \eta$$

$$\cdot\, n(\phi; e_i) \cdot t(f_{j-\phi+1}|e_i) \;\cdot \prod_{j'=j-\phi+2}^{j} t_2(f_{j'}|e_i)$$

This recursion is over a trellis of $l(N+1)m$ nodes.

Models are trained from a flat-start. We begin with 10 iterations of EM to train Model-1, followed by 5 EM iterations to train Model-2 (Brown and others, 1993). We initialize the parameters of the word-to-word HMM alignment model by collecting word alignment counts from the Model-2 Viterbi alignments, and refine the word-to-word HMM alignment model by 5 iterations of the Baum-Welch algorithm. We increase the order of the WtoP model (N) from 2 to the final value in increments of 1, by performing 5 Baum Welch iterations at each step. At the final value of N, we introduce the bigram translation probability; we use Witten-Bell smoothing (1991) as a backoff strategy for t_2, and other strategies are possible.

4 Bitext Word Alignment

We now investigate bitext word alignment performance. We start with the FBIS Chinese/English parallel corpus which consists of approx. 10M English/7.5M Chinese words. The Chinese side of the corpus is segmented into words by the LDC segmenter[1]. The alignment test set consists of 124 sentences from the NIST 2001 dry-run MT-eval[2] set that are manually word aligned.

We first analyze the distribution of word links within these manual alignments. Of the Chinese words which are aligned to more than one English words, 82% of these words align with consecutive English words (phrases). In the other direction, among all English words which are aligned to multiple Chinese words, 88% of these align to Chinese phrases. In this collection, at least, word-to-phrase alignments are plentiful.

Alignment performance is measured by the Alignment Error Rate (AER) (Och and Ney, 2003)

$$AER(B; B') = 1 - 2 \times |B \cap B'|/(|B'| + |B|)$$

where B is a set reference word links, and B' are the word links generated automatically.

AER gives a general measure of word alignment quality. We are also interested in how the model performs over the word-to-word and word-to-phrase alignments it supports. We split the reference alignments into two subsets: B_{1-1} contains word-to-word reference links (e.g. 1⟶1 in Fig 1); and B_{1-N} contains word-to-phrase reference links (e.g. 1⟶3, 1⟶4 in Fig 1); The automatic alignment B' is partitioned similarly. We define additional AERs: $AER_{1-1} = AER(B_{1-1}, B'_{1-1})$, and $AER_{1-N} = AER(B_{1-N}, B'_{1-N})$, which measure word-to-word and word-to-phrase alignment, separately.

Table 2 presents the three AER measurements for

Model	AER_{1-1}	AER_{1-N}	AER
	C⟶E		
Model-4	37.9	68.3	37.3
HMM, N=1	42.8	72.9	42.0
HMM, N=2	38.3	71.2	38.1
HMM, N=3	37.4	69.5	37.8
HMM, N=4	37.1	69.1	37.8
+ bigram t-table	37.5	65.8	37.1
	E⟶C		
Model-4	42.3	87.2	45.0
HMM, N=1	45.0	90.6	47.2
HMM, N=2	42.7	87.5	44.5
+ bigram t-table	44.2	85.5	45.1

Table 2: FBIS Bitext Alignment Error Rate.

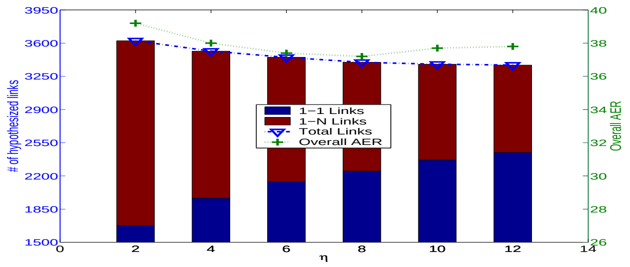

Figure 2: Balancing Word and Phrase Alignments

[1]http://www.ldc.upenn.edu/Projects/Chinese

[2]http://www.nist.gov/speech/tests/mt

the WtoP alignment models trained as described in Section 3. GIZA++ Model 4 alignment performance is also presented for comparison. We note first that the word-to-word HMM (N=1) alignment model is worse than Model 4, as expected. For the WtoP models in the C→E direction, we see reduced AER for phrases lengths up to 4, although in the E→C direction, AER is reduced only for phrases of length 2; performance for $N > 2$ is not reported.

In introducing the bigram phrase translation (the bigram t-table), there is a tradeoff between word-to-word and word-to-phrase alignment quality. As mentioned, the bigram t-table increases the likelihood of word-to-phrase alignments. In both translation directions, this reduces the AER_{1-N}. However, it also causes increases in AER_{1-1}, primarily due to a drop in recall: fewer word-to-word alignments are produced. For C→E, this is not severe enough to cause an overall AER increase; however, in E→C, AER does increase.

Fig. 2 (C→E, N=4) shows how the 1-1 and 1-N alignment behavior is balanced by the phrase count parameter. As η increases, the model favors alignments with more word-to-word links and fewer word-to-phrase links; the overall Alignment Error Rate (AER) suggests a good balance at $\eta = 8.0$.

After observing that the WtoP model performs as well as Model-4 over the FBIS C-E bitext, we investigated performance over these large bitexts :
- "NEWS" containing non-UN parallel Chinese/English corpora from LDC (mainly FBIS, Xinhua, Hong Kong, Sinorama, and Chinese Treebank).
- "NEWS+UN01-02" also including UN parallel corpora from the years 2001 and 2002.
- "ALL C-E" refers to all the C-E bitext available from LDC as of his submission; this consists of the NEWS corpora with the UN bitext from all years.

Over all these collections, WtoP alignment performance (Table 3) is comparable to that of Model-4. We do note a small degradation in the E→C WtoP alignments. It is quite possible that this one-to-many model suffers slightly with English as the source and Chinese as the target, since English sentences tend to be longer. Notably, simply increasing the amount of bitext used in training need not improve AER. However, larger aligned bitexts can give improved phrase pair coverage of the test set.

One of the desirable features of HMMs is that the

Bitext	English Words	Model	C→E	E→C
NEWS	71M	M-4	37.1	45.3
		WtoP	36.1	44.8
NEWS+ UN01-02	96M	M-4	36.1	43.4
		WtoP	36.4	44.2
ALL C-E	200M	WtoP	36.8	44.7

Table 3: AER Over Large C-E Bitexts.

Forward-Backward steps can be run in parallel: bitext is partitioned; the Forward-Backward algorithm is run over the subsets on different CPUs; statistics are merged to reestimate model parameters. Partitioning the bitext also reduces the memory usage, since different cooccurrence tables can be kept for each partition. With the "ALL C-E" bitext collection, a single set of WtoP models (C→E, N=4, bigram t-table) can be trained over 200M words of Chinese-English bitext by splitting training over 40 CPUs; each Forward-Backward process takes less than 2GB of memory and the training run finishes in five days. By contrast, the 96M English word NEWS+UN01-02 is about the largest C-E bitext over which we can train Model-4 with our GIZA++ configuration and computing infrastructure.

Based on these and other experiments, in this paper we set a maximum value of $N = 4$ for F→E; in E→F, we set N=2 and omit the bigram phrase translation probability; η is set to 8.0. We do not claim that this is optimal, however.

5 Phrase Pair Induction

A common approach to phrase-based translation is to extract an inventory of phrase pairs (PPI) from bitext (Koehn et al., 2003), For example, in the *phrase-extract* algorithm (Och, 2002), a word alignment $\hat{a}_1^m$ is generated over the bitext, and all word subsequences $e_{i_1}^{i_2}$ and $f_{j_1}^{j_2}$ are found that satisfy :

$$\hat{a}_1^m : \hat{a}_j \in [i_1, i_2] \text{ iff } j \in [j_1, j_2] \; . \qquad (1)$$

The PPI comprises all such phrase pairs $(e_{i_1}^{i_2}, f_{j_1}^{j_2})$.

The process can be stated slightly differently. First, we define a set of alignments :

$$A(i_1, i_2; j_1, j_2) = \{a_1^m : a_j \in [i_1, i_2] \text{ iff } j \in [j_1, j_2]\} \; .$$

If $\hat{a}_1^m \in A(i_1, i_2; j_1, j_2)$ then $(e_{i_1}^{i_2}, f_{j_1}^{j_2})$ form a phrase pair.

Viewed in this way, there are many possible alignments under which phrases might be paired, and the selection of phrase pairs need not be based on a single alignment. Rather than simply accepting a phrase pair $(e_{i_1}^{i_2}, f_{j_1}^{j_2})$ if the unique MAP alignment satisfies Equation 1, we can assign a probability to phrases occurring as translation pairs :

$$P(\mathbf{f},\, A(i_1,i_2;j_1,j_2\,)\,|\,\mathbf{e}) = \sum_{\mathbf{a}\,:\,a_1^m \in A(i_1,i_2;j_1,j_2\,)} P(\mathbf{f},\mathbf{a}|\mathbf{e})$$

For a fixed set of indices i_1, i_2, j_1, j_2, the quantity $P(\mathbf{f},\, A(i_1,i_2;j_1,j_2\,)\,|\,\mathbf{e})$ can be computed efficiently using a modified Forward algorithm. Since $P(\mathbf{f}|\mathbf{e})$ can also be computed by the Forward algorithm, the *phrase-to-phrase posterior distribution* $P(\,A(i_1,i_2;j_1,j_2\,)\,|\,\mathbf{f},\mathbf{e})$ is easily found.

PPI Induction Strategies In the *phrase-extract* algorithm (Och, 2002), the alignment $\hat{a}$ is generated as follows: Model-4 is trained in both directions (e.g. F→E and E→F); two sets of word alignments are generated by the Viterbi algorithm for each set of models; and the two alignments are merged. This forms a static aligned bitext. Next, all foreign word sequences up to a given length (here, 5 words) are extracted from the test set. For each of these, a phrase pair is added to the PPI if the foreign phrase can be found aligned to an English phrase under Eq 1. We refer to the result as the Model-4 Viterbi Phrase-Extract PPI.

Constructed in this way, the PPI is limited to phrase pairs which can be found in the Viterbi alignments. Some foreign phrases which do appear in the training bitext will not be included in the PPI because suitable English phrases cannot be found. To add these to the PPI we can use the phrase-to-phrase posterior distribution to find English phrases as candidate translations. This adds phrases to the Viterbi Phrase-Extract PPI and increase the test set coverage. A somewhat *ad hoc* PPI Augmentation algorithm is given to the right.

Condition (A) extracts phrase pairs based on the geometric mean of the E→F and F→E posteriors ($T_g = 0.01$ throughout). The threshold T_p selects additional phrase pairs under a more forgiving criterion: as T_p decreases, more phrase pairs are added and PPI coverage increases. Note that this algorithm is constructed specifically to improve a Viterbi PPI; it is certainly not the only way to extract phrase pairs under the phrase-to-phrase posterior distribution.

Once the PPI phrase pairs are set, the phrase translation probabilities are set based on the number of times each phrase pair is extracted from a sentence pair, i.e. from relative frequencies.

```
For each foreign phrase $v$ not in the Viterbi PPI :
  For all pairs $(f_1^m, e_1^l)$ and $j_1, j_2$ s.t. $f_{j_1}^{j_2} = v$ :
    For $1 \leq i_1 \leq i_2 \leq l$, find
      $f(i_1,i_2) = P_{F\to E}(\,A(i_1,i_2;j_1,j_2)\,|\,e_1^l, f_1^m)$
      $b(i_1,i_2) = P_{E\to F}(\,A(i_1,i_2;j_1,j_2)\,|\,e_1^l, f_1^m)$
      $g(i_1,i_2) = \sqrt{f(1_1,i_2)\,b(i_1,i_2)}$
      $(\hat{i}_1,\hat{i}_2) = \operatorname*{argmax}_{1\leq i_1,i_2\leq l} g(i_1,i_2)$ , and set $u = e_{\hat{i}_1}^{\hat{i}_2}$
    Add $(u,v)$ to the PPI if any of A, B, or C hold :
      $b(\hat{i}_1,\hat{i}_2) \geq T_g$ and $f(\hat{i}_1,\hat{i}_2) \geq T_g$    (A)
      $b(\hat{i}_1,\hat{i}_2) < T_g$ and $f(\hat{i}_1,\hat{i}_2) > T_p$    (B)
      $f(\hat{i}_1,\hat{i}_2) < T_g$ and $b(\hat{i}_1,\hat{i}_2) > T_p$    (C)
```

PPI Augmentation via Phrase-Posterior Induction

HMM-based models are often used if posterior distributions are needed. Model-1 can also be used in this way (Venugopal et al., 2003), although it is a relatively weak alignment model. By comparison, finding posterior distributions under Model-4 is difficult. The Word-to-Phrase alignment model appears not to suffer this tradeoff: it is a good model of word alignment under which statistics such as the phrase-to-phrase posterior can be calculated.

6 Translation Experiments

We evaluate the quality of phrase pairs extracted from the bitext through the translation performance of the Translation Template Model (TTM) (Kumar et al., 2005), which is a phrase-based translation system implemented using weighted finite state transducers. Performance is measured by BLEU (Papineni and others, 2001).

Chinese→English Translation We report performance on the NIST Chinese/English 2002, 2003 and 2004 (News only) MT evaluation sets. These consist of 878, 919, and 901 sentences, respectively. Each Chinese sentence has 4 reference translations.

We evaluate two C→E translation systems. The smaller system is built on the FBIS C-E bitext collection. The language model used for this system is a trigram word language model estimated with 21M

Table 4: Translation Analysis and Performance of PPI Extraction Procedures

words taken from the English side of the bitext; all language models are built with the SRILM toolkit using Kneser-Ney smoothing (Stolcke, 2002).

The larger system is based on alignments generated over all available C-E bitext (the "ALL C-E" collection of Section 4). The language model is an equal-weight interpolated trigram model trained over 373M English words taken from the English side of the bitext and the LDC Gigaword corpus.

Arabic→English Translation We also evaluate our WtoP alignment models in Arabic-English translation. We report results on a small and a large system. In each, Arabic text is tokenized by the Buckwalter analyzer provided by LDC. We test our models on NIST Arabic/English 2002, 2003 and 2004 (News only) MT evaluation sets that consists of 1043, 663 and 707 Arabic sentences, respectively. Each Arabic sentence has 4 reference translations.

In the small system, the training bitext is from A-E News parallel text, with ∼3.5M words on the English side. We follow the same training procedure and configurations as in Chinese/English system in both translation directions. The language model is an equal-weight interpolated trigram built over ∼400M words from the English side of the bitext, including UN text, and the LDC English Gigaword collection. The large Arabic/English system employs the same language model. Alignments are generated over all A-E bitext available from LDC as of this submission; this consists of approx. 130M words on the English side.

WtoP Model and Model-4 Comparison We first look at translation performance of the small A→E and C→E systems, where alignment models are trained over the smaller bitext collections. The baseline systems (Table 4, line 1) are based on Model-4 Viterbi Phrase-Extract PPIs.

We compare WtoP alignments directly to Model-4 alignments by extracting PPIs from the WtoP alignments using the Viterbi Phrase-Extract procedure (Table 4, line 3). In C→E translation, performance is comparable to that of Model-4; in A→E translation, performance lags slightly. As we add phrase pairs to the WtoP Viterbi Phrase-Extract PPI via the Phrase-Posterior Augmentation procedure (Table 4, lines 4-7), we obtain a ∼1% improvement in BLEU; the value of $T_p = 0.7$ gives improvements across all sets. In C→E translation, this yields good gains relative to Model-4, while in A→E we match or improve the Model-4 performance.

The performance gains through PPI augmentation are consistent with increased PPI coverage of the test set. We tabulate the percentage of test set phrases that appear in each of the PPIs (the 'cvg' values in Table 4). The augmentation scheme is designed specifically to increase coverage, and we find that BLEU score improvements track the phrase coverage of the test set. This is further confirmed by the experiment of Table 4, line 2 in which we take the PPI extracted from Model-4 Viterbi alignments, and add phrase pairs to it using the Phrase-Posterior augmentation scheme with $T_p = 0.7$. We find that the augmentation scheme under the WtoP models can be used to improve the Model-4 PPI itself.

We also investigate C→E and A→E translation performance with PPIs extracted from large bitexts.

Performance of systems based on Model-4 Viterbi Phrase-Extract PPIs is shown in Table 4, line 8. To train Model-4 using GIZA++, we split the bitexts into two (A-E) or three (C-E) partitions, and train models for each division separately; we find that memory usage is otherwise too great. These serve as a single set of alignments for the bitext, as if they had been generated under a single alignment model. When we translate with Viterbi Phrase-Extract PPIs taken from WtoP alignments created over all available bitext, we find comparable performance to the Model-4 baseline (Table 4, line 9). Using the Phrase-Posterior augmentation scheme with $T_p = 0.7$ yields further improvement (Table 4, line 10). Pooling the sets to form two large C→E and A→E test sets, the A→E system improvements are significant at a 95% level (Och, 2003); the C→E systems are only equivalent.

7 Conclusion

We have described word-to-phrase alignment models capable of good quality bitext word alignment. In Arabic-English and Chinese-English translation and alignment they compare well to Model-4, even with large bitexts. The model architecture was inspired by features of Model-4, such as fertility and distortion, but care was taken to ensure that dynamic programming procedures, such as EM and Viterbi alignment, could still be performed. There is practical value in this: training and alignment are easily parallelized. Working with HMMs also makes it straightforward to explore new modeling approaches. We show an augmentation scheme that adds to phrases extracted from Viterbi alignments; this improves translation with both the WtoP and the Model-4 phrase pairs, even though it would be infeasible to implement the scheme under Model-4 itself. We note that these models are still relatively simple, and we anticipate further alignment and translation improvement as the models are refined.

Abstract

Most statistical translation systems are based on phrase translation pairs, or "blocks", which are obtained mainly from word alignment. We use blocks to infer better word alignment and improved word alignment which, in turn, leads to better inference of blocks. We propose two new probabilistic models based on the inner-outer segmentations and use EM algorithms for estimating the models' parameters. The first model recovers IBM Model-1 as a special case. Both models outperform bi-directional IBM Model-4 in terms of word alignment accuracy by 10% absolute on the F-measure. Using blocks obtained from the models in actual translation systems yields statistically significant improvements in Chinese-English SMT evaluation.

1 Introduction

Today's statistical machine translation systems rely on high quality phrase translation pairs to acquire state-of-the-art performance, see (Koehn et al., 2003; Zens and Ney, 2004; Och and Ney, 2003). Here, phrase pairs, or "blocks" are obtained automatically from parallel sentence pairs via the underlying word alignments. Word alignments traditionally are based on IBM Models 1-5 (Brown et al., 1993) or on HMMs (Vogel et al., 1996). Automatic word alignment is challenging in that its accuracy is not yet close to inter-annotator agreement in some language pairs: for Chinese-English, inter-annotator agreement exceeds 90 on F-measure whereas IBM Model-4 or HMM accuracy is typically below 80s. HMMs assume that words "close-in-source" are aligned to words "close-in-target". While this locality assumption is generally sound, HMMs do have limitations: the self-transition probability of a state (word) is the only control on the duration in the state, the length of the phrase aligned to the word. Also there is no natural way to control repeated non-contiguous visits to a state. Despite these problems, HMMs remain attractive for their speed and reasonable accuracy.

We propose a new method for localizing word alignments. We use blocks to achieve locality in the following manner: a block in a sentence pair is a source phrase aligned to a target phrase. We assume that words inside the source phrase cannot align to words outside the target phrase and that words outside the source phrase cannot align to words inside the target phrase. Furthermore, a block divides the sentence pair into two smaller regions: the *inner* part of the block, which corresponds to the source and target phrase in the block, and the *outer* part of the block, which corresponds to the remaining source and target words in the parallel sentence pair. The two regions are non-overlapping; and each of them is shorter than the original parallel sentence pair. The regions are thus easier to align than the original sentence pairs (e.g., using IBM Model-1). While the model uses a single block to split the sentence pair into two independent regions, it is not clear which block we should select for this purpose. Therefore, we treat the splitting block as a hidden variable.

This proposed approach is far simpler than treating the entire sentence as a sequence of non-overlapping phrases (or chunks) and considering such sequential segmentation either explicitly or implicitly. For example, (Marcu and Wong, 2002) for a joint phrase based model, (Huang et al., 2003) for a translation memory system; and (Watanabe et al., 2003) for a complex model of insertion, deletion and head-word driven chunk reordering. Other approaches including (Watanabe et al., 2002) treat extracted phrase-pairs as new parallel data with limited success. Typically, they share a similar architecture of phrase level segmentation, reordering, translation as in (Och and Ney, 2002; Koehn and Knight, 2002; Yamada and Knight, 2001). The phrase level interaction has to be taken care of for the non-overlapping sequential segmentation in a complicated way. Our models model such interactions in a soft way. The hidden blocks are allowed to overlap with each other, while each block induced two non-overlapping regions, i.e. the model brackets the sentence pair into two independent parts which are generated synchronously. In this respect, it resembles bilingual bracketing (Wu, 1997), but our model has more lexical items in the blocks with many-to-many word alignment freedom in both inner and outer parts.

We present our localization constraints using blocks for word alignment in Section 2; we detail our two new probabilistic models and their EM training algorithms in Section 3; our baseline system, a maximum-posterior inference for word alignment, is explained in Section 4; experimental results of alignments and translations are in Section 5; and Section 6 contains discussion and conclusions.

2 Segmentation by a Block

We use the following notation in the remainder of this paper: $\mathbf{e}$ and $\mathbf{f}$ denote the English and foreign sentences with sentence lengthes of I and J, respectively. e_i is an English word at position i in $\mathbf{e}$; f_j is a foreign word at position j in $\mathbf{f}$. $\mathbf{a}$ is the alignment vector with a_j mapping the position of the English word e_{a_j} to which f_j connects. Therefore, we have the standard limitation that one foreign word cannot be connected to more than one English word. A *block* $\delta^{\square}$ is defined as a pair of brackets as follows:

$$\delta^{\square} = (\delta^{\mathbf{e}}, \delta^{\mathbf{f}}) = ([i_l, i_r], [j_l, j_r]), \tag{1}$$

where $\delta^{\mathbf{e}} = [i_l, i_r]$ is a bracket in English sentence defined by a pair of indices: the *left* position i_l and the *right* position i_r, corresponding to a English phrase $e_{i_l}^{i_r}$. Similar notations are for $\delta^{\mathbf{f}} = [j_l, j_r]$, which is one possible *projection* of $\delta^{\mathbf{e}}$ in $\mathbf{f}$. The subscript l and r are abbreviations of left and right, respectively.

$\delta^{\mathbf{e}}$ segments $\mathbf{e}$ into two parts: $(\delta^{\mathbf{e}}, \mathbf{e}) = (\delta^{\mathbf{e}}_{\in}, \delta^{\mathbf{e}}_{\notin})$. The inner part $\delta^{\mathbf{e}}_{\in} = \{e_i, i \in [i_l, i_r]\}$ and the outer part $\delta^{\mathbf{e}}_{\notin} = \{e_i, i \notin [i_l, i_r]\}$; $\delta^{\mathbf{f}}$ segments $\mathbf{f}$ similarly.

Thus, the block $\delta^{\square}$ splits the parallel sentence pair into two *non-overlapping* regions: the *Inner* $\delta^{\square}_{\in}$ and *Outer* $\delta^{\square}_{\notin}$ parts (see Figure 1). With this segmentation, we assume the words in the inner part are aligned to inner part only: $\delta^{\square}_{\in} = \delta^{\mathbf{e}}_{\in} \leftrightarrow \delta^{\mathbf{f}}_{\in} : \{e_i, i \in [i_l, i_r]\} \leftrightarrow \{f_j, j \in [j_l, j_r]\}$; and words in the outer part are aligned to outer part only: $\delta^{\square}_{\notin} = \delta^{\mathbf{e}}_{\notin} \leftrightarrow \delta^{\mathbf{f}}_{\notin} : \{e_i, i \notin [i_l, i_r]\} \leftrightarrow \{f_j, j \notin [j_l, j_r]\}$. We do not allow alignments to cross block boundaries. Words inside a block $\delta^{\square}$ can be aligned using a variety of models (IBM models 1-5, HMM, etc). We choose Model1 for simplicity. If the block boundaries are accurate, we can expect high quality word alignment. This is our proposed new localization method.

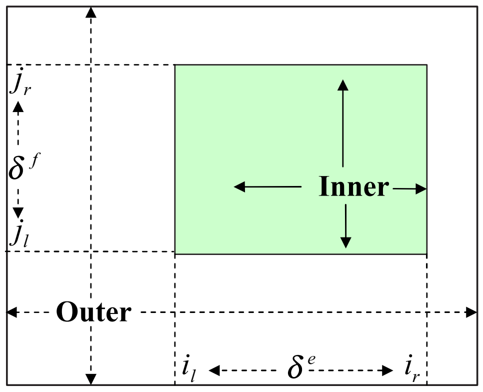

Figure 1: Segmentation by a Block

3 Inner-Outer Bracket Models

We treat the constraining block as a hidden variable in a generative model shown in Eqn. 2.

$$\begin{aligned} P(\mathbf{f}|\mathbf{e}) &= \sum_{\{\delta^{\square}\}} P(\mathbf{f}, \delta^{\square}|\mathbf{e}) \\ &= \sum_{\{\delta^{\mathbf{e}}\}} \sum_{\{\delta^{\mathbf{f}}\}} P(\mathbf{f}, \delta^{\mathbf{f}}|\delta^{\mathbf{e}}, \mathbf{e}) P(\delta^{\mathbf{e}}|\mathbf{e}), \end{aligned} \tag{2}$$

where $\delta^{\square} = (\delta^{\mathbf{e}}, \delta^{\mathbf{f}})$ is the hidden block. In the generative process, the model first generates a bracket $\delta^{\mathbf{e}}$ for $\mathbf{e}$ with a monolingual bracketing model of $P(\delta^{\mathbf{e}}|\mathbf{e})$. It then uses the segmentation of the English $(\delta^{\mathbf{e}}, \mathbf{e})$ to generate the projected bracket $\delta^{\mathbf{f}}$ of $\mathbf{f}$ using a generative translation model $P(\mathbf{f}, \delta^{\mathbf{f}}|\delta^{\mathbf{e}}, \mathbf{e}) = P(\delta^{\mathbf{f}}_{\notin}, \delta^{\mathbf{f}}_{\in}|\delta^{\mathbf{e}}_{\notin}, \delta^{\mathbf{e}}_{\in})$ — the key model to implement our proposed inner-outer constraints. With the hidden block $\delta^{\square}$ inferred, the model then generates word alignments within the inner and outer parts separately. We present two generating processes for the inner and outer parts induced by $\delta^{\square}$ and corresponding two models of $P(\mathbf{f}, \delta^{\mathbf{f}}|\delta^{\mathbf{e}}, \mathbf{e})$. These models are described in the following secions.

3.1 Inner-Outer Bracket Model-A

The first model assumes that the inner part and the outer part are generated independently. By the formal equivalence of (f, δ^f) with $(\delta^f_{\in}, \delta^f_{\notin})$, Eqn. 2 can be approximated as:

$$P(\mathbf{f}|\mathbf{e}) \approx \sum_{\{\delta^{\mathbf{e}}\}} \sum_{\{\delta^{\mathbf{f}}\}} P(\delta^{\mathbf{f}}_{\in}|\delta^{\mathbf{e}}_{\in}) P(\delta^{\mathbf{f}}_{\notin}|\delta^{\mathbf{e}}_{\notin}) P(\delta^{\mathbf{e}}|\mathbf{e}) P(\delta^{\mathbf{f}}|\delta^{\mathbf{e}}), \tag{3}$$

where $P(\delta^{\mathbf{f}}_{\in}|\delta^{\mathbf{e}}_{\in})$ and $P(\delta^{\mathbf{f}}_{\notin}|\delta^{\mathbf{e}}_{\notin})$ are two independent generative models for inner and outer parts, respectively and are futher decompsed into:

$$P(\delta^{\mathbf{f}}_{\in}|\delta^{\mathbf{e}}_{\in}) = \sum_{\{a_j \in \delta^{\mathbf{e}}_{\in}\}} \prod_{f_j \in \delta^{\mathbf{f}}_{\in}} P(f_j|e_{a_j}) P(e_{a_j}|\delta^{\mathbf{e}}_{\in})$$

$$P(\delta^{\mathbf{f}}_{\notin}|\delta^{\mathbf{e}}_{\notin}) = \sum_{\{a_j \in \delta^{\mathbf{e}}_{\notin}\}} \prod_{f_j \in \delta^{\mathbf{f}}_{\notin}} P(f_j|e_{a_j}) P(e_{a_j}|\delta^{\mathbf{e}}_{\notin}), \quad (4)$$

where $\{a_1^J\}$ is the word alignment vector. Given the block segmentation and word alignment, the generative process first randomly selects a e_i according to either $P(e_i|\delta^{\mathbf{e}}_{\in})$ or $P(e_i|\delta^{\mathbf{e}}_{\notin})$; and then generates f_j indexed by word alignment a_j with $i = a_j$ according to a word level lexicon $P(f_j|e_{a_j})$. This generative process using the two models of $P(\delta^{\mathbf{f}}_{\in}|\delta^{\mathbf{e}}_{\in})$ and $P(\delta^{\mathbf{f}}_{\notin}|\delta^{\mathbf{e}}_{\notin})$ must satisfy the constraints of segmentations induced by the hidden block $\delta^{\square} = (\delta^{\mathbf{e}}, \delta^{\mathbf{f}})$. The English words $\delta^{\mathbf{e}}_{\in}$ inside the block can only generate the words in $\delta^{\mathbf{f}}_{\in}$ and nothing else; likewise $\delta^{\mathbf{e}}_{\notin}$ only generates $\delta^{\mathbf{f}}_{\notin}$. Overall, the combination of $P(\delta^{\mathbf{f}}_{\in}|\delta^{\mathbf{e}}_{\in})P(\delta^{\mathbf{f}}_{\notin}|\delta^{\mathbf{e}}_{\notin})$ in Eqn. 3 collaborates each other quite well in practice. For a particular observation $\delta^{\mathbf{f}}_{\in}$, if $\delta^{\mathbf{e}}_{\in}$ is too small (i.e., missing translations), $P(\delta^{\mathbf{f}}_{\in}|\delta^{\mathbf{e}}_{\in})$ will suffer; and if $\delta^{\mathbf{e}}_{\in}$ is too big (i.e., robbing useful words from $\delta^{\mathbf{e}}_{\notin}$), $P(\delta^{\mathbf{f}}_{\notin}|\delta^{\mathbf{e}}_{\notin})$ will suffer. Therefore, our proposed model in Eqn. 3 combines the two costs and requires both inner and outer parts to be explained well at the same time.

Because the model in Eqn. 3 is essentially a two-level ($\delta^{\square}$ and $\mathbf{a}$) mixture model similar to IBM Models, the EM algorithm is quite straight forward as in IBM models. Shown in the following are several key E-step computations of the posteriors. The M-step (optimization) is simply the normalization of the fractional counts collected using the posteriors through the inference results from E-step:

$$P_{\delta^{\square}_{\in}}(a_j|\delta^{\mathbf{f}}_{\in}, \delta^{\mathbf{e}}_{\in}) = \frac{P(f_j|e_{a_j})}{\sum_{e_k \in \delta^{\mathbf{e}}_{\in}} P(f_j|e_k)}$$

$$P_{\delta^{\square}_{\notin}}(a_j|\delta^{\mathbf{f}}_{\notin}, \delta^{\mathbf{e}}_{\notin}) = \frac{P(f_j|e_{a_j})}{\sum_{e_k \in \delta^{\mathbf{e}}_{\notin}} P(f_j|e_k)} \quad (5)$$

The posterior probability of $P(a_1^J|\mathbf{f}, \delta^{\mathbf{f}}, \delta^{\mathbf{e}}, \mathbf{e}) = \prod_{j=1}^{J} P(a_j|\mathbf{f}, \delta^{\mathbf{f}}, \delta^{\mathbf{e}}, \mathbf{e})$, where $P(a_j|\mathbf{f}, \delta^{\mathbf{f}}, \delta^{\mathbf{e}}, \mathbf{e})$ is either $P_{\delta^{\square}_{\in}}(a_j|\delta^{\mathbf{f}}_{\in}, \delta^{\mathbf{e}}_{\in})$ when $(f_j, e_{a_j}) \in \delta^{\square}_{\in}$, or otherwise $P_{\delta^{\square}_{\notin}}(a_j|\delta^{\mathbf{f}}_{\notin}, \delta^{\mathbf{e}}_{\notin})$ when $(f_j, e_{a_j}) \in \delta^{\square}_{\notin}$. Assuming $P(\delta^{\mathbf{e}}|\mathbf{e})$ to be a uniform distribution, the posterior of selecting a hidden block given observations: $P(\delta^{\square} = (\delta^{\mathbf{e}}, \delta^{\mathbf{f}})|\mathbf{e}, \mathbf{f})$ is proportional to block level relative frequency $P_{rel}(\delta^{\mathbf{f}}_{\in}|\delta^{\mathbf{e}}_{\in})$ updated in each iteration; and can be smoothed with $P(\delta^{\mathbf{f}}|\delta^{\mathbf{e}}, \mathbf{f}, \mathbf{e}) = P(\delta^{\mathbf{f}}_{\in}|\delta^{\mathbf{e}}_{\in})P(\delta^{\mathbf{f}}_{\notin}|\delta^{\mathbf{e}}_{\notin}) / \sum_{\{\delta'^{\mathbf{f}}\}} P(\delta'^{\mathbf{f}}_{\in}|\delta^{\mathbf{e}}_{\in})P(\delta'^{\mathbf{f}}_{\notin}|\delta^{\mathbf{e}}_{\notin})$ assuming Model-1 alignment in the inner and outer parts independently to reduce the risks of data sparseness in estimations.

In principle, $\delta^{\mathbf{e}}$ can be a bracket of any length not exceeding the sentence length. If we restrict the bracket length to that of the sentence length, we recover IBM Model-1. Figure 2 summarizes the generation process for Inner-Outer Bracket Model-A.

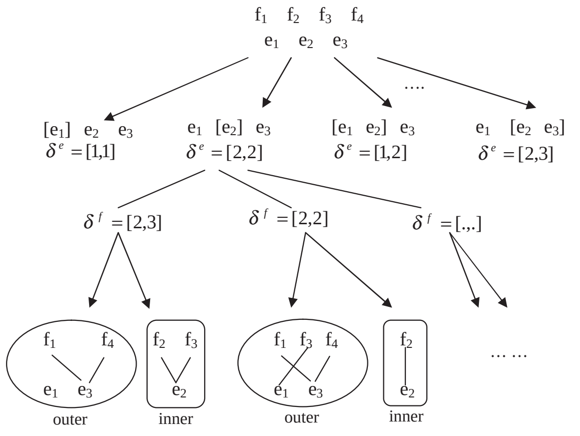

Figure 2: Illustration of generative Bracket Model-A

3.2 Inner-Outer Bracket Model-B

A block $\delta^{\square}$ invokes both the inner and outer generations simultaneously in Bracket Model A (BM-A). However, the generative process is usually more effective in the inner part as $\delta^{\square}$ is generally small and accurate. We can build a model focusing on generating only the inner part with careful inferences to avoid errors from noisy blocks. To ensure that all f_1^J are generated, we need to propose enough blocks to cover each observation f_j. This constraint can be met by treating the whole sentence pair as one block.

The generative process is as follows: First the model generates an English bracket $\delta^{\mathbf{e}}$ as before. The model then generates a projection $\delta^{\mathbf{f}}$ in $\mathbf{f}$ to localize all a_j's for the given $\delta^{\mathbf{e}}$ according to $P(\delta^{\mathbf{f}}|\delta^{\mathbf{e}}, \mathbf{e})$. $\delta^{\mathbf{e}}$ and $\delta^{\mathbf{f}}$ forms a hidden block $\delta^{\square}$. Given $\delta^{\square}$, the model then generates only the inner part $f_j \in \delta^{\mathbf{f}}_{\in}$ via $P(\mathbf{f}|\delta^{\mathbf{f}}, \delta^{\mathbf{e}}, \mathbf{e}) \simeq P(\delta^{\mathbf{f}}_{\in}|\delta^{\mathbf{f}}, \delta^{\mathbf{e}}, \mathbf{e})$. Eqn. 6 summarizes this by rewriting $P(\mathbf{f}, \delta^{\mathbf{f}}|\delta^{\mathbf{e}}, \mathbf{e})$:

$$\begin{aligned} P(\mathbf{f}, \delta^{\mathbf{f}}|\delta^{\mathbf{e}}, \mathbf{e}) &= P(\mathbf{f}|\delta^{\mathbf{f}}, \delta^{\mathbf{e}}, \mathbf{e})P(\delta^{\mathbf{f}}|\delta^{\mathbf{e}}, \mathbf{e}) \quad (6) \\ &= P(\mathbf{f}|\delta^{\mathbf{f}}, \delta^{\mathbf{e}}, \mathbf{e})P([j_l, j_r]|\delta^{\mathbf{e}}, \mathbf{e}) \\ &\simeq P(\delta^{\mathbf{f}}_{\in}|\delta^{\mathbf{f}}, \delta^{\mathbf{e}}, \mathbf{e})P([j_l, j_r]|\delta^{\mathbf{e}}, \mathbf{e}). \end{aligned}$$

$P(\delta^{\mathbf{f}}_{\in}|\delta^{\mathbf{f}}, \delta^{\mathbf{e}}, \mathbf{e})$ is a bracket level *emission* probabilistic model which generates a bag of contiguous words $f_j \in \delta^{\mathbf{f}}_{\in}$ under the constraints from the given hidden block $\delta^{\square} = (\delta^{\mathbf{f}}, \delta^{\mathbf{e}})$. The model is simplified in Eqn. 7 with the assumption of bag-of-words' independence within the bracket $\delta^{\mathbf{f}}$:

$$P(\delta^{\mathbf{f}}_{\in}|\delta^{\mathbf{f}}, \delta^{\mathbf{e}}, \mathbf{e}) = \sum_{a_1^J} \prod_{j \in \delta^{\mathbf{f}}_{\in}} P(f_j|e_{a_j}) P(e_{a_j}|\delta^{\mathbf{f}}, \delta^{\mathbf{e}}, \mathbf{e}). \quad (7)$$

The $P([j_l, j_r]|\delta^{\mathbf{e}}, \mathbf{e})$ in Eqn. 6 is a *localization* probabilistic model, which has resemblances to an HMM's transition probability, $P(a_j|a_{j-1})$, implementing the assumption "close-in-source" is aligned to "close-in-target". However, instead of using the simple position variable a_j, $P([j_l, j_r]|\delta^{\mathbf{e}}, \mathbf{e})$ is more expressive with word identities to localize words $\{f_j\}$ aligned to $\delta^{\mathbf{e}}_{\in}$. To model $P([j_l, j_r]|\delta^{\mathbf{e}}, \mathbf{e})$ reliably, $\delta^{\mathbf{f}} = [j_l, j_r]$ is equivalently defined as the *center* and *width* of the bracket $\delta^{\mathbf{f}}$: $(\odot_{\delta^{\mathbf{f}}}, w_{\delta^{\mathbf{f}}})$. To simplify it further, we assume that $w_{\delta^{\mathbf{f}}}$ and $\odot_{\delta^{\mathbf{f}}}$ can be predicted independently.

The *width* model, $P(w_{\delta^{\mathbf{f}}}|\delta^{\mathbf{e}}, \mathbf{e})$, depends on the length of the English bracket and the fertilities of English words in it. To simplify M-step computations, we can compute the expected width as in Eqn. 8.

$$E\{w_{\delta^{\mathbf{f}}}|\delta^{\mathbf{e}}, \mathbf{e}\} \simeq \gamma \cdot |i_r - i_l + 1|, \tag{8}$$

where γ is the expected bracket length ratio and is approximated by the average sentence length ratio computed using the whole parallel corpus. For Chinese-English, $\gamma = 1/1.3 = 0.77$. In practice, this estimation is quite reliable.

The *center* model $P(\odot_{\delta^{\mathbf{f}}}|\delta^{\mathbf{e}}, \mathbf{e})$ is harder. It is conditioned on the translational equivalence between the English bracket and its projection. We compute the expected $\odot_{\delta^{\mathbf{f}}}$ by averaging the weighted expected centers from all the English words in $\delta^{\mathbf{e}}$ as in Eqn. 9.

$$\begin{aligned} E\{\odot_{\delta^{\mathbf{f}}}|\delta^{\mathbf{e}}, \mathbf{e}\} &= \textstyle\sum_{j=0}^{J} j \cdot P(j|\delta^{\mathbf{e}}, \mathbf{e}) \\ &\simeq \textstyle\sum_{j=0}^{J} j \cdot \frac{\sum_{i \in \delta^{\mathbf{e}}} P(f_j|e_i)}{\sum_{j'=0}^{J} \sum_{i \in \delta^{\mathbf{e}}} P(f_{j'}|e_i)}. \end{aligned} \tag{9}$$

The expectations of $(\odot_{\delta^{\mathbf{f}}}, w_{\delta^{\mathbf{f}}})$ from Eqn. 8 and Eqn. 9 give a reliable starting point for a local search for the optimal estimation of $(\hat{\odot}_{\delta^{\mathbf{f}}}, \hat{w}_{\delta^{\mathbf{f}}})$ as in Eqn 10:

$$(\hat{\odot}_{\delta^{\mathbf{f}}}, \hat{w}_{\delta^{\mathbf{f}}}) = \underset{\{(\odot_{\delta^{\mathbf{f}}}, w_{\delta^{\mathbf{f}}})\}}{\arg\max}\ P(\delta^{\mathbf{f}}_{\in}|\delta^{\mathbf{e}}_{\in}) P(\delta^{\mathbf{f}}_{\notin}|\delta^{\mathbf{e}}_{\notin}), \tag{10}$$

where the score functions of $P(\delta^{\mathbf{f}}_{\in}|\delta^{\mathbf{e}}_{\in}) P(\delta^{\mathbf{f}}_{\notin}|\delta^{\mathbf{e}}_{\notin})$ are in Eqn. 4 with the word alignment explicitly given from the previous iteration. For the very first iteration, *full alignment* is assumed; this means that every word pair is connected in the parallel sentences. During the local search in Eqn. 10, one can choose the top-1 (Viterbi) $(\hat{\odot}_{\delta^{\mathbf{f}}}, \hat{w}_{\delta^{\mathbf{f}}})$ or top-N candidates and normalize over these candidates to obtain the posteriors. Except for the local search of $(\hat{\odot}_{\delta^{\mathbf{f}}}, \hat{w}_{\delta^{\mathbf{f}}})$, the remainder EM steps are similar to Bracket Model-A, though with different interpretations.

By performing local search in Eqn. 10, Model-B localizes hidden blocks more accurately than the scheme of the smoothed relative frequency in Model-A's EM iterations. The model is also more focused on the predictions in the inner part. Figure 3 summarizes the generative process of Model-B (BM-B).

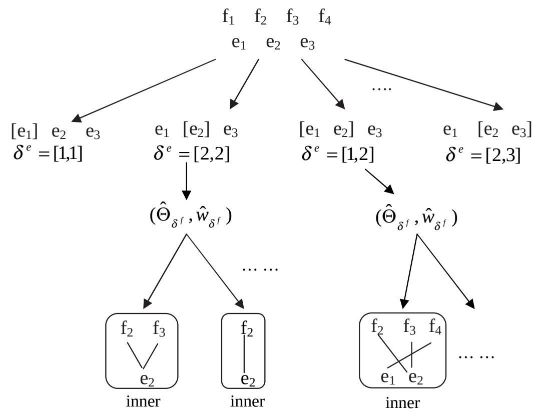

Figure 3: Generative Bracket Model-B

3.3 A Null Word Model

The null word model allows words to be aligned to nothing. In the traditional IBM models, there is a universal null word which is attached to every sentence pair to compete with word generators. In our inner-outer bracket models, we use two context-specific null word models which use both the left and right context as competitors in the generative process for each observation f_j: $P(f_j|f_{j-1}, \mathbf{e})$ and $P(f_j|f_{j+1}, \mathbf{e})$. This is similar to the approach in (Toutanova et al., 2002), in which the null word model is part of an extended HMM using left context only. With two null word models, we can associate f_j with its left or right context (i.e., a null link) when the null word models are very strong, or when the word's alignment is too far from the expected center $\hat{\odot}_{\delta^{\mathbf{f}}}$ in Eqn. 9.

4 A Max-Posterior for Word Alignment

In the HMM framework, (Ge, 2004) proposed a *maximum-posterior* method which worked much better than *Viterbi* for Arabic to English translations. The difference between maximum-posterior and Viterbi, in a nutshell, is that while Viterbi computes the best state *sequence* given the observation, the maximum-posterior computes the best state *one at a time.*

In the terminology of HMM, let the states be the words in the foreign sentence f_1^J and observations be the words in the English sentence e_1^T. We use the subscript t to note the fact that e_t is observed (or emitted) at time step t. The posterior probabilities $P(f_j|e_t)$ (state given observation) are obtained after the forward-backward training. The maximum-posterior word alignments are obtained by first computing a pair $(j,t)^*$:

$$(j,t)^* = \arg\max_{(j,t)} P(f_j|e_t), \qquad (11)$$

that is, the point at which the posterior is maximum. The pair (j,t) defines a word pair (f_j, e_t) which is then aligned. The procedure continues to find the next maximum in the posterior matrix. Contrast this with Viterbi alignment where one computes

$$\hat{f}_1^T = \arg\max_{\{f_1^T\}} P(f_1, f_2, \cdots, f_T|e_1^T), \qquad (12)$$

We observe, in parallel corpora, that when one word translates into multiple words in another language, it usually translates into a contiguous sequence of words. Therefore, we impose a contiguity constraint on word alignments. When one word f_j aligns to multiple English words, the English words must be contiguous in $\mathbf{e}$ and vice versa. The algorithm to find word alignments using max-posterior with contiguity constraint is illustrated in Algorithm 1.

Algorithm 1 A maximum-posterior algorithm with contiguity constraint

```
1: while $(j,t) = (j,t)^*$ (as computed in Eqn. 11) do
2:   if $(f_j, e_t)$ is not yet aligned then
3:     align($f_j$, $e_t$);
4:   else if ($e_t$ is contiguous to what $f_j$ is aligned) or ($f_j$ is contiguous to what $e_t$ is aligned) then
5:     align($f_j$, $e_t$);
6:   end if
7: end while
```

The algorithm terminates when there isn't any 'next' posterior maximum to be found. By definition, there are at most JxT 'next' maximums in the posterior matrix. And because of the contiguity constraint, not all (f_j, e_t) pairs are valid alignments. The algorithm is sure to terminate. The algorithm is, in a sense, *directionless*, for one f_j can align to multiple e_t's and vise versa as long as the multiple connections are contiguous. Viterbi, however, is *directional* in which one state can emit multiple observations but one observation can only come from one state.

5 Experiments

We evaluate the performances of our proposed models in terms of word alignment accuracy and translation quality. For word alignment, we have 260 hand-aligned sentence pairs with a total of 4676 word pair links. The 260 sentence pairs are randomly selected from the CTTP[1] corpus. They were then word aligned by eight bilingual speakers. In this set, we have one-to-one, one-to-many and many-to-many alignment links. If a link has one target *functional* word, it is considered to be a *functional* link (Examples of funbctional words are prepositions, determiners, etc. There are in total 87 such functional words in our experiments). We report the overall F-measures as well as F-measures for both content and functional word links. Our significance test shows an overall interval of ±1.56% F-measure at a 95% confidence level.

For training data, the small training set has 5000 sentence pairs selected from XinHua news stories with a total of 131K English words and 125K Chinese words. The large training set has 181K sentence pairs (5k+176K); and the additional 176K sentence pairs are from FBIS and Sinorama, which has in total 6.7 million English words and 5.8 million Chinese words.

5.1 Baseline Systems

The baseline is our implementation of HMM with the maximum-posterior algorithm introduced in section 4. The HMMs are trained unidirectionally. IBM Model-4 is trained with GIZA++ using the best reported settings in (Och and Ney, 2003). A few parameters, especially the maximum fertility, are tuned for GIZA++'s optimal performance. We collect *bi-directional* (**bi**) refined word alignment by growing the intersection of *Chinese-to-English* (**CE**) alignments and *English-to-Chinese* (**EC**) alignments with the neighboring unaligned word pairs which appear in the union similar to the "final-and" approaches (Koehn, 2003; Och and Ney, 2003; Tillmann, 2003). Table 1 summarizes our baseline with different settings. Table 1 shows that **HMM EC-P** gives the

F-measure(%)		**Func**	**Cont**	**Both**
Small	**HMM EC-P**	**54.69**	**69.99**	**64.78**
	HMM EC-V	31.38	53.56	55.59
	HMM CE-P	51.44	69.35	62.69
	HMM CE-V	31.43	63.84	55.45
Large	**HMM EC-P**	**60.08**	78.01	**71.92**
	HMM EC-V	32.80	74.10	64.26
	HMM CE-P	58.45	**79.44**	71.84
	HMM CE-V	35.41	79.12	68.33
Small	GIZA MH-bi	45.63	69.48	60.08
	GIZA M4-bi	48.80	73.68	63.75
Large	GIZA MH-bi	49.13	76.51	65.67
	GIZA M4-bi	52.88	81.76	70.24
-	Fully-Align [2]	5.10	15.84	9.28

Table 1: Baseline: **V**: **V**iterbi; **P**: Max-**P**osterior

best baseline, better than bidirectional refined word alignments from GIZA M4 and the HMM Viterbi aligners.

5.2 Inner-Outer Bracket Models

We trained HMM lexicon $P(f|e)$ to initialize the inner-outer Bracket models. Afterwards, up to 15–20 EM iterations are carried out. Iteration starts from the fully aligned[2] sentence pairs, which give an F-measure of 9.28% at iteration one.

5.2.1 Small Data Track

Figure 4 shows the performance of Model-A (BM-A) trained on the small data set. For each English bracket, *Top-1* means only the fractional counts from the Top-1 projection are collected, *Top-all* means counts from all possible projections are collected. *Inside* means the fractional counts are collected from the inner part of the block only; and *outside* means they are collected from the outer parts only. Using the Top-1 projection from the inner parts of the block (*top-1-inside*) gives the best performance: an F-measure of 72.29%, or a 7.5% absolute improvement over the best baseline at iteration 5. Figure 5 shows

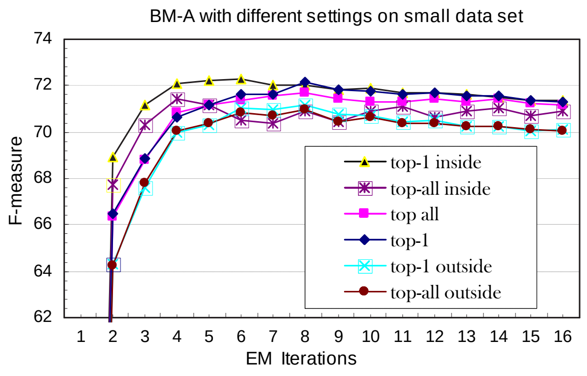

Figure 4: BM-A with different settings on small data

the performance of Inner-Outer Bracket Model-B (BM-B) over EM iterations. *smoothing* means when collecting the fractional counts, we reweigh the updated fractional count by 0.95 and give the remaining 0.05 weight to original fractional count from the links, which were aligned in the previous iteration. *w/null* means we applied the proposed Null word model in section 3.3 to infer null links. We also predefined a list of 15 English function words, for which there might be no corresponding Chinese words as translations. These 15 English words are "*a, an, the, of, to, for, by, up, be, been, being, does, do, did, -*". In the *drop-null* experiments, the links containing these predefined function words are simply dropped in the final word alignment (this means they are left unaligned).

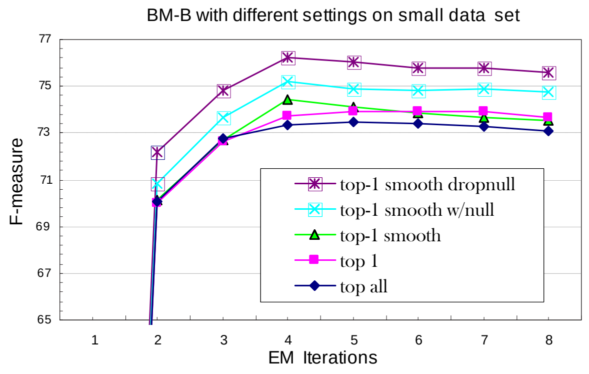

Figure 5: BM-B with different settings on small data

Empirically we found that doing more than 5 iterations lead to overfitting. The peak performance in our model is usually achieved around iteration 4∼5. At iteration 5, setting "BM-B Top-1" gives an F-measure of 73.93% which is better than BM-A's best performance (72.29%). This is because Model B leverages a local search for less noisy blocks and hence the inner part is more accurately generated (which in turn means the outer part is also more accurate). From this point on, all of our experiments are using Model B. With smoothing, BM-B improves to 74.46%. After applying the null word model, we get 75.20%. By simply dropping links containing the 15 English functional words, we get 76.24%, which is significantly better than our best baseline obtained from even the large training set (HMM EC-P: 71.92%).

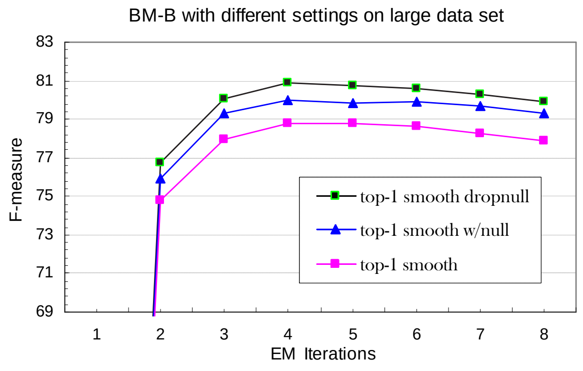

Figure 6: BM-B with different settings on large data

5.2.2 Large Data Track

Figure 6 shows performance pictures of model BM-B on the large training set. Without dropping English functional words, the best performance is

[2]Every possible word pair is aligned

80.38% at iteration 4 using the Top-1 projection together with the null word models. By additionally dropping the links containing the 15 functional English words, we get 81.47%. These results are all significantly better than our strongest baseline system: 71.92% F-measure using HMM EC-P (70.24% using bidirectional Model-4 for comparisons).

On this data set, we experimented with different maximum bracket length limits, from one word (unigram) to nine-gram. Results show that a maximum bracket length of four is already optimal (79.3% with top-1 projection), increased from 62.4% when maximum length is limited to one. No improvements are observed using longer than five-gram.

5.3 Evaluate Blocks in the EM Iterations

Our intuition was that good blocks can improve word alignment and, in turn, good word alignment can lead to better block selection. The experimental results above support the first claim. Now we consider the second claim that good word alignment leads to better block selection.

Given reference human word alignment, we extract reference blocks up to five-gram phrases on Chinese. The block extraction procedure is based on the procedures in (Tillmann, 2003).

During EM, we output all the hidden blocks actually inferred at each iteration, then we evaluate the precision, recall and F-measure of the hidden blocks according to the extracted reference blocks. The results are shown in Figure 7. Because we extract all

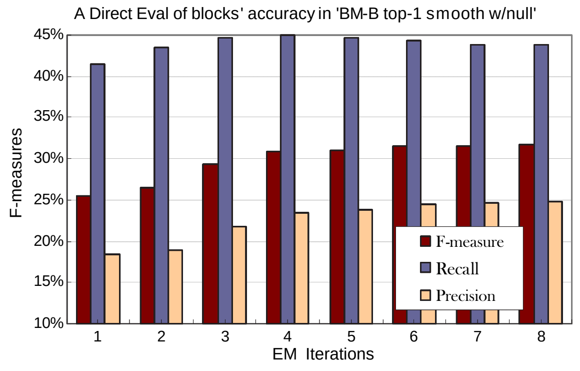

Figure 7: A Direct Eval. of Blocks in BM-B

possible n-grams at each position in **e**, the precision is low and the recall is relatively high as shown by Figure 7. It also shows that blocks do improve, presumably benefiting from better word alignments.

Table 2 summarizes word alignment performances of Inner-Outer BM-B in different settings. Overall, without the handcrafted function word list, BM-B gives about 8% absolute improvement in F-measure on the large training set and 9% for the small set with a confidence interval of ±1.56%.

F-measure(%)		**Func**	**Cont**	**Both**
Small	Baseline	54.69	69.99	64.78
	BM-B-drop	**62.76**	**82.99**	**76.24**
	BM-B w/null	61.24	82.54	75.19
	BM-B smooth	59.61	82.99	74.46
Large	Baseline	60.08	78.01	71.92
	BM-B-drop	**63.95**	**90.09**	**81.47**
	BM-B w/null	62.24	89.99	80.38
	BM-B smooth	60.49	90.09	79.31

Table 2: BM-B with different settings

5.4 Translation Quality Evaluations

We also carried out the translation experiments using the best settings for Inner-Outer BM-B (i.e. *BM-B-drop*) on the TIDES Chinese-English 2003 test set. We trained our models on 354,252 test-specific sentence pairs drawn from LDC-supplied parallel corpora. On this training data, we ran 5 iterations of EM using BM-B to infer word alignments. A monotone decoder similar to (Tillmann and Ney, 2003) with a trigram language model[3] is set up for translations. We report *case sensitive Bleu* (Papineni et al., 2002) score **BleuC** for all experiments. The baseline system (*HMM*) used phrase pairs built from the HMM-EC-P maximum posterior word alignment and the corresponding lexicons. The baseline BleuC score is 0.2276 ± 0.015. If we use the phrase pairs built from the bracket model instead (but keep the HMM trained lexicons), we get case sensitive BleuC score 0.2526. The improvement is statistically significant. If on the other hand, we use baseline phrase pairs with bracket model lexicons, we get a BleuC score 0.2325, which is only a marginal improvement. If we use *both* phrase pairs and lexicons from the bracket model, we get a case sensitive BleuC score 0.2750, which is a statistically significant improvement. The results are summarized in Table 3.

Settings	**BleuC**
Baseline (HMM phrases and lexicon)	0.2276
Bracket phrases and HMM lexicon	0.2526
Bracket lexicon and HMM phrases	0.2325
Bracket (phrases and lexicon)	0.2750

Table 3: Improved *case sensitive* BleuC using BM-B

Overall, using Model-B, we improve translation quality from 0.2276 to 0.2750 in case sensitive BleuC score.

[3]Trained on 1-billion-word ViaVoice English data; the same data is used to build our True Caser.

6 Conclusion

Our main contributions are two novel Inner-Outer Bracket models based on segmentations induced by hidden blocks. Modeling the Inner-Outer hidden segmentations, we get significantly improved word alignments for both the small training set and the large training set over the widely-practiced bidirectional IBM Model-4 alignment. We also show significant improvements in translation quality using our proposed bracket models. Robustness to noisy blocks merits further investigation.

Alignment Link Projection Using Transformation-Based Learning

Necip Fazil Ayan, Bonnie J. Dorr and **Christof Monz**

Abstract

We present a new word-alignment approach that learns errors made by existing word alignment systems and corrects them. By adapting transformation-based learning to the problem of word alignment, we project new alignment links from already existing links, using features such as POS tags. We show that our alignment link projection approach yields a significantly lower alignment error rate than that of the best performing alignment system (22.6% relative reduction on English-Spanish data and 23.2% relative reduction on English-Chinese data).

1 Introduction

Word-level alignment is a critical component of a wide range of NLP applications, such as construction of bilingual lexicons (Melamed, 2000), word sense disambiguation (Diab and Resnik, 2002), projection of language resources (Yarowsky et al., 2001), and statistical machine translation. Although word-level aligners tend to perform well when there is *enough* training data, the quality of word alignment decreases as the size of training data decreases. Moreover, word-alignment systems are often tripped up by many-to-many correspondences, morphological language distinctions, paraphrased and free translations, and a high percentage of function words (about 50% of the tokens in most texts).

At the heart of the matter is a set of assumptions that word-alignment algorithms must make in order to reduce the hypothesis space, since word alignment is an exponential problem. Because of these assumptions, learning algorithms tend to make similar errors throughout the entire data.

This paper presents a new approach—*Alignment Link Projection (ALP)*—that learns common alignment errors made by an alignment system and attempts to correct them. Our approach assumes the initial alignment system adequately captures certain kinds of word correspondences but fails to handle others. ALP starts with an initial alignment and then fills out (i.e., *projects*) new word-level alignment relations (i.e., *links*) from existing alignment relations. ALP then deletes certain alignment links associated with common errors, thus improving precision and recall.

In our approach, we adapt transformation-based learning (TBL) (Brill, 1995; Brill, 1996) to the problem of word alignment. ALP attempts to find an ordered list of transformation rules (within a prespecified search space) to improve a baseline annotation. The rules decompose the search space into a set of consecutive words (windows) within which alignment links are added, to or deleted from, the initial alignment. This window-based approach exploits the clustering tendency of alignment links, i.e., when there is a link between two words, there is frequently another link in close proximity.

TBL is an appropriate choice for this problem for the following reasons:

1. It can be optimized directly with respect to an evaluation metric.
2. It learns rules that improve the initial prediction iteratively, so that it is capable of correcting previous errors in subsequent iterations.
3. It provides a readable description (or classification) of errors made by the initial system, thereby enabling alignment refinements.

The rest of the paper is organized as follows: In the next section we describe previous work on improving word alignments. Section 3 presents a brief overview of TBL. Section 4 describes the adaptation of TBL to the word alignment problem. Section 5 compares ALP to various alignments and presents results on English-Spanish and English-Chinese. We show that ALP yields a significant reductions in alignment error rate over that of the best performing alignment system.

2 Related Work

One of the major problems with the IBM models (Brown et al., 1993) and the HMM models (Vogel et al., 1996) is that they are restricted to the alignment of each source-language word to at most one target-language word. The standard method to overcome this problem to use the model in both directions (interchanging the source and target languages) and applying heuristic-based combination techniques to produce a *refined alignment* (Och and Ney, 2000; Koehn et al., 2003)—henceforth referred to as "RA."

Several researchers have proposed algorithms for improving word alignment systems by injecting additional knowledge or combining different alignment models. These approaches include an enhanced HMM alignment model that uses part-of-speech tags (Toutanova et al., 2002), a log-linear combination of IBM translation models and HMM models (Och and Ney, 2003), techniques that rely on dependency relations (Cherry and Lin, 2003), and a log-linear combination of IBM Model 3 alignment probabilities, POS tags, and bilingual dictionary coverage (Liu et al., 2005). A common theme for these methods is the use of additional features for enriching the alignment process. These methods perform better than the IBM models and their variants but still tend to make similar errors because of the bias in their alignment modeling.

We adopt an approach that post-processes a given alignment using linguistically-oriented rules. The idea is similar to that of Ayan et al. (2004), where manually-crafted rules are used to correct alignment links related to language divergences. Our approach differs, however, in that the rules are extracted automatically—not manually—by examining an initial alignment and categorizing the errors according to features of the words.

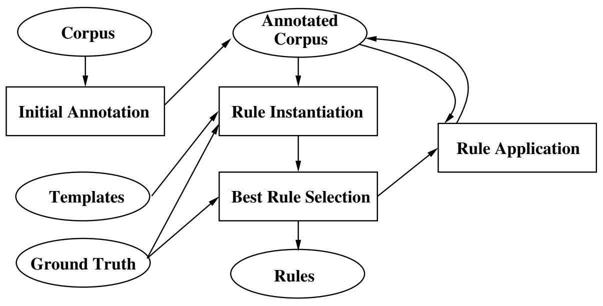

Figure 1: TBL Architecture

3 Transformation-based Learning

As shown in Figure 1, the input to TBL is an unannotated corpus that is first passed to an initial annotator and then iteratively updated through comparison to a manually-annotated reference set (or *ground truth*). On each iteration, the output of the previous iteration is compared against the ground truth, and an ordered list of transformation rules is learned that make the previous annotated data better resemble the ground truth.

A set of *rule templates* determines the space of allowable transformation rules. A rule template has two components: a triggering environment (condition of the rule) and a rewrite rule (action taken). On each iteration, these templates are instantiated with features of the constituents of the templates when the condition of the rule is satisfied.

This process eventually identifies all possible instantiated forms of the templates. Among all these possible rules, the transformation whose application results in the best score—according to some objective function—is identified. This transformation is added to the ordered list of transformation rules. The learning stops when there is no transformation that improves the current state of the data or a prespecified threshold is reached.

When presented with new data, the transformation rules are applied in the order that they were added to the list of transformations. The output of the system is the annotated data after all transformations are applied to the initial annotation.

4 Alignment Link Projection (ALP)

ALP is a TBL implementation that projects alignment links from an initial input alignment. We induce several variations of ALP by setting four parameters in different ways:

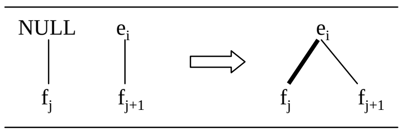

Figure 2: Graphical Representation of a Template

1. Initial alignment
2. Set of templates
3. Simple or generalized instantiation
4. Best rule selection

We describe each of these below using the following definitions and notation:

- $E = e_1, \ldots, e_i, \ldots, e_t$ is a sentence in language L_1 and $F = f_1, \ldots, f_j, \ldots, f_s$ is a sentence in language L_2.
- An *alignment link* (i, j) corresponds to a translational equivalence between e_i and f_j.
- A *neighborhood* of an alignment link (i, j)—denoted by $N(i, j)$—consists of 8 possible alignment links in a 3×3 window with (i, j) in the center of the window. Each element of $N(i, j)$ is called a *neighboring link* of (i, j).
- $nullE_A(i)$ is *true* if and only if e_i is not aligned to any word in F in a given alignment A. Similarly, $nullF_A(j)$ is *true* if and only if f_j is not aligned to any word in E in a given alignment A.

4.1 Initial Alignment

Any existing word-alignment system may be used for the initial annotation step of the TBL algorithm. For our experiments, we chose GIZA++ (Och and Ney, 2000) and the RA approach (Koehn et al., 2003)— the best known alignment combination technique— as our initial aligners.[1]

4.2 TBL Templates

Our templates consider consecutive words (of size 1, 2 or 3) in both languages. The condition portion of a TBL rule template tests for the existence of an alignment link between two words. The action portion involves the addition or deletion of an alignment link. For example, the rule template in Figure 2 is applicable only when a word (e_i) in one language is aligned to the second word (f_{j+1}) of a phrase (f_j, f_{j+1}) in the other language, and the first word (f_j) of the phrase is unaligned in the initial alignment. The action taken by this rule template is to add a link between e_i and f_j.[2]

ALP employs 3 different sets of templates to project new alignment links or delete existing links in a given alignment:

1. Expansion of the initial alignment according to another alignment
2. Deletion of spurious alignment links
3. Correction of multi-word (one-to-many or many-to-one) correspondences

Each of these is described below.

4.2.1 Expansion Templates

Expansion templates are used to extend an initial alignment given another alignment as the validation set. This approach is similar to the one used in the RA method in that it adds links based on knowledge about neighboring links, but it differs in that it *also* uses features of the words themselves to decide which neighboring links to add.

Our expansion templates are presented in Table 1. The first 8 templates add a new link to the initial alignment A if there is a neighboring link in the validation alignment V. The final two templates enforce the presence of at least two neighboring links in the validation set V before adding a new link.

Condition	**Action**
$(i,j) \in A, (i-1,j-1) \in V$	add $(i-1,j-1)$
$(i,j) \in A, (i-1,j) \in V$	add $(i-1,j)$
$(i,j) \in A, (i-1,j+1) \in V$	add $(i-1,j+1)$
$(i,j) \in A, (i,j-1) \in V$	add $(i,j-1)$
$(i,j) \in A, (i,j+1) \in V$	add $(i,j+1)$
$(i,j) \in A, (i+1,j-1) \in V$	add $(i+1,j-1)$
$(i,j) \in A, (i+1,j) \in V$	add $(i+1,j)$
$(i,j) \in A, (i+1,j+1) \in V$	add $(i+1,j+1)$
$(i-1,j-1) \in A, (i+1,j+1) \in A, (i,j) \in V$	add (i,j)
$(i+1,j-1) \in A, (i-1,j+1) \in A, (i,j) \in V$	add (i,j)

Table 1: Templates for Expanding the Alignment A According to a Validation Alignment V

4.2.2 Deletion Templates

Existing alignment algorithms (e.g., GIZA++) are biased toward aligning some words, especially infrequent ones, in one language to many words in the other language in order to minimize the number of unaligned words, even if many incorrect alignment

[1]We treat these initial aligners as black boxes.

[2]A thick line indicates an added link.

links are induced.[3] Deletion templates are useful for eliminating the resulting spurious links.

The basic idea is to remove alignment links that do not have a neighboring link if the word in question has already been aligned to another word. Table 2 lists two simple templates to clean up spurious links. We define the predicate $neighbor\_exists_A(i, j)$ to denote whether there is an alignment link in the neighborhood of the link (i, j) in a given alignment A. For example, the first template deletes spurious links for a particular word e_i in E.

Condition	**Action**
$(i, j) \in A, (i, k) \in A,$ $neighbor\_exists_A(i, j),$ $not(neighbor\_exists_A(i, k))$	del (i, k)
$(i, j) \in A, (k, j) \in A,$ $neighbor\_exists_A(i, j),$ $not(neighbor\_exists_A(k, j))$	del (e, j)

Table 2: Templates for Deleting Spurious Links in a Given Alignment A

4.2.3 Multi-Word Correction Templates

Current alignment algorithms produce one-to-one word correspondences quite successfully. However, accurate alignment of phrasal constructions (many-to-many correspondences) is still problematic. On the one hand, the ability to provide *fully* correct phrasal alignments is impaired by the occurrence of high-frequency function words and/or words that are not exact translations of the words in the other language. On the other hand, we have observed that most alignment systems are capable of providing *partially* correct phrasal alignments.[4]

Our templates for handling multi-word correspondences are grounded in the outcome of this finding. That is, we make the (frequently correct) assumption that at least one alignment link in a many-to-many correspondence is correctly identified in the initial alignment. Table 3 lists the templates for correcting alignment links in multi-word correspondences. The first five templates handle ($e_i \rightarrow f_j f_{j+1}$) correspondences, the next five handle ($e_i e_{i+1} \rightarrow f_j$) correspondences, the next four handle ($e_i e_{i+1} \rightarrow f_j f_{j+1}$) correspondences, and the final two handle ($e_{i-1} e_i e_{i+1} \rightarrow f_j$) and ($e_i \rightarrow f_{j-1} f_j f_{j+1}$) correspondences.

Condition	**Action**
$nullF_A(j), (i, j+1) \in A$	add (i, j)
$nullF_A(j+1), (i, j) \in A$	add $(i, j+1)$
$(i, j) \in A, (i, j+1) \in A$	del (i, j)
$(i, j) \in A, (i, j+1) \in A$	del $(i, j+1)$
$nullF_A(j), nullF_A(j+1)$	add (i, j), add $(i, j+1)$
$nullE_A(i), (i+1, j) \in A$	add (i, j)
$nullE_A(i+1), (i, j) \in A$	add $(i+1, j)$
$(i, j) \in A, (i+1, j) \in A$	del (i, j)
$(i, j) \in A, (i+1, j) \in A$	del $(i+1, j)$
$nullE_A(i), nullE_A(i+1)$	add (i, j) add $(i+1, j)$
$(i+1, j+1) \in A$ $nullE_A(i), nullF_A(j),$	add (i, j)
$(i, j) \in A, nullE_A(i+1),$ $nullF_A(j+1)$	add $(i+1, j+1)$
$(i, j) \in A, (i+1, j) \in A,$ $(i+1, j+1) \in A$	add $(i, j+1)$
$(i, j) \in A, (i, j+1) \in A,$ $(i+1, j+1) \in A$	add $(i+1, j)$
$(i-1, j) \in A, (i+1, j) \in A$ $nullE_A(i)$	add (i, j)
$(i, j-1) \in A, (i, j+1) \in A$ $nullF_A(j)$	add (i, j)

Table 3: Templates for Handling Multi-Word Correspondences in a Given Alignment A

Condition	**Action**
$(i, j) \in A$	del (i, j)
$nullE_A(i), nullF_A(j)$	add (i, j)

Table 4: Templates for Correcting One-to-One Correspondences in a Given Alignment A

The alignment rules given above may introduce errors that require additional cleanup. Thus, we introduce two simple templates (shown in Table 4) to accommodate the deletion or addition of links between a single pair of words.

4.3 Instantiation of Templates

ALP starts with a set of templates and an initial alignment and attempts to instantiate the templates during the learning process. The templates can be instantiated using two methods: Simple (a word is instantiated with a specific feature) or Generalized (a word is instantiated using a special keyword `any-`

[3]This is a well-known characteristic of statistical alignment systems—motivated by the need to ensure a target-word translation e_i for each source word f_j while modeling $p(F|E)$ —for downstream MT.

[4]Specifically, we conducted a preliminary study using 40 manually-aligned English-Spanish sentences from a mixed corpus (UN + Bible + FBIS) as our gold standard. We found that, in most cases where the human annotator aligned one word to two words, an existing alignment system identified at least one of the two alignment links correctly.

`thing`).

ALP requires only a small amount of manually aligned data for this process—a major strength of the system. However, if we were to instantiate the templates with the actual words of the manual alignment, the frequency counts (from such a small data set) would not be high enough to derive reasonable generalizations. Thus, ALP adds new links based on linguistic features of words, rather than the words themselves. Using these features is what sets ALP apart from systems like the RA approach. Specifically, three features are used to instantiate the templates:

- **POS tags on both sides**: We assign POS tags using the MXPOST tagger (Ratnaparkhi, 1996) for English and Chinese, and Connexor for Spanish.
- **Dependency relations**: ALP utilizes dependencies for a better generalization—if a dependency parser is available in either language. In our experiments, we used a dependency parser only in English (a version of the Collins parser (Collins, 1997) that has been adapted for building dependencies) but not in the other language.
- **A set of closed-class words**: We use 16 different classes, 9 of which are different semantic verb classes while the other 7 are function words, prepositions, and complementizers.[5]

If both POS tags and dependency relations are available, they can be used together to instantiate the templates. That is, a word can be instantiated in a TBL template with: (1) a POS tag (e.g., Noun, Adj); (2) a relation (e.g., Subj, Obj); (3) a parameter class (e.g., Change of State); or (4) different subsets of (1)–(3). We also employ a more generalized form of instantiation, where words in the templates may match the keyword `anything`.

4.4 Best Rule Selection

The rules are selected using two different metrics: The accuracy of the rule or the overall impact of the application of the rule on the entire data.

Two different mechanisms may be used for selecting the best rule after generating all possible instantiations of templates:

[5]These are based on the parameter classes of (Dorr et al., 2002).

1. **Rule Accuracy:** The goal is to minimize the errors introduced by the application of a transformation rule. To measure accuracy of a rule r, we use $good(r) - 2 \times bad(r)$, where $good(r)$ is the number of alignment links that are corrected by the rule, and $bad(r)$ is the number of incorrect alignment links produced.
2. **Overall impact on the training data:** The accuracy mechanism (above) is useful for biasing the system toward higher precision. However, if the overall system is evaluated using a metric other than precision (e.g., recall), the accuracy mechanism may not guarantee that the best rule is chosen at each step. Thus, we choose the best rule according to the evaluation metric to be used for the overall system.

5 Experiments and Results

This section describes our evaluation of ALP variants using different combinations of settings of the four parameters described above. The two language pairs examined are English-Spanish and English-Chinese.

5.1 Evaluation Metrics

Let A be the set of alignment links for a set of sentences. We take S to be the set of sure alignment links and P be the set of probable alignment links (in the gold standard) for the same set of sentences. Precision (Pr), recall (Rc) and alignment error rate (AER) are defined as follows:

$$Pr = \frac{|A \cap P|}{|A|} \quad Rc = \frac{|A \cap S|}{|S|}$$
$$AER = 1 - \frac{|A \cap S| + |A \cap P|}{|A| + |S|}$$

A manually aligned corpus is used as our gold standard. For English-Spanish data, the manual annotation was done by a bilingual English-Spanish speaker. Every link in the English-Spanish gold standard is considered a sure alignment link.

For English-Chinese, we used 2002 NIST MT evaluation test set, and each sentence pair was aligned by two native Chinese speakers who are fluent in English. Each alignment link appearing in both annotations was considered a sure link, and links appearing in only one set were judged as probable. The annotators were not aware of the specifics of our approach.

5.2 Evaluation Data

We evaluated ALP using 5-fold cross validation on two different data sets:

1. A set of 199 English-Spanish sentence pairs (nearly 5K words on each side) from a mixed corpus (UN + Bible + FBIS).
2. A set of 491 English-Chinese sentence pairs (nearly 13K words on each side) from 2002 NIST MT evaluation test set.

We divided the pairs of sentences randomly into 5 groups. Then, for each fold, we used 4 groups as the ground truth (for training), and used the other group as our gold standard (for evaluation). This process was repeated 5 times so that each sentence pair was tested exactly once. We computed precision, recall and error rate on the entire set for each data set.[6]

For an initial alignment, we used GIZA++ in both directions (E-to-F and F-to-E, where F is either Chinese (C) or Spanish (S)), and also two different combined alignments: intersection of E-to-F and F-to-E; and RA using a heuristic combination approach called *grow-diag-final* (Koehn et al., 2003).

For the English-Spanish experiments, GIZA++ was trained on 48K sentence pairs from a mixed corpus (UN + Bible + FBIS), with nearly 1.2M of words on each side, using 10 iterations of Model 1, 5 iterations of HMM and 5 iterations of Model 4. For the English-Chinese experiments, we used 107K sentence pairs from FBIS corpus (nearly 4.1M English and 3.3M Chinese words) to train GIZA++, using 5 iterations of Model 1, 5 iterations of HMM, 3 iterations of Model 3, and 3 iterations of Model 4.

5.3 Results for English-Spanish

For our initial alignments we used: (1) Intersection of GIZA++ English-to-Spanish and Spanish-to-English; (2) GIZA++ English-to-Spanish; (3) GIZA++ Spanish-to-English; and (4) RA. Of these, RA is the best, with an error rate of 21.2%. For ease of comparison, the RA score appears in all result tables below.

[6]The number of alignment links varies over each fold. Therefore, we chose to evaluate all data at once instead of evaluating on each fold and then averaging.

Tables 5–7 compare ALP to each of these four alignments using different settings of 4 parameters: ALP[*IA, T, I, BRS*], where *IA* is the initial alignment, T is the set of templates, I is the instantiation method, and *BRS* is the metric for the best rule selection at each iteration. T_E is the set of expansion templates from Table 1, T_D is the set of deletion templates from Table 2, and T_{MW} is the set of multi-word templates from Table 3 (supplemented with templates from Table 4).

As mentioned in Section 4.3, we use two instantiation methods: (1) simple instantiation (sim), where the words are instantiated using a specific POS tag, relation, parameter class or combination of those; and (2) generalized instantiation (gen), where the words can be instantiated using the keyword `anything`. Two different metrics are used to select the best rule: The accuracy of the rule (acc) and the AER on the entire training data after applying the rule (aer).[7]

We performed statistical significance tests using two-tailed paired t-tests. Unless otherwise indicated, the differences between ALP and initial alignments (for all ALP variations and all initial alignments) were found to be statistically significant within the 95% confidence interval. Moreover, the differences among ALP variations themselves were statistically significant within 95% confidence interval.

Using Intersection as Initial Alignment We ran ALP using the intersection of GIZA++ (E-to-S) and GIZA++(S-to-E) alignments as the initial alignment in two different ways: (1) With T_E using the union of the unidirectional GIZA++ alignments as the validation set, and (2) with T_D and T_{MW} applied one after another. Table 5 presents the precision, recall and AER results.

Alignments	**Pr**	**Rc**	**AER**
Intersection (Int)	**98.2**	59.6	25.9
ALP[Int, T_E, gen, aer]	90.9	69.9	21.0
ALP[$Int, (T_D, T_{MW}), gen, aer$]	88.8	72.3	**20.3**
RA	83.8	**74.4**	21.2

Table 5: ALP Results Using GIZA++ Intersection as Initial Alignment for English-Spanish

Using the expansion templates (T_E) against a val-

[7]We use only sure alignment links as the ground truth to learn rules inside ALP. Therefore, AER here refers to the AER of sure alignment links.

Alignments	**Pr**	**Rc**	**AER**
E-to-S	**87.0**	67.0	24.3
ALP[E-to-S,$(T_D, T_{MW}), gen, aer$]	85.6	**76.4**	**19.3**
S-to-E	**88.0**	67.5	23.6
ALP[S-to-E,$(T_D, T_{MW}), gen, aer$]	87.1	**76.7**	**18.4**
RA	83.8	74.4	21.2

Table 6: ALP Results Using GIZA++ (Each Direction) as Initial Alignment for English-Spanish

idation set produced results comparable to the RA method. The major difference is that ALP resulted in a much higher precision but in a lower recall because ALP is more selective in adding a new link during the expansion stage. This difference is due to the additional constraints provided by word features. The version of ALP that applies deletion (T_D) and multi-word (T_{MW}) templates sequentially achieves lower recall but higher precision than RA. In the best case, ALP achieves a statistically significant relative reduction of 21.6% in AER over the Intersection alignment. When compared to RA, ALP achieves a lower AER but the difference is not significant.

Using Unidirectional GIZA++ Alignments as Initial Alignment In a second set of experiments, we applied ALP to the unidirectional GIZA++ alignments, using deletion (T_D) and multi-word (T_{MW}) templates, generalized instantiation, and AER for the best rule selection. Table 6 presents the precision, recall and AER results.

For both directions, ALP achieves a lower precision but much higher recall than that of the initial unidirectional alignment. Overall, there was a relative reduction of 20.6–22.0% in AER. When compared to RA, the version of ALP that uses unidirectional GIZA++ alignments brings about significant reductions in AER: 9.0% relative reduction in one direction and 13.2% relative reduction in the other direction.

Using RA as Initial Alignment In a third experiment, we compared RA with variations of ALP using RA as the initial alignment. We used the templates in two different ways: (1) with a combination of T_D and T_{MW} (i.e., $T_D \cup T_{MW}$), and (2) with two consecutive runs of ALP, first with T_D and then with T_{MW} using the output of the first run as the initial annotation in the second run (i.e., T_D, T_{MW}). Table 7 presents precision, recall and AER results, using different methods for template instantiation and

Alignments	**Pr**	**Rc**	**AER**
ALP[$RA, (T_D, T_{MW}), sim, acc$]	87.8	77.7	17.6
ALP[$RA, (T_D, T_{MW}), sim, aer$]	**87.9**	79.0	16.8
ALP[$RA, (T_D \cup T_{MW}), gen, aer$]	86.2	80.0	17.0
ALP[$RA, (T_D, T_{MW}), gen, aer$]	86.9	**80.5**	**16.4**
RA	83.8	74.4	21.2

Table 7: ALP Results Using RA as Initial Alignment for English-Spanish

best rule selection.

The results indicate that using AER is better than using accuracy for choosing the best rule. Using generalized instantiation instead of simple instantiation results in a better AER. Running ALP with deletion (T_D) templates followed by multi-word (T_{MW}) templates results in a lower AER than running ALP only once with combined templates.

The highest performing variant of ALP, shown in the fourth line of the table, uses RA as the initial alignment, template sets T_D, T_{MW}, generalized instantiation, and AER for best rule selection. This variant is significantly better than RA, with a 22.6% relative reduction in AER. When compared to the unidirectional alignments (E-to-S and S-to-E) given in Table 6, this variant of ALP yields nearly the same precision (around 87.0%) but a 19.2% relative improvement in recall. The overall relative reduction in AER is 30.5% in the S-to-E direction and 32.5% in the E-to-S direction.

5.4 Results for English-Chinese

Our experiments for English-Chinese were designed with a similar structure to that of English-Spanish, i.e., the same four initial alignments. Once again, RA performs the best out of these initial alignments, with an error rate of 29.7%. The results of the initial alignments, and variations of ALP based on different initial alignments are shown in Table 8. For brevity, we include only the ALP parameter settings resulting in the best configurations from the English-Spanish experiments. For learning rules from the templates, we used only the sure alignment links as the ground truth while learning rules inside ALP.

On the English-Chinese data, ALP yields significantly lower error rates with respect to the initial alignments. When ALP is run with the intersection of two GIZA++ alignments, the relative reduction is 5.4% in AER. When ALP is run with E-to-C as initial alignment, the relative reduction in AER is 13.4%. For the other direction, ALP produces a rel-

Alignments	Pr	Rc	AER
Intersection (Int)	**94.8**	53.6	31.2
ALP[$Int, (T_D, T_{MW}), gen, aer$]	91.7	**56.8**	**29.5**
E-to-C	70.4	**68.3**	30.7
ALP[E-to-C,$(T_D, T_{MW}), gen, aer$]	**79.1**	68.1	**26.6**
C-to-E	66.0	**69.8**	32.2
ALP[C-to-E,$(T_D, T_{MW}), gen, aer$]	**83.3**	66.0	**26.2**
RA	61.9	**82.6**	29.7
ALP[RA,$(T_D, T_{MW}), gen, aer$]	**82.1**	72.7	**22.8**

Table 8: ALP Results Using Different Initial Alignments for English-Chinese

ative reduction of 18.6% in AER. Finally, when RA is given to ALP as an initial alignment, ALP results in a relative reduction of 23.2% in AER. When compared to RA, all variations of ALP, except the one starting with the intersection, yield statistically significantly lower AER. Another important finding is that ALP yields significantly higher precision than the initial alignments but usually lower recall.

6 Conclusion

We have presented ALP, a new approach that refines alignments by identifying the types of errors made by existing alignment systems and correcting them. Our approach adapts TBL to the problem of word-level alignment by examining word features as well as neighboring links. We use POS tags, closed-class words in both languages, and dependency relations in one language to classify the errors made by the initial alignment system. We show that ALP yields at least a 22.6% relative reduction on English-Spanish data and 23.2% relative reduction on English-Chinese data in alignment error rate over that of the best performing system.

We should note that ALP is not a stand-alone word alignment system but a supervised learning approach to improve already existing alignment systems. ALP takes advantage of clustering of alignment links to project new links given a reasonable initial alignment. We have shown that ALP is quite successful in projecting alignment links for two different languages—Spanish and Chinese.

Statistical alignment systems are more successful with increasing amount of training data. Whether ALP improves the statistical alignment systems when they are trained on more data is an interesting research problem, which we plan to tackle in future.

Finally, we will evaluate the improved alignments in the context of an end-to-end application, such as machine translation.

Abstract

We explore the benefit that users in several application areas can experience from a "tab-complete" editing assistance function. We develop an evaluation metric and adapt N-gram language models to the problem of predicting the subsequent words, given an initial text fragment. Using an instance-based method as baseline, we empirically study the predictability of call-center emails, personal emails, weather reports, and cooking recipes.

1 Introduction

Prediction of user behavior is a basis for the construction of assistance systems; it has therefore been investigated in diverse application areas. Previous studies have shed light on the predictability of the next unix command that a user will enter (Motoda and Yoshida, 1997; Davison and Hirsch, 1998), the next keystrokes on a small input device such as a PDA (Darragh and Witten, 1992), and of the translation that a human translator will choose for a given foreign sentence (Nepveu et al., 2004).

We address the problem of predicting the subsequent words, given an initial fragment of text. This problem is motivated by the perspective of assistance systems for repetitive tasks such as answering emails in call centers or letters in an administrative environment. Both instance-based learning and N-gram models can conjecture completions of sentences. The use of N-gram models requires the application of the Viterbi principle to this particular decoding problem.

Quantifying the benefit of editing assistance to a user is challenging because it depends not only on an observed distribution over documents, but also on the reading and writing speed, personal preference, and training status of the user. We develop an evaluation metric and protocol that is practical, intuitive, and independent of the user-specific trade-off between keystroke savings and time lost due to distractions. We experiment on corpora of service-center emails, personal emails of an Enron executive, weather reports, and cooking recipes.

The rest of this paper is organized as follows. We review related work in Section 2. In Section 3, we discuss the problem setting and derive appropriate performance metrics. We develop the N-gram-based completion method in Section 4. In Section 5, we discuss empirical results. Section 6 concludes.

2 Related Work

Shannon (1951) analyzed the predictability of sequences of letters. He found that written English has a high degree of redundancy. Based on this finding, it is natural to ask whether users can be supported in the process of writing text by systems that predict the intended next keystrokes, words, or sentences. Darragh and Witten (1992) have developed an *interactive keyboard* that uses the sequence of past keystrokes to predict the most likely succeeding keystrokes. Clearly, in an unconstrained application context, keystrokes can only be predicted with limited accuracy. In the specific context of entering URLs, completion predictions are commonly provided by web browsers (Debevc et al., 1997).

Motoda and Yoshida (1997) and Davison and Hirsch (1998) developed a Unix shell which predicts the command stubs that a user is most likely to enter, given the current history of entered commands. Korvemaker and Greiner (2000) have developed this idea into a system which predicts entire command lines. The Unix command prediction problem has also been addressed by Jacobs and Blockeel (2001) who infer macros from frequent command sequences and predict the next command using variable memory Markov models (Jacobs and Blockeel, 2003).

In the context of *natural language*, several typing assistance tools for apraxic (Garay-Vitoria and Abascal, 2004; Zagler and Beck, 2002) and dyslexic (Magnuson and Hunnicutt, 2002) persons have been developed. These tools provide the user with a list of possible word completions to select from. For these users, scanning and selecting from lists of proposed words is usually more efficient than typing. By contrast, scanning and selecting from many displayed options can slow down skilled writers (Langlais et al., 2002; Magnuson and Hunnicutt, 2002).

Assistance tools have furthermore been developed for translators. Computer aided translation systems combine a translation and a language model in order to provide a (human) translator with a list of suggestions (Langlais et al., 2000; Langlais et al., 2004; Nepveu et al., 2004). Foster et al. (2002) introduce a model that adapts to a user's typing speed in order to achieve a better trade-off between distractions and keystroke savings. Grabski and Scheffer (2004) have previously developed an indexing method that efficiently retrieves the sentence from a collection that is most similar to a given initial fragment.

3 Problem Setting and Evaluation

Given an initial text fragment, a predictor that solves the sentence completion problem has to conjecture *as much of the sentence that the user currently intends to write,* as is possible with high confidence—preferably, but not necessarily, the entire remainder.

The perceived benefit of an assistance system is highly subjective, because it depends on the expenditure of time for scanning and deciding on suggestions, and on the time saved due to helpful assistance. The user-specific benefit is influenced by quantitative factors that we can measure. We construct a system of two conflicting performance indicators: our definition of *precision* quantifies the inverse risk of unnecessary distractions, our definition of *recall* quantifies the rate of keystroke savings.

For a given sentence fragment, a completion method may – but need not – cast a completion conjecture. Whether the method suggests a completion, and how many words are suggested, will typically be controlled by a confidence threshold. We consider the entire conjecture to be falsely positive if at least one word is wrong. This harsh view reflects previous results which indicate that selecting, and then editing, a suggested sentence often takes longer than writing that sentence from scratch (Langlais et al., 2000). In a conjecture that is entirely accepted by the user, the entire string is a true positive. A conjecture may contain only a part of the remaining sentence and therefore the *recall*, which refers to the length of the missing part of the current sentence, may be smaller than 1.

For a given test collection, precision and recall are defined in Equations 1 and 2. *Recall* equals the fraction of saved keystrokes (disregarding the interface-dependent single keystroke that is most likely required to accept a suggestion); *precision* is the ratio of characters that the users have to scan for each character they accept. Varying the confidence threshold of a sentence completion method results in a *precision recall curve* that characterizes the system-specific trade-off between *keystroke savings* and *unnecessary distractions*.

$$Precision = \frac{\sum_{\text{accepted completions}} \text{string length}}{\sum_{\text{suggested completions}} \text{string length}} \quad (1)$$

$$Recall = \frac{\sum_{\text{accepted completions}} \text{string length}}{\sum_{\text{all queries}} \text{length of missing part}} \quad (2)$$

4 Algorithms for Sentence Completion

In this section, we derive our solution to the sentence completion problem based on linear interpolation of N-gram models. We derive a k best Viterbi decoding algorithm with a confidence-based stopping criterion which conjectures the words that most likely succeed an initial fragment. Additionally, we briefly discuss an instance-based method that provides an alternative approach and baseline for our experiments.

In order to solve the sentence completion problem with an N-gram model, we need to find the most likely word sequence $w_{t+1}, \ldots, w_{t+T}$ given a word N-gram model and an initial sequence $w_1, \ldots, w_t$ (Equation 3). Equation 4 factorizes the joint probability of the missing words; the N-th order Markov assumption that underlies the N-gram model simplifies this expression in Equation 5.

$$\begin{aligned} & \operatorname*{argmax}_{w_{t+1},\ldots,w_{t+T}} P(w_{t+1}, \ldots, w_{t+T} | w_1, \ldots, w_t) && (3) \\ = & \operatorname*{argmax}_{w_{t+1},\ldots,w_{t+T}} \prod_{j=1}^{T} P(w_{t+j} | w_1, \ldots, w_{t+j-1}) && (4) \\ = & \operatorname*{argmax} \prod_{j=1}^{T} P(w_{t+j} | w_{t+j-N+1}, \ldots, w_{t+j-1}) && (5) \end{aligned}$$

The individual factors of Equation 5 are provided by the model. The Markov order N has to balance sufficient context information and sparsity of the training data. A standard solution is to use a weighted linear mixture of N-gram models, $1 \leq n \leq N$, (Brown et al., 1992). We use an EM algorithm to select mixing weights that maximize the generation probability of a tuning set of sentences that have not been used for training.

We are left with the following questions: (a) how can we decode the most likely completion *efficiently*; and (b) how many words should we predict?

4.1 Efficient Prediction

We have to address the problem of finding the most likely completion, $\operatorname{argmax}_{w_{t+1},\ldots,w_{t+T}} P(w_{t+1}, \ldots, w_{t+T} | w_1, \ldots, w_t)$ *efficiently*, even though the size of the *search space* grows exponentially in the number of predicted words.

We will now identify the recursive structure in Equation 3; this will lead us to a Viterbi algorithm that retrieves the most likely word sequence. We first define an auxiliary variable $\delta_{t,s}(w'_1, \ldots, w'_N | w_{t-N+2}, \ldots, w_t)$ in Equation 6; it quantifies the greatest possible probability over all arbitrary word sequences $w_{t+1}, \ldots, w_{t+s}$, followed by the word sequence $w_{t+s+1} = w'_1, \ldots, w_{t+s+N} = w'_N$, conditioned on the initial word sequence $w_{t-N+2}, \ldots, w_t$.

In Equation 7, we factorize the last transition and utilize the N-th order Markov assumption. In Equation 8, we split the maximization and introduce a new random variable w'_0 for w_{t+s}. We can now refer to the definition of δ and see the recursion in Equation 9: $\delta_{t,s}$ depends only on $\delta_{t,s-1}$ and the N-gram model probability $P(w'_N | w'_1, \ldots, w'_{N-1})$.

$$\begin{aligned} & \delta_{t,s}(w'_1, \ldots, w'_N | w_{t-N+2}, \ldots, w_t) && (6) \\ & = \max_{w_{t+1},\ldots,w_{t+s}} P(w_{t+1}, \ldots, w_{t+s}, w_{t+s+1} = w'_1, \\ & \qquad \ldots, w_{t+s+N} = w'_N | w_{t-N+2}, \ldots, w_t) \\ & = \max_{w_{t+1},\ldots,w_{t+s}} P(w'_N | w'_1, \ldots, w'_{N-1}) && (7) \\ & \qquad P(w_{t+1}, \ldots, w_{t+s}, w_{t+s+1} = w'_1, \\ & \qquad \ldots, w_{t+s+N-1} = w'_{N-1} | w_{t-N+2}, \ldots, w_t) \\ & = \max_{w'_0} \max_{w_{t+1},\ldots,w_{t+s-1}} P(w'_N | w'_1, \ldots, w'_{N-1}) && (8) \\ & \qquad P(w_{t+1}, \ldots, w_{t+s-1}, w_{t+s} = w'_0, \\ & \qquad \ldots, w_{t+s+N-1} = w'_{N-1} | w_{t-N+2}, \ldots, w_t) \\ & = \max_{w'_0} P(w'_N | w'_1, \ldots, w'_{N-1}) && (9) \\ & \qquad \delta_{t,s-1}(w'_0, \ldots, w'_{N-1} | w_{t+N-2}, \ldots, w_t) \end{aligned}$$

Exploiting the N-th order Markov assumption, we can now express our target probability (Equation 3) in terms of δ in Equation 10.

$$\begin{aligned} & \max_{w_{t+1},\ldots,w_{t+T}} P(w_{t+1}, \ldots, w_{t+T} | w_{t-N+2}, \ldots, w_t) && (10) \\ & = \max_{w'_1,\ldots,w'_N} \delta_{t,T-N}(w'_1, \ldots, w'_N | w_{t-N+2}, \ldots, w_t) \end{aligned}$$

The last N words in the most likely sequence are simply the $\operatorname{argmax}_{w'_1,\ldots,w'_N} \delta_{t,T-N}(w'_1, \ldots, w'_N | w_{t-N+2}, \ldots, w_t)$. In order to collect the preceding most likely words, we define an auxiliary variable Ψ in Equation 11 that can be determined in Equation 12. We have now found a Viterbi algorithm that is linear in T, the completion length.

$$\begin{aligned} & \Psi_{t,s}(w'_1, \ldots, w'_N | w_{t-N+2}, \ldots, w_t) && (11) \\ & = \operatorname*{argmax}_{w_{t+s}} \max_{w_{t+1},\ldots,w_{t+s-1}} P(w_{t+1}, ..., w_{t+s}, w_{t+s+1} = w'_1, ..., \\ & \qquad w_{t+s+N} = w'_N | w_{t-N+2}, ..., w_t) \\ & = \operatorname*{argmax}_{w'_0} \delta_{t,s-1}(w'_0, \ldots, w'_{N-1} | w_{t-N+2}, \ldots, w_t) && (12) \\ & \qquad P(w'_N | w'_1, \ldots, w'_{N-1}) \end{aligned}$$

The Viterbi algorithm starts with the most recently entered word w_t and moves iteratively into the future. When the N-th token in the highest scored δ is a period, then we can stop as our goal is only to predict (parts of) the current sentence. However, since there is no guarantee that a period will eventually become the most likely token, we use an absolute confidence threshold as additional criterion: when the highest δ score is below a threshold θ, we stop the Viterbi search and fix T.

In each step, Viterbi stores and updates $|\text{vocabulary size}|^N$ many δ values—unfeasibly many except for very small N. Therefore, in Table 1 we develop a Viterbi beam search algorithm which is linear in T and in the beam width. Beam search cannot be guaranteed to always find the most likely word sequence: When the globally most likely sequence $w^*_{t+1}, \ldots, w^*_{t+T}$ has an initial subsequence $w^*_{t+1}, \ldots, w^*_{t+s}$ which is not among the k most likely sequences of length s, then that optimal sequence is not found.

Table 1: Sentence completion with Viterbi beam search algorithm.

```
Input: $N$-gram language model, initial sentence fragment $w_1, \ldots, w_t$, beam width $k$, confidence threshold $\theta$.

1. Viterbi initialization:
   Let $\delta_{t,-N}(w_{t-N+1}, \ldots, w_t | w_{t-N+1}, \ldots, w_t) = 1$;
   let $s = -N + 1$;
   $beam(s-1) = \{\delta_{t,-N}(w_{t-N+1}, \ldots, w_t | w_{t-N+1}, \ldots, w_t)\}$.
2. Do Viterbi recursion until break:
   (a) For all $\delta_{t,s-1}(w'_0, \ldots, w'_{N-1} | \ldots)$ in $beam(s-1)$, for all $w_N$ in vocabulary, store $\delta_{t,s}(w'_1, \ldots, w'_N | \ldots)$ (Equation 9) in $beam(s)$ and calculate $\Psi_{t,s}(w'_1, \ldots, w'_N | \ldots)$ (Equation 12).
   (b) If $\text{argmax}_{w_N} \max_{w'_1, \ldots, w'_{N-1}} \delta_{t,s}(w'_1, \ldots, w'_N | \ldots) = period$ then break.
   (c) If $\max \delta_{t,s}(w'_1, \ldots, w'_N | w_{t-N+1}, \ldots, w_t) < \theta$ then decrement $s$; break.
   (d) Prune all but the best $k$ elements in $beam(s)$.
   (e) Increment $s$.
3. Let $T = s + N$. Collect words by path backtracking:
      $(w^*_{t+T-N+1}, \ldots, w^*_{t+T}) = \text{argmax}\, \delta_{t,T-N}(w'_1, \ldots, w'_N | \ldots)$.
   For $s = T - N \ldots 1$:
      $w^*_{t+s} = \Psi_{t,s}(w^*_{t+s+1}, \ldots, w^*_{t+s+N} | w_{t-N+1}, \ldots, w_t)$.

Return $w^*_{t+1}, \ldots, w^*_{t+T}$.
```

4.2 Instance-based Sentence Completion

An alternative approach to sentence completion based on N-gram models is to retrieve, from the training collection, the sentence that starts most similarly, and use its remainder as a completion hypothesis. The cosine similarity of the TFIDF representation of the initial fragment to be completed, and an equally long fragment of each sentence in the training collection gives both a selection criterion for the nearest neighbor and a confidence measure that can be compared against a threshold in order to achieve a desired precision recall balance.

A straightforward implementation of this nearest neighbor approach becomes infeasible when the training collection is large because too many training sentences have to be processed. Grabski and Scheffer (2004) have developed an indexing structure that retrieves the most similar (using cosine similarity) sentence fragment in sub-linear time. We use their implementation of the instance-based method in our experimentation.

5 Empirical Studies

we investigate the following questions. (a) How does sentence completion with N-gram models compare to the instance-based method, both in terms of precision/recall and computing time? (b) How well can N-gram models complete sentences from collections with diverse properties?

Table 2 gives an overview of the four document collections that we use for experimentation. The first collection has been provided by a large online store and contains emails sent by the service center in reply to customer requests (Grabski and Scheffer, 2004). The second collection is an excerpt of the recently disclosed email correspondence of Enron's management staff (Klimt and Yang, 2004). We use 3189 personal emails sent by Enron executive Jeff Dasovich; he is the individual who sent the largest number of messages within the recording period.

The third collection contains textual daily weather reports for five years from a weather report provider on the Internet. Each report comprises about 20 sentences. The last collection contains about 4000 cooking recipes; this corpus serves as an example of a set of thematically related documents that might be found on a personal computer.

We reserve 1000 sentences of each data set for testing. As described in Section 4, we split the remaining sentences in training (75%) and tuning

Table 2: Evaluation data collections.

Name	Language	#Sentences	Entropy
service center	German	7094	1.41
Enron emails	English	16363	7.17
weather reports	German	30053	4.67
cooking recipes	German	76377	4.14

(25%) sets. We mix N-gram models up to an order of five and estimate the interpolation weights (Section 4). The resulting weights are displayed in Figure 1. In Table 2, we also display the entropy of the collections based on the interpolated 5-gram model. This corresponds to the average number of bits that are needed to code each word given the preceding four words. This is a measure of the intrinsic redundancy of the collection and thus of the predictability.

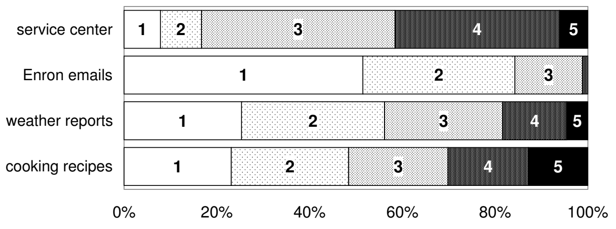

Figure 1: N-gram interpolation weights.

Our evaluation protocol is as follows. The beam width parameter k is set to 20. We randomly draw 1000 sentences and, within each sentence, a position at which we split it into initial fragment and remainder to be predicted. A human evaluator is presented both, the actual sentence from the collection and the initial fragment plus current completion conjecture. For each initial fragment, we first cast the most likely single word prediction and ask the human evaluator to judge whether they would accept this prediction (without any changes), given that they intend to write the actual sentence. We increase the length of the prediction string by one additional word and recur, until we reach a period or exceed the prediction length of 20 words.

For each judged prediction length, we record the confidence measure that would lead to that prediction. With this information we can determine the results for all possible threshold values of θ. To save evaluation time, we consider all predictions that are identical to the actual sentence as correct and skip those predictions in the manual evaluation.

We will now study how the N-gram method compares to the instance-based method. Figure 2 compares the precision recall curves of the two methods. Note that the maximum possible recall is typically much smaller than 1: recall is a measure of the keystroke savings, a value of 1 indicates that the user saves *all* keystrokes. Even for a confidence threshold of 0, a recall of 1 is usually not achievable.

Some of the precision recall curves have a concave shape. Decreasing the threshold value increases the number of predicted words, but it also increases the risk of at least one word being wrong. In this case, the entire sentence counts as an incorrect prediction, causing a decrease in both, precision and recall. Therefore – unlike in the standard information retrieval setting – recall does not increase monotonically when the threshold is reduced.

For three out of four data collections, the instance-based learning method achieves the highest maximum recall (whenever this method casts a conjecture, the entire remainder of the sentence is predicted—at a low precision), but for nearly all recall levels the N-gram model achieves a much higher precision. For practical applications, a high precision is needed in order to avoid distracting, wrong predictions. Varying the threshold, the N-gram model can be tuned to a wide range of different precision recall trade-offs (in three cases, precision can even reach 1), whereas the confidence threshold of the instance-based method has little influence on precision and recall.

We determine the standard error of the precision for the point of maximum F1-measure. For all data collections and both methods the standard error is below 0.016. Correct and incorrect prediction examples are provided in Table 3 for the service center data set, translated from German into English. The confidence threshold is adjusted to the value of maximum F1-measure. In two of these cases, the prediction nicely stops at fairly specific terms.

How do precision and recall depend on the string length of the initial fragment and the string length of the completion cast by the systems? Figure 3 shows the relationship between the length of the initial fragment and precision and recall. The performance of the instance-based method depends crucially on a long initial fragment. By contrast, when

the fragment length exceeds four with the N-gram model, then this length and the accuracy are nearly independent; the model considers no more than the last four words in the fragment.

Figure 4 details the relation between string length of the prediction and precision/recall. We see that we can reach a constantly high precision over the entire range of prediction lengths for the service center data with the N-gram model. For the other collections, the maximum prediction length is 3 or 5 words in comparison to much longer predictions cast by the nearest neighbor method. But in these cases, longer predictions result in lower precision.

How do instance-based learning and N-gram completion compare in terms of computation time? The Viterbi beam search decoder is linear in the prediction length. The index-based retrieval algorithm is constant in the prediction length (except for the final step of *displaying* the string which is linear but can be neglected). This is reflected in Figure 5 (left) which also shows that the absolute decoding time of both methods is on the order of few milliseconds on a PC. Figure 5 (right) shows how prediction time grows with the training set size.

We experiment on four text collections with diverse properties. The N-gram model performs remarkably on the service center email collection. Users can save 60% of their keystrokes with 85% of all suggestions being accepted by the users, or save 40% keystrokes at a precision of over 95%. For cooking recipes, users can save 8% keystrokes at 60% precision or 5% at 80% precision. For weather reports, keystroke savings are 2% at 70% correct suggestions or 0.8% at 80%. Finally, Jeff Dasovich of Enron can enjoy only a marginal benefit: below 1% of keystrokes are saved at 60% entirely acceptable suggestions, or 0.2% at 80% precision.

How do these performance results correlate with properties of the model and text collections? In Figure 1, we see that the mixture weights of the higher order N-gram models are greatest for the service center mails, smaller for the recipes, even smaller for the weather reports and smallest for Enron. With 50% of the mixture weights allocated to the 1-gram model, for the Enron collection the N-gram completion method can often only guess words with high prior probability. From Table 2, we can furthermore see that the entropy of the text collection is inversely proportional to the model's ability to solve the sentence completion problem. With an entropy

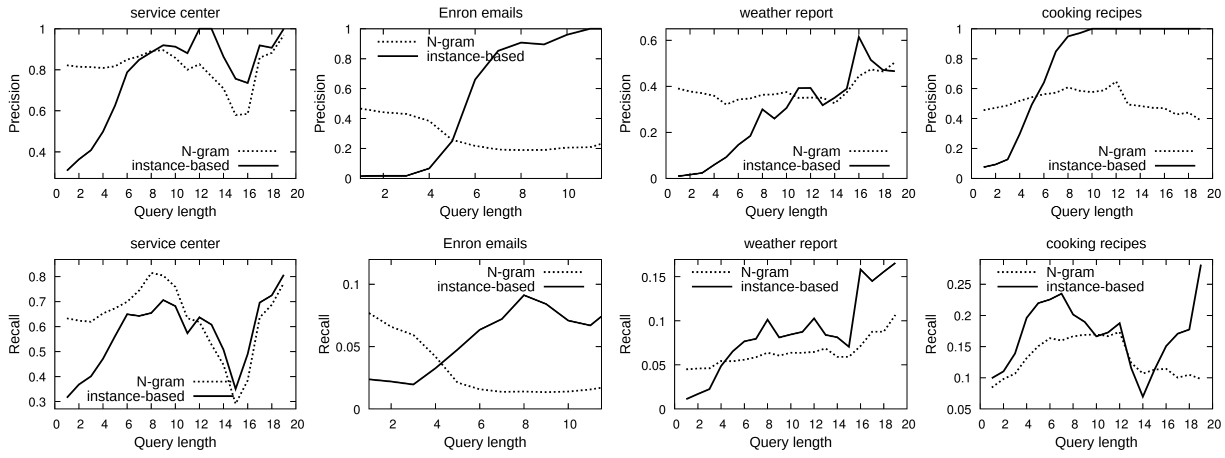

Figure 3: Precision and recall dependent on string length of initial fragment (words).

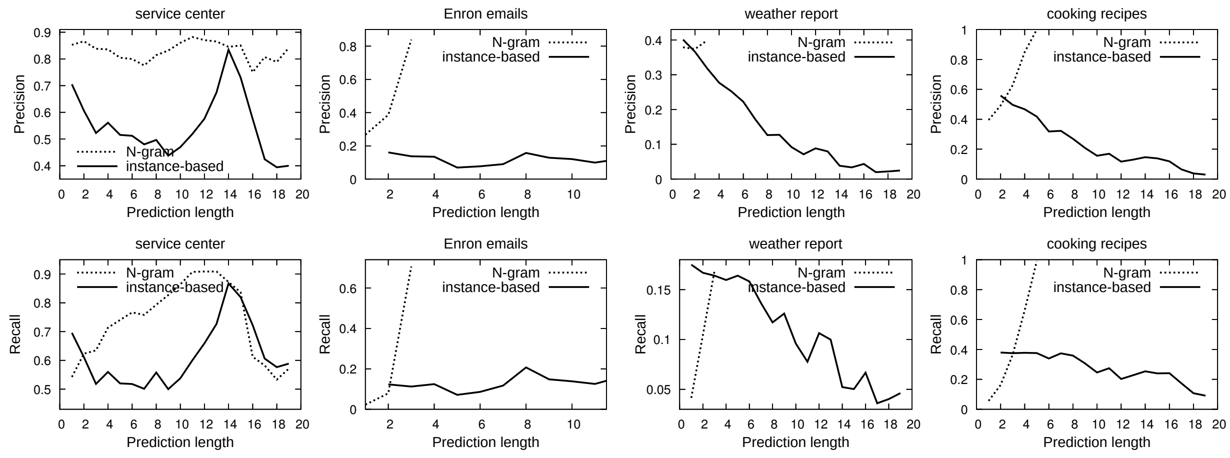

Figure 4: Precision and recall dependent on prediction string length (words).

of only 1.41, service center emails are excellently predictable; by contrast, Jeff Dasovich's personal emails have an entropy of 7.17 and are almost as unpredictable as Enron's share price.

6 Conclusion

We discussed the problem of predicting how a user will complete a sentence. We find precision (the number of suggested characters that the user has to read for every character that is accepted) and recall (the rate of keystroke savings) to be appropriate performance metrics. We developed a sentence completion method based on N-gram language models. We derived a k best Viterbi beam search decoder. Our experiments lead to the following conclusions:

(a) The N-gram based completion method has a better precision recall profile than index-based retrieval of the most similar sentence. It can be tuned to a wide range of trade-offs, a high precision can be obtained. The execution time of the Viterbi beam search decoder is in the order of few milliseconds.

(b) Whether sentence completion is helpful strongly depends on the diversity of the document collection as, for instance, measured by the entropy. For service center emails, a keystroke saving of 60% can be achieved at 85% acceptable suggestions; by contrast, only a marginal keystroke saving of 0.2% can be achieved for Jeff Dasovich's personal emails at 80% acceptable suggestions. A modest but significant benefit can be observed for thematically related documents: weather reports and cooking recipes.

Training Neural Network Language Models On Very Large Corpora [*]

Holger Schwenk and **Jean-Luc Gauvain**
LIMSI-CNRS
BP 133, 91436 Orsay cedex, FRANCE
schwenk,gauvain@limsi.fr

Abstract

During the last years there has been growing interest in using neural networks for language modeling. In contrast to the well known back-off n-gram language models, the neural network approach attempts to overcome the data sparseness problem by performing the estimation in a continuous space. This type of language model was mostly used for tasks for which only a very limited amount of in-domain training data is available.

In this paper we present new algorithms to train a neural network language model on very large text corpora. This makes possible the use of the approach in domains where several hundreds of millions words of texts are available. The neural network language model is evaluated in a state-of-the-art real-time continuous speech recognizer for French Broadcast News. Word error reductions of 0.5% absolute are reported using only a very limited amount of additional processing time.

1 Introduction

Language models play an important role in many applications like character and speech recognition, machine translation and information retrieval. Several approaches have been developed during the last decades like n-gram back-off word models (Katz, 1987), class models (Brown et al., 1992), structured language models (Chelba and Jelinek, 2000) or maximum entropy language models (Rosenfeld, 1996). To the best of our knowledge word and class n-gram back-off language models are still the dominant approach, at least in applications like large vocabulary continuous speech recognition or statistical machine translation. In many publications it has been reported that modified Kneser-Ney smoothing (Chen and Goodman, 1999) achieves the best results. All the reference back-off language models (LM) described in this paper are build with this technique, using the SRI LM toolkit (Stolcke, 2002).

The field of natural language processing has recently seen some changes by the introduction of new statistical techniques that are motivated by successful approaches from the machine learning community, in particular continuous space LMs using neural networks (Bengio and Ducharme, 2001; Bengio et al., 2003; Schwenk and Gauvain, 2002; Schwenk and Gauvain, 2004; Emami and Jelinek, 2004), Random Forest LMs (Xu and Jelinek, 2004) and Random cluster LMs (Emami and Jelinek, 2005). Usually new approaches are first verified on small tasks using a limited amount of LM training data. For instance, experiments have been performed using the Brown corpus (1.1M words), parts of the Wallstreet journal corpus (19M words) or transcriptions of acoustic training data (up to 22M words). It is much more challenging to compare the new statistical techniques to carefully optimized back-off LM trained on large amounts of data (several hundred millions words). Training may be difficult and very

[*]This work was partially financed by the European Commission under the FP6 Integrated Project TC-STAR.

time consuming and the algorithms used with several tens of millions examples may be impracticable for larger amounts. Training back-off LMs on large amounts of data is not a problem, as long as powerful machines with enough memory are available in order to calculate the word statistics. Practice has also shown that back-off LMs seem to perform very well when large amounts of training data are available and it is not clear that the above mentioned new approaches are still of benefit in this situation.

In this paper we compare the neural network language model to n-gram model with modified Kneser-Ney smoothing using LM training corpora of up to 600M words. New algorithms are presented to effectively train the neural network on such amounts of data and the necessary capacity is analyzed. The LMs are evaluated in a real-time state-of-the-art speech recognizer for French Broadcast News. Word error reductions of up to 0.5% absolute are reported.

2 Architecture of the neural network LM

The basic idea of the neural network LM is to project the word indices onto a continuous space and to use a probability estimator operating on this space (Bengio and Ducharme, 2001; Bengio et al., 2003). Since the resulting probability functions are smooth functions of the word representation, better generalization to unknown n-grams can be expected. A neural network can be used to simultaneously learn the projection of the words onto the continuous space and to estimate the n-gram probabilities. This is still a n-gram approach, but the LM posterior probabilities are "interpolated" for any possible context of length n-1 instead of backing-off to shorter contexts.

The architecture of the neural network n-gram LM is shown in Figure 1. A standard fully-connected multi-layer perceptron is used. The inputs to the neural network are the indices of the $n-1$ previous words in the vocabulary $h_j = w_{j-n+1}, ..., w_{j-2}, w_{j-1}$ and the outputs are the posterior probabilities of *all* words of the vocabulary:

$$P(w_j = i|h_j) \qquad \forall i \in [1, N] \tag{1}$$

where N is the size of the vocabulary. The input uses the so-called 1-of-n coding, i.e., the *i-th* word of the vocabulary is coded by setting the *i-th* element of the vector to 1 and all the other elements to

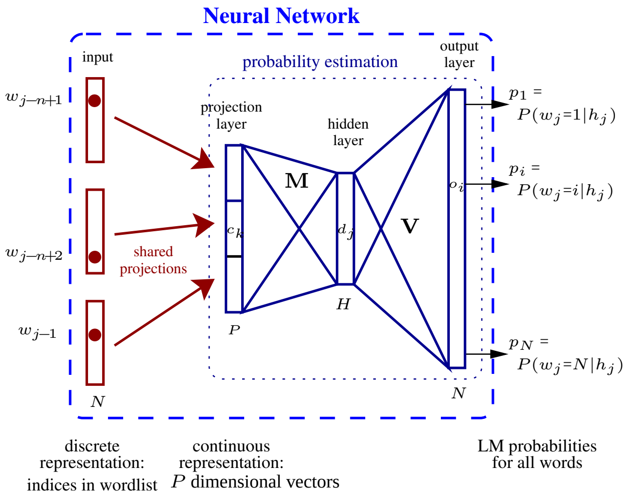

Figure 1: Architecture of the neural network language model. h_j denotes the context $w_{j-n+1}, ..., w_{j-1}$. P is the size of one projection and H and N is the size of the hidden and output layer respectively. When shortlists are used the size of the output layer is much smaller then the size of the vocabulary.

0. The *i-th* line of the $N \times P$ dimensional projection matrix corresponds to the continuous representation of the i-th word. Let us denote c_k these projections, d_j the hidden layer activities, o_i the outputs, p_i their softmax normalization, and m_{jl}, b_j, v_{ij} and k_i the hidden and output layer weights and the corresponding biases. Using these notations the neural network performs the following operations:

$$d_j = \tanh\left(\sum_l m_{jl}\, c_l + b_j\right) \tag{2}$$

$$o_i = \sum_j v_{ij}\, d_j + k_i \tag{3}$$

$$p_i = e^{o_i} \Big/ \sum_{k=1}^{N} e^{o_k} \tag{4}$$

The value of the output neuron p_i corresponds directly to the probability $P(w_j = i|h_j)$. Training is performed with the standard back-propagation algorithm minimizing the following error function:

$$E = \sum_{i=1}^{N} t_i \, log\, p_i + \beta(\sum_{jl} m_{jl}^2 + \sum_{ij} v_{ij}^2) \tag{5}$$

where t_i denotes the desired output, i.e., the probability should be 1.0 for the next word in the training sentence and 0.0 for all the other ones. The first part of this equation is the cross-entropy between the output and the target probability distributions, and the second part is a regularization term that aims to prevent the neural network from overfitting the training data (weight decay). The parameter β has to be determined experimentally.

It can be shown that the outputs of a neural network trained in this manner converge to the posterior probabilities. Therefore, the neural network directly minimizes the perplexity on the training data. Note also that the gradient is back-propagated through the projection-layer, which means that the neural network learns the projection of the words onto the continuous space that is best for the probability estimation task. The complexity to calculate one probability with this basic version of the neural network LM is quite high:

$$O = (n-1) \times P \times H + H + H \times N + N \quad (6)$$

where P is the size of one projection and H and N is the size of the hidden and output layer respectively. Usual values are n=4, P=50 to 200, H=400 to 1000 and N=40k to 200k. The complexity is dominated by the large size of the output layer. In this paper the improvements described in (Schwenk, 2004) have been used:

1. *Lattice rescoring*: speech recognition is done with a standard back-off LM and a word lattice is generated. The neural network LM is then used to rescore the lattice.

2. *Shortlists*: the neural network is only used to predict the LM probabilities of a subset of the whole vocabulary.

3. *Regrouping*: all LM probabilities needed for one lattice are collected and sorted. By these means all LM probability requests with the same context h_t lead to only one forward pass through the neural network.

4. *Block mode*: several examples are propagated at once through the neural network, allowing the use of faster matrix/matrix operations.

5. *CPU optimization*: machine specific BLAS libraries are used for fast matrix and vector operations.

The idea behind shortlists is to use the neural network only to predict the s most frequent words, $s \ll |V|$, reducing by these means drastically the complexity. All words of the word list are still considered at the input of the neural network. The LM probabilities of words in the shortlist ($\hat{P}_N$) are calculated by the neural network and the LM probabilities of the remaining words ($\hat{P}_B$) are obtained from a standard 4-gram back-off LM:

$$\hat{P}(w_t|h_t) = \begin{cases} \hat{P}_N(w_t|h_t) P_S(h_t) & \text{if } w_t \in \text{shortlist} \\ \hat{P}_B(w_t|h_t) & \text{else} \end{cases} \quad (7)$$

$$P_S(h_t) = \sum_{w \in shortlist(h_t)} \hat{P}_B(w|h_t) \quad (8)$$

It can be considered that the neural network redistributes the probability mass of all the words in the shortlist. This probability mass is precalculated and stored in the data structures of the back-off LM. A back-off technique is used if the probability mass for a requested input context is not directly available.

Normally, the output of a speech recognition system is the most likely word sequence given the acoustic signal, but it is often advantageous to preserve more information for subsequent processing steps. This is usually done by generating a lattice, a graph of possible solutions where each arc corresponds to a hypothesized word with its acoustic and language model scores. In the context of this work LIMSI's standard large vocabulary continuous speech recognition decoder is used to generate lattices using a n-gram back-off LM. These lattices are then processed by a separate tool and all the LM probabilities on the arcs are replaced by those calculated by the neural network LM. During this lattice rescoring LM probabilities with the same context h_t are often requested several times on potentially different nodes in the lattice. Collecting and regrouping all these calls prevents multiple forward passes since all LM predictions for the same context are immediately available at the output.

Further improvements can be obtained by propagating several examples at once though the network, also known as bunch mode (Bilmes et al., 1997; Schwenk, 2004). In comparison to equation 2 and 3, this results in using matrix/matrix instead of matrix/vector operations which can be aggressively optimized on current CPU architectures. The Intel

Math Kernel Library was used.[1] Bunch mode is also used for training the neural network. Training of a typical network with a hidden layer with 500 nodes and a shortlist of length 2000 (about 1M parameters) take less than one hour for one epoch through four million examples on a standard PC.

3 Application to Speech Recognition

In this paper the neural network LM is evaluated in a real-time speech recognizer for French Broadcast News. This is a very challenging task since the incorporation of the neural network LM into the speech recognizer must be very effective due to the time constraints. The speech recognizer itself runs in 0.95xRT[2] and the neural network in less than 0.05xRT. The compute platform is an Intel Pentium 4 extreme (3.2GHz, 4GB RAM) running Fedora Core 2 with hyper-threading.

The acoustic model uses tied-state position-dependent triphones trained on about 190 hours of Broadcast News data. The speech features consist of 39 cepstral parameters derived from a Mel frequency spectrum estimated on the 0-8kHz band (or 0-3.8kHz for telephone data) every 10ms. These cepstral coefficients are normalized on a segment cluster basis using cepstral mean removal and variance normalization. The feature vectors are linearly transformed (MLLT) to better fit the diagonal covariance Gaussians used for acoustic modeling.

Decoding is performed in two passes. The first fast pass generates an initial hypothesis, followed by acoustic model adaptation (CMLLR and MLLR) and a second decode pass using the adapted models. Each pass generates a word lattice which is expanded with a 4-gram LM. The best solution is then extracted using pronunciation probabilities and consensus decoding. Both passes use very tight pruning thresholds, especially for the first pass, and fast Gaussian computation based on Gaussian short lists. For the final decoding pass, the acoustic models include 23k position-dependent triphones with 12k tied states, obtained using a divisive decision tree based clustering algorithm with a 35 base phone set.

[1]http://www.intel.com/software/products/mkl/

[2]In speech recognition, processing time is measured in multiples of the length of the speech signal, the real time factor xRT. For a speech signal of 2h, a processing time of 0.5xRT corresponds to 1h of calculation.

The system is described in more detail in (Gauvain et al., 2005).

The neural network LM is used in the last pass to rescore the lattices. A short-list of length 8192 was used in order to fulfill the constraints on the processing time (the complexity of the neural network to calculate a LM probability is almost linear with the length of the short-list). This gives a coverage of about 85% when rescoring the lattices, i.e. the percentage of LM requests that are actually performed by the neural network.

3.1 Language model training data

The following resources have been used for language modeling:

- Transcriptions of the acoustic training data (4.0M words)
- Commercial transcriptions (88.5M words)
- Newspaper texts (508M words)
- WEB data (13.6M words)

First a language model was built for each corpus using modified Kneser-Ney smoothing as implemented in the SRI LM toolkit (Stolcke, 2002). The individual LMs were then interpolated and merged together. An EM procedure was used to determine the coefficients that minimize the perplexity on the development data. Table 1 summarizes the characteristics of the individual text corpora.

corpus	**#words**	**Perpl.**	**Coeffs.**
Acoustic transcr.	4M	107.4	0.43
Commercial transcr.	88.5M	137.8	0.14
Newspaper texts	508M	103.0	0.35
WEB texts	13.6M	136.7	0.08
All interpolated	614M	70.2	-

Table 1: Characteristics of the text corpora (number of words, perplexity on the development corpus and interpolation coefficients)

Although the detailed transcriptions of the audio data represent only a small fraction of the available data, they get an interpolation coefficient of 0.43. This shows clearly that they are the most appropriate text source for the task. The commercial transcripts, the newspaper and WEB texts reflect less well the speaking style of broadcast news, but this is to some extent counterbalanced by the large amount of data. One could say that these texts are helpful to learn the general grammar of the language. The word list includes 65301 words and the OOV rate is 0.95% on a development set of 158k words.

3.2 Training on in-domain data only

Following the above discussion, it seems natural to first train a neural network LM on the transcriptions of the acoustic data only. The architecture of the neural network is as follows: a continuous word representation of dimension 50, one hidden layer with 500 neurons and an output layer limited to the 8192 most frequent words. This results in 3.2M parameters for the continuous representation of the words and about 4.2M parameters for the second part of the neural network that estimates the probabilities. The network is trained using standard stochastic back-propagation.[3] The learning rate was set to 0.005 with an exponential decay and the regularization term is weighted with 0.00003. Note that fast training of neural networks with more than 4M parameters on 4M examples is already a challenge. The same fast algorithms as described in (Schwenk, 2004) were used. Apparent convergence is obtained after about 40 epochs though the training data, each one taking 2h40 on standard PC equipped with two Intel Xeon 2.8GHz CPUs.

The neural network LM alone achieves a perplexity of 103.0 which is only a 4% relative reduction with respect to the back-off LM (107.4, see Table 1). If this neural network LM is interpolated with the back-off LM trained on the whole training set the perplexity decreases from 70.2 to 67.6. Despite this small improvements in perplexity a notable word error reduction was obtained from 14.24% to 14.02%, with the lattice rescoring taking less than 0.05xRT. In the following sections, it is shown that larger improvements can be obtained by training the neural network on more data.

3.3 Adding selected data

Training the neural network LM with stochastic back-propagation on all the available text corpora would take quite a long time. The estimated time for one training epoch with the 88M words of commercial transcriptions is 58h, and more than 12 days if all the 508M words of newspaper texts were used. This is of course not very practicable. One solution to this problem is to select a subset of the data that seems to be most useful for the task. This was done by selecting six month of the commercial transcriptions that minimize the perplexity on the development set. This gives a total of 22M words and the training time is about 14h per epoch.

One can ask if the capacity of the neural network should be augmented in order to deal with the increased number of examples. Experiments with hidden layer sizes from 400 to 1000 neurons have been performed (see Table 2).

size	**400**	**500**	**600**	**1000***
Tr. time	11h20	13h50	16h15	11+16h
Px alone	100.5	100.1	99.5	94.5
interpol.	68.3	68.3	68.2	68.0
Werr	13.99%	13.97%	13.96%	13.92%

* Interpolation of networks with 400 and 600 hidden units.

Table 2: Performance for a neural network LM and training time per epoch as a function of the size of the hidden layer (fixed 6 months subset of commercial transcripts).

Although there is a small decrease in perplexity and word error when increasing the dimension of the hidden layer, this is at the expense of a higher processing time. The training and recognition time are in fact almost linear to the size of the hidden layer. An alternative approach to augment the capacity of the neural network is to modify the dimension of the continuous representation of the words (in the range 50 to 150). The idea behind this is that the probability estimation may be easier in a higher dimensional space (instead of augmenting the capacity of the non-linear probability estimator itself). This is similar in spirit to the theory behind support vector machines (Vapnik, 1998).

Increasing the dimension of the projection layer has several advantages as can be seen from the Figure 2. First, the perplexity and word error rates are lower than those obtained when the size of the

[3]The weights are updated after each example.

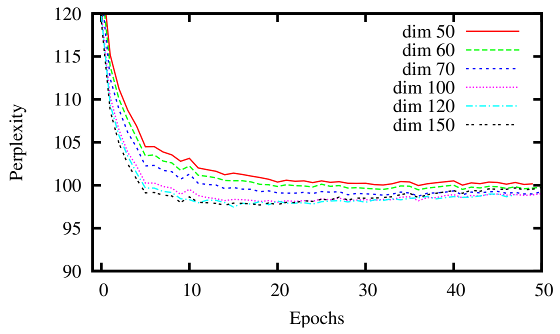

Figure 2: Perplexity in function of the size of the continuous word representation (500 hidden units, fixed 6 months subset of commercial transcripts).

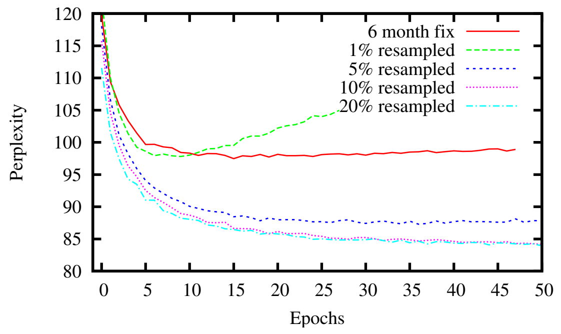

Figure 3: Perplexity when resampling different random subsets of the commercial transcriptions. (word representation of dimension 120, 500 hidden units)

hidden layer is increased. Second, convergence is faster: the best result is obtained after about 15 epochs while up to 40 are needed with large hidden layers. Finally, increasing the size of the continuous word representation has only a small effect on the training and recognition complexity of the neural network[4] since most of the calculation is done to propagate and learn the connections between the hidden and the output layer (see equation 6). The best result was obtained with a 120 dimensional continuous word representation. The perplexity is 67.9 after interpolation with the back-off LM and the word error rate is 13.88%.

3.4 Training on all available data

In this section an algorithm is proposed for training the neural network on arbitrary large training corpora. The basic idea is quite simple: instead of performing several epochs over the whole training data, a different small random subset is used at each epoch. This procedure has several advantages:

- There is no limit on the amount of training data,
- After some epochs, it is likely that all the training examples have been seen at least once,
- Changing the examples after each epoch adds noise to the training procedure. This potentially increases the generalization performance.

This algorithm is summarized in figure 4. The parameters of this algorithm are the size of the random subsets that are used at each epoch. We chose to always use the full corpus of transcriptions of the acoustic data since this is the most appropriate data for the task. Experiments with different random subsets of the commercial transcriptions and the newspaper texts have been performed (see Figure 3 and 5). In all cases the same neural network architecture was used, i.e a 120 dimensional continuous word representation and 500 hidden units. Some experiments with larger hidden units showed basically the same convergence behavior. The learning rate was again set to 0.005, but with a slower exponential decay.

First of all it can be seen from Figure 3 that the results are better when using random subsets instead of a fixed selection of 6 months, although each random subset is actually smaller (for instance a total of 12.5M examples for a subset of 10%). Best results were obtained when taking 10% of the commercial

transcriptions. The perplexity is 66.7 after interpolation with the back-off LM and the word error rate is 13.81% (see summary in Table 3). Larger subsets of the commercial transcriptions lead to slower training, but don't give better results.

Encouraged by these results, we also included the 508M words of newspaper texts in the training data. The size of the random subsets were chosen in order to use between 4 and 9M words of each corpus. Figure 5 summarizes the results. There seems to be no obvious benefit from resampling large subsets of the individual corpora. We choose to resample 10% of the commercial transcriptions and 1% of the newspaper texts.

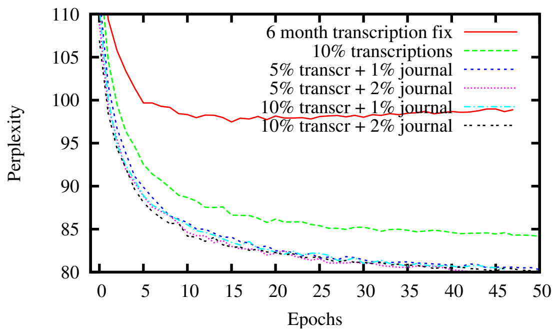

Figure 5: Perplexity when resampling different random subsets of the commercial transcriptions and the newspaper texts.

Table 3 summarizes the results of the different neural network LMs. It can be clearly seen that the perplexity of the neural network LM alone decreases significantly with the amount of training data used. The perplexity after interpolation with the back-off LM changes only by a small amount, but there is a notable improvement in word error rate. This is another experimental evidence that the perplexity of a LM is not directly related to the word error rate.

The best neural network LM achieves a word error reduction of 0.5% absolute with respect to the carefully tuned back-off LM (14.24% → 13.75%). The additional processing time needed to rescore the lattices is less than 0.05xRT. This is a significant improvement, in particular for a fast real-time continuous speech recognition system. When more processing time is available a word error rate of 13.61% can be achieved by interpolating three neural networks together (in 0.14xRT).

3.5 Using a better speech recognizer

The experimental results have also been validated using a second speech recognizer running in about 7xRT. This systems differs from the real-time recognizer by a larger 200k word-list, additional acoustic model adaptation passes and less pruning. Details are described in (Gauvain et al., 2005). The word error rate of the reference system using a back-off LM is 10.74%. This can be reduced to 10.51% using a neural network LM trained on the fine transcriptions only and to 10.20% when the neural network LM is trained on all data using the described resampling approach. Lattice rescoring takes about 0.2xRT.

4 Conclusions and future work

Neural network language models are becoming a serious alternative to the widely used back-off language models. Consistent improvements in perplexity and word error rate have been reported (Bengio et al., 2003; Schwenk and Gauvain, 2004; Schwenk and Gauvain, 2005; Emami and Jelinek, 2004). In these works, the amount of training data was however limited to a maximum of 20M words due to the high complexity of the training algorithm.

In this paper new techniques have been described to train neural network language models on large amounts of text corpora (up to 600M words). The evaluation with a state-of-the-art speech recognition system for French Broadcast News showed a significant word error reduction of 0.5% absolute. The neural network LMs is incorporated into the speech recognizer by rescoring lattices. This is done in less than 0.05xRT.

Several extensions of the learning algorithm itself are promising. We are in particular interested in smarter ways to select different subsets from the large corpus at each epoch (instead of a random choice). One possibility would be to use active learning, i.e. focusing on examples that are most useful to decrease the perplexity. One could also imagine to associate a probability to each training example and to use these probabilities to weight the random sampling. These probabilities would be updated after each epoch. This is similar to boosting techniques (Freund, 1995) which build sequentially classifiers that focus on examples wrongly classified by the preceding one.

5 Acknowledgment

The authors would like to thank Yoshua Bengio for fruitful discussions and helpful comments. The authors would like to recognize the contributions of G. Adda, M. Adda and L. Lamel for their involvement in the development of the speech recognition systems on top of which this work is based.

Abstract

This paper proposes a new discriminative training method, called *minimum sample risk* (MSR), of estimating parameters of language models for text input. While most existing discriminative training methods use a loss function that can be optimized easily but approaches only approximately to the objective of minimum error rate, MSR minimizes the training error directly using a heuristic training procedure. Evaluations on the task of Japanese text input show that MSR can handle a large number of features and training samples; it significantly outperforms a regular trigram model trained using maximum likelihood estimation, and it also outperforms the two widely applied discriminative methods, the boosting and the perceptron algorithms, by a small but statistically significant margin.

1 Introduction

Language modeling (LM) is fundamental to a wide range of applications, such as speech recognition and Asian language text input (Jelinek 1997; Gao et al. 2002). The traditional approach uses a parametric model with *maximum likelihood estimation* (MLE), usually with smoothing methods to deal with data sparseness problems. This approach is optimal under the assumption that the true distribution of data on which the parametric model is based is known. Unfortunately, such an assumption rarely holds in realistic applications.

An alternative approach to LM is based on the framework of discriminative training, which uses a much weaker assumption that training and test data are generated from the same distribution but the form of the distribution is unknown. Unlike the traditional approach that maximizes the function (i.e. likelihood of training data) that is loosely associated with error rate, discriminative training methods aim to directly minimize the error rate on training data even if they reduce the likelihood. So, they potentially lead to better solutions. However, the error rate of a finite set of training samples is usually a step function of model parameters, and cannot be easily minimized. To address this problem, previous research has concentrated on the development of a loss function that approximates the exact error rate and can be easily optimized. Though these methods (e.g. the boosting method) have theoretically appealing properties, such as convergence and bounded generalization error, we argue that the approximated loss function may prevent them from attaining the original objective of minimizing the error rate.

In this paper we present a new estimation procedure for LM, called *minimum sample risk* (MSR). It differs from most existing discriminative training methods in that instead of searching on an approximated loss function, MSR employs a simple heuristic training algorithm that minimizes the error rate on training samples directly. MSR operates like a multidimensional function optimization algorithm: first, it selects a subset of features that are the most effective among all candidate features. The parameters of the model are then optimized iteratively: in each iteration, only the parameter of one feature is adjusted. Both feature selection and parameter optimization are based on the criterion of minimizing the error on training samples. Our evaluation on the task of Japanese text input shows that MSR achieves more than 20% error rate reduction over MLE on two newswire data sets, and it also outperforms the other two widely applied discriminative methods, the boosting method and the perceptron algorithm, by a small but statistically significant margin.

Although it has not been proved in theory that MSR is always *robust*, our experiments of cross-domain LM adaptation show that it is. MSR can effectively adapt a model trained on one domain to

[1] The work was done while the second, third and fourth authors were visiting Microsoft Research Asia. Thanks to Hisami Suzuki for her valuable comments.

different domains. It outperforms the traditional LM adaptation method significantly, and achieves at least comparable or slightly better results to the boosting method and the perceptron algorithm.

2 IME Task and LM

This paper studies LM on the task of Asian language (e.g. Chinese or Japanese) text input. This is the standard method of inputting Chinese or Japanese text by converting the input phonetic symbols into the appropriate word string. In this paper we call the task IME, which stands for *input method editor*, based on the name of the commonly used Windows-based application.

Performance on IME is measured in terms of the character error rate (CER), which is the number of characters wrongly converted from the phonetic string divided by the number of characters in the correct transcript. Current IME systems make about 5-15% CER in conversion of real data in a wide variety of domains (e.g. Gao et al. 2002).

Similar to speech recognition, IME is viewed as a Bayes decision problem. Let A be the input phonetic string. An IME system's task is to choose the most likely word string W^* among those candidates that could be converted from A:

$$W^* = \arg\max_{W \in \mathbf{GEN}(A)} P(W \mid A) = \arg\max_{W \in \mathbf{GEN}(A)} P(W)P(A \mid W) \quad (1)$$

where $\mathbf{GEN}(A)$ denotes the candidate set given A.

Unlike speech recognition, however, there is no acoustic ambiguity since the phonetic string is inputted by users. Moreover, if we do not take into account typing errors, it is reasonable to assume a unique mapping from W and A in IME, i.e. $P(A \mid W) = 1$. So the decision of Equation (1) depends solely upon $P(W)$, making IME a more *direct* evaluation test bed for LM than speech recognition. Another advantage is that it is easy to convert W to A (for Chinese and Japanese), which enables us to obtain a large number of training data for discriminative learning, as described later.

The values of $P(W)$ in Equation (1) are traditionally calculated by MLE: the optimal model parameters $\boldsymbol{\lambda}^*$ are chosen in such a way that $P(W|\boldsymbol{\lambda}^*)$ is maximized on training data. The arguments in favor of MLE are based on the assumption that the form of the underlying distributions is known, and that only the values of the parameters characterizing those distributions are unknown. In using MLE for LM, one always assumes a multinomial distribution of language. For example, a trigram model makes the assumption that the next word is predicted depending only on two preceding words. However, there are many cases in natural language where words over an arbitrary distance can be related. MLE is therefore not optimal because the assumed model form is incorrect.

What are the best estimators when the model is known to be false then? In IME, we can tackle this question empirically. Best IME systems achieve the least CER. Therefore, the best estimators are those which minimize the expected error rate on unseen test data. Since the distribution of test data is unknown, we can approximately minimize the error rate on some given training data (Vapnik 1999). Toward this end, we have developed a very simple heuristic training procedure called *minimum sample risk*, as presented in the next section.

3 Minimum Sample Risk

3.1 Problem Definition

We follow the general framework of linear discriminant models described in (Duda et al. 2001). In the rest of the paper we use the following notation, adapted from Collins (2002).

• Training data is a set of example input/output pairs. In LM for IME, training samples are represented as $\{A_i, W_i^R\}$, for $i = 1…M$, where each A_i is an input phonetic string and W_i^R is the reference transcript of A_i.

• We assume some way of generating a set of candidate word strings given A, denoted by $\mathbf{GEN}(A)$. In our experiments, $\mathbf{GEN}(A)$ consists of top N word strings converted from A using a baseline IME system that uses only a word trigram model.

• We assume a set of D+1 features $f_d(W)$, for $d = 0…D$. The features could be arbitrary functions that map W to real values. Using vector notation, we have $\mathbf{f}(W) \in \Re^{D+1}$, where $\mathbf{f}(W) = [f_0(W), f_1(W), …, f_D(W)]^T$. Without loss of generality, $f_0(W)$ is called the base feature, and is defined in our case as the log probability that the word trigram model assigns to W. Other features ($f_d(W)$, for $d = 1…D$) are defined as the counts of word n-grams (n = 1 and 2 in our experiments) in W.

• Finally, the parameters of the model form a vector of D+1 dimensions, each for one feature function, $\boldsymbol{\lambda} = [\lambda_0, \lambda_1, …, \lambda_D]$. The score of a word string W can be written as

$$Score(W, \boldsymbol{\lambda}) = \boldsymbol{\lambda}\mathbf{f}(W) = \sum_{d=0}^{D} \lambda_d f_d(W) \cdot \quad (2)$$

The decision rule of Equation (1) is rewritten as

$$W^*(A, \boldsymbol{\lambda}) = \arg\max_{W \in \mathbf{GEN}(A)} Score(W, \boldsymbol{\lambda}) \cdot \quad (3)$$

Equation (3) views IME as a ranking problem, where the model gives the ranking score, not probabilities. We therefore do not evaluate the model via perplexity.

Now, assume that we can measure the number of conversion errors in W by comparing it with a reference transcript W^R using an error function $\mathrm{Er}(W^R,W)$ (i.e. the string edit distance function in our case). We call the sum of error counts over the training samples *sample risk*. Our goal is to minimize the sample risk while searching for the parameters as defined in Equation (4), hence the name *minimum sample risk* (MSR). W_i^* in Equation (4) is determined by Equation (3),

$$\boldsymbol{\lambda}_{MSR} \overset{def}{=} \arg\min_{\boldsymbol{\lambda}} \sum_{i=1\ldots M} \mathrm{Er}(W_i^R, W_i^*(A_i, \boldsymbol{\lambda})) \cdot \quad (4)$$

We first present the basic MSR training algorithm, and then the two improvements we made.

3.2 Training Algorithm

The MSR training algorithm is cast as a multidimensional function optimization approach (Press et al. 1992): taking the feature vector as a set of directions; the first direction (i.e. feature) is selected and the objective function (i.e. sample risk) is minimized along that direction using a *line search*; then from there along the second direction to its minimum, and so on, cycling through the whole set of directions as many times as necessary, until the objective function stops decreasing.

This simple method can work properly under two assumptions. First, there exists an implementation of line search that optimizes the function along one direction efficiently. Second, the number of candidate features is not too large, and these features are not highly correlated. However, neither of the assumptions holds in our case. First of all, Er(.) in Equation (4) is a step function of $\boldsymbol{\lambda}$, thus cannot be optimized directly by regular gradient-based procedures – a grid search has to be used instead. However, there are problems with simple grid search: using a large grid could miss the optimal solution whereas using a fine-grained grid would lead to a very slow algorithm. Secondly, in the case of LM, there are millions of candidate features, some of which are highly correlated. We address these issues respectively in the next two subsections.

3.3 Grid Line Search

Our implementation of a grid search is a modified version of that proposed in (Och 2003). The modifications are made to deal with the efficiency issue due to the fact that there is a very large number of features and training samples in our task, compared to only 8 features used in (Och 2003). Unlike a simple grid search where the intervals between any two adjacent grids are equal and fixed, we determine for each feature a sequence of grids with differently sized intervals, each corresponding to a different value of sample risk.

As shown in Equation (4), the loss function (i.e. sample risk) over all training samples is the sum of the loss function (i.e. Er(.)) of each training sample. Therefore, in what follows, we begin with a discussion on minimizing Er(.) of a training sample using the line search.

Let $\boldsymbol{\lambda}$ be the current model parameter vector, and f_d be the selected feature. The line search aims to find the optimal parameter λ_d^* so as to minimize Er(.). For a training sample (A, W^R), the score of each candidate word string $W \in \mathbf{GEN}(A)$, as in Equation (2), can be decomposed into two terms:

$$Score(W, \boldsymbol{\lambda}) = \boldsymbol{\lambda}\mathbf{f}(W) = \sum_{d'=0 \vee d' \neq d}^{D} \lambda_{d'} f_{d'}(W) + \lambda_d f_d(W),$$

where the first term on the right hand side does not change with λ_d. Note that if several candidate word strings have the same feature value $f_d(W)$, their relative rank will remain the same for any λ_d. Since $f_d(W)$ takes integer values in our case ($f_d(W)$ is the count of a particular *n*-gram in W), we can group the candidates using $f_d(W)$ so that candidates in each group have the same value of $f_d(W)$. In each group, we define the candidate with the highest value of

$$\sum\nolimits_{d'=0 \vee d' \neq d}^{D} \lambda_{d'} f_{d'}(W)$$

as the *active* candidate of the group because no matter what value λ_d takes, only this candidate could be selected according to Equation (3).

Now, we reduce $\mathbf{GEN}(A)$ to a much smaller list of active candidates. We can find a set of intervals for λ_d, within each of which a particular active candidate will be selected as W^*. We can compute the Er(.) value of that candidate as the Er(.) value for the corresponding interval. As a result, for each training sample, we obtain a sequence of intervals and their corresponding Er(.) values. The optimal value λ_d^* can then be found by traversing the sequence and taking the midpoint of the interval with the lowest Er(.) value.

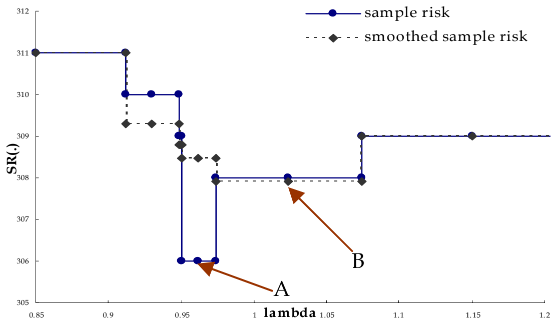

Figure 1. Examples of line search.

This process can be extended to the whole training set as follows. By merging the sequence of intervals of each training sample in the training set, we obtain a global sequence of intervals as well as their corresponding sample risk. We can then find the optimal value λ_d^* as well as the minimal sample risk by traversing the global interval sequence. An example is shown in Figure 1.

The line search can be unstable, however. In some cases when some of the intervals are very narrow (e.g. the interval A in Figure 1), moving the optimal value λ_d^* slightly can lead to much larger sample risk. Intuitively, we prefer a stable solution which is also known as a robust solution (with even slightly higher sample risk, e.g. the interval B in Figure 1). Following Quirk et al. (2004), we evaluate each interval in the sequence by its corresponding *smoothed sample risk*. Let λ be the midpoint of an interval and $\text{SR}(\lambda)$ be the corresponding sample risk of the interval. The smoothed sample risk of the interval is defined as

$$\int_{\lambda-b}^{\lambda+b} \text{SR}(\lambda)\, d\lambda$$

where b is a smoothing factor whose value is determined empirically (0.06 in our experiments). As shown in Figure 1, a more stable interval B is selected according to the smoothed sample risk.

In addition to reducing **GEN**(A) to an active candidate list described above, the efficiency of the line search can be further improved. We find that the line search only needs to traverse a small subset of training samples because the distribution of features among training samples are very sparse. Therefore, we built an inverted index that lists for each feature all training samples that contain it. As will be shown in Section 4.2, the line search is very efficient even for a large training set with millions of candidate features.

3.4 Feature Subset Selection

This section describes our method of selecting among millions of features a small subset of highly effective features for MSR learning. Reducing the number of features is essential for two reasons: to reduce computational complexity and to ensure the generalization property of the linear model. A large number of features lead to a large number of parameters of the resulting linear model, as described in Section 3.1. For a limited number of training samples, keeping the number of features sufficiently small should lead to a simpler model that is less likely to overfit to the training data.

The first step of our feature selection algorithm treats the features *independently*. The effectiveness of a feature is measured in terms of the reduction of the sample risk on top of the base feature f_0. Formally, let $\text{SR}(f_0)$ be the sample risk of using the base feature only, and $\text{SR}(f_0 + \lambda_d f_d)$ be the sample risk of using both f_0 and f_d and the parameter λ_d that has been optimized using the line search. Then the effectiveness of f_d, denoted by $E(f_d)$, is given by

$$E(f_d) = \frac{\text{SR}(f_0) - \text{SR}(f_0 + \lambda_d f_d)}{\max\limits_{f_i, i=1\ldots D}(\text{SR}(f_0) - \text{SR}(f_0 + \lambda_i f_i))}, \qquad (5)$$

where the denominator is a normalization term to ensure that $E(f) \in [0, 1]$.

The feature selection procedure can be stated as follows: The value of $E(.)$ is computed according to Equation (5) for each of the candidate features. Features are then ranked in the order of descending values of $E(.)$. The top l features are selected to form the feature vector in the linear model.

Treating features independently has the advantage of computational simplicity, but may not be effective for features with high correlation. For instance, although two features may carry rich discriminative information when treated separately, there may be very little gain if they are combined in a feature vector, because of the high correlation between them. Therefore, in what follows, we describe a technique of incorporating correlation information in the feature selection criterion.

Let x_{md}, $m = 1\ldots M$ and $d = 1\ldots D$, be a Boolean value: $x_{md} = 1$ if the sample risk reduction of using the d-th feature on the m-th training sample, computed by Equation (5), is larger than zero, and 0 otherwise. The cross correlation coefficient between two features f_i and f_j is estimated as

$$C(i,j) = \frac{\sum_{m=1}^{M} x_{mi} x_{mj}}{\sqrt{\sum_{m=1}^{M} x_{mi}^2 \sum_{m=1}^{M} x_{mj}^2}}. \qquad (6)$$

It can be shown that $C(i, j) \in [0, 1]$. Now, similar to (Theodoridis and Koutroumbas 2003), the feature selection procedure consists of the following steps, where f_i denotes any selected feature and f_j denotes any candidate feature to be selected.

Step 1. For each of the candidate features (f_d, for $d = 1\ldots D$), compute the value of $E(f)$ according to Equation (5). Rank them in a descending order and choose the one with the highest $E(.)$ value. Let us denote this feature as f_1.

Step 2. To select the second feature, compute the cross correlation coefficient between the selected feature f_1 and each of the remaining M-1 features, according to Equation (6).

Step 3. Select the second feature f according to

$$j^* = \arg\max_{j=2\ldots D} \{\alpha E(f_j) - (1-\alpha)C(1,j)\}$$

where α is the weight that determines the relative importance we give to the two terms. The value of α is optimized on held-out data (0.8 in our experiments). This means that for the selection of the second feature, we take into account not only its impact of reducing the sample risk but also the correlation with the previously selected feature. It is expected that choosing features with less correlation gives better sample risk minimization.

Step 4. Select k-th features, $k = 3\ldots K$, according to

$$j^* = \arg\max_{j} \left\{ \alpha E(f_j) - \frac{1-\alpha}{k-1} \sum_{i=1}^{k-1} C(i,j) \right\} \qquad (7)$$

That is, we select the next feature by taking into account its average correlation with all previously selected features. The optimal number of features, l, is determined on held-out data.

Similarly to the case of line search, we need to deal with the efficiency issue in the feature selection method. As shown in Equation (7), the estimates of $E(.)$ and $C(.)$ need to be computed. Let D and K ($K << D$) be the number of all candidate features and the number of features in the resulting model, respectively. According to the feature selection method described above, we need to estimate $E(.)$ for each of the D candidate features only once in Step 1. This is not very costly due to the efficiency of our line search algorithm. Unlike the case of $E(.)$, $O(K \times D)$ estimates of $C(.)$ are required in Step 4. This is computationally expensive even for a medium-sized K. Therefore, every time a new feature is selected (in Step 4), we only estimate the value of $C(.)$ between each of the selected features and each of the top N remaining features with the highest value of $E(.)$. This reduces the number of estimates of $C(.)$ to $O(K \times N)$. In our experiments we set $N = 1000$, much smaller than D. This reduces the computational cost significantly without producing any noticeable quality loss in the resulting model.

The MSR algorithm used in our experiments is summarized in Figure 2. It consists of feature selection (line 2) and optimization (lines 3 - 5) steps.

```
1  Set $\lambda_0 = 1$ and $\lambda_d = 0$ for $d=1\ldots D$
2  Rank all features and select the top $K$ features, using
   the feature selection method described in Section 3.4
3  For $t = 1\ldots T$ (T= total number of iterations)
4      For each $k = 1\ldots K$
5          Update the parameter of $f_k$ using line search.
```

Figure 2: The MSR algorithm

4 Evaluation

4.1 Settings

We evaluated MSR on the task of Japanese IME. Two newspaper corpora are used as training and test data: Nikkei and Yomiuri Newspapers. Both corpora have been pre-word-segmented using a lexicon containing 167,107 entries. A 5,000-sentence subset of the Yomiuri Newspaper corpus was used as held-out data (e.g. to determine learning rate, number of iterations and features etc.). We tested our models on another 5,000-sentence subset of the Yomiuri Newspaper corpus.

We used an 80,000-sentence subset of the Nikkei Newspaper corpus as the training set. For each A, we produced a word lattice using the baseline system described in (Gao et al. 2002), which uses a word trigram model trained via MLE on anther 400,000-sentence subset of the Nikkei Newspaper corpus. The two subsets do not overlap so as to simulate the case where unseen phonetic symbol strings are converted by the baseline system. For efficiency, we kept for each training sample the best 20 hypotheses in its candidate conversion set **GEN**(A) for discriminative training. The oracle best hypothesis, which gives the minimum number of errors, was used as the reference transcript of A.

	Model	CER (%)	% over MLE
1.	**MLE**	3.70	--
2.	**MSR (*K*=2000)**	**2.95**	**20.9**
3.	**Boosting**	3.06	18.0
4.	**Perceptron**	3.07	17.8

Table 1. Comparison of CER results.

4.2 Results

We used unigrams and bigrams that occurred more than once in the training set as features. We did not use trigram features because they did not result in a significant improvement in our pilot study. The total number of candidate features we used was around 860,000.

Our main experimental results are shown in Table 1. Row 1 is our baseline result using the word trigram model. Notice that the result is much better than the state-of-the-art performance currently available in the marketplace (e.g. Gao et al. 2002), presumably due to the large amount of training data we used, and to the similarity between the training and the test data. Row 2 is the result of the model trained using the MSR algorithm described in Section 3. We also compared the MSR algorithm to two of the state-of-the-art discriminative training methods: **Boosting** in Row 3 is an implementation of the improved algorithm for the boosting loss function proposed in (Collins 2000), and **Perceptron** in Row 4 is an implementation of the averaged perceptron algorithm described in (Collins 2002).

We see that all discriminative training methods outperform MLE significantly (p-value < 0.01). In particular, MSR outperforms MLE by more than 20% CER reduction. Notice that we used only unigram and bigram features that have been included in the baseline trigram model, so the improvement is solely attributed to the high performance of MSR. We also find that MSR outperforms the perceptron and boosting methods by a small but statistically significant margin.

The MSR algorithm is also very efficient: using a subset of 20,000 features, it takes less than 20 minutes to converge on an XEON(TM) MP 1.90GHz machine. It is as efficient as the perceptron algorithm and slightly faster than the boosting method.

4.3 Robustness Issues

Most theorems that justify the robustness of discriminative training algorithms concern two questions. First, is there a guarantee that a given algorithm converges even if the training samples are not linearly separable? This is called the *convergence* problem. Second, how well is the training error reduction preserved when the algorithm is applied to unseen test samples? This is called the *generalization* problem. Though we currently cannot give a theoretical justification, we present empirical evidence here for the robustness of the MSR approach.

As Vapnik (1999) pointed out, the most robust linear models are the ones that achieve the least training errors with the least number of features. Therefore, the robustness of the MSR algorithm are mainly affected by the feature selection method. To verify this, we created four different subsets of features using different settings of the feature selection method described in Section 3.4. We selected different numbers of features (i.e. 500 and 2000) with and without taking into account the correlation between features (i.e. α in Equation (7) is set to 0.8 and 1, respectively). For each of the four feature subsets, we used the MSR algorithm to generate a set of models. The CER curves of these models on training and test data sets are shown in Figures 3 and 4, respectively.

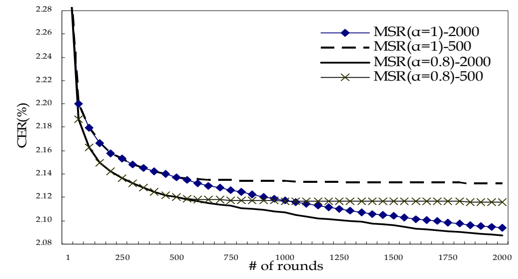

Figure 3. Training error curves of the MSR algorithm

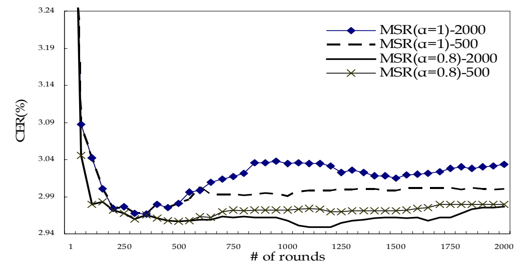

Figure 4. Test error curves of the MSR algorithm

The results reveal several facts. First, the convergence properties of MSR are shown in Figure 3 where in all cases, training errors drop consistently with more iterations. Secondly, as expected, using more features leads to overfitting, For example, MSR(α =1)-2000 makes fewer errors than MSR(α =1)-500 on training data but more errors on test data. Finally, taking into account the correlation between features (e.g. α = 0.8 in Equation (7)) results in a better subset of features that lead to not only fewer training errors, as shown in Figure 3, but also better generalization properties (fewer test errors), as shown in Figure 4.

4.4 Domain Adaptation Results

Though MSR achieves impressive performance in CER reduction over the comparison methods, as described in Section 4.2, the experiments are all performed using newspaper text for both training and testing, which is not a realistic scenario if we are to deploy the model in an application. This section reports the results of additional experiments in which we adapt a model trained on one domain to a different domain, i.e., in a so-called cross-domain LM adaptation paradigm. See (Suzuki and Gao 2005) for a detailed report.

The data sets we used stem from five distinct sources of text. The Nikkei newspaper corpus described in Section 4.1 was used as the background domain, on which the word trigram model was trained. We used four adaptation domains: Yomiuri (newspaper corpus), TuneUp (balanced corpus containing newspapers and other sources of text), Encarta (encyclopedia) and Shincho (collection of novels). For each of the four domains, we used an 72,000-sentence subset as adaptation training data, a 5,000-sentence subset as held-out data and another 5,000-sentence subset as test data. Similarly, all corpora have been word-segmented, and we kept for each training sample, in the four adaptation domains, the best 20 hypotheses in its candidate conversion set for discriminative training.

We compared MSR with three other LM adaptation methods:

Baseline is the background word trigram model, as described in Section 4.1.

MAP (maximum a *posteriori*) is a traditional LM adaptation method where the parameters of the background model are adjusted in such a way that maximizes the likelihood of the adaptation data. Our implementation takes the form of linear interpolation as $P(w_i|h) = \lambda P_b(w_i|h) + (1-\lambda)P_a(w_i|h)$, where P_b is the probability of the background model, P_a is the probability trained on adaptation data using MLE and the history h corresponds to two preceding words (i.e. P_b and P_a are trigram probabilities). λ is the interpolation weight optimized on held-out data.

Perceptron, **Boosting** and **MSR** are the three discriminative methods described in the previous sections. For each of them, the base feature was

Model	Yomiuri	TuneUp	Encarta	Shincho
Baseline	3.70	5.81	10.24	12.18
MAP	3.69	5.47	7.98	10.76
MSR	**2.73**	**5.15**	**7.40**	**10.16**
Boosting	2.78	5.33	7.53	10.25
Perceptron	2.78	5.20	7.44	10.18

Table 2. CER(%) results on four adaptation test sets .

derived from the word trigram model trained on the background data, and other n-gram features (i.e. f_d, d = 1…D in Equation (2)) were trained on adaptation data. That is, the parameters of the background model are adjusted in such a way that minimizes the errors on adaptation data made by background model.

Results are summarized in Table 2. First of all, in all four adaptation domains, discriminative methods outperform MAP significantly. Secondly, the improvement margins of discriminative methods over MAP correspond to the similarities between background domain and adaptation domains. When the two domains are very similar to the background domain (such as Yomiuri), discriminative methods outperform MAP by a large margin. However, the margin is smaller when the two domains are substantially different (such as Encarta and Shincho). The phenomenon is attributed to the underlying difference between the two adaptation methods: MAP aims to improve the likelihood of a distribution, so if the adaptation domain is very similar to the background domain, the difference between the two underlying distributions is so small that MAP cannot adjust the model effectively. However, discriminative methods do not have this limitation for they aim to reduce errors directly. Finally, we find that in most adaptation test sets, MSR achieves slightly better CER results than the two competing discriminative methods. Specifically, the improvements of MSR are statistically significant over the boosting method in three out of four domains, and over the perceptron algorithm in the Yomiuri domain. The results demonstrate again that MSR is robust.

5 Related Work

Discriminative models have recently been proved to be more effective than generative models in some NLP tasks, e.g., parsing (Collins 2000), POS tagging (Collins 2002) and LM for speech recognition (Roark et al. 2004). In particular, the linear models, though simple and non-probabilistic in nature, are preferred to their probabilistic counterpart such as logistic regression. One of the reasons, as pointed out by Ng and Jordan (2002), is that the parameters of a discriminative model can be fit either to maximize the conditional likelihood on training data, or to minimize the training errors. Since the latter optimizes the objective function that the system is graded on, it is viewed as being more truly in the *spirit* of discriminative learning.

The MSR method shares the same motivation: to minimize the errors directly as much as possible. Because the error function on a finite data set is a step function, and cannot be optimized easily, previous research approximates the error function by loss functions that are suitable for optimization (e.g. Collins 2000; Freund et al. 1998; Juang et al. 1997; Duda et al. 2001). MSR uses an alternative approach. It is a simple heuristic training procedure to minimize training errors directly without applying any approximated loss function.

MSR shares many similarities with previous methods. The basic training algorithm described in Section 3.2 follows the general framework of multi-dimensional optimization (e.g., Press et al. 1992). The line search is an extension of that described in (Och 2003; Quirk et al. 2005. The extension lies in the way of handling large number of features and training samples. Previous algorithms were used to optimize linear models with less than 10 features. The feature selection method described in Section 3.4 is a particular implementation of the feature selection methods described in (e.g., Theodoridis and Koutroumbas 2003). The major difference between the MSR and other methods is that it estimates the effectiveness of each feature in terms of its expected training error reduction while previous methods used metrics that are loosely coupled with reducing training errors. The way of dealing with feature correlations in feature selection in Equation (7), was suggested by Finette et al. (1983).

6 Conclusion and Future Work

We show that MSR is a very successful discriminative training algorithm for LM. Our experiments suggest that it leads to significantly better conversion performance on the IME task than either the MLE method or the two widely applied discriminative methods, the boosting and perceptron methods. However, due to the lack of theoretical underpinnings, we are unable to prove that MSR will always succeed. This forms one area of our future work.

One of the most interesting properties of MSR is that it can optimize any objective function (whether its gradient is computable or not), such as error rate in IME or speech, BLEU score in MT, precision and recall in IR (Gao et al. 2005). In particular, MSR can be performed on large-scale training set with millions of candidate features. Thus, another area of our future work is to test MSR on wider varieties of NLP tasks such as parsing and tagging.

A Salience Driven Approach to Robust Input Interpretation in Multimodal Conversational Systems

Joyce Y. Chai **Shaolin Qu**

East Lansing, MI 48824
{jchai@cse.msu.edu, qushaoli@cse.msu.edu}

Abstract

To improve the robustness in multimodal input interpretation, this paper presents a new salience driven approach. This approach is based on the observation that, during multimodal conversation, information from deictic gestures (e.g., point or circle) on a graphical display can signal a part of the physical world (i.e., representation of the domain and task) of the application which is salient during the communication. This salient part of the physical world will prime what users tend to communicate in speech and in turn can be used to constrain hypotheses for spoken language understanding, thus improving overall input interpretation. Our experimental results have indicated the potential of this approach in reducing word error rate and improving concept identification in multimodal conversation.

1 Introduction

Multimodal conversational systems promote more natural and effective human machine communication by allowing users to interact with systems through multiple modalities such as speech and gesture (Cohen et al., 1996; Johnston et al., 2002; Pieraccini et al., 2004). Despite recent advances, interpreting what users communicate to the system is still a significant challenge due to insufficient recognition (e.g., speech recognition) and understanding (e.g., language understanding) performance. Significant improvement in the robustness of multimodal interpretation is crucial if multimodal systems are to be effective and practical for real world applications.

Previous studies have shown that, in multimodal conversation, multiple modalities tend to complement each other (Cassell et al. 1994). Fusing two or more modalities can be an effective means of reducing recognition uncertainties, for example, through mutual disambiguation (Oviatt 1999). For semantically-rich modalities such as speech and pen-based gesture, mutual disambiguation usually happens at the fusion stage where partial semantic representations from individual modalities are disambiguated and combined into an overall interpretation (Johnston 1998, Chai et al., 2004a). One problem is that some critical but low probability information from individual modalities (e.g., recognized alternatives with low probabilities) may never reach the fusion stage. Therefore, this paper addresses how to use information from one modality (e.g., deictic gesture) to directly influence the semantic processing of another modality (e.g., spoken language understanding) even before the fusion stage.

In particular we present a new salience driven approach that uses gesture to influence spoken language understanding. This approach is based on the observation that, during multimodal conversation, information from deictic gestures (e.g., point or circle) on a graphical interface can signal a part of the physical world (i.e., representation of the domain and task) of the application which is salient during the communication. This salient part of the physical world will prime what users tend to communicate in speech and thus in turn can be used to constrain hypotheses for spoken language understanding. In particular, this approach incorporates a notion of salience from deictic gestures into language models for spoken language processing. Our experimental results indicate the potential of this approach in reducing word error rate and improving concept identification from spoken utterances.

Proceedings of Human Language Technology Conference and Conference on Empirical Methods in Natural Language Processing (HLT/EMNLP), pages 217–224, Vancouver, October 2005. ©2005 Association for Computational Linguistics

In the following sections, we first introduce the current architecture for multimodal interpretation. Then we describe our salience driven approach and present empirical results.

2 Input Interpretation

Input interpretation is the identification of semantic meanings in user inputs. In multimodal conversation, user inputs can come from multiple channels (e.g., speech and gesture). Thus, most work on input interpretation is based on semantic fusion that includes individual recognizers and a sequential integration processes as shown in Figure 1. In this approach, a system first creates possible partial meaning representations from recognized hypotheses (e.g., N-best lists) independently of other modalities. For example, suppose a user says "what is the price of this painting" and at the same time points to a position on the screen. The partial meaning representations from the speech input and the gesture input are shown in (a-b) in Figure 1. The system uses the partial meaning representations to disambiguate each other and combines compatible partial representations together into an overall semantic representation as in Figure1(c).

In this architecture, the partial semantic representations from individual modalities are crucial for mutual disambiguation during multimodal fusion. The quality of partial semantic representations depends on how individual modalities are processed. For example, if the speech input is recognized as "what is the prize of this pant", then the partial representation from the speech input will not be created in the first place. Without a candidate partial representation, it is not likely for multimodal fusion to reach an overall meaning of the input given this late fusion architecture.

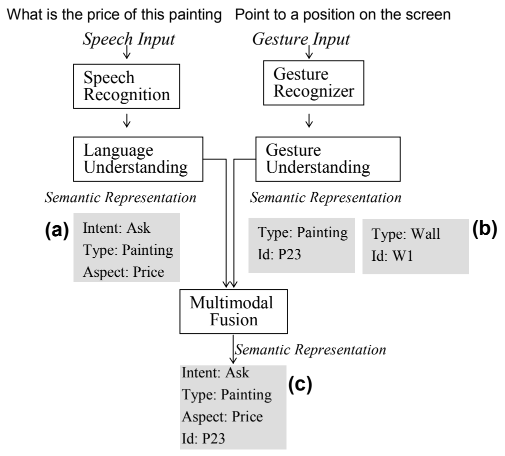

Figure 1: Semantics-based multimodal interpretation

Thus, a problem with the semantics-based fusion approach is that information from multiple modalities is only used during the fusion stage to disambiguate or combine partial semantic representations. This late use of information from other sources in the pipelined process can cause the loss of some low probability information (e.g., recognized alternatives with low probabilities which did not make it to the N-best list) which could be very crucial in terms of the overall interpretation. It is desirable to use information from multiple sources at an earlier stage before partial representations are created from individual modalities. For example, in ((Bangalore and Johnston 2000), a finite-state approach was applied to tightly couple multimodal language processing (e.g., gesture and speech) and speech recognition to improve recognition hypotheses. To further address this issue, in this paper, we present a salience driven approach that particularly applies gesture information (e.g., pen-based deictic gestures) to robust spoken language understanding before multimodal fusion.

3 Related Work on Salience Modeling

We first give a brief overview on the notion of salience and how salience modeling is applied in earlier work on natural language and multimodal language processing.

Linguistic salience describes the accessibility of entities in a speaker/hearer's memory and its implication in language production and interpretation. Many theories on linguistic salience have been developed, including how the salience of entities affects the form of referring expressions as in the Givenness Hierarchy (Gundel et al., 1993) and the local coherence of discourse as in the Centering Theory (Grosz et al., 1995). Salience modeling is used for both language generation and language interpretation; the latter is more relevant to our work. Most salience-based interpretation has focused on reference resolution for both linguistic referring expressions (e.g., pronouns) (Lappin and Leass 1995) and multimodal expressions (Hul et al. 1995; Eisenstein and Christoudias 2004).

Visual salience considers an object salient when it attracts a user's visual attention more than others. The cause of such attention depends on many factors including user intention, familiarity, and physical characteristics of objects. For example, an object may be salient when it has some properties the others do not have, such as it is the only one that is highlighted, or the only one of a certain size, category, or color

(Landragin et al., 2001). Visual salience can also be useful in input interpretation, for example, for multimodal reference resolution (Kehler 2000) and cross-modal coreference interpretation (Byron et al., 2005).

We believe that salience modeling should go beyond reference resolution. Our view is that the salience not only affects the use of referring expressions (and thus is useful for interpreting referring expressions), but also influences the linguistic context of the referring expressions. The spoken utterances that contain these expressions tend to describe information relating to the salient objects (e.g., properties or actions). Therefore, our goal in this paper is to take salience modeling a step further from reference resolution, towards overall language understanding.

4 A Salience Driven Approach

The new salience driven approach is based on the cognitive theory of Conversation Implicature (Grice 1975) and earlier empirical findings of user speech and gesture behavior in multimodal conversation (Oviatt 1999). The theory of Conversation Implicature (Grice 1975) states that speakers tend to make their contribution as informative as is required (for the current purpose of communication) and not make their contribution more informative than is required. In the context of multimodal conversation that involves speech and pen-based gesture, this theory indicates that users most likely will not make any unnecessary deictic gestures unless those gestures help in communicating users' intention. This is especially true since gestures usually take an extra effort from a user. When a pen-based gesture is intentionally delivered by a user, the information conveyed is often a crucial component in interpretation (Chai et al., 2005).

Speech and gesture also tend to complement each other. For example, when a speech utterance is accompanied by a deictic gesture (e.g., point or circle) on a graphical display, the speech input tends to issue commands or inquiries about properties of objects, and the deictic gestures tend to indicate the objects of interest. In addition, as shown in (Oviatt 1999), the deictic gestures often occur before spoken utterances. Our previous work (Chai et al., 2004b) also showed that 85% of time gestures occurred before corresponding speech units. Therefore, gestures can be used as an earlier indicator to anticipate the content of communication in the subsequent spoken utterances.

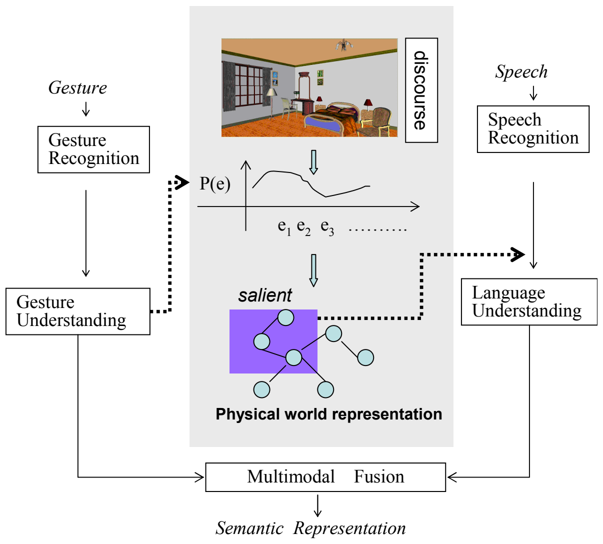

Figure 2: The salience driven approach: the salience distribution calculated from gesture is used to tailor language models for spoken language understanding

4.1 Overview

The general idea of the salience based approach is shown in Figure 2. For each application domain, there is a physical world representation that captures domain knowledge (details are described later). A deictic gesture can activate several objects on the graphical display. This activation will signal a distribution of objects that are salient. The salient objects are mapped to the physical world representation to indicate a salient part of representation that includes relevant properties or tasks related to the salient objects. This salient part of the physical world is likely to be the potential content of the spoken communication, and thus can be used to tailor language models for spoken language understanding. This process is shown in the middle shaded box of Figure 2. It bridges gesture understanding and language understanding at a stage before multimodal fusion. Note that the use of gesture information can be applied at different stages: during speech recognition to generate hypotheses or post processing of recognized hypotheses before language understanding. In this paper, we focus on the latter.

The physical world representation includes the following components:

• Domain Model. This component captures the relevant knowledge about the domain including domain objects, properties of the objects, relations between objects, and task models related to objects. Previous studies have shown that domain knowledge can be used to improve spoken language understanding (Wai et al, 2001). Currently, we apply a frame-based representation where a frame represents an object (or a type of object) in the domain and frame elements represent attributes and tasks related to the objects. Each frame element is associated with a semantic tag which indicates the semantic content of that element. In the future, the domain model might also include knowledge about the interface, for example, visual properties and spatial relations between objects on the interface.

• Domain Grammar. This component specifies grammar and vocabularies used to process language inputs. There are two types of representation. The first type is a semantics-based context free grammar where each non-terminal symbol represents a semantic tag (indicating semantic information such as the semantic type of an object, etc). Each word (i.e., the terminal symbol) in the lexicon relates to one or more semantic tags. Some of these semantic tags are directly linked to the frame elements in the domain model since they represent certain properties or tasks. This grammar was manually developed.

The second type of representation is based on annotated user spoken utterances. The data are annotated in terms of relevant semantic information (i.e., using semantic tags) in the utterance and the intended objects of interest (which are directly linked to the domain model). Based on the annotated data, N-grams can be learned to represent the dependency of language in our domain.

Based on the physical world representation, our approach supports the following operations:

Salience modeling. This operation calculates a salience distribution of entities in the physical world. In our current investigation, we limit the scope of entities to a closed set of objects from our physical world representation since the system has knowledge about those objects. These entities could have different salience values depending on whether they are visible on the graphical display, gestured by a user, or mentioned in the prior conversation. In this paper, we focus on the salience modeling using gesture information only.

Salience driven language understanding. This operation maps the salience distribution to the physical world representation and uses the salient world to influence spoken language understanding. Note that, in this paper, we are not concerned with acoustic models for speech recognition, but rather we are interested in the use of the salience distribution to prime language models and facilitate language understanding.

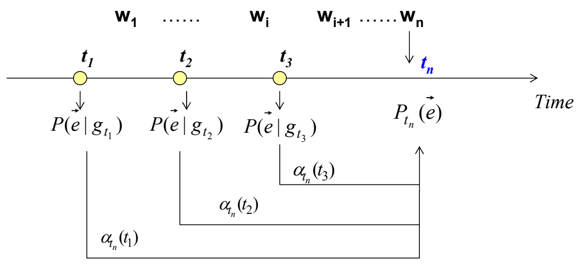

Figure 3: Salience modeling: the salience distribution at time t_n is calculated by a joint effect of gestures that happen before t_n.

4.2 Salience Modeling

We use a vector $\vec{e}$ to represent entities in the physical world representation. For each entity $e_k \in \vec{e}$, we use $P_{t_n}(e_k)$ to represent its salience value at time t_n. For all the entities, we use $P_{t_n}(\vec{e})$ to represent a salience distribution at time t_n. Figure 3 shows a sequence of words with corresponding gestures that occur at t_1, t_2, and t_3. As shown in Figure 3, the salience distribution at any given time t_n is influenced by a joint effect from this sequence of gestures that happen before t_n etc. Depending on its time of occurrence, each gesture may have a different impact on the salience distribution at time t_n. Note that although each gesture may have a short duration, here we only consider the beginning time of a gesture. Therefore, for an entity e_k, its salience value at time t_n is computed as follows:

$$P_{t_n}(e_k) = \frac{\sum_{i=1}^{m} \alpha_{t_n}(g_{t_i}) P(e_k | g_{t_i})}{\sum_{e \in \vec{e}} \sum_{i=1}^{m} \alpha_{t_n}(g_{t_i}) P(e | g_{t_i})} \qquad (1)$$

In Equation (1), m ($m \geq 1$) is the number of gestures that have occurred before t_n. The different impact of a gesture g_{t_i} at time t_i that contributes to the salience distribution at time t_n is represented as the weight $\alpha_{t_n}(g_{t_i})$ in Equation (1). Currently, we calculate the weight depending on the temporal distance as follows:

$$\alpha_{t_n}(g_{t_i}) = \exp[\frac{-(t_n - t_i)}{2000}] \quad (t_n \geq t_i) \qquad (2)$$

Equation (2) indicates that at a given time t_n (measured in milliseconds), the closer a gesture (at t_i) is to the time t_n, the higher impact this gesture has on the salience distribution (Chai et al., 2004b).

It is worth mentioning that a deictic gesture on the graphic display (e.g., pointing and circling) could have ambiguous interpretation by itself. For example, given an interface, a point or a circle on the screen could result in selection of different entities with different probabilities. Therefore, in Equation (1), $P(e \mid g_{t_i})$ is the selection probability which indicates the likelihood of selecting an entity *e* given a gesture at time t_i. This selection probability is calculated by a function of the distance between the location of the entity and the focus point of the recognized gesture on the display (Chai et al., 2004a). A normalization factor is incorporated to ensure that the summation of selection probabilities over all possible entities adds up to one.

When no gesture is involved in a given input, the salience distribution at any given time is a uniform distribution. If one or more gestures are involved, then Equation (1) is used to calculate the salience distribution.

4.3 Salience Driven Spoken Language Understanding

The salience distribution of entities identified based on the gesture information (as described above) is used to constrain hypotheses for language understanding. More specifically, for each onset of a spoken word at time *t* (i.e., the beginning time stamp of a spoken word), the salience distribution at *t* can be calculated based on a sequence of gestures that happen before *t* by Equation (1). This salience distribution can then be used to prime language models for spoken language processing.

Language Modeling

We first give a brief background of language modeling. Given an observed speech utterance O, the goal of speech recognition is to find a sequence of words W* so that $W^* = \arg\max P(O \mid W)P(W)$, where *P(O|W)* is the acoustic model and *P(W)* is the language model. In traditional speech recognition systems, the acoustic model provides the probability of observing the acoustic features given hypothesized word sequences and the language model provides the probability of a sequence of words. The language model is computed as follows:

$$P(w_1^n) = P(w_1)P(w_2 \mid w_1)P(w_3 \mid w_1 w_2)...P(w_n \mid w_1^{n-1})$$

Using the Markov assumption, the language model can be approximated by a bigram model as in:

$$P(w_1^n) = \prod_{i=1}^{n} P(w_i \mid w_{i-1})$$

To improve the speech understanding results for spoken language interfaces, many systems have applied a loosely-integrated approach which decouples the language model from the acoustic model (Zue et al., 1991, Harper et al., 2000). This allows the development of powerful language models independent of the acoustic model, for example, utilizing topics of the utterances (Gildea and Hofmann 1999), syntactic or semantic labels (Heeman 1999), and linguistic structures (Chelba and Jelinek 2000, Wang and Harper 2002). Recently, we have seen work on language understanding based on environment (Schuler 2003) and language modeling using visual context (Roy and Mukherjee 2005). Our salience driven approach is inspired by this earlier work. Here, we do not address the acoustic model of speech recognition, but rather incorporate the salience distribution for language modeling. In particular, our focus is on investigating the effect of incorporating additional information from other modalities (e.g., gesture) with traditional language models.

Primed Language Model

The calculated salience distribution is used to prime the language model. More specifically, we use a class-based bigram model from (Brown et al, 1992):

$$P(w_i \mid w_{i-1}) = P(w_i \mid c_i)P(c_i \mid c_{i-1}) \quad (3)$$

In Equation (3), c_i is the class of the word w_i, which could be a syntactic class or a semantic class. $P(c_i \mid c_{i-1})$ is the class transition probability, which reflects the grammatical formation of utterances. $P(w_i \mid c_i)$ is the word class probability which measures the probability of seeing a word w_i given a class c_i. The class-based N-gram model can make better use of limited training data by clustering words into classes. A number of researchers have shown that the class-based N-gram model can successfully improve the performance of speech recognition (Jelinek 1990, Heeman 1999, Kneser and Ney 1993, Samuelsson and Reichl, 1999).

In our approach, the "class" used in the class-based bigram model comes from combined semantic and functional classes designed for our domain. For example, "this" is tagged as Demonstrative, and "price" is tagged as AttrPrice. As shown in Equation (3), there are two types of parameter estimation. In terms of the class transition probability, as in earlier work, we directly use the annotated data. In terms of the word class distribution, we incorporate the notion of salience. We use the salience distribution to dynamically adjust the world class probability $P(w_i \mid c_i)$ as follows:

$$P(w_i \mid c_i) = \sum_{e_k \in \vec{e}} \frac{P(w_i, c_i \mid e_k)}{P(c_i \mid e_k)} P_{t_i}(e_k) \qquad (4)$$

In Equation (4), $P_{t_i}(e_k)$ is the salience value for an entity e_k at time t_i (the onset of the spoken word w_i), which can be calculated by Equation (1). Equation (4) indicates that only information associated with the salient entities is used to estimate the word class distribution. In other words, the word class probability favors the salient physical world as indicated by the salience distribution $P_{t_i}(\vec{e})$. More specifically, at time t_i, given a semantic class c_i, the choice of word "w_i" is dependent on the salient physical world at the moment, which is represented as the salience distribution $P_{t_i}(\vec{e})$ at time t_i. For all w_i, the summation of this word class probability is equal to one. Furthermore, given an entity e_k, $P(w_i, c_i \mid e_k)$ and $P(c_i \mid e_k)$ are not dependent on time t_i, but rather on the domain and the use of language expressions. Therefore they can be estimated based on the training data that are annotated in terms of semantic information and the intended objects of interest (as discussed in Section 4.1). Since the annotated data is very limited, the sparse data can become a problem for the maximum likelihood estimation. Therefore, a smoothing technique based on the Katz backoff model (Katz, 1987) is applied. For example, to calculate $P(w_i, c_i \mid e_k)$, if a word w_i has one or more occurrences in the training data associated with the class c_i and the entity e_k, then its count is discounted by a fraction in the maximum likelihood estimation. If w_i does not occur, then this approach backs off to the domain grammar and redistributes the remaining probability mass uniformly among words in the lexicon that are linked with class c_i and entity e_k.

5 Evaluation

We evaluated the salience model during post processing recognized hypotheses. Given possible hypotheses from a speech recognizer, we use the salience-based language model to identify the most likely sequence of words. The salience distribution based on gesture was used to favor words that are consistent with the attention indicated by gestures.

The data collected from our previous user studies were used in our evaluation (Chai et al., 2004b). In these studies, users interacted with our multimodal interface using both speech and deictic gestures to find information about real estate properties. In particular, each user was asked to accomplish five tasks. Each of these tasks required the user to retrieve different types of information from our interface. For example, one task was to find the least expensive house in the most populated town. The data were recorded from eleven subjects including five non-native speakers and six native speakers. Each user's voice was individually trained before the study. Table 1 shows the relevant information about the data such as the total number of inputs (or turns) from each subject, the number of speech alone inputs without any gesture, and the baseline recognition results without using salience-based post processing in terms of the word error rate (WER). In total, we have collected 226 user inputs with an average of eight words per spoken utterance[1]. As shown in Table 1, the majority of inputs consisted of both speech and gesture. Since currently we only use gesture

User index	# of Inputs	# inputs w/o gesture	Baseline WER
1	21	0	0.287
2	31	0	0.335
3	27	0	0.399
4	10	0	0.680
5	8	1	0.200
6	36	0	0.387
7	18	0	0.250
8	25	1	0.278
9	23	0	0.482
10	11	0	0.117
11	16	3	0.255

Table 1: Related information about the evaluation data: user type, the number of turns per user, and the baseline word recognition rate.

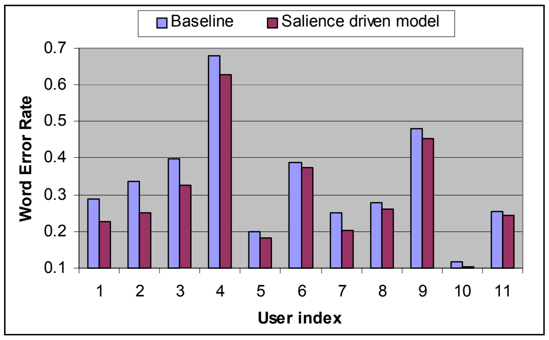

Figure 5: Comparison of the baseline and the result from post-processing in terms of WER

[1] The difference between the number of user inputs reported here and that in (Chai et al., 2004b) was caused by the situation where one intended user input (which was the unit for counting in our previous work) was split into a couple turns (which constitute the new counts here).

information in salience modeling, our approach will not affect speech only inputs.

To train the salience-based model, we applied the leave-one-out approach. The data from each user was held out as the testing data and the remaining users were used as the training data to acquire relevant probability estimations in Equation (3) and (4).

Figure 5 shows the comparison results between the baseline and the salience-based model in terms of word error rate (WER). The word error rate as a result of salience-based post processing is significantly better than that from the baseline recognizer (t = 4.75, p < 0.001). The average WER reduction is about 12%.

We further evaluated how the salience based model affects the final understanding results. This is because an improvement in WER may not directly lead to an improvement in understanding. We applied our semantic grammar on a sequence of words resulting from both the baseline and the salience-based post-processing to identify key concepts. In total, there were 686 concepts from the transcribed speech utterances. Table 2 shows the evaluation results. Precision measures the percentage of correctly identified concepts out of the total number of concepts identified based on a sequence of words. Recall measures the percentage of correctly identified concepts out of the total number of intended concepts from user's utterance. F-measurement combines precision and recall together as follows:

$$F = \frac{(\beta^2 + 1) \times \text{Precision} \times \text{Recall}}{\beta^2 \text{Precision} + \text{Recall}}, \quad where\, \beta = 1.$$

Table 2 shows that, on average, the concept identification based on the word sequence resulting from the salience-based approach performs better than the baseline in terms of both precision and recall. Figure 6 provides two examples to show the difference between the baseline recognition and the salience-based post processing.

The evaluation reported here is only an initial step based on a limited domain. The small scale in the number of objects and the vocabulary size can only demonstrate the potential of the salience-based approach to a limited degree. To further understand the advantages and issues of this approach, we are currently working on a more complex domain with richer concepts and relations, as well as larger vocabularies.

It is worth mentioning that the goal of this work is to explore whether salience modeling based on other modalities (e.g., gesture) can be used to prime traditional language models to facilitate spoken language processing. The salience driven approach based on additional modalities can be combined with more sophisticated language modeling (e.g., better parameter estimation) in the future.

User #	Baseline	Salience-based
Precision	80.3%	84.6%
Recall	75.7%	83.8%
F-measure	77.9%	84.2%

Table2. Overall concept identification comparison between the baseline and the salience driven model.

Example 1:
Transcription: What is the population of this town
Baseline recognition: What is the <u>publisher</u> of this <u>time</u>
Salience-based processing: what is the **population** of this **town**

Example 2:
Transcription: How much is this gray house
Baseline recognition: How much is this <u>great</u> house
Salience-based processing: How much is this **gray** house

Figure 6: Examples of utterances with baseline recognition and improved recognition from the salience-based processing.

6 Conclusion and Future Work

This paper presents a new salience driven approach to robust input interpretation in multimodal conversational systems. This approach takes advantage of rich information from multiple modalities. Information from deictic gestures is used to identify a part of the physical world that is salient at a given point of communication. This salient part of the physical world is then used to prime language models for spoken language understanding. Our experimental results have shown the potential of this approach in reducing word error rate and improving concept identification from spoken utterances in our application. Although currently we have only investigated the use of gesture information in salience modeling, the salience driven approach can be extended to include other modalities (e.g., eye gaze) and information (e.g., conversation context). Our future work will specifically investigate how to combine information from multiple sources in salience modeling and how to apply the salience models in different early stages of processing.

Abstract

We describe the error handling architect-ture underlying the RavenClaw dialog management framework. The architecture provides a robust basis for current and future research in error detection and recovery. Several objectives were pursued in its development: task-independence, ease-of-use, adaptability and scalability. We describe the key aspects of architectural design which confer these properties, and discuss the deployment of this architect-ture in a number of spoken dialog systems spanning several domains and interaction types. Finally, we outline current research projects supported by this architecture.

1 Introduction

Over the last decade, improvements in speech recognition and other component technologies have paved the way for the emergence of complex task-oriented spoken dialog systems. While traditionally the research community has focused on building information-access and command-and-control systems, recent efforts aim towards building more sophisticated language-enabled agents, such as personal assistants, interactive tutors, open-domain question answering systems, etc. At the other end of the complexity spectrum, simpler systems have already transitioned into day-to-day use and are becoming the norm in the phone-based customer-service industry.

Nevertheless, a number of problems remain in need of better solutions. One of the most important limitations in today's spoken language interfaces is their lack of robustness when faced with understanding errors. This problem appears across all domains and interaction types, and stems primarily from the inherent unreliability of the speech recognition process. The recognition difficulties are further exacerbated by the conditions under which these systems typically operate: spontaneous speech, large vocabularies and user populations, and large variability in input line quality. In these settings, average word-error-rates of 20-30% (and up to 50% for non-native speakers) are quite common.

Left unchecked, speech recognition errors can lead to two types of problems in a spoken dialog system: *misunderstandings* and *non-understandings*. In a *misunderstanding,* the system obtains an incorrect semantic interpretation of the user's turn. In the absence of robust mechanisms for assessing the reliability of the decoded inputs, the system will take the misunderstanding as fact and will act based on invalid information. In contrast, in a *non-understanding* the system fails to obtain an interpretation of the input altogether. Although no false information is incorporated in this case, the situation is not much better: without an appropriate set of recovery strategies and a mechanism for diagnosing the problem, the system's follow-up options are limited and uninformed. In general, unless mitigated by accurate error awareness and robust recovery mechanisms, speech recognition errors exert a strong negative impact on the quality and ultimately on the success of the interactions (Sanders et al, 2002).

Two pathways towards increased robustness can be easily envisioned. One is to improve the accuracy of the speech recognition process. The second is to create mechanisms for detecting and gracefully handling potential errors at the conversation level. Clearly, these two approaches do not stand in opposition and a combined effort would lead to the best results. The error handling architecture we describe in this paper embodies the second approach: it aims to provide the mechanisms for robust error handling at the dialog management level of a spoken dialog system.

The idea of handling errors through conversation has already received a large amount of attention from the research community. On the theoretical side, several models of grounding in communication have been proposed (Clark and Schaefer, 1989; Traum, 1998). While these models provide useful insights into the grounding process as it happens in human-human communication, they lack the decision-making aspects required to drive the interaction in a real-life spoken dialog system. In the Conversational Architectures project, Paek and Horvitz (2000) address this challenge by developing a computational implementation of the grounding process using Bayesian belief networks. However, questions still remain: the structure and parameters of the belief networks are handcrafted, as are the utilities for the various grounding actions; due to scalability and task-representation issues, it is not known yet how the proposed approach would transfer and scale to other domains.

Three ingredients are required for robust error handling: (1) the ability to detect the errors, (2) a set of error recovery strategies, and (3) a mechanism for engaging these strategies at the appropriate time. For some of these issues, various solutions have emerged in the community. For instance, systems generally rely on recognition confidence scores to detect potential misunderstandings (e.g. Krahmer et al., 1999; Walker et al., 2000) and use explicit and implicit confirmation strategies for recovery. The decision to engage these strategies is typically based on comparing the confidence score against manually preset thresholds (e.g. Kawahara and Komatani, 2000). For non-understandings, detection is less of a problem (systems know by definition when non-understandings occur). Strategies such as asking the user to repeat or rephrase, providing help, are usually engaged via simple heuristic rules.

At the same time, a number of issues remain unsolved: can we endow systems with better error awareness by integrating existing confidence annotation schemes with correction detection mechanisms? Can we diagnose the non-understanding errors on-line? What are the tradeoffs between the various non-understanding recovery strategies? Can we construct a richer set of such strategies? Can we build systems which automatically tune their error handling behaviors to the characteristics of the domains in which they operate?

We have recently engaged in a research program aimed at addressing such issues. More generally, our goal is to develop a task-independent, easy-to-use, adaptive and scalable approach for error handling in task-oriented spoken dialog systems. As a first step in this program, we have developed a modular error handling architecture, within the larger confines of the RavenClaw dialog management framework (Bohus and Rudnicky, 2003). The proposed architecture provides the infrastructure for our current and future research on error handling. In this paper we describe the proposed architecture and discuss the key aspects of architectural design which confer the desired properties. Subsequently, we discuss the deployment of this architecture in a number of spoken dialog systems which operate across different domains and interaction types, and we outline current research projects supported by the proposed architecture.

2 RavenClaw Dialog Management

We begin with a brief overview of the RavenClaw dialog management framework, as it provides the larger context for the error handling architecture.

RavenClaw is a dialog management framework for task-oriented spoken dialog systems. To date, it has been used to construct a large number of systems spanning multiple domains and interaction types (Bohus and Rudnicky, 2003): information access (RoomLine, the Let's Go Bus Information System), guidance through procedures (LARRI), command-and-control (TeamTalk), taskable agents (Vera). Together with these systems, RavenClaw provides the larger context as well as a test-bed for evaluating the proposed error handling architecture. More generally, RavenClaw provides a robust basis for research in various other aspects of dialog management, such as learning at the task and discourse levels, multi-participant dialog, timing and turn-taking, etc.

A key characteristic of the RavenClaw framework is the separation it enforces between the domain-specific and domain-independent aspects of dialog control. The domain-specific dialog control logic is described by a *Dialog Task Specification*, essentially a hierarchical dialog plan provided by the system author. A fixed, domain-independent *Dialog Engine* manages the conversation by executing the given Dialog Task Specification. In the process, the Dialog Engine also contributes a set of domain-independent conversational skills, such as error handling (discussed extensively in Section 4), timing and turn-taking, etc. The system authoring effort is therefore minimized and focused entirely on the domain-specific aspects of dialog control.

2.1 The Dialog Task Specification

A Dialog Task Specification consists of a tree of *dialog agents*, where each agent manages a subpart of the interaction. Figure 1 illustrates a portion of the dialog task specification from RoomLine, a spoken dialog system which can assist users in making conference room reservations. The root node subsumes several children: Welcome, which produces an introductory prompt, GetQuery which obtains the time and room constraints from the user, DoQuery which performs the database query, and DiscussResults which handles the follow-up negotiation dialog. Going one level deeper in the tree, GetQuery contains GetDate which requests the date for the reservation, GetStartTime and GetEndTime which request the times, and so on. This type of hierarchical task representation has a number of advantages: it scales up gracefully, it can be dynamically extended at runtime, and it implicitly captures a notion of context in dialog.

The agents located at the leaves of the tree are called *basic dialog agents*, and each of them implements an atomic dialog action (dialog move). There are four types of basic dialog agents: ***I****nform* – conveys information to the user (e.g. Welcome), ***R****equest* – asks a question and expects an answer (e.g. GetDate), ***E****xpect* – expects information without explicitly asking for it, and ***EX****ecute* – implements a domain specific operation (e.g. DoQuery). The agents located at non-terminal positions in the tree are called *dialog agencies* (e.g. RoomLine, GetQuery). Their role is to plan for and control the execution of their sub-agents. For each agent in the tree, the system author may specify preconditions, completion criteria, effects and triggers; various other functional aspects of the dialog agents (e.g. state-specific language models for request-agents, help-prompts) are controlled through parameters.

The information the system acquires and manipulates in conversation is captured in *concepts*, associated with various agents in the tree (e.g. date, start_time). Each concept maintains a history of previous values, information about current candidate hypotheses and their associated confidence scores, information about when the concept was last updated, as well as an extended set of flags which describe whether or not the concept has been conveyed to the user, whether or not the concept has been grounded, etc. This rich representation provides the necessary support for concept-level error handling.

2.2 The Dialog Engine

The Dialog Engine is the core domain-independent component which manages the interaction by executing a given Dialog Task Specification. The control algorithms are centered on two data-structures: a dialog stack, which captures the dialog structure at runtime, and an expectation agenda, which captures the system's expectations for the user input at each turn in the dialog. The dialog is controlled by interleaving *Execution Phases* with *Input Phases*.

During an Execution Phase, dialog agents from the tree are placed on, and executed from the dialog stack. At the beginning of the dialog, the root agent is placed on the stack. Subsequently, the engine repeatedly takes the agent on the top of the stack and executes it. When dialog agencies are executed, they typically schedule one of their subagents for execution by placing it on the stack. The dialog stack will therefore track the nested structure of the dialog at runtime. Ultimately, the execution of the basic dialog agents on the leaves of the tree generates the system's responses and actions.

During an Input Phase, the system assembles the expectation agenda, which captures what the system expects to hear from the user in a given turn. The agenda subsequently mediates the transfer of semantic information from the user's input into the various concepts in the task tree. For the interested reader, these mechanisms are described in more detail in (Bohus and Rudnicky, 2003)

Additionally, the Dialog Engine automatically provides a number of conversational strategies, such as the ability to handle various requests for help, repeating the last utterance, suspending and resuming the dialog, starting over, reestablishing the context, etc. These strategies are implemented as *library dialog agencies*. Their corresponding sub-trees are automatically added to the Dialog Task Specification provided by the system author (e.g. the Start-Over agency in Figure 1.) The automatic availability of these strategies lessens development efforts and ensures a certain uniformity of behavior both within and across tasks.

3 The Error Handling Architecture

The error handling architecture in the RavenClaw dialog management framework subsumes two main components: (1) a set of *error handling strategies* (e.g. explicit and implicit confirmation, asking the user to repeat, etc.) and (2) an *error handling process* which engages these strategies.

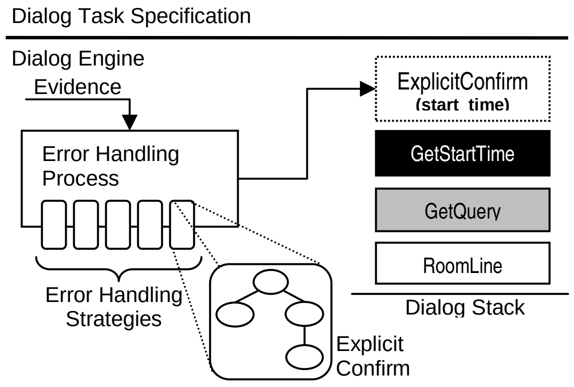

Figure 2: Error Handling – Block Diagram

The error handling strategies are implemented as library dialog agents. The decision process which engages these strategies is part of the Dialog Engine. This design, in which both the strategies and the decision process are decoupled from the dialog task, as well as from each other, provides a number of advantages. First, it ensures that the error handling mechanisms are reusable across different dialog systems. Second, the approach guarantees a certain uniformity and consistency in error handling behaviors both within and across systems. Third, as new error handling strategies are developed, they can be easily plugged into any existing system. Last, but not least, the approach significantly lessens the system authoring effort by allowing developers to focus exclusively on describing the dialog control logic.

The responsibility for handling potential understanding errors[1] is delegated to the Error Handling Process which runs in the Dialog Engine (see Figure 2). At each system turn, this process collects evidence and makes a decision with respect to engaging any of the error handling strategies. When necessary, it will insert an error handling strategy on the dialog stack (e.g. the ExplicitConfirm (start_time) strategy in Figure 2), thus modifying on-the-fly the task originally specified by the system author. The strategy executes and, once completed, it is removed from the stack and the dialog resumes from where it was left off.

[1] Note that the proposed framework aims to handle understanding errors. The corresponding strategies are generic and can be applied in any domain. Treatment of domain or task-specific errors (e.g. database access error, etc) still needs to be implemented as part of the dialog task specification.

3.1 Error Handling Strategies

The error handling strategies can be divided into two groups: strategies for handling potential misunderstandings and strategies for handling non-understandings.

For handling potential misunderstandings, three strategies are currently available: *Explicit Confirmation*, *Implicit Confirmation* and *Rejection*.

For non-understandings, a larger number of error recovery strategies are currently available: *AskRepeat* – the system asks the user to repeat; *AskRephrase* – the system asks the user to rephrase; *Reprompt* – the system repeats the previous prompt; *DetailedReprompt* – the system repeats a more verbose version of the previous prompt, *Notify* – the system simply notifies the user that a non-understanding has occurred; *Yield* – the system remains silent, and thus implicitly notifies the user that a non-understanding has occurred; *MoveOn* – the system tries to advance the task by giving up on the current question and moving on with an alternative dialog plan (note that this strategy is only available at certain points in the dialog); *YouCanSay* – the system gives an example of what the user could say at this point in the dialog; *FullHelp* – the system provides a longer help message which includes an explanation of the current state of the system, as well as what the user could say at this point. An in-depth analysis of these strategies and their relative tradeoffs is available in (Bohus and Rudnicky, 2005a). Several sample dialogs illustrating these strategies are available on-line (RoomLine, 2003).

3.2 Error Handling Process

The error handling decision process is implemented in a distributed fashion, as a collection of local decision processes. The Dialog Engine automatically associates a local error handling process with each concept, and with each request agent in the dialog task tree, as illustrated in Figure 3. The error handling processes running on individual concepts are in charge of recovering from misunderstandings on those concepts. The error handling processes running on individual request agents are in charge or recovering from non-understandings on the corresponding requests.

At every system turn, each concept- and request-agent error handling process computes and forwards its decision to a gating mechanism, which queues up the actions (if necessary) and executes them one at a time. For instance, in the example in Figure 3, the error handling decision process for the start_time concept decides to engage an explicit confirmation on that concept, while the other decision processes do not take any action. In this case the gating mechanism creates a new instance of an explicit confirmation agency, passes it the pointer to the concept to be confirmed (start_time), and places it on the dialog stack. On completion, the strategy updates the confidence score of the confirmed hypothesis in light of the user response, and the dialog resumes from where it was left off.

The specific implementation of the local decision processes constitutes an active research issue. Currently, they are modeled as Markov Decision Processes (MDP). The error handling processes running on individual concepts (*concept-MDPs* in

Figure 3) are partially-observable MDPs, with 3 underlying hidden states: c*orrect*, *incorrect* and *empty*. The belief state is constructed at each time step from the confidence score of the top-hypothesis for the concept. For instance, if the top hypothesis for the start_time concept is 10 a.m. with confidence 0.76, then the belief state for the POMDP corresponding to this concept is: {P(correct)=0.76, P(incorrect)=0.24, P(empty)=0}. The action-space for these models contains the three error recovery strategies for handling potential misunderstandings, and *no-action*. The third ingredient in the model is the *policy*. A policy defines which action the system should take in each state, and is indirectly described by specifying the utility of each strategy in each state. Currently, a number of predefined policies (e.g. always-explicit-confirm, pessimistic, and optimistic) are available in the framework. Alternatively, system authors can specify and use their own policies.

The error handling processes running on request agents (*request-MDPs* in Figure 3) are in charge of handling non-understandings on those requests. Currently, two types of models are available for this purpose. The simplest model has three states: *non-understanding, understanding* and *inactive*. A second model also includes information about the number of consecutive non-understandings that have already happened. In the future, we plan to identify more features which carry useful information about the likelihood of success of individual recovery strategies and use them to create more complex models. The action-space is defined by the set of non-understanding recovery strategies presented in the previous subsection, and *no-action*. Similar to the concept-MDPs, a number of default policies are available; alternatively, system authors can specify their own policy for engaging the strategies.

While the MDP implementation allows us to encode various expert-designed policies, our ultimate goal is to learn such policies from collected data using reinforcement learning. Reinforcement learning has been previously used to derive dialog control policies in systems operating with small tasks (Scheffler and Young, 2002; Singh et al, 2000). The approaches proposed to date suffer however from one important shortcoming, which has so far prevented their use in large, practical spoken dialog systems. The problem is lack of scalability: the size of the state space grows very fast with the size of the dialog task, and this renders the approach unfeasible in complex domains. A second important limitation of reinforcement learning techniques proposed to date is that the learned policies cannot be reused across tasks. For each new system, a new MDP has to be constructed, new data has to be collected, and a new training phase is necessary. This requires a significant amount of expertise and effort from the system author.

We believe that the error handling architecture we have described addresses these issues in several ways. The central idea behind the distributed nature of the approach is to keep the learning problem tractable by leveraging independence relationships between different parts of the dialog. First, the state and action-spaces can be maintained relatively small since we are only focusing on making error handling decisions (as opposed to other dialog control decisions). A more complex task translates into a larger number of MDP instantiations rather than a more complex model structure. Second, both the model structure and parameters (i.e. the transition probabilities) can be tied across models: for instance the MDP for grounding the start_time concept can be identical to the one for grounding the end_time concept; all models for grounding Yes/No concepts could be tied together, etc. Model tying has the potential to greatly improve scalability since data is polled together and the total number of model parameters to be learned grows sub-linearly with the size of the task. Third, since the individual MDPs are decoupled from the actual system task, the policies learned in a particular system can potentially be reused in other systems (e.g. we expect that grounding yes/no concepts functions similarly at different locations in the dialog, and across domains). Last but not least, the approach can easily accommodate dynamic task generation. In traditional reinforcement learning approaches the state and action-spaces of the underlying MDP are task-specific. The task therefore has to be fixed, known in advance: for instance the slots that the system queries the user about (in a slot-filling system) are fixed. In contrast, in the RavenClaw architecture, the dialog task tree (e.g. the dialog plan) can be dynamically expanded at runtime with new questions and concepts, and the corresponding request- and concept-MDPs are automatically created by the Dialog Engine.

4 Deployment and Current Research

While a quantitative evaluation of design characteristics such as task-independence, scalability, and ease-of-use is hard to perform, a first-order empirical evaluation of the proposed error handling architecture can be accomplished by using it in different systems and monitoring the system authoring process and the system's operation.

To date, the architecture has been successfully deployed in three different spoken dialog systems. A first system, RoomLine (2003), is a phone-based mixed-initiative system that assists users in making conference room reservations on campus. A second system, the Let's Go! Bus Information System (Raux et al, 2005), provides information about bus routes and schedules in the greater Pittsburgh area (the system is available to the larger public). Finally, Vera is a phone-based taskable agent that can be instructed to deliver messages to a third party, make wake-up calls, etc. Vera actually consists of two dialog systems, one which handles incoming requests (Vera In) and one which performs message delivery (Vera Out). In each of these systems, the authoring effort with respect to error handling consisted of: (1) specifying which models and policies should be used for the concepts and request-agents in the dialog task tree, and (2) writing the language generation prompts for explicit and implicit confirmations for each concept.

Even though the first two systems operate in similar domains (information access), they have very different user populations: students and faculty on campus in the first case versus the entire Pittsburgh community in the second case. As a result, the two systems were configured with different error handling strategies and policies (see Table 1). RoomLine uses explicit and implicit confirmations with an optimistic policy to handle potential misunderstandings. In contrast, the Let's Go Public Bus Information System always uses explicit confirmations, in an effort to increase robustness (at the expense of potentially longer dialogs). For non-understandings, RoomLine uses the full set of non-understanding recovery strategies presented in section 3.1. The Let's Go Bus Information system uses the *YouCanSay* and *FullHelp* strategies. Additionally a new *GoToAQuieterPlace* strategy was developed for this system (and is now available for use into any other RavenClaw-based system). This last strategy asks the user to move to a quieter place, and was prompted by the observation that a large number of users were calling the system from noisy environments.

While the first two systems were developed by authors who had good knowledge of the RavenClaw dialog management framework, the third system, Vera, was developed as part of a class project, by a team of six students who had no prior experience with RavenClaw. Modulo an initial lack of documentation, no major problems were encountered in configuring the system for automatic error handling. Overall, the proposed error handling architecture adapted easily and provided the desired functionality in each of these domains: while new strategies and recovery policies were developed for some of the systems, no structural changes were required in the error handling architecture.

	RoomLine	Let's Go Public	Vera In / Out

5 Conclusion and Future Work

We have described the error handling architecture underlying the RavenClaw dialog management framework. Its design is modular: the error handling strategies as well as the mechanisms for engaging them are decoupled from the actual dialog task specification. This significantly lessens the development effort: system authors focus exclusively on the domain-specific dialog control logic, and the error handling behaviors are generated transparently by the error handling process running in the core dialog engine. Furthermore, we have argued that the distributed nature of the error handling process leads to good scalability properties and facilitates the reuse of policies within and across systems and domains.

The proposed architecture represents only the first (but an essential step) in our larger research program in error handling. Together with the systems described above, it sets the stage for a number of current and future planned investigations in error detection and recovery. For instance, we have recently conducted an extensive investigation of non-understanding errors and the ten recovery strategies currently available in the RavenClaw framework. The results of that study fall beyond the scope of this paper and are presented separately in (Bohus and Rudnicky, 2005a). In another project supported by this architecture, we have developed a model for updating system beliefs over concept values in light of initial recognition confidence scores and subsequent user responses to system actions. Initially, our confirmation strategies used simple heuristics to update the system's confidence score for a concept in light of the user response to the verification question. We have showed that a machine learning based approach which integrates confidence information with correction detection information can be used to construct significantly more accurate system beliefs (Bohus and Rudnicky, 2005b). Our next efforts will focus on using reinforcement learning to automatically derive the error recovery policies.

Effective Use of Prosody in Parsing Conversational Speech

Jeremy G. Kahn[†] **Matthew Lease**[*]

Abstract

We identify a set of prosodic cues for parsing conversational speech and show how such features can be effectively incorporated into a statistical parsing model. On the Switchboard corpus of conversational speech, the system achieves improved parse accuracy over a state-of-the-art system which uses only lexical and syntactic features. Since removal of edit regions is known to improve downstream parse accuracy, we explore alternatives for edit detection and show that PCFGs are not competitive with more specialized techniques.

1 Introduction

For more than a decade, the Penn Treebank's Wall Street Journal corpus has served as a benchmark for developing and evaluating statistical parsing techniques (Collins, 2000; Charniak and Johnson, 2005). While this common benchmark has served as a valuable shared task for focusing community effort, it has unfortunately led to the relative neglect of other genres, particularly speech. Parsed speech stands to benefit from practically every application envisioned for parsed text, including machine translation, information extraction, and language modeling. In contrast to text, however, speech (in particular, conversational speech) presents a distinct set of opportunities and challenges. While new obstacles arise from the presence of speech repairs, the possibility of word errors, and the absence of punctuation and sentence boundaries, speech also presents a tremendous opportunity to leverage multi-modal input, in the form of acoustic or even visual cues.

As a step in this direction, this paper identifies a set of useful prosodic features and describes how they can be effectively incorporated into a statistical parsing model, ignoring for now the problem of word errors. Evaluated on the Switchboard corpus of conversational telephone speech (Graff and Bird, 2000), our prosody-aware parser out-performs a state-of-the-art system that uses lexical and syntactic features only. While we are not the first to employ prosodic cues in a statistical parsing model, previous efforts (Gregory et al., 2004; Kahn et al., 2004) incorporated these features as word tokens and thereby suffered from the side-effect of displacing words in the n-gram models by the parser. To avoid this problem, we generate a set of candidate parses using an off-the-shelf, k-best parser, and use prosodic (and other) features to rescore the candidate parses.

Our system architecture combines earlier models proposed for parse reranking (Collins, 2000) and filtering out edit regions (Charniak and Johnson, 2001). Detecting and removing edits prior to parsing is motivated by the claim that probabilistic context-free grammars (PCFGs) perform poorly at detecting edit regions. We validate this claim empirically: two state-of-the-art PCFGs (Bikel, 2004; Charniak and Johnson, 2005) are both shown to perform significantly below a state-of-the-art edit detection system (Johnson et al., 2004).

2 Previous Work

As mentioned earlier, conversational speech presents a different set of challenges and opportunities than encountered in parsing text. This paper focuses on the challenges associated with disfluencies (Sec. 2.1) and the opportunity of leveraging acoustic-prosodic cues at the sub-sentence level (Sec. 2.2). Here, sentence segmentation is assumed to be known (though punctuation is not available);

$$\text{...while}\quad \underbrace{\text{I think,}}_{\text{Reparandum}}\quad + \quad \underbrace{\text{uh, I mean,}}_{\text{Editing phrase}}\ \underbrace{\text{I know}}_{\text{Repair}}\ \text{that...}$$

Figure 1: The structure of a typical repair, with "+" indicating the interruption point.

the impact of automatic segmentation is addressed in other work (Kahn et al., 2004).

2.1 Speech Repairs and Parsing

Spontaneous speech abounds with disfluencies such as partial words, filled pauses (e.g., "uh", "um"), conversational fillers (e.g., "you know"), and parenthetical asides. One type of disfluency that has proven particularly problematic for parsing is speech repairs: when a speaker amends what he is saying mid-sentence (see Figure 1). Following the analysis of (Shriberg, 1994), a speech repair can be understood as consisting of three parts: the *reparandum* (the material repaired), the *editing phrase* (that is typically either empty or consists of a filler), and the *repair*. The point between the reparandum and the editing phrase is referred to as the *interruption point* (IP), and it is the point that may be acoustically marked. We refer to the reparandum and editing phrase together as an *edit* or *edit region*. Speech repairs are difficult to model with HMM or PCFG models, because these models can induce only linear or tree-structured dependencies between words. The relationship between reparandum and repair is quite different: the repair is often a "rough copy" of the reparandum, using the same or very similar words in roughly the same order. A language model characterizing this dependency with hidden stack operations is proposed in (Heeman and Allen, 1999).

Several parsing models have been proposed which accord special treatment to speech repairs. Most prior work has focused on handling disfluencies and continued to rely on hand-annotated transcripts that include punctuation, case, and known sentence boundaries (Hindle, 1983; Core and Schubert, 1999; Charniak and Johnson, 2001; Engel et al., 2002).

Of particular mention is the analysis of the relationship between speech repairs and parsing accuracy presented by Charniak and Johnson (2001), as this directly influenced our work. They presented evidence that improved edit detection (i.e. detecting the reparandum and edit phrase) leads to better parsing accuracy, showing a relative reduction in F-score error of 14% (2% absolute) between oracle and automatic edit removal. Thus, this work adopts their edit detection preprocessing approach. They have subsequently presented an improved model for detecting edits (Johnson et al., 2004), and our results here complement their analysis of the edit detection and parsing relationship, particularly with respect to the limitations of PCFGs in edit detection.

2.2 Prosody and parsing

While spontaneous speech poses problems for parsing due to the presence of disfluencies and lack of punctuation, there is information in speech associated with prosodic cues that can be taken advantage of in parsing. Certainly, prosodic cues are useful for sentence segmentation (Liu *et al.*, 2004), and the quality of automatic segmentation can have a significant impact on parser performance (Kahn et al., 2004). There is also perceptual evidence that prosody provides cues to human listeners that aid in syntactic disambiguation (Price *et al.*, 1991), and the most important of these cues seems to be the prosodic phrases (perceived groupings of words) or the boundary events marking them. However, the utility of sentence-internal prosody in parsing conversational speech is not well established.

Most early work on integrating prosody in parsing was in the context of human-computer dialog systems, where parsers typically operated on isolated utterances. The primary use of prosody was to rule out candidate parses (Bear and Price, 1990; Batliner *et al.*, 1996). Since then, parsing has advanced considerably, and the use of statistical parsers makes the candidate pruning benefits of prosody less important. This raises the question of whether prosody is useful for improving parsing accuracy for conversational speech, apart from its use in sentence

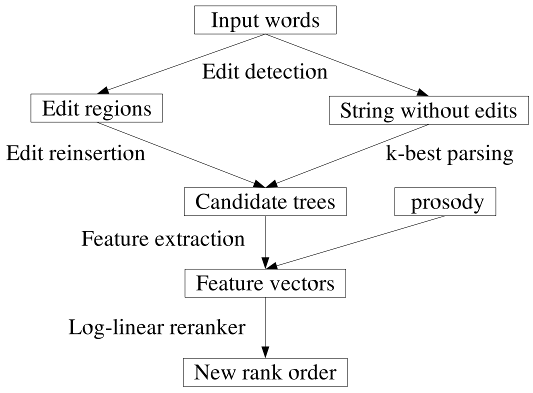

Figure 2: System architecture

boundary detection. Extensions of Charniak and Johnson (2001) look at using quantized combinations of prosodic features as additional "words", similar to the use of punctuation in parsing written text (Gregory et al., 2004), but do not find that the prosodic features are useful. It may be that with the short "sentences" in spontaneous speech, sentence-internal prosody is rarely of use in parsing. However, in edit detection using a parsing model (Johnson et al., 2004), posterior probabilities of automatically detected IPs based on prosodic cues (Liu *et al.*, 2004) are found to be useful. The seeming discrepancy between results could be explained if prosodic cues to IPs are useful but not other sub-sentence prosodic constituents. Alternatively, it could be that including a representation of prosodic features as terminals in (Gregory et al., 2004) displaces words in the parser n-gram model history. Here, prosodic event posteriors are used, with the goal of providing a more effective way of incorporating prosody than a word-like representation.

3 Approach

3.1 Overall architecture

Our architecture, shown in Figure 2, combines the parse reranking framework of (Collins, 2000) with the edit detection and parsing approach of (Charniak and Johnson, 2001). The system operates as follows:

1. Edit words are identified and removed.
2. Each resulting string is parsed to produce a set of k candidate parses.
3. Edit words reinserted into the candidates with a new part-of-speech tag EW. Consecutive sequences of edit words are inserted as single, flat EDITED constituents.
4. Features (syntactic and/or prosodic) are extracted for each candidate, i.e. candidates are converted to feature vector representation.
5. The candidates are rescored by the reranker to identify the best parse.

Use of Collins' parse reranking model has several advantages for our work. In addition to allowing us to incorporate prosody without blocking lexical dependencies, the discriminative model makes it relatively easy to experiment with a variety of prosodic features, something which is considerably more difficult to do directly with a typical PCFG parser.

Our use of the Charniak-Johnson approach of separately detecting disfluencies is motivated by their result that edit detection error degrades parser accuracy, but we also include experiments that omit this step (forcing the PCFG to model the edits) and confirm the practical benefit of separating responsibilities between the edit detection and parsing tasks.

3.2 Baseline system

We adopt an existing parser-reranker as our baseline (Charniak and Johnson, 2005). The parser component supports k-best parse generation, and the reranker component is used to rescore candidate parses proposed by the parser. In detail, the reranker selects from the set of k candidates $T = \{t_1, \ldots t_k\}$ the parse $t^\star \in T$ with the highest bracket F-score (in comparison with a hand-annotated reference). To accomplish this, a feature-extractor converts each candidate parse $t \in T$ into a vector of real-valued features $f(t) = (f_1(t), \ldots, f_m(t))$ (e.g., the value $f_j(t)$ of the feature f_j might be the number of times a certain syntactic structure appears in t). The reranker training procedure associates each feature f_j with a real-valued weight λ_j, and $\lambda' f(t)$ (the dot product of the feature vector and the weight vector λ) is a single scalar weight for each parse candidate. The reranker employs a maximum-entropy estimator that selects the λ that minimizes the log loss of the highest bracket F-score parse $t^\star$ conditioned on T (together with a Gaussian regularizer to prevent overtraining). Informally, λ is chosen to make high F-score parses as likely as possible under the (conditional) distribution defined by f and λ. As in (Collins, 2000), we generate training data for the reranker by reparsing the training corpus, using $n-1$ folds as training data to parse the n-th fold.

The existing system also includes a feature extractor that identifies interesting syntactic relationships not included in the PCFG parsing model (but used in the reranker). These features are primarily related to non-local dependencies, including parallelism of conjunctions, the number of terminals dominated by coordinated structures, right-branching root-to-leaf length, lexical/functional head pairs, n-gram style sibling relationships, etc.

3.3 Prosodic Features

Most theories of prosody have a symbolic representation for prosodic phrasing, where different combinations of acoustic cues (fundamental frequency, energy, timing) combine to give categorical perceptual differences. Our approach to integrating prosody in parsing is to use such symbolic boundary events, including prosodic break labels that build on linguistic notions of intonational phrases and hesitation phenomena. These events are predicted from a combination of continuous acoustic correlates, rather than using the acoustic features directly, because the intermediate representation simplifies training with high-level (sparse) structures. Just as phone-based acoustic models are useful in speech recognition systems as an intermediate level between words and acoustic features (especially for characterizing unseen words), the small set of prosodic boundary events are used here to simplify modeling the inter-dependent set of continuous-valued acoustic cues related to prosody. However, also as in speech recognition, we use posterior probabilities of these events as features rather than making hard decisions about presence vs. absence of a constituent boundary.

In the past, the idea of using perceptual categories has been dismissed as impractical due to the high cost of hand annotation. However, with advances in weakly supervised learning, it is possible to train prosodic event classifiers with only a small amount of hand-labeled data by leveraging information in syntactic parses of unlabeled data. Our strategy is similar to that proposed in (Nöth *et al.*, 2000), which uses categorical labels defined in terms of syntactic structure and pause duration. However, their system's category definitions are without reference to human perception, while we leverage learned relations between perceptual events and syntax with other acoustic cues, without predetermining the relation or requiring a direct coupling to syntax.

More specifically, we represent three classes of prosodic boundaries (or, breaks): major intonational phrase, hesitation, and all other word boundaries.[1] A small set of hand-labeled data from the treebanked portion of the Switchboard corpus (Ostendorf *et al.*, 2001) was used to train initial break prediction models based on both parse and acoustic cues. Next, the full set of treebanked Switchboard data is used with an EM algorithm that iterates between: i) finding probabilities of prosodic breaks in unlabeled data based on the current model, again using parse and acoustic features, and ii) re-estimating the model using the probabilities as weighted counts. Finally, a new acoustic-only break prediction model was designed from this larger data set for use in the parsing experiments.

In each stage, we use decision trees for models, in part because of an interest in analyzing the prosody-syntax relationships learned. The baseline system trained on hand-labeled data has error rates of 9.6% when all available cues are used (both syntax and prosody) and 16.7% when just acoustic and part-of-speech cues are provided (our target environment). Using weakly supervised (EM) training to incorporate unannotated data led to a 15% reduction in error rate to 14.2% for the target trees. The final decision tree was used to generate posteriors for each of the three classes, one for each word in a sentence.

¿From perceptual studies and decision tree analyses, we know that major prosodic breaks tend to co-occur with major clauses, and that hesitations often occur in edit regions or at high perplexity points in the word sequence. To represent the co-occurrence as a feature for use in parse reranking, we treat the prosodic break posteriors as weighted counts in accumulating the number of constituents in parse t of type i with break type j at their right edge, which (with some normalization and binning) becomes feature f_{ij}. Note that the unweighted count

[1]The intonational phrase corresponds to a break of "4" in the ToBI labeling system (Pitrelli et al., 1994), and a hesitation is marked with the "p" diacritic.

for constituent i corresponds directly to a feature in the baseline set, but the baseline set of features also includes semantic information via association with specific words. Here, we simply use syntactic constituents. It is also known that major prosodic breaks tend to be associated with longer syntactic constituents, so we used the weighted count strategy with length-related features as well. In all, the various attributes associated with prosodic break counts were the constituent label of the subtree, its length (in words), its height (maximal distance from the constituent root to any leaf), and the depth of the rightmost word (distance from the right word to the subtree root). For each type in each of these categories, there are three prosodic features, corresponding to the three break types.

3.4 Edit detection

To provide a competitive baseline for our parsing experiments, we used an off-the-shelf, state-of-the-art TAG-based model as our primary edit detector (Johnson et al., 2004).[2] This also provided us a competitive benchmark for contrasting the accuracy of PCFGs on the edit detection task (Section 4.2).

Whereas the crossing-dependencies inherent in speech repairs makes them difficult to model using HMM or PCFG approaches (Section 2.1), Tree Adjoining Grammars (TAGs) are capable of capturing these dependencies. To model both the crossed-dependencies of speech repairs and the linear or tree-structured dependencies of non-repaired speech, Johnson et al.'s system applies the noisy channel paradigm: a PCFG language model defines a probability distribution over non-repaired speech, and a TAG is used to model the optional insertion of edits. The output of this noisy channel model is a set of candidate edits which are then reranked using a max-ent model (similar to what is done here for parse reranking). This reranking step enables incorporation of features based on an earlier word-based classifier (Charniak and Johnson, 2001) in addition to output features of the TAG model. Acoustic features are not yet incorporated.

[2]We also evaluated another state-of-the-art edit detection system (Liu *et al.*, 2004) but found that it suffered from a mismatch between the current LDC specification of edits (LDC, 2004) and that used in the treebank.

4 Experimental design

4.1 Corpus

Experiments were carried out on conversational speech using the hand-annotated transcripts associated with the Switchboard treebank (Graff and Bird, 2000). As was done in (Kahn et al., 2004), we resegmented the treebank's sentences into V5-style sentence-like units (SUs) (LDC, 2004), since our ultimate goal was to be able to parse speech given automatically detected boundaries. Unfortunately, the original transcription effort did not provide punctuation guidelines, and the Switchboard treebanking was performed on the transcript unchanged, without reference to the audio. As a result, the sentence boundaries sometimes do not match human listener decisions using SU annotation guidelines, with differences mainly corresponding to treatment of discourse markers and backchannels. In the years since the original Switchboard annotation was performed, LDC has iteratively refined guidelines for annotating SUs, and significant progress has been made in automatically recovering SU boundaries annotated according to this standard (Liu *et al.*, 2004). To eventually leverage this work, we have taken the Meteer-annotated SUs (Meteer et al., 1995), for which there exists treebanked training data, and automatically adjusted them to be more like the V5 LDC standard, and resegmented the Switchboard treebank accordingly. In cases where the original syntactic constituents span multiple SUs, we discard any constituents violating the SU boundary, and in the event that an SU spans a treebank sentence boundary, a new top-level constituent SUGROUP is inserted to produce a proper tree (and evaluated like any other constituent in the gold tree).[3] While this SU resegmentation makes it difficult to compare our experimental results to past work, we believe this is a necessary step towards developing a more realistic baseline for fully automated parsing of speech.

In addition to resegmention, we removed all punctuation and case from the corpus to more closely reflect the form of output available from a speech recognizer. We retained partial words for consis-

[3]SU and treebank segments disagree at about 5% in each direction, due mostly to the analysis of discourse markers as conjunctions (sentences of >1 SU) and the separation of backchannels into separate treebank sentences (SUs of >1 sentence).

Table 1: Statistics on the Switchboard division used.

Section	Sides	SUs	Words
Train	1,031	87,599	659,437
Tune	126	13,147	103,500
Test	128	8,726	61,313
Total	1,285	109,472	824,250

tency with other work (Liu *et al.*, 2004; Johnson et al., 2004), although word fragments would not typically be available from ASR. Finally, of the 1300 total conversation sides, we discarded 15 for which we did not have prosodic data. Our corpus division statistics are given in Table 1. During development, experiments were carried out on the *tune* section; the *test* section was reserved for a final test run.

4.2 Experimental Variables

Our primary goal is to evaluate the extent to which prosodic cues could augment and/or stand-in for lexical and syntactic features. Correspondingly, we report on using three flavors of *feature extraction*: syntactic and lexical features (Section 3.2), prosodic features (Section 3.3), and both sets of features combined. For all three conditions, the first-stage score for each parse (generated by the off-the-shelf k-best parser) was always included as a feature.

A second parameter varied in the experiments was the method of upstream *edit detection* employed prior to parsing: PCFG, TAG-based, and oracle knowledge of treebank edit annotations. While it had been claimed that PCFGs perform poorly as edit detectors (Charniak and Johnson, 2001), we could not find empirical evidence in the literature quantifying the severity of the problem. Therefore, we evaluated two PCFGs (Bikel, 2004; Charniak and Johnson, 2005) on edit detection and compared their performance to a state-of-the-art TAG-based edit detection system (Johnson et al., 2004). For this experiment, we evaluated edit detection accuracy on a per-word basis, where any tree terminal is considered an edit word if and only if it is dominated by an EDITED constituent in the gold tree. The PCFGs were trained on the train section of the treebank data with the flattened edit regions included[4] and then used to parse the test data.[5] The TAG-based detector was trained on the same conversation sides, with its channel model trained on the Penn Treebank disfluency-annotated files and its language model trained on trees with the EDITED nodes excised. As shown in Table 2, we did find that both PCFGs performed significantly below the TAG-based detector.

[4]Training on flattened EDITED nodes improved detection accuracy for both PCFGs: as much as 15% for Bikel-Collins.

Table 2: Edit word detection performance for two word-based PCFGs and the TAG-based edit detector. F-score and error are word-based measures.

Edit Detector	Edit F-score	Edit Error
Bikel-Collins PCFG	65.3	62.1
Charniak PCFG	65.8	59.9
TAG-based	78.2	42.2

Table 3: Parsing F-score of various feature and edit-detector combinations.

	PCFG	TAG	Oracle
Edit F (Table 2)	65.8	78.2	100.0
Parser 1-best	84.4	85.0	86.9
Prosodic feats	85.0	85.6	87.6
Syntactic feats	85.9	86.4	88.4
Combined feats	86.0	86.6	88.6
Oracle-rate	92.6	93.2	95.2

5 Results

In evaluating parse accuracy, we adopt the *relaxed edited* revision (Charniak and Johnson, 2001) to the standard PARSEVAL metric, which penalizes systems that get EDITED spans wrong, but does not penalize disagreements in the attachment or internal structure of edit regions. This metric is based on the assumption that there is little reason to recover syntactic structure in regions of speech that have been repaired or restarted by the speaker.

Table 3 shows the F-scores for the top-ranked parses after reranking, where the first-stage PCFG parser was run with a beam-size of 50. The first and last rows show lower and upper bounds, respectively, for reranked parsing accuracy on each edit condition. As the oracle rate[6] shows, there is con-

[5]For the Charniak parser, edits were detected using only its PCFG component in 1-best mode, not its 2nd stage reranker.

[6]Oracle F uses the best parse in the 50-best list.

siderable room for improvement. Statistical significance was computed using a non-parametric shuffle test similar to that in (Bikel, 2004). For TAG and oracle *edit detection* conditions, the improvement from using the combined features over either prosodic or syntactic features in isolation was significant ($p < 0.005$). (For PCFG edit detection, $p < 0.04$.) Similarly, for all three *feature extraction* conditions, the improvement from using the TAG-based edit detector instead of the PCFG edit detector was also significant ($p < 0.001$). Interestingly, the TAG's 34% reduction in edit detection error relative to the PCFG yielded only about 23% of the parse accuracy differential between the PCFG and oracle conditions. Nevertheless, there remains a promising 2.0% difference in parse F-score between the TAG and oracle detection conditions to be realized by further improvements in edit detection. Training for the *syntactic* feature condition resulted in a learned weight λ with approximately 50K features, while the *prosodic* features used only about 1300 features. Despite this difference in the length of the λ vectors, the prosodic feature condition achieved 40–50% of the improvement of the syntactic features.

In some situations, e.g. for language modeling, improving the ordering and weights of the entire parse set (an not just the top ranked parse) is important. To illustrate the overall improvement of the reranked order, in Table 4 we report the reranked-oracle rate over the top s parses, varying the beam s. The error for each feature condition, relative to using the PCFG parser in isolation, is shown in Figure 3. Both the table and figure show that the reranked beam achieves a consistent trend in parse accuracy improvement relative to the PCFG beam, similar to what is demonstrated by the 1-best scores (Table 3).

Table 4: Reranked-oracle rate parse F-score for the top s parses with reference edit detection.

s	1	2	3	5	10	25
PCFG	86.9	89.8	91.0	92.2	93.4	94.6
Pros.	87.6	90.3	91.5	92.7	93.9	94.8
Syn.	88.4	91.3	92.4	93.4	94.3	95.0
Comb.	88.6	91.5	92.5	93.5	94.4	95.0

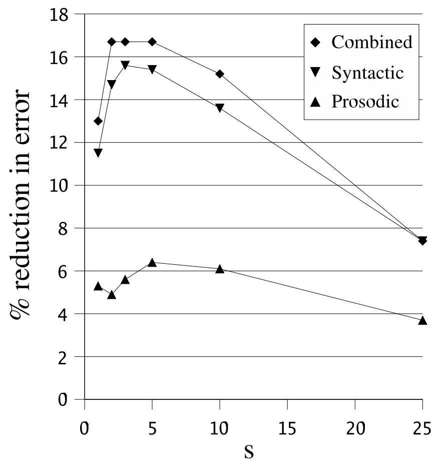

Figure 3: Reduction in error (Error $= 1 - F$) for the s-best reranked-oracle relative to the parser-only oracle, for different feature rerankings (reference edit detection).

6 Conclusion

This study shows that incorporating prosodic information into the parse selection process, along with non-local syntactic information, leads to improved parsing accuracy on accurate transcripts of conversational speech. Gains are shown to be robust to difficulties introduced by automatic edit detection and, in addition to improving the one-best performance, the overall ordering of the parse candidates is improved. While the gains from combining prosodic and syntactic features are not additive, since the prosodic features incorporates some constituent-structure information, the combined gains are significant. These results are consistent with related experiments with a different type of prosodically cued event, which showed that automatically detected IPs based on prosodic cues (Liu *et al.*, 2004) are useful in the reranking stage of a TAG-based speech repair detection system (Johnson et al., 2004).

The experiments described here used automatically extracted prosodic features in combination with human-produced transcripts. It is an open question as to whether the conclusions will hold for errorful ASR transcripts and automatically detected SU boundaries. However, there is reason to believe that relative gains from using prosody may be larger than those observed here for reference transcripts (though overall performance will degrade), based on prior work combining prosody and lexical cues to detect other language structures (Shriberg and Stolcke, 2004). While the prosody feature extraction depends on timing of the hypothesized word sequence, the acoustic cues are relatively robust to word errors and the break model can be retrained on recognizer output to automatically learn to discount the lexical evidence. Furthermore, if parse reranking operates on the top N ASR hypotheses, the reranking procedure can improve recognition outputs, as demonstrated in (Kahn, 2005) for syntactic features alone. Allowing for alternative SU hypotheses in reranking may also lead to improved SU segmentation.

In addition to assessing the impact of prosody in a fully automatic system, other avenues for future work include improving feature extraction. One could combine IP and prosodic break features (so far explored separately), find new combinations of prosody and syntactic structure, and/or incorporate other prosodic events. Finally, it may also be useful to integrate the prosodic events directly into the PCFG, in addition to their use in reranking.

This work was supported by the NSF under grants DMS-0074276, IIS-0085940, IIS-0112432, IIS-0326276, and LIS-9721276. Conclusions are those of the authors and do not necessarily reflect the views of the NSF.

Automatically Learning Cognitive Status for Multi-Document Summarization of Newswire

Ani Nenkova and **Advaith Siddharthan** and **Kathleen McKeown**
Department of Computer Science
Columbia University
{ani,advaith,kathy}@cs.columbia.edu

Abstract

Machine summaries can be improved by using knowledge about the cognitive status of news article referents. In this paper, we present an approach to automatically acquiring distinctions in cognitive status using machine learning over the forms of referring expressions appearing in the input. We focus on modeling references to people, both because news often revolve around people and because existing natural language tools for named entity identification are reliable. We examine two specific distinctions—whether a person in the news can be assumed to be known to a target audience (hearer-old vs hearer-new) and whether a person is a major character in the news story. We report on machine learning experiments that show that these distinctions can be learned with high accuracy, and validate our approach using human subjects.

1 Introduction

Multi-document summarization has been an active area of research over the past decade (Mani and Maybury, 1999) and yet, barring a few exceptions (Daumé III et al., 2002; Radev and McKeown, 1998), most systems still use shallow features to produce an extractive summary, an age-old technique (Luhn, 1958) that has well-known problems. Extractive summaries contain phrases that the reader cannot understand out of context (Paice, 1990) and irrelevant phrases that happen to occur in a relevant sentence (Knight and Marcu, 2000; Barzilay, 2003). Referring expressions in extractive summaries illustrate this problem, as sentences compiled from different documents might contain too little, too much or repeated information about the referent.

Whether a referring expression is appropriate depends on the location of the referent in the hearer's mental model of the discourse—the referent's *cognitive status* (Gundel et al., 1993). If, for example, the referent is unknown to the reader at the point of mention in the discourse, the reference should include a description, while if the referent was known to the reader, no descriptive details are necessary.

Determining a referent's cognitive status, however, implies the need to model the intended audience of the summary. Can such a cognitive status model be inferred automatically for a general readership? In this paper, we address this question by performing a study with human subjects to confirm that reasonable agreement on the distinctions can be achieved between different humans (cf. §5). We present an automatic approach for inferring what the typical reader is likely to know about people in the news. Our approach uses machine learning, exploiting features based on the form of references to people in the input news articles (cf. §4). Learning cognitive status of referents is necessary if we want to ultimately generate new, more appropriate references for news summaries.

1.1 Cognitive status

In human communication, the wording used by speakers to refer to a discourse entity depends on their *communicative goal* and their beliefs about *what listeners already know*. The speaker's goals and beliefs about the listener's knowledge are both a part of a cognitive/mental model of the discourse.

Cognitive status distinctions depend on two parameters related to the referent—*a)* whether it already exists in the hearer's model of the discourse, and *b)* its degree of salience. The influence of these distinctions on the form of referring expressions has been investigated in the past. For example, centering theory (Grosz et al., 1995) deals predominantly with local salience (local attentional status), and the givenness hierarchy (information status) of Prince (1992) focuses on how a referent got in the discourse model (e.g. through a direct mention in the current discourse, through previous knowledge, or through inference), leading to distinctions such as discourse-old, discourse-new, hearer-old, hearer-new, inferable and containing inferable. Gundel et al. (1993) attempt to merge salience and givenness in a single hierarchy consisting of six distinctions in cognitive status (in focus, activated, familiar, uniquely identifiable, referential, type-identifiable).

Among the distinctions that have an impact on the form of references in a summary are the *familiarity* of the referent:

D. Discourse-old vs discourse-new

H. Hearer-old vs hearer-new

and its global salience[1]:

M. Major vs minor

In general, initial (discourse-new) references to entities are longer and more descriptive, while subsequent (discourse-old) references are shorter and have a purely referential function. Nenkova and McKeown (2003) have studied this distinction for references to people in summaries and how it can be used to automatically rewrite summaries to achieve better fluency and readability.

The other two cognitive status distinctions, whether an entity is central to the summary or not (major or minor) and whether the hearer can be assumed to be already familiar with the entity (hearer-old vs hearer-new status), have not been previously studied in the context of summarization. There is a tradeoff, particularly important for a short summary, between what the speaker wants to convey and how much the listener needs to know. The hearer-old/new distinction can be used to determine whether a description for a character is required from the listener's perspective. The major/minor distinction plays a role in defining the communicative goal, such as what the summary should be about and which characters are important enough to refer to by name.

[1]The notion of global salience is very important to summarization, both during content selection and during generation on initial references to entities. On the other hand, *in focus* or *local attentional state* are relevant to anaphoric usage during subsequent mentions.

1.2 Hearer-Old vs Hearer-New

Hearer-new entities in a summary should be described in necessary detail, while hearer-old entities do not require an introductory description. This distinction can have a significant impact on overall length and intelligibility of the produced summaries. Usually, summaries are very short, 100 or 200 words, for input articles totaling 5,000 words or more. Several people might be involved in a story, which means that if all participants are fully described, little space will be devoted to actual news. In addition, introducing already familiar entities might distract the reader from the main story (Grice, 1975). It is thus a good strategy to refer to an entity that can be assumed hearer-old by just a title + last name, e.g. *President Bush*, or by full name only, with no accompanying description, e.g. *Michael Jackson*.

1.3 Major vs Minor

Another distinction that human summarizers make is whether a character in a story is a major or a minor one and this distinction can be conveyed by using different forms of referring expressions. It is common to see in human summaries references such as *the dissident's father*. Usually, discourse-initial references solely by common noun, without the inclusion of the person's name, are employed when the person is not the main focus of a story (Sanford et al., 1988). By detecting the cognitive status of a character, we can decide whether to name the character in the summary. Furthermore, many summarization systems use the presence of named entities as a feature for computing the importance of a sentence (Saggion and Gaizaukas, 2004; Guo et al., 2003). The ability to identify the major story characters and use only them for sentence weighting can benefit such systems since only 5% of all people mentioned in the input are also mentioned in the summaries.

2 Why care about people in the news?

News reports (and consequently, news summaries) tend to have frequent references to people (in DUC data - see §3 for description - from 2003 and 2004, there were on average 3.85 references to people per 100-word human summary); hence it is important for news summarization systems to have a way of modeling the cognitive status of such referents and a theory for referring to people.

It is also important to note that there are differences in references to people between news reports and human summaries of news. Journalistic conventions for many mainstream newspapers dictate that initial mentions to people include a minimum description such as their role or title and affiliation. However, in human summaries, where there are greater space constraints, the nature of initial references changes. Siddharthan et al. (2004) observed that in DUC'04 and DUC'03 data[2], news reports contain on average one appositive phrase or relative clause every 3.9 sentences, while the human summaries contain only one per 8.9 sentences on average. In addition to this, we observe from the same data that the average length of a first reference to a named entity is 4.5 words in the news reports and only 3.6 words in human summaries. These statistics imply that human summarizers do compress references, and thus can save space in the summary for presenting information about the events. Cognitive status models can inform a system when such reference compression is appropriate.

3 Data preparation: the DUC corpus

The data we used to train classifiers for these two distinctions is the Document Understanding Conference collection (2001–2004) of 170 pairs of document input sets and the corresponding human-written multi-document summaries (2 or 4 per set). Our aim is to identify every person mentioned in the 10 news reports and the associated human summaries for each set, and assign labels for their cognitive status (hearer old/new and major/minor). To do this, we first preprocess the data (§3.1) and then perform the labeling (§3.2).

[2]The data provided under DUC for these years includes sets of about 10 news reports, 4 human summaries for each set, and the summaries by participating machine summarizers.

3.1 Automatic preprocessing

All documents and summaries were tagged with BBN's IDENTIFINDER (Bikel et al., 1999) for named entities, and with a part-of-speech tagger and simplex noun-phrase chunker (Grover et al., 2000). In addition, for each named entity, relative clauses, appositional phrases and copula constructs, as well as pronominal co-reference were also automatically annotated (Siddharthan, 2003). We thus obtained coreference information (cf. Figure 1) for each person in each set, across documents and summaries.

Andrei Sakharov	
Doc 1:	[IR] laureate Andrei D. Sakharov [CO] Sakharov [CO] Sakharov [CO] Sakharov [CO] Sakharov [PR] his [CO] Sakharov [PR] his [CO] Sakharov [RC] who acted as an unofficial Kremlin envoy to the troubled Transcaucasian region last month [PR] he [PR] He [CO] Sakharov
Doc 1:	[IR] Andrei Sakharov [AP] , 68 , a Nobel Peace Prize winner and a human rights activist , [CO] Sakharov [IS] a physicist [PR] his [CO] Sakharov

Figure 1: Example information collected for *Andrei Sakharov* from two news report. 'IR' stands for 'initial reference', 'CO' for noun co-reference, 'PR' for pronoun reference, 'AP' for apposition, 'RC' for relative clause and 'IS' for copula constructs.

The tools that we used were originally developed for processing single documents and we had to adapt them for use in a multi-document setting. The goal was to find, for each person mentioned in an input set, the list of all references to the person in both input documents and human summaries. For this purpose, all input documents were concatenated and processed with IDENTIFINDER. This was then automatically post-processed to mark-up coreferring names and to assign a unique canonical name (unique id) for each name coreference chain. For the coreference, a simple rule of matching the last name was used, and the canonical name was the "FirstName LastName" string where the two parts of the name could be identified [3]. Concatenating all documents assures that the same canonical name will be assigned to all named references to the same person.

[3]Occasionally, two or more different people with the same last name are discussed in the same set and this algorithm would lead to errors in such cases. We did keep a list of first names associated with the entity, so a more refined matching model could be developed, but this was not the focus of this work.

The tools for pronoun coreference and clause and apposition identification and attachment were run separately on each document. Then the last name of each of the canonical names derived from the IDENTIFINDER output was matched with the initial reference in the generic coreference list for the document with the last name. The tools that we used have been evaluated separately when used in normal single document setting. In our cross-document matching processes, we could incur more errors, for example when the general coreference chain is not accurate. On average, out of 27 unique people per cluster identified by IDENTIFINDER, 4 people and the information about them are lost in the matching step for a variety of reasons such as errors in the clause identifier, or the coreference.

3.2 Data labeling

Entities were automatically labeled as hearer-old or new by analyzing the syntactic form that human summarizers used for initial references to them. The labeling rests on the assumption that the people who produced the summaries used their own model of the reader when choosing appropriate references for the summary. The following instructions had been given to the human summarizers, who were not professional journalists: "To write this summary, assume you have been given a set of stories on a news topic and that your job is to summarize them for the general news sections of the Washington Post. Your audience is the educated adult American reader with varied interests and background in current and recent events." Thus, the human summarizers were given the freedom to use their assumptions about what entities would be generally hearer-old and they could refer to these entities using short forms such as (1) title or role+ last name or (2) full name only with no pre- or post-modification. Entities that the majority of human summarizers for the set referred to using form (1) or (2) were labeled as hearer-old. From the people mentioned in human summaries, we obtained 118 examples of hearer-old and 140 examples of hearer-new persons - 258 examples in total - for supervised machine learning.

In order to label an entity as major or minor, we again used the human summaries—entities that were mentioned *by name* in at least one summary were labeled *major*, while those not mentioned by name in any summary were labeled *minor*. The underlying assumption is that people who are not mentioned in any human summary, or are mentioned without being named, are not important. There were 258 major characters who made it to a human summary and 3926 minor ones that only appeared in the news reports. Such distribution between the two classes is intuitively plausible, since many people in news articles express opinions, make statements or are in some other way indirectly related to the story, while there are only a few main characters.

4 Machine learning experiments

The distinction between hearer-old and hearer-new entities depends on the readers. In other words, we are attempting to automatically infer which characters would be hearer-old *for the intended readership of the original reports*, which is also expected to be the intended readership of the summaries. For our experiments, we used the WEKA (Witten and Frank, 2005) machine learning toolkit and obtained the best results for hearer-old/new using a support vector machine (SMO algorithm) and for major/minor, a tree-based classifier (J48). We used WEKA's default settings for both algorithms.

We now discuss what features we used for our two classification tasks (cf. list of features in table 1). Our hypothesis is that features capturing the frequency and syntactic and lexical forms of references are sufficient to infer the desired cognitive model.

Intuitively, pronominalization indicates that an entity was particularly salient at a specific point of the discourse, as has been widely discussed in attentional status and centering literature (Grosz and Sidner, 1986; Gordon et al., 1993). Modified noun phrases (with apposition, relative clauses or premodification) can also signal different status.

In addition to the syntactic form features, we used two months worth of news articles collected over the web (and independent of the DUC collection we use in our experiments here) to collect unigram and bigram lexical models of first mentions of people. The names themselves were removed from the first mention noun phrase and the counts were collected over the premodifiers only. One of the lexical features we used is whether a person's description contains any of the 20 most frequent description words from our web corpus. We reasoned that these frequent de-

0,1:	Number of references to the person, including pronouns (total and normalized by feature 16)	2,3:	Number of times apposition was used to describe the person(total and normalized by feature 16)
4,5:	Number of times a relative clause was used to describe the person (total and normalized by 16)	6:	Number of times the entity was referred to by name after the first reference
7,8:	Number of copula constructions involving the person (total and normalized by feature 16)	9,10:	Number of apposition, relative clause or copula descriptions (total and normalized by feature 16)
11,12,13:	Probability of an initial reference according to the bigram model (av.,max and min of all initial references)	14:	Number of top 20 high frequency description words (from references to people in large news corpus) present in initial references
15:	Proportion of first references containing full name	16:	Total number of documents containing the person
17,18:	Number of appositives or relative clause attaching to initial references (total and normalized by feature 16)		

Table 1: List of Features provided to WEKA.

scriptors may signal importance; the full list is:

president, former, spokesman, sen, dr, chief, coach, attorney, minister, director, gov, rep, leader, secretary, rev, judge, US, general, manager, chairman.

Another lexical feature was the overall likelihood of a person's description using the bigram model from our web corpus. This indicates whether a person has a role or affiliation that is frequently mentioned. We performed 20-fold cross validation for both classification tasks. The results are shown in Table 2 (accuracy) and Table 3 (precision/recall).

4.1 Major vs Minor results

For major/minor classification, the majority class prediction has 94% accuracy, but is not a useful baseline as it predicts that *no* person should be mentioned by name and all are minor characters. J48 correctly predicts 114 major characters out of 258 in the 170 document sets. As recall appeared low, we further analyzed the 148 persons from DUC'03 and DUC'04 sets, for which DUC provides four human summaries. Table 4 presents the distribution of recall taking into account *how many* humans mentioned the person by name in their summary (originally, entities were labeled as main if *any* summary had a reference to them, cf. §3.2). It can be seen that recall is high (0.84) when all four humans consider a character to be major, and falls to 0.2 when only one out of four humans does. These observations reflect the well-known fact that humans differ in their choices for content selection, and indicate that in the automatic learning is more successful when there is more human agreement.

In our data there were 258 people mentioned by name in at least one human summary. In addition, there were 103 people who were mentioned in at least one human summary using only a common noun reference (these were identified by hand, as common noun coreference cannot be performed reliably enough by automatic means), indicating that 29% of people mentioned in human summaries are not actually named. Examples of such references include *an off duty black policeman*, *a Nigerian born Roman catholic priest*, *Kuwait's US ambassador*. For the purpose of generating references in a summary, it is important to evaluate how many of these people are correctly classified as minor characters. We removed these people from the training data and kept them as a test set. WEKA achieved a testing accuracy of 74% on these 103 test examples. But as discussed before, different human summarizers sometimes made different decisions on the form of reference to use. Out of the 103 referent for which a non-named reference was used by a summarizer, there were 40 where other summarizers used named reference. Only 22 of these 40 were labeled as minor characters in our automatic procedure. Out of the 63 people who were not named in *any* summary, but mentioned in at least one by common noun reference, WEKA correctly predicted 58 (92%) as minor characters. As before, we observe that when human summarizers generate references of the same form (reflecting consensus on conveying the perceived importance of the character), the machine predictions are accurate.

We performed feature selection to identify which are the most important features for the classification task. For the major/minor classification, the important features used by the classifier were the number of documents the person was mentioned in (feature 16), number of mentions within the document set (features 1,6), number of relative clauses (feature

4,5) and copula (feature 8) constructs, total number of apposition, relative clauses and copula (feature 9), number of high frequency premodifiers (feature 14) and the maximum bigram probability (feature 12). It was interesting that presence of apposition did not select for either major or minor class. It is not surprising that the frequency of mention within and across documents were significant features—a frequently mentioned entity will naturally be considered important for the news report. Interestingly, the syntactic form of the references was also a significant indicator, suggesting that the centrality of the character was signaled by the journalists by using specific syntactic constructs in the references.

	Major/Minor	Hearer New/Old
WEKA	0.96 (J48)	0.76 (SMO)
Majority class prediction	0.94	0.54

Table 2: Cross validation *testing* accuracy results.

	Class	Precision	Recall	F-measure
SMO	hearer-new	0.84	0.68	0.75
	hearer-old	0.69	0.85	0.76
J48	major-character	0.85	0.44	0.58
	minor-character	0.96	0.99	0.98

Table 3: Cross validation *testing* P/R/F results.

Number of summaries containing the person	Number of examples	Number and % recalled by J48
1 out of 4	59	15 (20%)
2 out of 4	35	20 (57%)
3 out of 4	29	23 (79%)
4 out of 4	25	21 (84%)

Table 4: J48 Recall results and human agreement.

4.2 Hearer Old vs New Results

The majority class prediction for the hearer-old/new classification task is that no one is known to the reader and it leads to overall classification accuracy of 54%. Using this prediction in a summarizer would result in excessive detail in referring expressions and a consequent reduction in space available to summarize the news events. The SMO prediction outperformed the baseline accuracy by 22% and is more meaningful for real tasks.

For the hearer-old/new classification, the feature selection step chose the following features: the number of appositions (features 2,3) and relative clauses (feature 5), number of mentions within the document set (features 0,1), total number of apposition, relative clauses and copula (feature 10), number of high frequency premodifiers (feature 14) and the minimum bigram probability (feature 13). As in the minor-major classification, the syntactic choices for reference realization were useful features.

We conducted an additional experiment to see how the hearer old/new status impacts the use of apposition or relative clauses for elaboration in references produced in human summaries. It has been observed (Siddharthan et al., 2004) that on average these constructs occur 2.3 times *less* frequently in human summaries than in machine summaries. As we show, the use of postmodification to elaborate relates to the hearer-old/new distinction.

To determine when an appositive or relative clause can be used to modify a reference, we considered the 151 examples out of 258 where there was at least one relative clause or apposition describing the person in the input. We labeled an example as positive if *at least* one human summary contained an apposition or relative clause for that person and negative otherwise. There were 66 positive and 85 negative examples. This data was interesting because while for the majority of examples (56%) all the human summarizers agreed not to use postmodification, there were very few examples (under 5%) where all the humans agreed to postmodify. Thus it appears that for around half the cases, it should be obvious that no postmodification is required, but for the other half, human decisions go either way.

Notably, none of the hearer-old persons (using test predictions of SMO) were postmodified. Our cognitive status predictions cleanly partition the examples into those where postmodification is not required, and those where it might be. Since no intuitive rule handled the remaining examples, we added the testing predictions of hearer-old/new and major/minor as features to the list in Table 1, and tried to learn this task using the tree-based learner J48. We report a testing accuracy of 71.5% (majority class baseline is 56%). There were only three useful features—the predicted hearer-new/old status, the number of high frequency premodifiers for that person in the input (feature 14 in table 1) and the average number of postmodified initial references in the input documents (feature 17).

5 Validating the results on current news

We tested the classifiers on data different from that provided by DUC, and also tested human consensus on the hearer-new/old distinction. For these purposes, we downloaded 45 clusters from one day's output from Newsblaster[4]. We then automatically compiled the list of people mentioned in the machine summaries for these clusters. There were 107 unique people that appeared in the machine summaries, out of 1075 people in the input clusters.

5.1 Human agreement on hearer-old/new

A question arises when attempting to infer hearer-new/old status: Is it meaningful to generalize this across readers, seeing how dependent it is on the world knowledge of individual readers?

To address this question, we gave 4 American graduate students a list of the names of people in the DUC human summaries (cf. §3), and asked them to write down for each person, their country/state/organization affiliation and their role (writer/president/attorney-general etc.). We considered a person hearer-old to a subject if they correctly identified both role and affiliation for that person. For the 258 people in the DUC summaries, the four subjects demonstrated 87% agreement ($\kappa = 0.74$)[5].

Similarly, they were asked to perform the same task for the Newsblaster data, which dealt with contemporary news[6], in contrast with the DUC data that contained news from the the late 80s and early 90s. On this data, the human agreement was 91% ($\kappa = 0.78$). This is a high enough agreement to suggest that the classification of national and international figures as hearer old/new across *the educated adult American reader with varied interests and background in current and recent events* is a well defined task. This is not necessarily true for the full range of cognitive status distinctions; for example Poesio and Vieira (1998) report lower human agreement on more fine-grained classifications of definite descriptions.

5.2 Results on the Newsblaster data

We measured how well the models trained on DUC data perform with current news labeled using human judgment. For each person who was mentioned in the automatic summaries for the Newsblaster data, we compiled one judgment from the 4 human subjects: an example was labeled as hearer-new if two or more out of the four subjects had marked it as hearer new. Then we used this data as *test data*, to test the model trained solely on the DUC data. The classifier for hearer-old/hearer-new distinction achieved 75% accuracy on Newsblaster data labeled by humans, while the cross-validation accuracy on the automatically labeled DUC data was 76%. These numbers are very encouraging, since they indicate that the performance of the classifier is stable and does not vary between the DUC and Newsblaster data. The precision and recall for the Newsblaster data are also very similar for those obtained from cross-validation on the DUC data:

Class	Precision	Recall	F-Measure
Hearer-old	0.88	0.73	0.80
Hearer-new	0.57	0.79	0.66

5.3 Major/Minor results on Newsblaster data

For the Newsblaster data, no human summaries were available, so no direct indication on whether a human summarizer will mention a person in a summary was available. In order to evaluate the performance of the classifier, we gave a human annotator the list of people's names appearing in the machine summaries, together with the input cluster and the machine summary, and asked which of the names on the list would be a suitable keyword for the set (keyword lists are a form of a very short summary). Out of the 107 names on the list, the annotator chose 42 as suitable for descriptive keyword for the set.

The major/minor classifier was run on the 107 examples; only 40 were predicted to be major characters. Of the 67 test cases that were predicted by the classifier to be minor characters, 12 (18%) were marked by the annotator as acceptable keywords. In comparison, of the 40 characters that were predicted to be major characters by the classifier, 30 (75%) were marked as possible keywords. If the keyword selections of the annotator are taken as ground truth, the automatic predictions have precision and recall of 0.75 and 0.71 respectively for the *major* class.

6 Conclusions

Cognitive status distinctions are important when generating summaries, as they help determine both

[4]`http://newsblaster.cs.columbia.edu`

[5]κ (kappa) is a measure of inter-annotator agreement over and above what might be expected by pure chance (See Carletta (1996) for discussion of its use in NLP). $\kappa = 1$ if there is perfect agreement between annotators and $\kappa = 0$ if the annotators agree only as much as you would expect by chance.

[6]The human judgments were made within a week of the news stories appearing.

what to say and how to say it. However, to date, no one has attempted the task of inferring cognitive status from unrestricted news.

We have shown that the hearer-old/new and major/minor distinctions can be inferred using features derived from the lexical and syntactic forms and frequencies of references in the news reports. We have presented results that show agreement on the *familiarity* distinction between educated adult American readers with an interest in current affairs, and that the learned classifier accurately predicts this distinction. We have demonstrated that the acquired cognitive status is useful for determining which characters to name in summaries, and which named characters to describe or elaborate. This provides the foundation for a principled framework in which to address the question of how much references can be shortened without compromising readability.

Bayesian Learning in Text Summarization

Tadashi Nomoto
National Institute of Japanese Literature

Tokyo 142-8585 Japan
nomoto@acm.org

Abstract

The paper presents a Bayesian model for text summarization, which explicitly encodes and exploits information on how human judgments are distributed over the text. Comparison is made against non Bayesian summarizers, using test data from Japanese news texts. It is found that the Bayesian approach generally leverages performance of a summarizer, at times giving it a significant lead over non-Bayesian models.

1 Introduction

Consider figure 1. What is shown there is the proportion of the times that sentences at particular locations are judged as relevant to summarization, or worthy of inclusion in a summary. Each panel shows judgment results on 25 Japanese texts of a particular genre; columns (G1K3), editorials (G2K3) and news stories (G3K3). All the documents are from a single Japanese news paper, and judgments are elicited from some 100 undergraduate students. While more will be given on the details of the data later (Section 3.2), we can safely ignore them here.

Each panel has the horizontal axis representing location or order of sentence in a document, and the vertical axis the proportion of the times sentences at particular locations are picked as relevant to summarization. Thus in G1K3, we see that the first sentence (to appear in a document) gets voted for about 12% of the time, while the 26th sentence is voted for less than 2% of the time.

Curiously enough, each of the panels exhibits a distinct pattern in the way votes are spread across a document: G1K3 has the distribution of votes (DOV) with sharp peaks around 1 and 14; in G2K3, the distribution is peaked around 1, with a small bump around 19; in G3K3, the distribution is sharply skewed to the left, indicating that the majority of votes went to the initial section of a document. What is interesting about the DOV is that we could take it as indicating a collective preference for what to extract for a summary. A question is then, can we somehow exploit the DOV in summarization? To our knowledge, no prior work seems to exist that addresses the question. The paper discusses how we could do this under a Bayesian modeling framework, where we explicitly represent and make use of the DOV by way of Dirichlet posterior (Congdon, 2003).[1]

2 Bayesian Model of Summaries

Since the business of extractive summarization, such as one we are concerned with here, is about ranking sentences according to how useful/important they are as part of summary, we will consider here a particular ranking scheme based on the probability of a sentence being part of summary under a given DOV, i.e.,

$$P(y|\boldsymbol{v}), \tag{1}$$

where y denotes a given sentence, and $\boldsymbol{v} = (v_1, \ldots, v_n)$ stands for a DOV, an array of observed vote counts for sentences in the text; v_1 refers to the count of votes for a sentence at the text initial position, v_2 to that for a sentence occurring at the second place, etc.

Thus given a four sentence long text, if we have three people in favor of a lead sentence, two in favor

[1]See Yu et al. (2004) and Cowans (2004) for its use in IR.

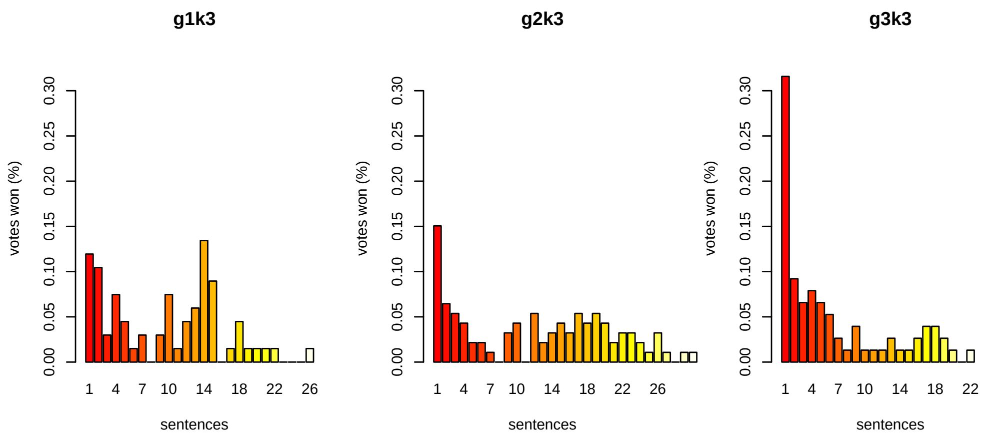

Figure 1: Genre-by-genre vote distribution

of the second, one for the third, and none for the fourth, then we would have $\boldsymbol{v} = (3, 2, 1, 0)$.

Now suppose that each sentence y_i (i.e., a sentence at the i-th place in the order of appearance) is associated with what we might call a prior preference factor θ_i, representing how much a sentence at a particular position is favored as part of a summary in general. Then the probability that y_i finds itself in a summary is given as:

$$\phi(y_i|\theta_i)P(\theta_i), \tag{2}$$

where ϕ denotes some likelihood function, and $P(\theta_i)$ a prior probability of θ_i.

Since the DOV is something we could actually observe about θ_i, we might as well couple θ_i with $\boldsymbol{v}$ by making a probability of θ_i conditioned on $\boldsymbol{v}$. Formally, this would be written as:

$$\phi(y_i|\theta_i)P(\theta_i|\boldsymbol{v}). \tag{3}$$

The problem, however, is that we know nothing about what each θ_i looks like, except that it should somehow be informed by $\boldsymbol{v}$. A typical Bayesian solution to this is to 'erase' θ_i by marginalizing (summing) over it, which brings us to this:

$$P(y_i|\boldsymbol{v}) = \int \phi(y_i|\theta_i)P(\theta_i\,|\boldsymbol{v})\, d\theta_i. \tag{4}$$

Note that equation 4 no longer talks about the probability of y_i under a particular θ_i; rather it talks about the expected probability for y_i with respect to a preference factor dictated by $\boldsymbol{v}$. All we need to know about $P(\theta_i|\boldsymbol{v})$ to compute the expectation is $\boldsymbol{v}$ and a probability distribution P, and not θ_i's, anymore.

$$\begin{tikzcd} \boldsymbol{v} \arrow[r] \arrow[rr, bend left] & \boldsymbol{\theta} \arrow[r] & y_i \end{tikzcd}$$

Figure 2: A graphical view

We know something about $\boldsymbol{v}$, and this would leave us P. So what is it? In principle it could be any probability distribution. However largely for the sake of technical convenience, we assume it is one component of a multinomial distribution known as the Dirichlet distribution. In particular, we talk about Dirichlet($\boldsymbol{\theta}|\boldsymbol{v}$), namely a Dirichlet posterior of θ, given observations $\boldsymbol{v}$, where $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_i, \ldots, \theta_n)$, and $\sum_i^n \theta_i = 1$ $(\theta_i > 0)$. (Remarkably, if $P(\theta)$ is a Dirichlet, so is $P(\theta|\boldsymbol{v})$.) $\boldsymbol{\theta}$ here represents a vector of preference factors for n sentences — which constitute the text.[2]

Accordingly, equation 4 could be rewritten as:

$$P(y_i|\boldsymbol{v}) = \int \phi(y_i|\boldsymbol{\theta})P(\boldsymbol{\theta}\,|\boldsymbol{v})\, d\boldsymbol{\theta}. \tag{5}$$

An interesting way to look at the model is by way of a graphical model (GM), which gives some intuitive idea of what the model looks like. In a GM perspective, our model is represented as a simple tripartite structure (figure 2), in which each node corresponds to a variable (parameter), and arcs represent

[2]Since texts generally vary in length, we may set n to a sufficiently large number so that none of texts of interest may exceed it in length. For texts shorter than n, we simply add empty sentences to make them as long as n.

dependencies among them. $x \rightarrow y$ reads 'y depends on x.' An arc linkage between $\boldsymbol{v}$ and y_i is meant to represent marginalization over $\boldsymbol{\theta}$.

Moreover, we will make use of a scale parameter $\lambda \geq 1$ to have some control over the shape of the distribution, so we will be working with Dirichlet($\theta|\lambda\boldsymbol{v}$) rather than Dirichlet($\theta|\boldsymbol{v}$). Intuitively, we might take λ as representing a degree of confidence we have in a set of empirical observations we call $\boldsymbol{v}$, as increasing the value of λ has the effect of reducing variance over each θ_i in θ.

The expectation and variance of Dirichlet($\boldsymbol{\theta}|\boldsymbol{v}$) are given as follows.[3]

$$E[\theta_i] = \frac{v_i}{v_0} \tag{6}$$

$$Var[\theta_i] = \frac{v_i(v_0 - v_i)}{v_0^2(v_0 + 1)}, \tag{7}$$

where $v_0 = \sum_i^n v_i$. Therefore the variance of a scaled Dirichlet is:

$$Var[\theta_i|\lambda\boldsymbol{v}] = \frac{v_i(v_0 - v_i)}{v_0^2(\lambda v_0 + 1)}. \tag{8}$$

See how λ is stuck in the denominator. Another obvious fact about the scaling is that it does not affect the expectation, which remains the same.

To get a feel for the significance of λ, consider figure 3; the left panel shows a histogram of 50,000 variates of p_1 randomly drawn from Dirichlet($p_1, p_2|\lambda c_1, \lambda c_2$), with $\lambda = 1$, and both c_1 and c_2 set to 1. The graph shows only the p_1 part but things are no different for p_2. (The x-dimension represents a particular value p_1 takes (which ranges between 0 and 1) and the y-dimension records the number of the times p_1 takes that value.) We see that points are spread rather evenly over the probability space. Now the right panel shows what happens if you increase λ by a factor of 1,000 (which will give you $P(p_1, p_2|1000, 1000)$); points take a bell shaped form, concentrating in a small region around the expectation of p_1. In the experiments section, we will return to the issue of λ and discuss how it affects performance of summarization.

Let us turn to the question of how to find a solution to the integral in equation 5. We will be concerned here with two standard approaches to the issue: one is based on MAP (maximum a posteriori) and another on numerical integration. We start off with a MAP based approach known as Bayesian Information Criterion or BIC.

For a given model m, BIC seeks an analytical approximation for equation 4, which looks like the following:

$$\ln P(y_i|m) = \ln \phi(y_i|\hat{\boldsymbol{\theta}}, m) - \frac{k}{2} \ln N, \tag{9}$$

where k denotes the number of free parameters in m, and N that of observations. $\hat{\boldsymbol{\theta}}$ is a MAP estimate of $\boldsymbol{\theta}$ under m, which is $E[\boldsymbol{\theta}]$. It is interesting to note that BIC makes no reference to prior. Also worthy of note is that a minus of BIC equals MDL (Minimum Description Length).

Alternatively, one might take a more straightforward (and fully Bayesian) approach known as the Monte Carlo integration method (MacKay, 1998) (MC, hereafter) where the integral is approximated by:

$$P(y_i|\boldsymbol{v}) \approx \frac{1}{n} \sum_{j=1}^{n} \phi(y_i|x^{(j)}), \tag{10}$$

where we draw each sample $x^{(j)}$ randomly from the distribution $P(\boldsymbol{\theta}|\boldsymbol{v})$, and n is the number of $x^{(i)}$'s so collected. Note that MC gives an expectation of $P(y_i|\boldsymbol{v})$ with respect to $P(\boldsymbol{\theta}|\boldsymbol{v})$.

Furthermore, ϕ could be any probabilistic function. Indeed any discriminative classifier (such as C4.5) will do as long as it generates some kind of probability. Given ϕ, what remains to do is essentially training it on samples bootstrapped (i.e., resampled) from the training data based on $\boldsymbol{\theta}$ — which we draw from Dirichlet($\boldsymbol{\theta}|\boldsymbol{v}$).[4] To be more specific, suppose that we have a four sentence long text and an array of probabilities $\boldsymbol{\theta} = (0.4, 0.3, 0.2, 0.1)$ drawn from a Dirichlet distribution: which is to say, we have a preference factor of 0.4 for the lead sentence, 0.3 for the second sentence, etc. Then we resample with replacement lead sentences from training data with the probability of 0.4, the second with the probability of 0.3, and so forth. Obviously, a

[3]http://www.cis.hut.fi/ahonkela/dippa/dippa.html

[4]It is fairly straightforward to sample from a Dirichlet posterior by resorting to a gamma distribution, which is what is happening here. In case one is working with a distribution it is hard to sample from, one would usually rely on Markov chain Monte Carlo (MCMC) or variational methods to do the job.

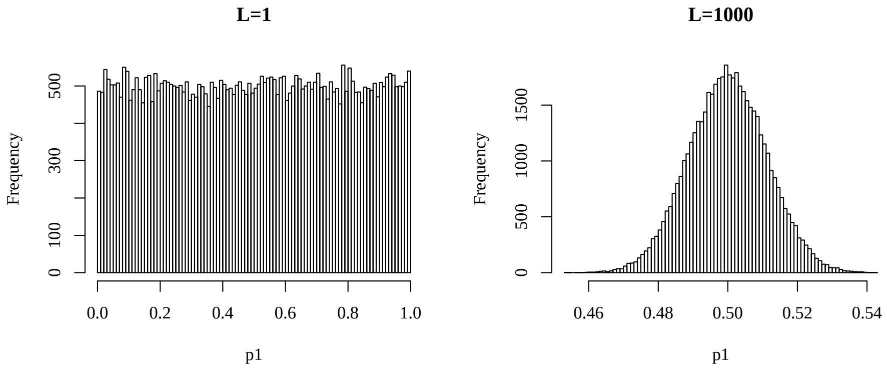

Figure 3: Histograms of random draws from Dirichlet$(p_1, p_2|\lambda c_1, \lambda c_2)$ with $\lambda = 1$ (left panel), and $\lambda = 1000$ (right panel).

high preference factor causes the associated sentence to be chosen more often than those with a low preference.

Thus given a text $T = (a, b, c, d)$ with $\boldsymbol{\theta} = (0.4, 0.3, 0.2, 0.1)$, we could end up with a data set dominated by a few sentence types, such as $T' = (a, a, a, b)$, which we proceed to train a classifier on in place of T. Intuitively, this amounts to inducing the classifier to attend to or focus on a particular region or area of a text, and dismiss the rest. Note an interesting parallel to boosting (Freund and Schapire, 1996) and the alternating decision tree (Freund and Mason, 1999).

In MC, for each $\boldsymbol{\theta}^{(k)}$ drawn from Dirichlet$(\boldsymbol{\theta}|\boldsymbol{v})$, we resample sentences from the training data using probabilities specified by $\boldsymbol{\theta}^{(k)}$, use them for training a classifier, and run it on a test document d to find, for each sentence in d, its probability of being a 'pick' (summary-worthy) sentence,i.e., $P(y_i|\boldsymbol{\theta}^{(k)})$, which we average across $\boldsymbol{\theta}$'s. In experiments later described, we apply the procedure for 20,000 runs (meaning we run a classifier on each of 20,000 $\boldsymbol{\theta}$'s we draw), and average over them to find an estimate for $P(y_i|\boldsymbol{v})$.

As for BIC, we generally operate along the lines of MC, except that we bootstrap sentences using only $E[\boldsymbol{\theta}]$, and the model complexity term, namely, $-\frac{k}{2}\ln N$ is dropped as it has no effect on ranking sentences. As with MC, we train a classifier on the bootstrapped samples and run it on a test document. Though we work with a set of fixed parameters, a bootstrapping based on them still fluctuates, producing a slightly different set of samples each time we run the operation. To get a reasonable convergence in experiments, we took the procedure to 5,000 iterations and averaged over the results.

Either with BIC or with MC, building a summarizer on it is a fairly straightforward matter. Given a document d and a compression rate r, what a summarizer would do is simply rank sentences in d based on $P(y_i|\boldsymbol{v})$ and pick an r portion of highest ranking sentences.

3 Working with Bayesian Summarist

3.1 C4.5

In what follows, we will look at whether and how the Bayesian approach, when applied for the C4.5 decision tree learner (Quinlan, 1993), leverages its performance on real world data. This means our model now operates either by

$$P(y_i|\boldsymbol{v}) \approx \frac{1}{n}\sum_{j=1}^{n}\phi_{c4.5}(y_i|x^{(j)}), \qquad (11)$$

or by

$$\ln P(y_i|m) = \ln \phi_{c4.5}(y_i|\hat{\boldsymbol{\theta}}, m) - \frac{k}{2}\ln N, \qquad (12)$$

with the likelihood function ϕ filled out by C4.5. Moreover, we compare two versions of the classifier; one with BIC/MC and one without. We used Weka implementations of the algorithm (with default settings) in experiments described below (Witten and Frank, 2000).

While C4.5 here is configured to work in a binary (positive/negative) classification scheme, we run it in a 'distributional' mode, and use a particular class membership probability it produces, namely, the probability of a sentence being positive, i.e., a pick (summary-worthy) sentence, instead of a category label.

Attributes for C4.5 are broadly intended to represent some aspects of a sentence in a document, an object of interest here. Thus for each sentence ψ, its encoding involves reference to the following set of attributes or features. 'LocSen' gives a normalized location of ψ in the text, i.e., a normalized distance from the top of the text; likewise, 'LocPar' gives a normalized location of the paragraph in which ψ occurs, and 'LocWithinPar' records its normalized location within a paragraph. Also included are a few length-related features such as the length of text and sentence. Furthermore we brought in some language specific feature which we call 'EndCue.' It records the morphology of a linguistic element that ends ψ, such as inflection, part of speech, etc.

In addition, we make use of the weight feature ('Weight') for a record on the importance of ψ based on tf.idf. Let $\psi = w_1, \ldots, w_n$, for some word w_i. Then the weight $W(\psi)$ is given as:

$$W(\psi) = \sum_{w} (1 + \log(\text{tf}(w))) \cdot \log(N/\text{df}(w)).$$

Here 'tf(w)' denotes the frequency of word w in a given document, 'df(w)' denotes the 'document frequency' of w, or the number of documents which contain an occurrence of w. N represents the total number of documents.[5]

Also among the features used here is 'Pos,' a feature intended to record the position or textual order of ψ, given by how many sentences away it occurs from the top of text, starting with 0.

While we do believe that the attributes discussed above have a lot to do with the likelihood that a given sentence becomes part of summary, we choose not to consider them parameters of the Bayesian model, just to keep it from getting unduly complex. Recall the graphical model in figure 2.

[5]Although one could reasonably argue for normalizing $W(\psi)$ by sentence length, it is not entirely clear at the moment whether it helps in the way of improving performance.

3.2 Test Data

Here is how we created test data. We collected three pools of texts from different genres, columns, editorials and news stories, from a Japanese financial paper (*Nihon Keizai Shinbun*) published in 1995, each with 25 articles. Then we asked 112 Japanese students to go over each article and identify 10% worth of sentences they find most important in creating a summary for that article. For each sentence, we recorded how many of the subjects are in favor of its inclusion in summary. On average, we had about seven people working on each text. In the following, we say sentences are 'positive' if there are three or more people who like to see them in a summary, and 'negative' otherwise. For convenience, let us call the corpus of columns G1K3, that of editorials G2K3 and that of news stories G3K3. Additional details are found in table 1.

4 Results and Discussion

Tables 2 through 4 show how the Bayesian summarist performs on G1K3, G2K3, and G3K3. The tables list results in precision at compression rates (r) of interest ($0 < r < 1$). The figures thereof indicate performance averaged over leave-one-out cross validation folds. What this means is that you leave out one text for testing and use the rest for training, which you repeat for each one of the texts in the data. Since we have 25 texts for each data set, this leads to a 25-fold cross validation. Precision is defined by the ratio of hits (positive sentences) to the number of sentences retrieved, i.e., r-percent of sentences in the text.[6]

In each table, figures to the left of the vertical line indicate performance of summarizers with BIC/MC and those to the right that of summarizers without them. Parenthetical figures like '(5K)' and '(20K)' indicate the number of iterations we took them to: thus BIC(5K) refers to a summarizer based on C4.5/BIC with scores averaged over 5,000 runs. BSE denotes a reference summarizer based on a regular C4.5, which it involves no resampling of training data. LEAD refers to a summarizer which works

[6]We do not use recall for a evaluation measure, as the number of positive instances varies from text to text, and may indeed exceed the length of a summary under a particular compression rate.

Table 1: N represents the number of sentences in G1K3 to G3K3. Sentences with three or more votes in their favor are marked positive, that is, for each sentence marked positive, at least three people are in favor of including it in a summary.

Genre	N	Positive (≥ 3)	Negative	P/N Ratio
G1K3	426	67	359	0.187
G2K3	558	93	465	0.200
G3K3	440	76	364	0.210

Table 2: G1K3. $\lambda = 5$. Dashes indicate no meaningful results.

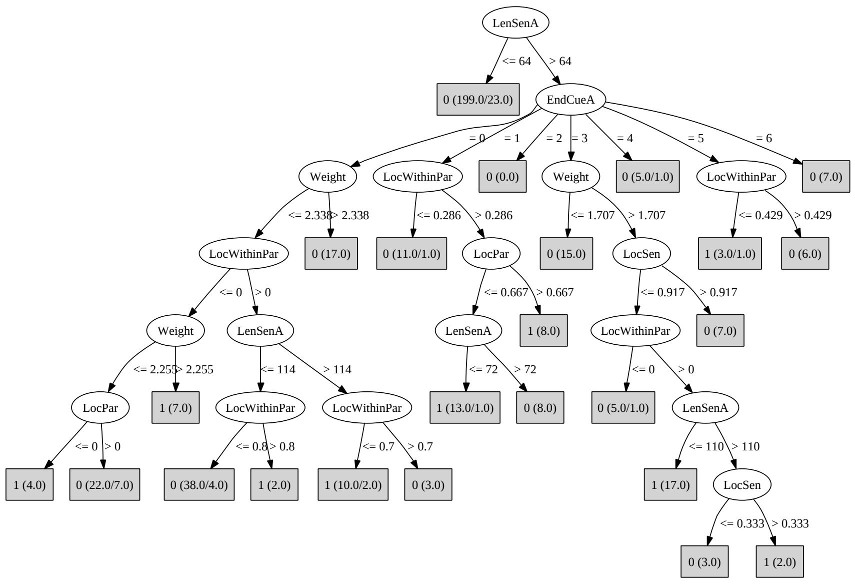

Figure 5: A Bayesian (MC) C4.5 trained on G1K3.

by selecting sentences from the top of the text. It is generally considered a hard-to-beat approach in the summarization literature.

Table 4 shows results for G3K3 (a news story domain). There we find a significantly improvement to performance of C4.5, whether it operates with BIC or MC. The effect is clearly visible across a whole range of compression rates, and more so at smaller rates.

Table 3 demonstrates that the Bayesian approach is also effective for G2K3 (an editorial domain), outperforming both BSE and LEAD by a large margin.

Similarly, we find that our approach comfortably beats LEAD in G1K3 (a column domain). Note the dashes for BSE. What we mean by these, is that we obtained no meaningful results for it, because we were unable to rank sentences based on predictions by BSE. To get an idea of how this happens, let us look at a decision tree BSE builds for G1K3, which is shown in figure 4. What we have there is a decision tree consisting of a single leaf.[7] Thus for whatever sentence we feed to the tree, it throws back the same membership probability, which is 65/411. But then this would make a BSE based summarizer utterly useless, as it reduces to generating a summary by picking at random, a particular portion of text.[8]

Now Figure 5 shows what happens with the Bayesian model (MC), for the same data. There we see a tree of a considerable complexity, with 24 leaves and 18 split nodes.

Let us now turn to the issues with λ. As we might recall, λ influences the shape of a Dirichlet distribution: a large value of λ causes the distribution to have less variance and therefore to have a more acute peak around the expectation. What this means is that increasing the value of λ makes it more likely to have us drawing samples closer to the expectation. As a consequence, we would have the MC model acting more like the BIC model, which is based on MAP estimates. That this is indeed the case is demonstrated by table 5, which gives results for the MC model on G1K3 to G3K3 at $\lambda = 1$. We see that the MC behaves less like the BIC at $\lambda = 1$ than at $\lambda = 5$ (table 2 through 4).

Of a particular interest in table 5 is G1K3, where the MC suffers a considerable degradation in performance, compared to when it works with $\lambda = 5$. G2K3 and G3K3, again, witness some degradation in performance, though not as extensive as in G1K3. It is interesting that at times the MC even works better with $\lambda = 1$ than $\lambda = 5$ in G2K3 and G3K3.[9]

[7]This is not at all surprising as over 80% of sentences in a non resampled text are negative for the most of the time.

[8]Its expected performance (averaged over 10^6 runs) comes to: 0.1466 ($r = 0.05$), 0.1453 ($r = 0.1$), 0.1508 ($r = 0.15$), 0.1530 ($r = 0.2$), 0.1534 ($r = 0.25$), and 0.1544 ($r = 0.3$).

[9]The results suggest that if one like to have some improvement, it is probably a good idea to set λ to a large value. But

Table 5: MC (20K). $\lambda = 1$.

r	G1K3	G2K3	G3K3
0.05	0.3333	0.5400	0.9600
0.10	0.3333	0.3867	0.7800
0.15	0.2917	0.3960	0.5867
0.20	0.2549	0.3373	0.5200
0.25	0.2480	0.2910	0.4347
0.30	0.2594	0.2652	0.4100

All in all, the Bayesian model proves more effective in leveraging performance of the summarizer on a DOV exhibiting a complex, multiply peaked form as in G1K3 and G2K3, and less on a DOV which has a simple, single-peak structure as in G3K3 (cf. figure 1).[10]

5 Concluding Remarks

The paper showed how it is possible to incorporate information on human judgments for text summarization in a principled manner through Bayesian modeling, and also demonstrated how the approach leverages performance of a summarizer, using data collected from human subjects.

The present study is motivated by the view that that summarization is a particular form of collaborative filtering (CF), wherein we view a summary as a particular set of sentences favored by a particular user or a group of users just like any other things people would normally have preference for, such as CDs, books, paintings, emails, news articles, etc. Importantly, under CF, we would not be asking, what is the 'correct' or gold standard summary for document X? – the question that consumed much of the past research on summarization. Rather, what we are asking is, what summary is popularly favored for X?

Indeed the fact that there could be as many summaries as angles to look at the text from may favor the CF view of summary: the idea of what constitutes a good summary may vary from person to person, and may well be influenced by particular interests and concerns of people we elicit data from.

Among some recent work with similar concerns, one notable is the Pyramid scheme (Nenkova and Passonneau, 2004) where one does not declare a particular human summary a absolute reference to compare summaries against, but rather makes every one of multiple human summaries at hand bear on evaluation; Rouge (Lin and Hovy, 2003) represents another such effort. The Bayesian summarist represents yet another, whereby one seeks a summary most typical of those created by humans.

in general how to best set λ requires some experimenting with data and the optimal value may vary from domain to domain. An interesting approach would be to empirically optimize λ using methods suggested in MacKay and Peto (1994).

[10]Incidentally, summarizers, Bayesian or not, perform considerably better on G3K3 than on G1K3 or G2K3. This happens presumably because a large portion of votes concentrate in a rather small region of text there, a property any classifier should pick up easily.

Discourse Chunking and its Application to Sentence Compression

Caroline Sporleder and **Mirella Lapata**

Edinburgh EH8 9LW, UK
{csporled,mlap}@inf.ed.ac.uk

Abstract

In this paper we consider the problem of analysing sentence-level discourse structure. We introduce discourse chunking (i.e., the identification of intra-sentential nucleus and satellite spans) as an alternative to full-scale discourse parsing. Our experiments show that the proposed modelling approach yields results comparable to state-of-the-art while exploiting knowledge-lean features and small amounts of discourse annotations. We also demonstrate how discourse chunking can be successfully applied to a sentence compression task.

1 Introduction

The computational treatment of discourse phenomena has recently attracted much attention, partly due to their increasing importance for potential applications. In summarisation, for example, the extraction of sentences to include in a summary crucially depends on their rhetorical status (Marcu, 2000; Teufel and Moens, 2002); one might want to extract contrastive or explanatory statements while omitting sentences that contain background information. In information extraction, discourse-level knowledge can be used to identify co-referring events (Humphreys et al., 1997) and to determine their temporal order. Discourse processing could further enhance question answering systems by interpreting the user's question either in isolation or in the context of preceding questions (Chai and Jing, 2004).

Discourse analysis is often viewed as a parsing task. Rhetorical Structure Theory (RST, Mann and Thomson, 1988), one of the most influential frameworks in discourse processing, represents texts by trees whose leaves correspond to elementary discourse units (*edus*) and whose nodes specify how these and larger units (e.g., multi-sentence segments) are linked to each other by rhetorical relations (e.g., *Contrast*, *Elaboration*). Discourse units are further characterised in terms of their text importance: *nuclei* denote central segments, whereas *satellites* denote peripheral ones.

Recent advances in discourse modelling have greatly benefited from the availability of resources annotated with discourse-level information such as the RST Discourse Treebank (RST-DT, Carlson et al., 2002). Even though discourse parsing at the document-level still poses a significant challenge to data-driven methods, sentence-level discourse models (e.g., Soricut and Marcu, 2003) trained on the RST-DT have attained accuracies comparable to human performance. The availability of discourse annotations is partly responsible for the success of these models. Another important reason is the development of robust syntactic parsers (e.g., Charniak, 2000) that can be used to provide critical structural and lexical information to the discourse parser. Unfortunately, discourse annotated corpora are largely absent for languages other than English. Furthermore, reliance on syntactic parsing renders discourse parsing practically impossible for languages for which state-of-the-art parsers are unavailable.

In this paper we propose discourse chunking as an alternative to discourse parsing. Analogous to sentence chunking, discourse chunking is an intermediate step towards full parsing. Following an RST-style analysis, we focus solely on two subtasks: (a) discourse segmentation, i.e., determining which word sequences form *edus* and (b) inferring whether these *edus* function as nuclei or satellites. The motivation for tackling these subtasks is two-fold. First, they are of crucial importance for full-scale discourse parsing. For example, Soricut and Marcu (2003) show that perfect discourse segmentation delivers an error reduction of 29% in the performance of their discourse parser. Second, some applications may not require full-scale discourse parsing. For example, it has been shown that nuclearity is important for summarisation, i.e., nuclei are more likely to be retained when summarising than satellites (Marcu, 2000). While nuclearity alone may not be sufficient for document summarisation (Marcu, 1998), such knowledge could prove useful at the sentence level, for example for producing sentence compressions.

The algorithms introduced in this paper are purposely knowledge-lean. We abstain from using syntactic parsers or semantic databases such as WordNet (Fellbaum, 1998), thus exploring the portability of our methods to languages for which such resources are not available. We employ lexical and low-level syntactic information (e.g., parts of speech, syntactic chunks) and show that the performance of our discourse chunker on the two subtasks (mentioned above) is comparable to that of a state-of-the-art sentence-level discourse parser (Soricut and Marcu, 2003). We also assess its application potential on a sentence compression task (Knight and Marcu, 2003).

2 Related Work

Initial work towards the development of discourse parsers has primarily relied on hand-crafted rules for specifying world knowledge or constraints on tree structures (e.g., Hobbs 1993). Recent work has seen the emergence of treebanks annotated with discourse structure, thus enabling the development of more robust, data-driven models. Marcu (2000) presents a shift-reduce parsing model that segments texts into *edus* and determines how they should be assembled into rhetorical structure trees. Soricut and Marcu (2003) introduce a syntax-based sentence-level discourse parser, which consists of two components: a statistical segmentation model and a parser working on the output of the segmenter. Both components are trained on the RST-DT and exploit lexical features as well as syntactic dominance features (which are taken from syntactic parse trees).

Given that discourse-level information plays an important role in human summarisation (Endres-Niggemeyer, 1998), it is not surprising that models of discourse structure have found use in automatic summarisation. For instance, Marcu (2000) proposes a summarisation algorithm that builds an RST tree for the entire text, and identifies its most important parts according to discourse salience.

Our work differs from previous approaches in two key respects. First, we do not attempt to produce a hierarchical discourse structure. We introduce discourse chunking, a less resource demanding task than full discourse parsing. We show that good chunking performance can be achieved with low-level information. Second, we apply our discourse chunker to sentence compression. Although previous approaches have utilised discourse information for document summarisation, its application to sentence condensation is novel to our knowledge.

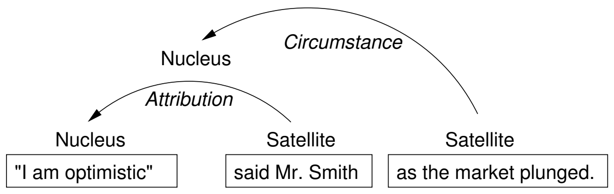

Figure 1: Discourse Tree in RST-DT

3 Discourse Chunking

3.1 Data and Representation

We propose a supervised machine learning approach to discourse chunking. Our data were obtained from the RST-DT (Carlson et al., 2002), which consists of 385 Wall Street Journal articles manually annotated with discourse structures in the framework of Mann and Thompson (1987). An example of an RST-based tree representation is shown in Figure 1; rectangular boxes denote *edus* and arcs indicate which relations (e.g., *Circumstance* or *Attribution*) hold between them. Relations are typically binary with one unit being the nucleus (indicated by arrows in Figure 1) and the other the satellite, but multi-nuclear and non-binary relations are also possible.

We are only interested in the lowest level of the tree, i.e., we aim to identify the *edus* and determine whether they are nuclei or satellites. For example, in the sentence in Figure 1 we want to identify the three *edus* *"I am optimistic"*, *said Mr. Smith*, and *as the market plunged.* and determine that the first of these functions as a nucleus at the lowest level of the tree whereas the latter two function as satellites. We do not try to determine that the first two *edus* are merged at a higher level and then function as the overall nucleus of the sentence.

The discourse chunking task assumes a non-hierarchical representation. We converted each sentence-level discourse tree into a flat chunk representation by assigning each token (i.e., word or punctuation mark) a tag encoding its nuclearity status at the *edu* level. We adopted the chunk representation proposed by Ramshaw and Marcus (1995) and used four different tags: B-NUC and B-SAT for nucleus and satellite-initial tokens, and I-NUC and I-SAT for non-initial tokens, i.e., tokens inside a nucleus and satellite span. As all tokens belong either to a nucleus or a satellite span, we do not need a special tag (typically denoted by O in syntactic chunking) to indicate elements outside a chunk. The chunk representation for the sentence in Figure 1 is thus:

"/B-NUC I/I-NUC am/I-NUC optimistic/I-NUC "/I-NUC said/B-SAT Mr./I-SAT Smith/I-SAT as/B-SAT the/I-SAT market/I-SAT plunged/I-SAT ./I-SAT

Discourse and sentence structure do not always correspond, and for 5% of sentences in the RST-DT no discourse tree exists. We excluded these from our data. We also disregarded sentences without internal structure, i.e., those which consist of only one *edu*. The RST-DT is partitioned into a training (342 articles) and test set (43 articles). We preserved this split in all our experiments. 52 articles in the RST-DT are doubly annotated. We used these to compute human agreement on the discourse chunking task (see Section 4.1).

3.2 Modelling

Using a chunk-based representation effectively renders discourse processing a sequence labelling task. Two modelling approaches are possible. The simplest model performs segmentation and labelling simultaneously. In our case this involves training a classifier that labels each token with one of our four tags (i.e., B-NUC, I-NUC, B-SAT, I-SAT). Alternatively, we could treat discourse chunking as two distinct subtasks involving two binary classifiers: a segmenter, which determines the chunk boundaries and assigns each token a chunk-initial (B) or non-chunk-initial tag (I), and a labeller, which classifies each chunk identified by the segmenter as either nucleus (NUC) or satellite (SAT).[1]

The second approach has a number of advantages. First, abstracting away from a token-based representation in the second step makes it easier to model sentence-level distributional properties of nuclei and satellites, e.g., the fact that every sentence has at least one nucleus. This can be achieved by incorporating additional features into the labeller, such as the number of chunks in the sentence or the length of the current chunk. A two-step approach also avoids the creation of illegal chunk sequences, such as "B-SAT I-NUC". However, a potential drawback is that the number of training examples for the labeller is reduced as the instances to be classified are chunks rather than tokens. We explore the performance of the one-step and the two-step methods in Sections 4.2 and 4.3, respectively.

[1]A similar approach has been proposed for syntactic chunking, e.g., Tjong Kim Sang (2000).

A variety of learning schemes can be employed for the discourse chunking task. We have experimented with Boosting (Schapire and Singer, 2000), Conditional Random Fields (Lafferty et al., 2001), and Support Vector Machines (Vapnik, 1998). Discussion of our results focuses exclusively on boosting, since it had a slight advantage over the other methods. Boosting combines many simple, moderately accurate categorisation rules into a single, highly accurate rule. We used BoosTexter's (Schapire and Singer, 2000) implementation, which combines boosting with simple decision rules. The system permits three different types of features: numeric, nominal and "text". Text-valued features can, for example, encode sequences of words or parts of speech. BoosTexter applies *n*-gram models when forming classification hypotheses for text-valued features.

3.3 Features for the Token-Based Models

While we use similar features for all our classifiers, their concrete implementation depends on whether the classifier is token-based (i.e., the one-step model and the segmenter in the two-step method) or span-based (i.e., the labeller in the two-step method). We first describe the features for the former.

Each token is represented as a feature vector encoding information about the token itself and its context. We intentionally limited our features to a basic set representing grammatical, syntactic, and lexical information.

Tokens This feature simply encodes the identity of the current token; we used raw tokens, without lemmatisation or stemming.

Part-of-Speech Tags Tokens were also annotated with parts of speech using a publicly available state-of-the-art tagger (Mikheev, 1997).

Syntactic Chunks Chunk information is a valuable cue for determining discourse segments; it is unlikely that a segment boundary occurs within a syntactic chunk. We applied a chunker (Mikheev, 1997) to our data to discover noun and verb phrase chunks. The chunker assigned one of five labels to each token, encoding the first element of a noun or verb chunk (B-NP and B-VP, respectively), a non-initial element in a chunk (I-NP and I-VP), and an element outside a chunk (O). We used these chunk labels directly as features and also encoded generalisations over chunk and boundary types (i.e., VP vs. NP and B vs. I, respectively).

Clause Information Knowing where clause boundaries lie is important for segmentation, since discourse segments often correspond to clauses. We used a rule-based algorithm (Leffa, 1998) to identify clauses from the syntactic chunker's output and recorded for every token whether it is clause-initial (S) or not (X).

Discourse Connectives Discourse connectives such as *but* often indicate which rhetorical relation holds between two spans. While we do not aim to infer the relation proper, knowing the type of relation holding between spans often helps in determining whether they should be labelled as nucleus or satellite. For example, *Contrast* relations (e.g., signalled by *but*) hold between two nuclei whereas *Cause* relations (e.g., signalled by *because*) hold between a nucleus and a satellite. Hence, we recorded the presence of discourse connectives in a sentence to capture, albeit in a shallow manner, the interdependency between rhetorical relations and nuclearity.

We used Knott's (1996) inventory of discourse connectives and encoded two types of information for each token: (a) whether the token is a connective (C) or not (X) and (b) the identity of the connective if the token is a connective (zero otherwise).[2]

Token Position For each token we calculated its relative position in the sentence (defined as the token position divided by the number of tokens). This information is useful to capture potential positional differences between nuclei and satellites, i.e., it may be that nuclei are more likely at the beginning of a sentence than at the end.

Context In addition to the nine features above, which encode information about the token itself, we also implemented 16 contextual features to encode information about its neighbouring tokens. Syntactic chunking approaches typically capture contextual information by defining a small window of a few tokens to the left and right of the current token (see Veenstra, 1998). However, we used the whole sentence as context, since BoosTexter is fairly good at determining automatically relevant *n*-grams within a longer string of tokens. We included this contextual information for all nominal features; that is, we encoded not only the string of preceding and following tokens but also the string of preceding and following part-of-speech tags, syntactic chunk labels, clause labels, and connectives. For example, we had three token features, one encoding the current token itself, and two contextual features (one encoding the string of preceding tokens, and one encoding the string of following tokens); similarly we had three part-of-speech features, nine syntactic chunk features three using the complete chunk tags, three using only the chunk type, and three using the boundary type), and so on.

[2]Some words can have syntactic as well as discourse marking functions (e.g., *but* sometimes functions as a synonym for *except* rather than as a *Contrast* marker). We do not disambiguate between these two usages.

3.4 Features for the Span-Based Model

For the labeller we encoded information about spans rather than tokens. This gave rise to six non-contextual, text-valued features: the string of tokens in the current span, their parts of speech, syntactic chunk tags, clause tags, and the presence and identity of connectives. The positional feature was redefined in terms of relative span position, i.e., the position of the current span divided by the number of spans in the sentence. We restricted contextual features to information about immediately preceding and following spans (within a sentence). We did not include information about non-adjacent spans because only a minority of sentences in our data contained more than three spans. Again, we included contextual information for all nominal features. Finally, to capture intra-sentential span-structure, we added the following features:

Span Length Span length was measured in terms of the number of tokens in it and was represented by three features: the length of the current span, and the lengths of its adjacent spans. Span length information captures differences in the average length of nuclei and satellite spans.

Number of Spans We encoded the number of spans in the sentence overall and the number of spans preceding and following the current span.

4 Experiments

In this section we describe the experiments that assess the merits of the discourse chunking framework introduced above. We also give details regarding parameter estimation and training for our models and introduce the baseline and state-of-the-art methods used for comparison with our approach.

4.1 Upper Bound

Before presenting the results of our modelling experiments, it is worth considering how well humans agree on discourse chunk segmentation and labelling in order to establish an upper bound for the task. We measured both unlabelled and labelled agreement on the 52 doubly annotated RST-DT texts. The former measures whether humans agree in placing chunk boundaries, whereas the latter additionally measures whether humans agree in assigning chunk labels. To facilitate comparison with our models we report inter-annotator agreement in terms of accuracy and F-score.[3] For the unlabelled case we also report *Window Difference* (*WDiff*), a commonly used evaluation measure for segmentation tasks (Pevzner and Hearst, 2002). It returns values between 0 (identical segmentations) and 1 (maximally different segmentations) and differs from accuracy in that predicted boundaries which are only slightly off are penalised less than those which are completely wrong.

Human agreement is relatively high[4] on both segmentation and span labelling (see Table 1), which can be explained by the fact that (i) the RST-DT annotators were given very detailed and precise instructions and (ii) assigning boundaries and labels is an easier task than creating full-scale discourse trees.

4.2 One-Step Chunking

For the one-step chunking method, our training set consists of approximately 130,000 instances (i.e., tokens). We set aside 10% as a development set for optimising BoosTexter's parameters (i.e., the number of training iterations and the maximal length of the n-grams considered for text-valued features). We then re-trained BoosTexter with the optimal setting (700 iterations, $n = 2$) and applied it to the test set, which contained around 15,500 instances.

By default, the one-step method treats every token in isolation, i.e., it assigns each token a tag without taking its neighbouring tags into account. This is not an entirely adequate model, since the likelihood of a tag is influenced by its surrounding tags. For example, the probability of a token being tagged as I-NUC should increase if the preceding token was tagged as B-NUC. One way to take information about surrounding tags into account is by stacking classifiers, i.e., adding the output of one classifier to the input of another. Stacking is frequently used in chunking tasks (e.g., Veenstra, 1998). We stack two BoosTexter classifiers, by adding the string of all preceding and following tags (within a given sentence) to each token's feature vector for the second classifier.

It would be possible to generate training material for the second classifier directly from the original training set by using the gold standard output tags in the augmented feature vector. However, we found that this leads BoosTexter to rely too much on these tags, largely ignoring other features. This causes problems when the model is applied to the test set where the class tags are predicted and may contain errors. Hence, we applied the original model (BT-1-Step) to obtain predicted output tags for the training data and then used these, rather than the gold standard tags, to train the second classifier. Similarly, during testing, we first applied BT-1-Step and used its output tags to augmented the feature vectors of the second classifier.

For comparison, we also applied two baseline models to our data. The first (BaseMaj) is obtained by always assigning the tag that is most common in the training data (I-NUC). This strategy makes no attempt at guessing span boundaries. The second (BaseClMaj) indirectly assesses the importance of clause boundary detection. It implements a strategy which assumes that span boundaries always coincide with clause boundaries. To obtain clause boundaries, we used the gold standard annotation of our data in the Penn Treebank. We then labelled all clause-initial tokens as B-NUC and all other tokens as I-NUC. Note, that the use of gold standard clause boundaries makes this a relatively high baseline. We also applied Spade[5], Soricut and Marcu's (2003) sentence-level discourse parser (see Section 2) to our test set. For evaluation purposes, Spade's output was converted to our chunk representation. It is important to note that Spade is a much more sophisticated model than the ones presented in this paper. We therefore do not expect to be able to obtain a better performance. It is nevertheless interesting to see how far one can go with a modest feature space and considerably less structural information.

Table 1 shows the results. A set of diacritics is used to indicate significance (on accuracy) throughout this paper, see Table 2. On the segmentation task (unlabelled) BT-1-Step and its stacked variant significantly outperform the majority baseline (BaseMaj) but are significantly less accurate than BaseClMaj, which uses gold standard clause boundaries. The two BoosTexter models also perform significantly worse than Spade on segmentation. However, the higher WDiff for Spade on the segmentation task suggests that the boundaries predicted by our models contain more "near misses" than those predicted by Spade. When segmentation and span labelling are taken into account (labelled), our one-step models significantly outperform both baselines but are significantly less accurate than Spade. Classifier stack-

[3]For the unlabelled case, we report the F-score on boundaries; for the labelled case, we report the average F-score over all class labels weighted by class frequency in the training set.

[4]Using the Kappa statistic agreement on segmentation is $K = .97$ and on span labelling $K = .81$.

ing leads to slight improvements over the simple BoosTexter model, but the difference is not statistically significant.

4.3 Two-Step Chunking

In the two-step model, chunking consists of two separate subtasks: segmentation and labelling. To generate training material for the segmenter, we replaced the four chunk labels in the original data set by their corresponding boundary labels (B, I). For the labeller, training instances are spans rather than tokens. We used the gold standard span boundaries to convert the original training set to a span-based representation. This new training set contained around 15,000 instances (compared to 130,000 instances in the token-based set). For both the segmenter and labeller, we set aside 10% of the material as development data to optimise BoosTexter's parameters (900 iterations, $n = 3$ for segmentation, and 600 iterations, $n = 2$ for labelling).

For testing, we first applied the segmenter to obtain discourse chunk boundaries. We then used the predicted boundaries to convert the test data into a span-based representation, which we then used as input for the labeller. For evaluation, the output of the labeller was converted back to a token-based representation. As with one-step chunking, we also implemented a stacked variant, stacking both the segmentation and the labelling models.

It can be seen in Table 1 that the two-step models outperform the one-step models. This difference is significant except for the stacked model on the labelling task (labelled). Both two-step models significantly outperform both baselines on segmentation (unlabelled) and labelling (labelled). They also significantly outperform Spade on the boundary prediction task, which is in itself an important subtask for discourse parsing. The unstacked two-step BoosTexter model performs comparably to Spade with respect to labelled accuracy; the difference between the two models is not statistically significant. Hence, we achieve results similar to Spade but with much simpler and knowledge-leaner features. As with the one-step method, the stacked model performs (insignificantly) better than its unstacked counterpart on the segmentation task. However, on the labelling task, the stacked variant performs significantly worse. We conjecture that the reduced training set size for the labeller causes the stacked model (which is effectively trained twice) to overfit. Expectedly, all models perform significantly worse than humans on both tasks.

To assess whether our discourse chunker could be ported to languages for which discourse treebanks are not yet available, we investigated how much annotated data is required to achieve satisfactory results. Assuming that annotators proceed sentence-by-sentence, we varied the amount of sentences in our training data and determined its effect on the learner's (BT-2-Step) performance. Figure 2 shows that satisfactory labelled and unlabelled performance (86.52% and 74.64% F-score, respectively) can be achieved with approximately half the training data (i.e., around 2,000 sentences). In fact, using the entire data set yields a moderate increase of 1.78% for the unlabelled task and 3.68% for the labelled task. Hence, it seems that our knowledge-lean method is suitable even for relatively small training sets. We next examine whether the two-step chunking model can be usefully employed in a practical application such as sentence compression.

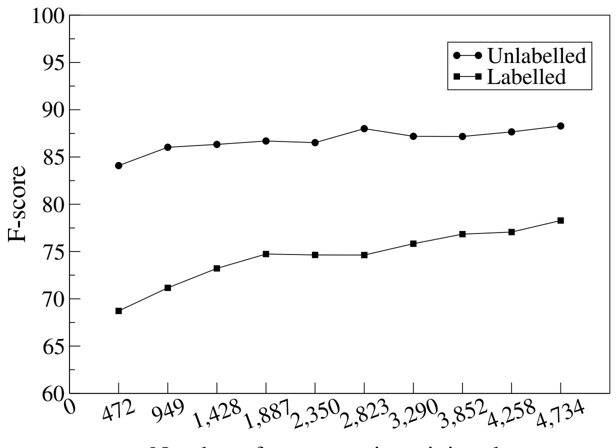

Figure 2: Learning curve for discourse segmentation (unlabelled) and span labelling (labelled)

4.4 Sentence Compression

Sentence compression can be likened to summarisation at the sentence level. The task has an immediate impact on several applications ranging from summarisation to audio scanning devices for the blind and caption generation (see Knight and Marcu, 2002 and the references therein). Previous data-driven approaches (Knight and Marcu, 2003; Riezler et al., 2003) relied on parallel corpora to determine what is important in a sentence. The models learned correspondences between long sentences and their shorter counterparts, typically employing a rich feature space induced from parse trees. The task is challenging since the compressed sentences should retain essential information and convey it grammatically.

Here, we propose a complementary approach which utilises discourse chunking. A compressed sentence can be obtained from the output of the chunker simply by removing satellites. We thus capitalise on RST's (Mann and Thompson, 1987) notion of nuclearity and the widely held assumption that spans functioning as satellites can often be deleted without disrupting coherence. To evaluate the compressions produced by our chunking model, we elicited judgements from human subjects. We describe our elicitation study and results as follows.

Data We randomly selected 40 sentences from the test portion of the RST-DT. Average sentence length was 38.75. The sentences were compressed by chunking them with our (unstacked) two-step model (BT-2-Step) and then dropping satellites. We applied the same strategy to derive compressed sentences from the output of Spade (Soricut and Marcu, 2003), and also produced human compressions. Finally, we added a simple baseline compression algorithm proposed by Jing and McKeown (2000) which removed all prepositional phrases, clauses, to-infinitives, and gerunds. Both the baseline and Spade operate on parse trees which were obtained from Charniak's (2000) parser. Our set of experimental materials contained $4 \times 40 = 160$ compressions.

Table 3: Example compressions

Compression	AvgLen	Rating
Baseline	9.70	1.93
BT-2-Step	22.06	3.21
Spade	19.09	3.10
Humans	20.07	3.83

Table 4: Mean ratings for automatic compressions

Procedure and Subjects We obtained compression ratings during an elicitation study completed by 45 unpaid volunteers, all native speaker of English. The study was conducted remotely over the Internet. Participants first saw a set of instructions that explained the task, and defined sentence compression using multiple examples. The materials consisted of the original sentences together with their compressed versions. They were randomised in lists following a Latin square design ensuring that no two compressions in a list were generated from the same sentence. As in Knight and Marcu's (2003) study, participants were asked to use a five point scale to rate the systems' compressions (taking into account the felicity of the compression as well as its grammaticality); they were told that all outputs were generated automatically. Examples of the compressions our participants saw are given in Table 3.

Results We carried out an Analysis of Variance (ANOVA) to examine the effect of different types of compressions (Baseline, BT-2-Step, Spade, and Human). Statistical tests were done using the mean of the ratings shown in Table 4. The ANOVA revealed a reliable effect of compression type by subjects ($F_1(3,90) = 149.50$, $p < 0.001$) and by items ($F_2(3;117) = 40.23$, $p < 0.001$). Post-hoc Tukey tests indicated that human compressions are perceived as significantly better than the compressions produced by the baseline, BT-2-Step, and Spade ($\alpha = 0.01$). The discourse chunker and Spade are significantly better than the baseline ($\alpha = 0.01$). The Tukey test revealed no statistically significant difference between these two algorithms ($\alpha = 0.01$). To summarise, both BoosTexter and Spade perform closer to human performance than the baseline; yet, humans perform significantly better than our compression algorithms.

5 Conclusions

In this paper we proposed discourse chunking as an alternative to full-scale parsing. Central in our approach is the use of low-level syntactic and grammatical information which we argue holds promise for the development of discourse processing models across languages and domains. We showed that a knowledge-lean feature space achieves good performance both on segmentation and span labelling. Furthermore, we assessed the application potential of our chunker and showed that it can be successfully employed to generate sentence compressions, thus confirming one of RST's main claims regarding the nuclearity of discourse spans (at least on the sentence-level).

An important future direction lies in extending our model to the document-level and the assignment of rhetorical relations, thus going beyond the basic nucleus-satellite distinction. Our results indicate that a modular approach to discourse processing (i.e., treating segmentation as separate from labelling) could increase performance. In the future, we plan to investigate how to combine our chunker with models like Spade for improved prediction on both local and global levels.

Abstract

This paper presents comparative experimental results on four techniques of language model adaptation, including a maximum *a posteriori* (MAP) method and three discriminative training methods, the boosting algorithm, the average perceptron and the minimum sample risk method, on the task of Japanese Kana-Kanji conversion. We evaluate these techniques beyond simply using the character error rate (CER): the CER results are interpreted using a metric of domain similarity between background and adaptation domains, and are further evaluated by correlating them with a novel metric for measuring the side effects of adapted models. Using these metrics, we show that the discriminative methods are superior to a MAP-based method not only in terms of achieving larger CER reduction, but also of being more robust against the similarity of background and adaptation domains, and achieve larger CER reduction with fewer side effects.

1 Introduction

Language model (LM) adaptation attempts to adjust the parameters of a LM so that it performs well on a particular (sub-)domain of data. Currently, most LMs are based on the Markov assumption that the prediction of a word depends only on the preceding *n*–1 words, but such *n*-gram statistics are known to be extremely susceptible to the characteristics of training samples. This is true even when the data sources are supposedly similar: for example, Rosenfeld (1996) showed that perplexity doubled when a LM trained on the Wall Street Journal (1987-1989) was tested on the AP newswire stories of the same period. This observation, coupled with the fact that training data is available in large quantities only in selected domains, facilitates the need for LM adaptation.

There have been two formulations of the LM adaptation problem. One is the *within-domain adaptation*, in which adapted LMs are created for different topics in a single domain (e.g., Seymore and Rosenfeld, 1997; Clarkson and Robinson, 1997; Chen et al., 1998). In these studies, a domain is defined as a body of text originating from a single source, and the main goal of LM adaptation is to fine-tune the model parameters so as to improve the LM performance on a specific sub-domain (or topic) using the training data at hand.

The other formulation, which is the focus of the current study, is to adapt a LM to a novel domain, for which only a very small amount of training data is available. This is referred to as *cross-domain adaptation*. Following Bellegarda (2001), we call the domain used to train the original model the *background* domain, and the novel domain with a small amount of training data as the *adaptation* domain. Two major approaches to cross-domain adaptation have been investigated: maximum *a posteriori* (MAP) estimation and discriminative training methods. In MAP estimation methods, adaptation data is used to adjust the parameters of the background model so as to maximize the likelihood of the adaptation data. Count merging and linear interpolation of models are the two MAP estimation methods investigated in speech recognition experiments (Iyer et al., 1997; Bacchiani and Roark, 2003), with count merging reported to slightly outperform linear interpolation.

Discriminative approaches to LM adaptation, on the other hand, aim at using the adaptation data to directly minimize the errors on the adaptation data made by the background model. These techniques have been applied successfully to the task of language modeling in non-adaptation (Roark et al.,

2004) as well as adaptation (Bacchiani et al., 2004) scenarios.

In this paper, we present comparative experimental results on four language model adaptation techniques and evaluate them from various angles, attempting to elucidate the characteristics of these models. The four models we compare are a maximum *a posteriori* (MAP) method and three discriminative training methods, namely the boosting algorithm (Collins, 2000), the average perceptron (Collins, 2002) and the minimum sample risk method (Gao et al., 2005). Our evaluation of these techniques is unique in that we go beyond simply comparing them in terms of character error rate (CER): we use a metric of distributional similarity to measure the distance between background and adaptation domains, and attempt to correlate it with the CER of each adaptation method. We also propose a novel metric for measuring the side effects of adapted models using the notion of *backward compatibility*, which is very important from a software deployment perspective.

Our experiments are conducted in the setting of Japanese Kana-Kanji conversion, as we believe this task is excellently suited for evaluating LMs. We begin with the description of this task in the following section.

2 Language Modeling in the Task of IME

This paper studies language modeling in the context of Asian language (e.g., Chinese or Japanese) text input. The standard method for doing this is that the users first input the phonetic strings, which are then converted into the appropriate word string by software. The task of automatic conversion has been the subject of language modeling research in the context of *Pinyin-to-Character conversion* in Chinese (Gao et al., 2002a) and *Kana-Kanji conversion* in Japanese (Gao et al., 2002b). In this paper, we call the task *IME* (Input Method Editor), based on the name of the commonly used Windows-based application.

The performance of IME is typically measured by the *character error rate* (CER), which is the number of characters wrongly converted from the phonetic string divided by the number of characters in the correct transcript. Current IME systems exhibit about 5-15% CER on real-world data in a wide variety of domains.

In many ways, IME is a similar task to speech recognition. The most obvious similarity is that IME can also be viewed as a Bayesian decision problem: let A be the input phonetic string (which corresponds to the acoustic signal in speech); the task of IME is to choose the most likely word string W^* among those candidates that could have been converted from A:

$$W^* = \underset{W\in\mathbf{GEN}(A)}{\arg\max} P(W \mid A) = \underset{W\in\mathbf{GEN}(A)}{\arg\max} P(W)P(A \mid W) \qquad (1)$$

where $\mathbf{GEN}(A)$ denotes the candidate set given A.

Unlike speech recognition, however, there is no acoustic ambiguity in IME, because the phonetic string is provided directly by users. Moreover, we can assume a unique mapping from W to A in IME, i.e., $P(A|W) = 1$. So the decision of Equation (1) depends solely on $P(W)$, which makes IME ideal for testing language modeling techniques. Another advantage of using IME for language modeling research is that it is relatively easy to convert W to A, which facilitates the creation of training data for discriminative learning, as described later.

From the perspective of LM adaptation, IME faces the same problem speech recognition faces: the quality of the model depends heavily on the similarity of the training and test data. This poses a serious challenge to IME, as it is currently the most widely used method of inputting Chinese or Japanese characters, used by millions of users for inputting text of *any* domain. LM adaptation in IME is therefore an imminent requirement for improving user experience, not only as we build static domain-specific LMs, but also in making online user adaptation possible in the future.

3 Discriminative Algorithms for LM Adaptation

This section describes three discriminative training methods we used in this study. For a detailed description of each algorithm, readers are referred to Collins (2000) for the boosting algorithm, Collins (2002) for perceptron learning, and Gao et al. (2005) for the minimum sample risk method.

3.1 Definition

The following set-up, adapted from Collins (2002), was used for all three discriminative training methods:

- Training data is a set of input-output pairs. In the task of IME, we have training samples $\{A_i, W_i^R\}$, for $i = 1\ldots M$, where each A_i is an input phonetic string and each W_i^R is the reference transcript of A_i.
- We assume a set of $D + 1$ features $f_d(W)$, for $d = 0\ldots D$. The features could be arbitrary functions that map W to real values. Using vector notation, we have $\mathbf{f}(W)\in\Re^{D+1}$, where $\mathbf{f}(W) = \{f_0(W), f_1(W), \ldots, f_D(W)\}$. The feature $f_0(W)$ is called the *base model* feature, and is defined as the log probability that the word trigram model assigns to W. The features $f_d(W)$ for $d = 1\ldots D$ are defined as the word n-gram counts (n = 1 and 2 in our experiments) in W.
- The parameters of the model form a vector of $D + 1$ dimensions, one for each feature function, $\boldsymbol{\lambda}= \{\lambda_0, \lambda_1, \ldots, \lambda_D\}$. The likelihood score of a word string W can then be written as

$$Score(W,\boldsymbol{\lambda}) = \boldsymbol{\lambda}\mathbf{f}(W) = \sum_{d=0}^{D}\lambda_d f_d(W)\,. \tag{2}$$

Given a model $\boldsymbol{\lambda}$ and an input A, the decision rule of Equation (1) can then be rewritten as

$$W^*(A,\boldsymbol{\lambda}) = \arg\max_{W\in\mathbf{GEN}(A)} Score(W,\boldsymbol{\lambda}). \tag{3}$$

We can obtain the number of conversion errors in W by comparing it with the reference transcript W^R using an error function $\mathrm{Er}(W^R,W)$, which is an edit distance in our case. We call the sum of error counts over the training set the *sample risk* (SR). Discriminative training methods strive to optimize the parameters of a model by minimizing SR, as in Equation (4).

$$\boldsymbol{\lambda}^* = \arg\min_{\boldsymbol{\lambda}} SR(\boldsymbol{\lambda}) = \arg\min_{\boldsymbol{\lambda}} \sum_{i=1\ldots M}\mathrm{Er}(W_i^R, W_i(A_i,\boldsymbol{\lambda})) \tag{4}$$

However, (4) cannot be optimized directly by regular gradient-based procedures as it is a piecewise constant function of $\boldsymbol{\lambda}$ and its gradient is undefined. The discriminative training methods described below differ in how they achieve the optimization: the boosting and perceptron algorithms approximate SR by loss functions that are suitable for optimization; the minimum sample risk method, on the other hand, uses a simple heuristic training procedure to minimize SR directly without resorting to an approximated loss function.

3.2 The boosting algorithm

The boosting algorithm we used is based on Collins (2000). Instead of measuring the number of conversion errors directly, it uses a loss function that measures the number of ranking errors, i.e., cases where an incorrect candidate W receives a higher score than the correct conversion W^R. The *margin* of the pair (W^R, W) with respect to the model λ is given by

$$M(W^R, W) = Score(W^R,\boldsymbol{\lambda}) - Score(W,\boldsymbol{\lambda}) \tag{5}$$

The loss function is then defined as

$$\mathrm{RLoss}(\boldsymbol{\lambda}) = \sum_{i=1\ldots M}\sum_{W_i\in\mathbf{GEN}(A_i)} I[M(W_i^R, W_i)] \tag{6}$$

where $I[\pi] = 1$ if $\pi \le 0$, and 0 otherwise. Note that RLoss takes into account all candidates in $\mathbf{GEN}(A)$.

Since optimizing (6) is NP-complete, the boosting algorithm optimizes its upper bound:

$$\mathrm{ExpLoss}(\boldsymbol{\lambda}) = \sum_{i=1\ldots M}\sum_{W_i\in\mathbf{GEN}(A_i)} \exp(-M(W_i^R, W_i)) \tag{7}$$

Figure 1 summarizes the boosting algorithm we used. After initialization, Step 2 and 3 are repeated N times; at each iteration, a feature is chosen and its weight is updated. We used the following update for the dth feature f_d:

$$\delta_d = \frac{1}{2}\log\frac{C_d^+ + \varepsilon Z}{C_d^- + \varepsilon Z} \tag{8}$$

where C_d^+ is a value increasing exponentially with the sum of margins of (W^R, W) pairs over the set where f_d is seen in W^R but not in W; C_d^- is the value related to the sum of margins over the set where f_d is seen in W but not in W^R. ε is a smoothing factor (whose value is optimized on held-out data) and Z is a normalization constant.

```
1  Set $\lambda_0 = 1$ and $\lambda_d = 0$ for $d=1\ldots D$
2  Select a feature $f_d$ which has largest estimated im-
   pact on reducing ExpLoss of Equation (7)
3  Update $\lambda_d$ by Equation (8), and return to Step 2
```

Figure 1: The boosting algorithm

3.3 The perceptron algorithm

The perceptron algorithm can be viewed as a form of incremental training procedure that optimizes a *minimum square error* (MSE) loss function, which is an approximation of SR (Mitchell, 1997). As shown in Figure 2**,** it starts with an initial parameter setting and updates it for each training sample. We used the average perceptron algorithm of Collins (2002) in our experiments, a variation that has been proven to be more effective than the standard algorithm shown in Figure 2. Let $\lambda_d^{t,i}$ be the

```
1 Set $\lambda_0$ = 1 and $\lambda_d$ = 0 for $d$=1…$D$
2 For $t$ = 1…$T$ ($T$ = the total number of iterations)
3   For each training sample ($A_i$, $W_i^R$), $i$ = 1…$M$
4     Choose the best candidate $W_i$ from GEN($A_i$)
      according to Equation (3)
5     For each $\lambda_d$ ($\eta$ = size of learning step)
6       $\lambda_d = \lambda_d + \eta(f_d(W_i^R) - f_d(W_i))$
```

Figure 2: The perceptron algorithm

value for the *d*th parameter after the *i*th training sample has been processed in pass *t* over the training data. The average parameters are defined as

$$(\lambda_d)_{avg} = (\sum_{t=1}^{T}\sum_{i=1}^{M}\lambda_d^{t,i})/(T \cdot M). \tag{9}$$

3.4 The minimum sample risk method

The minimum sample risk (MSR, Gao et al., 2005) training algorithm is motivated by analogy with the feature selection procedure for the boosting algorithm (Freund et al., 1998). It is a greedy procedure for selecting a small subset of the features that have the largest contribution in reducing SR in a sequential manner. Conceptually, MSR operates like any multidimensional function optimization approach: a direction (i.e., feature) is selected and SR is minimized along that direction using a *line search*, i.e., adjusting the parameter of the selected feature while keeping all other parameters fixed. This is repeated until SR stops decreasing.

Regular numerical line search algorithms cannot be applied directly because, as described above, the value of a feature parameter versus SR is not smooth and there are many local minima. MSR thus adopts the method proposed by Och (2003). Let **GEN**(A) be the set of n-best candidate word strings that could be converted from A. By adjusting λ_d for a selected feature f_d, we can find a set of intervals for λ_d within which a particular candidate word string is selected. We can compute *Er*(.) for the candidate and use it as the *Er*(.) value for the corresponding interval. As a result, we obtain an ordered sequence of *Er*(.) values and a corresponding sequence of λ intervals for each training sample. By summing *Er*(.) values over all training samples, we obtain a global sequence of SR and the corresponding global sequence of λ_d intervals. We can then find the optimal λ_d as well as its corresponding SR by traversing the sequence.

Figure 3 summarizes the MSR algorithm. See Gao et al. (2005) for a complete description of the MSR implementation and the empirical justification for its performance.

```
1 Set $\lambda_0$ = 1 and $\lambda_d$ = 0 for $d$=1…$D$
2 Rank all features by its expected impact on reduc-
  ing SR and select the top $N$ features
3 For each $n$ = 1…$N$
4   Update the parameter of $f$ using line search
```

Figure 3: The MSR algorithm

4 Experimental Results

4.1 Data

The data used in our experiments come from five distinct sources of text. A 36-million-word *Nikkei* newspaper corpus was used as the background domain. We used four adaptation domains: *Yomiuri* (newspaper corpus), *TuneUp* (balanced corpus containing newspaper and other sources of text), *Encarta* (encyclopedia) and *Shincho* (collection of novels). The characteristics of these domains are measured using the information theoretic notion of cross entropy, which is described in the next subsection.

For the experiment of LM adaptation, we used the training data consisting of 8,000 sentences and test data of 5,000 sentences from each adaptation domain. Another 5,000-sentence subset was used as held-out data for each domain, which was used to determine the values of tunable parameters. All the corpora used in our experiments are pre-segmented into words using a baseline lexicon consisting of 167,107 entries.

4.2 Computation of domain characteristics

Yuan et al. (2005) introduces two notions of domain characteristics: a within-domain notion of *diversity*, and a cross-domain concept of *similarity*. Diversity is measured by the entropy of the corpus and indicates the inherent variability within the domain. Similarity, on the other hand, is intended to capture the difficulty of a given adaptation task, and is measured by the cross entropy.

For the computation of these metrics, we extracted 1 million words from the training data of each domain respectively, and created a lexicon consisting of the words in our baseline lexicon plus all words in the corpora used for this experiment (resulting in 216,565 entries) to avoid the effect of out-of-vocabulary items. Given two domains *A* and

	N	Y	T	E	S
Nikkei	**3.94**	7.46	7.65	9.81	10.10
Yomiuri		**4.09**	7.82	8.96	9.29
TuneUp			**4.41**	8.82	8.56
Encarta				**4.40**	9.20
Shincho					**4.61**

Table 1: Cross entropy

Domain	Base	LI	MSR	Boost	Percep
Yomiuri	3.70	3.69	2.89	2.88	**2.85**
TuneUp	5.81	5.70	5.48	**5.47**	**5.47**
Encarta	10.24	8.64	8.39	8.54	**8.34**
Shincho	12.18	11.47	**11.05**	11.09	11.20

Table 2: CER results (%) (Base=baseline model; LI=linear interpolation)

B, we then trained a word trigram model for each domain *B*, and used the resulting model in computing the cross entropy of domain *A*. For simplicity, we denote this as *H*(*A*,*B*).

Table 1 summarizes our corpora along this dimension. Note that the cross entropy is not symmetric, i.e., H(*A*,*B*) is not necessarily the same as H(*B*,*A*), so we only present the *average cross entropy* in Table 1. We can observe that Yomiuri and TuneUp are much more *similar* to the background Nikkei corpus than Encarta and Shincho.

H(*A*,*A*) along the diagonal of Table 1 (in boldface) is the entropy of the corpus, indicating the corpus *diversity*. This quantity indeed reflects the in-domain variability of text: newspaper and encyclopedia articles are highly edited text, following style guidelines and often with repetitious content. In contrast, Shincho is a collection of novels, on which no style or content restriction is imposed. We use these metrics in the interpretation of CER results in Section 5.

4.3 Results of LM adaptation

The discriminative training procedure was carried out as follows: for each input phonetic string *A* in the adaptation training set, we produced a word lattice using the baseline trigram models described in Gao et al. (2002b). We kept the top 20 hypotheses from this lattice as the candidate conversion set **GEN**(*A*). The lowest CER hypothesis in the lattice rather than the reference transcript was used as W^R. We used unigram and bigram features that occurred more than once in the training set.

We compared the performance of discriminative methods against a MAP estimation method as the baseline, in this case the linear interpolation method. Specifically, we created a word trigram model using the adaptation data for each domain, which was then linearly interpolated at the word level with the baseline model. The probability according to the combined model is given by

$$p(w_i \mid h) = \lambda P_B(w_i \mid h) + (1-\lambda) P_A(w_i \mid h) ,$$

where P_B is the probability of the background model, P_A the probability of the adaptation model, and the history *h* corresponds to two preceding words. λ was tuned using the held-out data.

In evaluating both MAP estimation and discriminative models, we used an *N*-best rescoring approach. That is, we created *N* best hypotheses using the baseline trigram model (*N*=100 in our experiments) for each sentence in the test data, and used adapted models to rescore the *N*-best list. The oracle CERs (i.e., the minimal possible CER given the available hypotheses) ranged from 1.45% to 5.09% depending on the adaptation domain.

The results of the experiments are shown in Table 2. We can make some observations from the table. First, all discriminative methods significantly outperform the linear interpolation (statistically significant according to the *t*-test at $p < 0.01$). In contrast, the differences among three discriminative methods are very subtle and most of them are not statistically significant. Secondly, the CER results correlate well with the metric of domain similarity in Table 1 (*r*=0.94 using the Pearson product moment correlation coefficient). This is consistent with our intuition that the closer the adaptation domain is to the background domain, the easier the adaptation task.

Regarding the similarity of the adaptation domain to the background, we also observe that the CER reduction of the linear interpolation model is particularly limited when the adaptation domain is similar to the background domain: the CER reduction of the linear interpolation model for Yomiuri and TuneUp over the baseline is 0% and 1.89% respectively, in contrast to ~22% and ~5.8% improvements achieved by the discriminative models. The discriminative methods are therefore more robust against the similarity of the adaptation and background data than the linear interpolation.

Our results differ from Bacchiani et al. (2004) in that in our system, the perceptron algorithm alone achieved better results than MAP estimation. However, the difference may only be apparent, given different experimental settings for the two studies. We used the *N*-best reranking approach with the same *N*-best list for both MAP estimation and discriminative training, while in Bacchiani et al. (2004), two different lattices were used: the perceptron model was applied to rerank the lattice created by the background model, while the MAP adaptation model was used to produce the lattice itself. The fact that the combination of these models (i.e., first use the MAP estimation to create hypotheses and then use the perceptron algorithm to rerank them) produced the best results indicates that given a candidate lattice, the perceptron algorithm is effective in candidate reranking, thus making our results compatible with theirs.

5 Discussion

The results in Section 4 demonstrate that discriminative training methods for adaptation are overall superior to MAP adaptation methods. In this section, we show additional advantages of discriminative methods beyond simple CER improvements.

5.1 Using metrics for side effects

In the actual deployment of LM adaptation, one issue that bears particular importance is the number of side effects that are introduced by an adapted model. For example, consider an adapted model which achieves 10% CER improvements over the baseline. Such a model can be obtained by improving 10%, or by improving 20% *and* by introducing 10% of new errors. Clearly, the former model is preferred, particularly if the models before and after adaptation are both to be exposed to users. This concept is more widely acknowledged within the software industry as *backward compatibility* – a requirement that an updated version of software supports all features of its earlier versions. In IME, it means that all phonetic strings that can be converted correctly by the earlier versions of the system should also be converted correctly by the new system as much as possible. Users are typically more intolerant to seeing errors on the strings that used to be converted correctly than seeing errors that also existed in the previous version. Therefore, it is crucial that when we adapt to a new domain, we do so by introducing the smallest number of side effects, particularly in the case of an incremental adaptation to the domain of a particular *user*, i.e., to building a model with incremental learning capabilities.

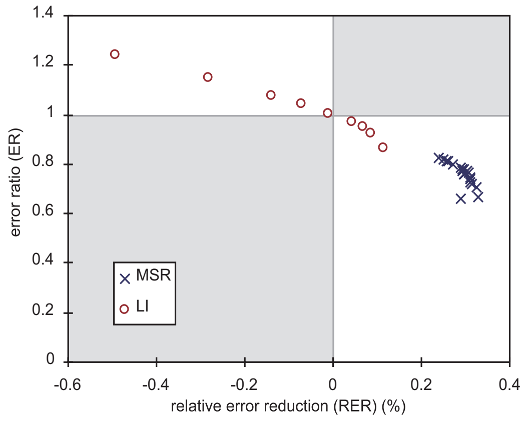

Figure 4: RER/ER plot for MSR and LI models for TuneUp domain

5.2 Error ratio

In order to measure side effects, we introduce the notion of *error ratio* (ER), which is defined as

$$ER = \frac{|E_A|}{|E_B|},$$

where $|E_A|$ is the number of errors found *only* in the new (adaptation) model, and $|E_B|$ the number of errors corrected by the new model. Intuitively, this quantity captures the *cost* of improvement in the adaptation model, corresponding to the number of newly introduced errors per each improvement. The smaller the ratio is, the better the model is at the same CER: ER=0 if the adapted model introduces no new errors, ER<1 if the adapted model makes CER improvements, ER=1 if the CER improvement is zero (i.e., the adapted model makes as many new mistakes as it corrects old mistakes), and ER>1 when the adapted model has worse CER performance than the baseline model.

Given the notion of CER and ER, a model can be plotted on a graph as in Figure 4: the *relative error reduction* (RER, i.e., the CER difference between the background and adapted models) is plotted along the x-axis, and ER along the y-axis. Figure 4 plots the models obtained after various numbers of iterations for MSR training and at various interpolation weights for linear interpolation for the TuneUp domain. The points in the upper-left quadrant, ER>1 and RER<0, are the models that performed worse than the baseline model (some of the interpolated models fall into this category); the shaded areas (upper-right and lower-left quadrants) are by definition empty. The lower-right quadrant is the area of interest to us, as they

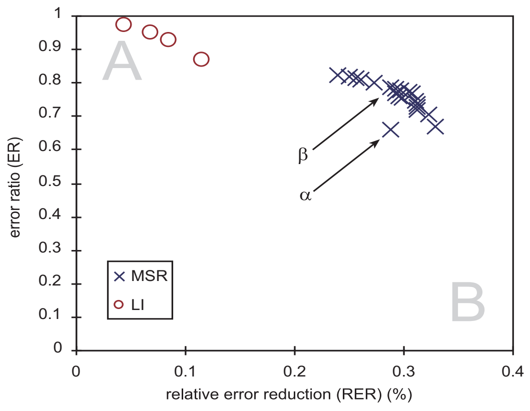

Figure 5: RER/ER plot for the models with ER<1 and RER>0 for TuneUp domain. See Figure 8 for the description of *α* and *β*

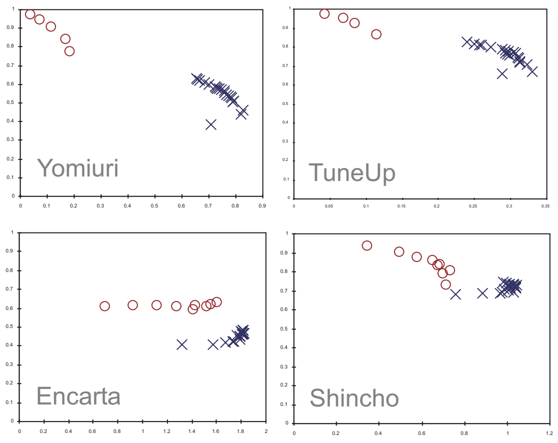

Figure 6: RER/ER plot for all four domains
x-axes: RER (%); y-axes: ER
○: linear interpolation models; ×:MSR models

represent the models that led to CER improvements; we will focus only on this area now in Figure 5.

In this figure, a model is considered to have fewer side effects when the ER is smaller at the same RER (i.e., smaller value of *y* for a fixed value of *x*), or when the RER is larger at the same ER (i.e., larger value of *x* at the fixed *y*). That is, the closer a model is plotted to the corner B of the graph, the better the model is; the closer it is to the corner A, the worse the model is.

5.3 Model comparison using RER/ER

From Figure 5, we can clearly see that MSR models have better RER/ER-performance than linear interpolation models, as they are plotted closer to the corner B. Figure 6 displays the same plot for all four domains: the same trend is clear from all graphs. We can therefore conclude that a discriminative method (in this case MSR) is superior to linear interpolation not only in terms of CER reduction, but also of having fewer side effects. This desirable result is attributed to the nature of discriminative training, which works specifically to adjust feature weights so as to minimize error.

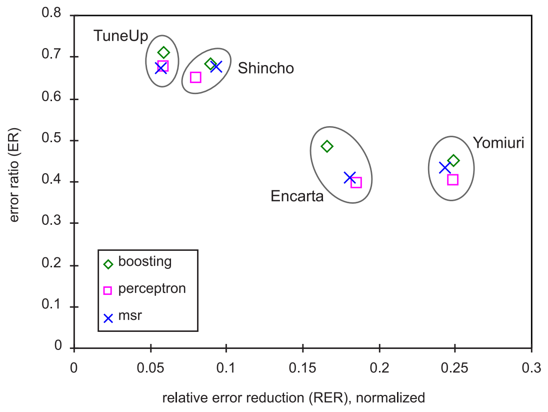

Figure 7: RER/ER plot for MSR, boosting and perceptron models (X-axis is normalized to represent relative error *rate* reduction)

Figure 7 compares the three discriminative models with respect to RER/ER by plotting the best models (i.e., models used to produce the results in Table 1) for each algorithm. We can see that even though the boosting and perceptron algorithms have the same CER for Yomiuri and TuneUp from Table 2, the perceptron is better in terms of ER; this may be due to the use of exponential loss function in the boosting algorithm which is less robust against noisy data (Hastie et al., 2001). We also observe that Yomiuri and Encarta do better in terms of side effects than TuneUp and Shincho for all algorithms, which can be explained by corpus diversity, as the former set is less stylistically diverse and thus more consistent within the domain.

5.4 Overfitting and side effects

The RER/ER graph also casts the problem of *overfitting* in an interesting perspective. Figure 8 is derived from running MSR on the TuneUp test corpus, which depicts a typical case of overfitting: the CER drops in the beginning, but after a certain number of iterations, it goes up again. The models indicated by *α* and *β* in the graph are of the same CER, and as such, these models are equivalent. When plotted on the RER/ER graph in Figure 5,

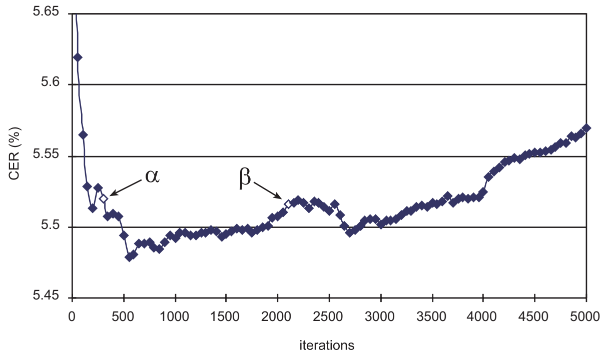

Figure 8: MSR test error curve for TuneUp

however, it is clear that the overfit model β has the worse ER than the non-overfit counterpart α. In other words, models α and β have the same CER, but they are not equivalent: model β is not only worse in light of containing more features, but also in terms of causing more side effects.

6 Conclusion and Future Work

We have presented a comparison of three discriminative learning approaches with a MAP estimation method in the task of LM adaptation for IME. We have shown that all discriminative models are significantly better than the linear interpolation method, in that they achieve larger CER reduction with fewer side effects across different domains.

One direction of future research is to apply this technique to an incremental learning scenario, i.e., to incrementally build models using incoming data for adaptation, taking all previously available data as background corpus. The new metric for backward compatibility we proposed in the paper will play a particularly important role in such a scenario.

PP-attachment disambiguation using large context

Marian Olteanu and Dan Moldovan

Abstract

Prepositional Phrase-attachment is a common source of ambiguity in natural language. The previous approaches use limited information to solve the ambiguity – four lexical heads – although humans disambiguate much better when the full sentence is available. We propose to solve the PP-attachment ambiguity with a Support Vector Machines learning model that uses complex syntactic and semantic features as well as unsupervised information obtained from the World Wide Web. The system was tested on several datasets obtaining an accuracy of 93.62% on a Penn Treebank-II dataset; 91.79% on a FrameNet dataset when no manually-annotated semantic information is provided and 92.85% when semantic information is provided.

1 Problem description

1.1 PP-attachment ambiguity problem

Prepositional Phrase-attachment is a source of ambiguity in natural language that generates a significant number of errors in syntactic parsing. For example the sentence "I saw yesterday the man in the park with a telescope" has 5 different semantic interpretations based on the way the prepositional phrases "in the park" and "with the telescope" are attached: *I saw yesterday [the man [in the park [with a telescope]]]*; *I saw yesterday [the man [in the park] [with a telescope]]*; *I saw yesterday [the man [in the park]] [with a telescope]*; *I saw yesterday [the man] [in the park [with a telescope]]* and *I saw yesterday [the man] [in the park] [with a telescope].*

The problem can be viewed as a decision of attaching a prepositional phrase (PP) to one of the preceding head nouns or verbs. The ambiguity expressed by the number of potential parse trees generated by Context-Free Grammars increases exponentially with the number of PPs. For a PP that follows the object of a verb there are 2 parse trees, for a chain of 2, 3, 4 and 5 PPs there are respectively 5, 14, 42 and 132 parse trees. Usually the average number of consecutive PPs in a sentence increases linearly with the length of the sentence.

Lexical and syntactic information alone is not sufficient to resolve the PP-attachment problem; often semantic and/or contextual information is necessary. For example, in *"I ate a pizza with anchovies"*, *"with anchovies"* attaches to the noun "pizza", where as in *"I ate a pizza with friends."*, *"with friends"* attaches to the verb "eat" – example found in (McLauchlan, 2001). There are instances of PP-attachment, like the one in *"I saw the car in the picture"* that can be disambiguated only by using contextual discourse information.

Usually, people don't have much trouble in finding the right way to attach PPs. But if one limits the information used for disambiguation of the PP-attachment to include only the verb, the noun representing its object, the preposition and the main noun in the PP, the accuracy for human decision degrades from 93.2% to 88.2% (Ratnaparkhi et al., 1994) on a dataset extracted from Penn Treebank (Marcus et al., 1993).

1.2 Motivation

Syntactic parsing is essential for many natural language applications such as Machine Translation, Question Answering, Information Extraction, Information Retrieval, Automatic Speech Recognition. Since parsing occurs early in the chain of NLP processing steps it has a large impact on the overall system performance.

2 Approach

Our approach to solve the PP-attachment ambiguity is based on a Support Vector Machines learner (Cortes and Vapnik, 1995). The feature set contains complex information extracted automatically from candidate syntax trees generated by parsing (Charniak, 2000), trees that will be improved by more accurate PP-attachment decisions. Some of these features were proven efficient for semantic information labeling (Gildea and Jurafsky, 2002). The feature set also includes unsupervised information obtained from a very large corpus (World Wide Web). Features containing manually annotated semantic information about the verb and about the objects of the verb have also been used. We adopted the standard approach to distinguish between verb and noun attachment; thus the classifier has to choose between two classes: V when the prepositional phrase is attached to the verb and N when the prepositional phrase is attached to the preceding head noun.

3 Data

To be able to extract the required features from a dataset instance, one must identify the verb, the phrase identifying the object of the verb that precedes the prepositional phrase in question ($np1$) which usually is part of the predicate-argument structure of the verb, its head noun, the prepositional phrase ($np2$), its preposition and its head noun (the second most important word in the PP).

We have adopted the notation from (Collins and Brooks, 1995), where v is the verb, n_1 is the head noun of object phrase, p is the preposition and n_2 is the head noun of the prepositional phrase.

Compared to our datasets, Ratnaparkhi's dataset (Ratnaparkhi et al., 1994) contains only the lexical heads v, n_1, p and n_2. Thus, our methodology cannot be applied to Ratnaparkhi's dataset (RRR).

In our experiments we used two datasets:

- **FN** – extracted from FrameNet II 1.1 (Baker et al., 1998)
- **TB2** – extracted from Penn Treebank-II

Table 1 presents the datasets[1]. The creation of the datasets is described in details in (Olteanu, 2004).

4 Features

The experiments described in this paper use a set of discrete (alphanumeric) and continuous (numeric) features. All features are fully deterministic, except the features **count-ratio** and **pp-count** that are based on information provided by an external resource - Google search engine (`http://www.google.com`).

In describing the features, we will use the Penn Treebank-II parse tree associated with the sentence *"The Lorillard spokeswoman said asbestos was used in "very modest amounts" in making paper for the filters in the early 1950s and replaced with a different type of filter in 1956"*.

Table 2 describes the features and the origin of each feature. The preposition is the feature with the most discriminative power, because of preferences of particular prepositions to attach to verbs or nouns. Table 3 shows the distribution of top 10 most frequently used prepositions in the FN and TB2 datasets.

The features were carefully designed so that, when they are extracted from gold parse trees, they don't provide more information useful for disambiguation than when they are automatically generated using a parser. This claim is validated by the experimental results that show a strong correlation between the results on the two datasets – one based on automatically generated parse trees (FN) and one based on gold parse trees (TB2).

Next, we describe in further detail the features presented in Table 2.

v-frame represents the *frame of the verb* – the frame to which the verb belongs, as it is present in FrameNet (manually annotated). We used this feature because the frame of the verb describes very well the semantic behavior of the verb including the predicate-argument structure of the verb, which entails the affinity of the verb for certain prepositions.

[1]The datasets are available at `http://www.utdallas.edu/~mgo031000/ppa/`

	FN	**TB2**
Source	FrameNet annotation samples (British National Corpus)	Penn Treebank-II (WSJ articles)
Instance identification	Semantic-centered (related to Frame Elements)	Syntactic-centered (related to the structure of the parse tree)
Parse trees	Automatically generated (Charniak)	Gold standard
Total size	27,421 instances	60,699 instances
Distribution statistics	70.28% ambiguous verb attachments 2.36:1 v-attch:n-attch	35.71% ambiguous verb attachments 1:1.8 v-attch:n-attch
Training / test sets	90% - 10% – homogenously distributed (one in every 10 instances is selected for the test set)	
Location of PP	Both before and after verb	Only after verb
Other properties	– Partial identification of ambiguous PP-attachment instances in the corpus, derived from manual annotation of FEs (Olteanu, 2004) – Semantic information readily available	

Table 1: The datasets and their characteristics

Feature: description *[origin]*
v-surface: surface form of the verb *[Hindle'93, ...]*
n1-surface: surface form of n_1. May be morphologically processed *[Hindle'93, ...]*
p: the preposition, lower-cased *[Hindle'93, ...]*
n2-surface: surface form of n_2. May be morphologically processed *[Ratnaparkhi'94, Collins'95, ...]*
n1-mp/n1-mpf: morph. processing of n_1 *[Collins'95]*
n2-mp/n2-mpf: morph. processing of n_2 *[Collins'95]*
v-lemma: lemma of the verb *[Collins'95]*
path: path in the candidate parse tree between the verb and *np1* *[Gildea'02]*
subcategorization: subcategorization of the verb *[modified from Pradhan'03]*
v-pos: part-of-speech of the verb
v-voice: voice of the verb
n1-pos: part-of-speech of n_1
n1-lemma: lemma of n_1. May be morphologically processed
n2-pos: part-of-speech of n_2
n2-lemma: lemma of n_2. May be morphologically processed
position: position of *np1* relative to the verb *[new]*
v-frame: frame of the verb *[new in PPA]*
n1-sr: semantic role of *np1* *[new in PPA]*
n1-tr: thematic role of *np1* *[new in PPA]*
n1-preposition: preposition that heads *np1*, if *np1* is a PP *[new]*
n1-parent: label of the parent of *np1* in the candidate parse tree *[new in PPA]*
n1-np-label: label of *np1* in the candidate parse tree *[new in PPA]*
n2-det: determination of *np2* *[new]*
parser-vote: choice of the automatic parser in attaching PP *[new in PPA]*
count-ratio: WWW statistics about verb-attachment vs. noun-attachment for that particular instance *[new]*
pp-count: WWW statistics about co-occurrence of *v* and n_2 *[new]*
n1-p-distance: the distance between n_1 and *p* *[new]*

Table 2: Features

Prep.	**% of FN**	**% v-att FN**	**% of TB2**	**% v-att TB2**
of	13.47%	6.17%	30.14%	2.74%
to	13.27%	80.14%	9.55%	60.49%
in	12.42%	73.64%	16.94%	42.58%
for	6.87%	82.44%	8.95%	39.72%
on	6.21%	75.51%	5.16%	47.73%
with	6.17%	86.30%	3.79%	46.92%
from	5.37%	75.90%	5.76%	52.76%

by	3.53%	88.02%	3.27%	68.11%

Table 3: Distribution of the first 10 most-frequent prepositions in the FN and TB2 datasets

n1-sr represents the *semantic role of the object phrase np1* – the label attached to the Frame Element (manual semantic annotation that can be found in FrameNet). This feature was introduced because of the relation between the underlying meaning of *np1* and its semantic role.

n1-tr represents the *thematic role of the object phrase np1* – a coarse-grained role based on the label attached to the Frame Element (manual semantic annotation that can be found in FrameNet). It was introduced to reduce data sparseness for the **n1-sr** feature. The conversion from fine-grained semantic role to coarse-grained semantic role is done automatically using a table that maps a pair of a frame-level semantic role (FE label) and a frame to a thematic role.

subcategorization contains a semi-lexicalized description of the structure of the verb phrase. A subcategorization frame is closely related to the predicate argument structure and to the underlying meaning of the verb. It contains an ordered set of all the phrase labels that are siblings of the verb, plus a marker for the verb. If the child phrase of the verb is a PP, then the label will also contain the preposition (the headword of the PP). This feature is a modified form of the sub-categorization feature described in (Pradhan et al., 2003): the differences in various part-of-speeches for the verb were ignored and the preposition that heads a prepositional phrase is also attached to the label. Therefore, for the sentence "*The stock declined in June by 4%*", the value for this feature is **-PPin-PPby*.

In the TB2 dataset the parse trees are gold standard (contain the expected output value for PP-ambiguity resolution). In the case of a verb attachment, if the selected PP is a child of the selected VP, then by applying the algorithm, the value of the feature will contain the PP label plus the preposition. This clearly is a clue for the learner that the instance is a *verb attachment*. To overcome this problem for datasets based on gold-standard parse trees, when computing the value of the **subcategorization** feature the selected PP will not be used. Figure 1 shows the subcategorization for the phrase *"replaced with a different type of filter in 1956"*.

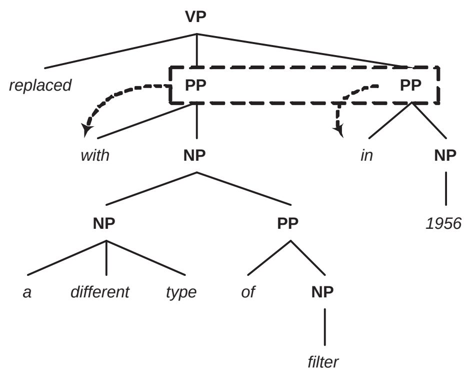

Figure 1: Subcategorization feature: **-PPin-PPby*

path expresses the syntactic relation between the verb v and the object phrase *np1*. Its purpose is to describe the syntactic relation of np1 to the rest of the clause by the syntactic relation of *np1* with the head of the clause – v. We adopted this feature from (Gildea and Jurafsky, 2002). **path** describes the chain of labels in the tree from v to *np1*, including the label of v and *np1*. Ascending movements and descending movements are depicted separately. We used two variants of this feature to determine the optimum version for our problem – one with full POS of the verb and one with POS reduced to "VB". The experiments proved that the second variant provides a better performance. Figure 2 depicts the path between "replaced" and "a different type of filter": VBN↑VP↓PP↓NP or VB↑VP↓PP↓NP.

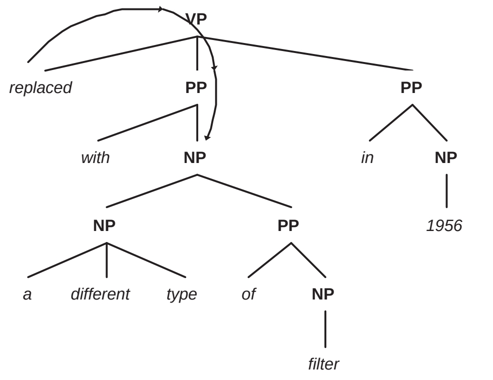

Figure 2: Example of a path feature

position indicates the *position of the n_1-p-n_2 construction relative to the verb*, i.e. whether the prepositional phrase in question lies before the verb or after the verb in the sentence. Position is very important in deciding the type of attachment, considering the totally different distribution of PPs constructions preceding the verb and PPs constructions following the verb.

Morphological processing applied to n_1 and n_2 was inspired by the algorithm described in (Collins and Brooks, 1995). We analyzed the impact of different levels of morphological processing by using two types: partial morphological processing (only numbers and years are converted) – identified by adding **-mp** as a suffix to the name of this feature – and full morphological processing (numbers, years and capitalized names) – identified by adding **-mpf** as a suffix to the name of this feature. The purpose of morphological processing is data sparseness reduction by clustering similar values for this feature.

n1-parent represents the phrase label of the parent of np1 and it cannot be used on gold parse trees (TB2 dataset) because it will provide a clue about the correct attachment type.

n2-det is called the *determination of the prepositional phrase np2*. This novel feature tells if n_2 is preceded in *np2* by a possessive pronoun or by a determiner. This is used to differentiate between *"buy books for children"* (which is probably a noun attachment) and *"buy books for her children"* (which very probably is a verb attachment).

parser-vote feature represents the choice of the parser (Charniak's parser) in the PP-attachment resolution. It cannot be used with gold-standard parse trees because it will provide the right answer.

count-ratio represents the estimated ratio between the frequency of an unambiguous verb attachment construction based on v, p and n_2 and the frequency of a probably unambiguous noun attachment construction based on n_1, p and n_2 in a very large corpus. A very large corpus is required to overcome the data sparseness inherent for complex constructions like those described above.

We chose the World Wide Web as a corpus and Google as a query interface (see (Olteanu, 2004) for details).

Let's consider the estimated frequency of unambiguous verb-attachments and respectively noun-attachments defined as:

$$f_v = \frac{c_{v-p-n2}}{c_v \cdot c_{p-n2}}$$

$$f_n = \frac{c_{n1-p-n2}}{c_{n1} \cdot c_{p-n2}}$$

where:

- c_{v-p-n2} is the number of occurrences of the phrase "v p n_2", "v $p{*}n_2$" (where * symbolizes any word), "*v-lemma p* n_2" or "*v-lemma p * n_2*" in World Wide Web, as reported by Google
- c_v is the number of occurrences of the word "v" or "*v-lemma*" in WWW
- c_{p-n2} is the number of occurrences of the phrase "p n_2" or "$p * n_2$" in WWW
- $c_{n1-p-n2}$ is the number of occurrences of the phrase "n_1 p n_2" or "v $p * n_2$" in WWW
- c_{n1} is the number of occurrences of the word "n_1" in WWW

The value for this feature is:

$$\mathbf{count-ratio} = \log_{10} \frac{f_v}{f_n} = \log_{10} \frac{c_{v-p-n2} \cdot c_{n1}}{c_{n1-p-n2} \cdot c_v}$$

We chose logarithmic values for this feature because experiments showed that logarithmic values provide a higher accuracy than linear values. Also, by experimentation we concluded that value bounding is helpful, and the feature was bounded to values between -3 and 3 on the logarithmic scale, unless specified otherwise in the experiment description.

This feature resembles the approach adopted in (Volk, 2001).

pp-count depicts the estimated count of occurrences in World Wide Web of the prepositional phrases based on p and n_2. The count is estimated by c_{p-n2}. Therefore **pp-count** = $log_{10}(c_{p-n2} + c_{p-*-n2})$.

n1-p-distance depicts the distance (in tokens) between n_1 and p. Let d_{n1-p} be the distance between n_1 and p ($d = 1$ if there is no other token between n_1 and p). Thus **n1-p-distance** = $\log_{10}(1 + \log_{10} d_{n1-p})$.

5 Learning model and procedure

We used in our experiments a Support Vector Machines learner with Radial Basis Function kernel as implemented in the LIBSVM toolkit (`http://www.csie.ntu.edu.tw/~cjlin/libsvm/`).

We converted the feature tuples (containing discrete alphanumeric and continuous values) to multi-dimensional vectors using the following procedure:

- Discrete features: assign to each possible value of each feature a dimension in the vector space, and to each feature value in each training or test example put 1 in the dimension corresponding to the feature value and 0 in all other dimensions associated with that feature.
- Continuous features: assign a dimension and put the scaled value in the multi-dimensional vector (all examples in training data will span between 0 and 1 for that particular dimension).

SVM training was preceded by finding the optimal γ and C parameters required for training using 2-fold cross validation, which was found to be superior in model accuracy and training time over higher folds cross-validations (Olteanu, 2004).

The criterion for selecting the best set of features was the accuracy on the cross-validation. Thus, the development of the models was performed entirely on the training set, which acted also as a development set. We later computed the accuracy on the test set on some representative models.

6 Experiments, results and analysis

For each dataset, we conducted experiments to determine an efficient combination of features and the accuracy on test data for the best combination of features. We also run the experimental procedure on the original Ratnaparkhi's dataset in order to compare SVM with other machine learning techniques applied to PP-attachment problem. Table 4 summarizes the experiments performed on all datasets.

Experiment	% on dev / x-val	% on test
FN-basic-flw	86.25	86.44
FN-lex-syn-flw	88.55	89.61
FN-best-no-sem	90.93	91.79
FN-best-sem	91.87	92.85
TB2-basic	85.75	87.47
TB2-best-no-www	92.06	92.81
TB2-best	92.92	93.62
RRR-basic	84.32	84.60
RRR-basic-mpf	84.34	85.14

Table 4: Results

FN-basic-flw uses **v-surface**, **n1-surface**, **p** and **n2-surface** on examples that follow the verb. *FN-lex-syn-flw* uses **v-surface**, **v-pos**, **v-lemma**, **subcategorization**, **path** (full POS), **position**, **n1-preposition**, **n1-surface**, **n1-pos**, **n1-lemma**, **n1-parent**, **p**, **n2-surface**, **n2-pos**, **n2-lemma**, **n2-det** and **parser-vote** on examples that follow the verb. *FN-best-no-sem* uses **v-surface**, **v-pos**, **v-lemma**, **subcategorization**, **path** (reduced POS), **position**, **n1-preposition**, **n1-surface**, **n1-pos**, **n1-lemma-mpf**, **n1-parent**, **p**, **n2-surface**, **n2-pos**, **n2-lemma-mpf**, **n2-det**, **parser-vote**, **count-ratio** and **pp-count** on all examples. *FN-best-sem* uses the same set of features as *FN-best-no-sem* plus **v-frame** and **n1-sr**.

TB2-basic uses **v-surface**, **n1-surface-mpf**, **p** and **n2-surface-mpf**. *TB2-best-no-www* uses **v-surface**, **v-pos**, **v-lemma**, **subcategorization**, **path** (reduced POS), **n1-preposition**, **n1-surface**, **n1-mpf**, **n1-pos**, **n1-lemma**, **n1-np-label**, **p**, **n2-surface**, **n2-mpf** and **n1-p-distance**. *TB2-best* also uses **count-ratio** and **pp-count**.

RRR-basic uses **v-surface**, **n1-surface**, **p** and **n2-surface**. *RRR-basic-mpf* uses **v-surface**, **n1-surface-mpf**, **p** and **n2-surface-mpf**.

On the FN dataset, all features except **v-voice** have a positive contribution to the system (**n2-det**, choice between semantic vs. thematic role and how should morphological processing be applied is questionable). The negative impact for the **v-voice** feature may be explained by the fact that the only situation in which it may potentially help is extremely rare: passive voice and the agent headed by *"by"* appears after another argument of the verb (i.e.: *"The painting was presented to the audience by its author."*). Moreover the PP-attachment based on the preposition *"by"* is not highly ambiguous; as seen in Table 3 in the FrameNet dataset, 88% of the *"by"* ambiguity instances are verb-attachments.

The experiment with the highest cross-validation accuracy has an accuracy of 92.85% on the test data. The equivalent experiment that doesn't include manually annotated semantic information has an accuracy of 91.79% on the test data.

On TB2 dataset, the results are close to the results obtained on the FrameNet corpus, although the distribution of noun and verb attachment differs considerably between the two data sets (70.28% are verb-attachments in FN2 and 35.71% in TB2). The best accuracy in cross-validation is 92.92%, which leads to an accuracy on test set of 93.62%.

7 Comparison with previous work

Because we couldn't use the standard dataset used in PP-attachment resolution (Ratnaparkhi's), we implemented back-off algorithm developed by Collins and Brooks (1995) and applied it to our TB2 dataset. Both RRR and TB2 datasets are extracted from Penn Treebank. This algorithm, trained on TB2 training set, obtains an accuracy on TB2 test set of 86.1% (85.8% when no morphological processing is applied). The same algorithm provides an accuracy on RRR dataset of 84.5% (84.1% without morphological processing). The difference in accuracy between the two datasets is 1.6% (1.7% without morphological processing when using Collins and Brooks's algorithm.

The difference in accuracy between a SVM model applied to RRR dataset (*RRR-basic* experiment) and the same experiment applied to TB2 dataset (*TB2-*

Table 5: Accuracy of PP-attachment ambiguity resolution (our results in bold)

basic experiment) is 2.9%. Also, the baseline – the most probable PP type for each preposition – is approximately the same for the two datasets (72.19% on RRR and 72.30% on TB2).

One may hypothesize that the majority of the algorithms for PP-attachment disambiguation obtain no more than 4% increase in accuracy on the TB2 compared to the results on the RRR dataset. One important difference between the two datasets is the size – 20,801 training examples in RRR vs. 54,629 training examples in TB2. We plan to implement more algorithms described in literature in order to verify this statement.

Table 5 summarizes the results in PP-attachment ambiguity resolution found in literature along with our best results.

Other acronyms used in this table:

- AP – dataset of 13 million word sample of Associated Press news stories from 1999 (Hindle and Rooth, 1993).
- LexSpace - Lexical Space – a method to measure the similarity of the words (Zavrel et al., 1997).
- LSA – Latent Semantic Analysis – measure the lexical preferences between a preposition and a noun or a verb (McLauchlan, 2001)
- DWS – Distributional Word Similarity. Words that tend to appear in the same contexts tend to have similar meanings (Zhao and Lin, 2004)
- PR-WWW – the probability ratio between verb-preposition-noun and noun-preposition-noun constructs measured using World Wide Web searching.

8 Conclusions

The Penn Treebank-II results indicate that the new features used for the disambiguation of PP-attachment provide a very substantial improvement in accuracy over the base line (from 87.48% to 93.62%). This represents an absolute improvement of approximately 6.14%, equivalent to a 49% error drop. The performance of the system on Penn Treebank-II exceeds the reported human expert performance on Penn Treebank-I (Ratnaparkhi et al., 1994) by about 0.4%. A significant improvement comes from the unsupervised information collected from a very large corpus; this method proved to be efficient to overcome the data sparseness problem.

By analyzing the results from the FrameNet dataset, we conclude that the contribution of the gold semantic features (frame and semantic role) is significant (1.05% difference in accuracy; 12.8% reduction in the error). We will further investigate this issue by replacing gold semantic information with automatically detected semantic information. Our additional lexico-syntactic features increase the accuracy of the system from 86.44% to 89.61% for PPs following the verb. This suggests that on the FrameNet dataset the proposed syntactic features have a considerable impact on the accuracy.

The best TB2 feature set is approximately the same as the best FN feature set in spite of the differences between the datasets (Parse trees: TB2 – gold standard; FN – automatically generated. PP-attachment ambiguity identification: TB2 – parse trees; FN – a combination of trees and FE annotation. Data source: TB2 – WSJ articles; FN – BNC). This fact suggests that the selected feature sets do not exploit particularities of the datasets and that the features are relevant to the PP-attachment ambiguity problem.

Johns Hopkins University, Baltimore, MD 21218 USA
{jason,goldlust,nasmith}@cs.jhu.edu

Abstract

Weighted deduction with aggregation is a powerful theoretical formalism that encompasses many NLP algorithms. This paper proposes a declarative specification language, Dyna; gives general *agenda-based* algorithms for computing weights and gradients; briefly discusses Dyna-to-Dyna program transformations; and shows that a first implementation of a Dyna-to-C++ compiler produces code that is efficient enough for real NLP research, though still several times slower than hand-crafted code.

1 Introduction

In this paper, we generalize some modern probabilistic parsing techniques to a broader class of weighted deductive algorithms. Our implemented system encapsulates these implementation techniques behind a clean interface—a small high-level specification language, Dyna, which compiles into C++ classes. This system should help the HLT community to experiment more easily with new models and algorithms.

1.1 Dynamic programming as deduction

The "parsing as deduction" framework (Pereira and Warren, 1983) is now over 20 years old. It provides an elegant notation for specifying a variety of parsing algorithms (Shieber et al., 1995), including algorithms for probabilistic or other semiring-weighted parsing (Goodman, 1999). In the parsing community, new algorithms are often stated simply as a set of deductive inference rules (Sikkel, 1997; Eisner and Satta, 1999).

It is also straightforward to specify other NLP algorithms this way. Syntactic MT models, language models, and stack decoders can be easily described using deductive rules. So can operations on finite-state and infinite-state machines.

[*]We thank Joshua Goodman, David McAllester, and Paul Ruhlen for useful early discussions; pioneer users Markus Dreyer, David Smith, and Roy Tromble for their feedback and input; John Blatz for discussion of program transformations; and several reviewers for useful criticism. This work was supported by NSF ITR grant IIS-0313193, ONR MURI grant N00014-01-1-0685, and a Hertz Foundation fellowship to the third author. The views expressed are not necessarily endorsed by the sponsors.

1.2 The role of toolkits

One might regard deductive inference as merely a helpful perspective for teaching old algorithms and thinking about new ones, linking NLP to logic and classical AI. Real implementations would then be carefully hand-coded in a traditional language.

That was the view ten years ago of finite-state machines—that FSMs were part of the theoretical backbone of CL, linking the field to the theory of computation. Starting in the mid-1990's, however, finite-state methods came to the center of *applied* NLP as researchers at Xerox, AT&T, Groningen and elsewhere improved the expressive power of FSMs by moving from automata to transducers, adding semiring weights, and developing powerful new regular-expression operators and algorithms for these cases. They also developed software. Karttunen et al. (1996) built an FSM toolkit that allowed construction of morphological analyzers for many languages. Mohri et al. (1998) built a *weighted* toolkit that implemented novel algorithms (e.g., weighted minimization, on-the-fly composition) and scaled up to handle large-vocabulary continuous ASR. At the same time, renewed community-wide interest in shallow methods for information extraction, chunking, MT, and dialogue processing meant that such off-the-shelf FS toolkits became the core of diverse systems used in cutting-edge research.

The weakness of FSMs, of course, is that they are only finite-state. One would like something like AT&T's FSM toolkit that also handles the various formalisms now under consideration for lexicalized grammars, non-context-free grammars, and syntax-based MT—and hold the promise of extending to other formalisms and applications not yet imagined.

We believe that deductive inference should play the role of regular expressions and FSMs, providing the theoretical foundation for such an effort. Many engineering ideas in the field can be regarded, we

```
1. :- double item=0.                                      % declares that all item values are doubles, default is 0
2. constit(X,I,K) += rewrite(X,W) * word(W,I,K).          % a constituent is either a word ...
3. constit(X,I,K) += rewrite(X,Y,Z) * constit(Y,I,J) * constit(Z,J,K).  % ... or a combination of two adjacent subconstituents
4. goal += constit("s",0,N) whenever ?ends_at(N).         % a parse is any s constituent that covers the input string
```

Figure 1: A probabilistic CKY parser written in Dyna. Axioms are in boldface.

believe, as ideas for how to specify, transform, or compile systems of inference rules.

2 A Language for Deductive Systems

Any toolkit needs an interface. For example, FS toolkits offer a regular expression language. We propose a simple but Turing-complete language, Dyna, for specifying weighted deductive-inference algorithms. We illustrate it here by example; see `http://dyna.org` for more details and a tutorial.

The short Dyna program in Fig. 1 expresses the inside algorithm for PCFGs (i.e., the probabilistic generalization of CKY recognition). Its 3 **inference rules** schematically specify many *equations*, over an arbitrary number of unknowns. This is possible bcause the unknowns (**items**) have *structured names* (**terms**) such as constit("s",0,3). They resemble typed variables in a C program, but we use **variable** instead to refer to the capitalized identifiers X, I, K, ...in lines 2–4. Each rule gives a **consequent** on the left-hand side of the +=, which can be built by combining the **antecedents** on the right-hand side.[1]

Lines 2–4 are equational schemas that specify how to compute the value of items such as constit("s",0,3) from the values of other items. Using the summation operator +=, lines 2–3 say that for any X, I, and K, constit(X,I,K) is defined by summing over the remaining variables, as $\sum_{\mathsf{W}}$ rewrite(X,W)*word(W,I,K) $+$ $\sum_{\mathsf{Y,Z,J}}$ rewrite(X,Y,Z)*constit(Y,I,J)*constit(Z,J,K). For example, constit("s",0,3) is a sum of quantities such as rewrite("s", "np", "vp")*constit("np",0,1)*constit("vp",1,3). The whenever operator in line 4 specifies a **side condition** that restricts the set of expressions in the sum (i.e., only when N is the sentence length).

To fully define the system of equations, non-default values (in this case, non-zero values) should be **asserted** for some **axioms** at runtime. (Axioms, shown in bold in Fig. 1, are items that never appear as a consequent.) If the PCFG contains a rewrite rule np $\rightarrow$ Mary with probability $p(\mathsf{Mary} \mid \mathsf{np})$=0.005, the user should assert that rewrite("np", "Mary") has value 0.005. If the input is *John loves Mary*, values of 1 should be asserted for word("John",0,1), word("loves",1,2), word("Mary",2,3), and ends_at(3).

Given the axioms as base cases, the equations in Fig. 1 enable deduction of values for other items. The value of the **theorem** constit("s",0,3) will be the inside probability $\beta_{\mathsf{s}}(0,3)$,[2] and the value of goal will be the total probability of all parses.

If one replaces += by max= throughout, then constit("s",0,3) will accumulate the maximum rather than the sum of these quantities, and goal will accumulate the probability of the *best* parse.

With different input, the same program carries out lattice parsing. Simply assert axioms that correspond to (weighted) lattice arcs, such as word("John",17,50), where 17 and 50 are arbitrary terms denoting states in the lattice. It is also quite straightforward to lexicalize the nonterminals or extend to synchronous grammars.

A related context-free parsing strategy, shown in Fig. 2, is Earley's algorithm. These equations illustrate nested terms such as lists. The side condition in line 2 prevents building any constituent until one has built a left context that calls for it.

3 Relation to Previous Work

There is a large relevant literature. Some of the well-known CL papers, notably Goodman (1999), were already mentioned in section 1.1. Our project has three main points of difference from these.

First, we provide an efficient, scalable, open-source implementation, in the form of a compiler from Dyna to C++ classes. (Related work is in §7.2.) The C++ classes are efficient and easy to use, with statements such as c[rewrite("np",2,3)]=0.005 to assert axiom values into a chart named c (i.e., a deduc-

[1]Much of our notation and terminology comes from logic programming: term, variable, inference rule, antecedent/consequent, assert/retract, axiom/theorem.

[2]That is, the probability that s would stochastically rewrite to the first three words of the input. If this can happen in more than one way, the probability sums over multiple derivations.

```
1. need("s",0) = 1.                                                        % begin by looking for an s that starts at position 0
2. constit(Nonterm/Needed,I,I) += rewrite(Nonterm,Needed) whenever ?need(Nonterm, I).     % traditional predict step
3. constit(Nonterm/Needed,I,K) += constit(Nonterm/cons(W,Needed),I,J) * word(W,J,K).      % traditional scan step
4. constit(Nonterm/Needed,I,K) += constit(Nonterm,cons(X,Needed),I,J) * constit(X/nil,J,K).  % traditional complete step
5. goal += constit("s"/nil,0,N) whenever ?ends_at(N).                 % we want a complete s constituent covering the sentence
6. need(Nonterm,J) += constit(_/cons(Nonterm,_),_,J).       % Note: underscore matches anything (anonymous wildcard)
```

Figure 2: An Earley parser that recovers inside probabilities (Earley, 1970; Stolcke, 1995). The rule np $\rightarrow$ det n should be encoded as the axiom rewrite("np",cons("det",cons("n",nil))), a nested term. "np"/Needed is the label of a partial np constituent that is still missing the *list* of subconstituents in Needed. need("np",3) is derived if some partial constituent seeks an np subconstituent starting at position 3. As in Fig. 1, lattice parsing comes for free, as does training.

tive database) and expressions like c[goal] to extract the values of the resulting theorems, which are computed as needed. The C++ classes also give access to the proof forest (e.g., the forest of parse trees), and integrate with parameter optimization code.

Second, we fully generalize the agenda-based strategy of Shieber et al. (1995) to the weighted case—in particular supporting a *prioritized* agenda. That allows probabilities to guide the search for the best parse(s), a crucial technique in state-of-the-art context-free parsers.[3] We also give a "reverse" agenda algorithm to compute gradients or outside probabilities for parameter estimation.

Third, regarding weights, the Dyna language is designed to express systems of arbitrary, heterogeneous equations over item values. In previous work such as (Goodman, 1999; Nederhof, 2003), one only specifies the inference rules as unweighted Horn clauses, and then weights are added automatically in a standard way: all values have the same type $\mathcal{W}$, and all rules transform to equations of the form $c \oplus= a_1 \otimes a_2 \otimes \cdots \otimes a_k$, where $\oplus$ and $\otimes$ give $\mathcal{W}$ the structure of a semiring.[4] In Dyna one writes these equations explicitly in place of Horn clauses (Fig. 1). Accordingly, *heterogeneous* Dyna programs, to be supported soon by our compiler, will allow items of different types to have values of different types, computed by different aggregation operations over arbitrary right-hand-side expressions. This allows specification of a wider class of algorithms from NLP and elsewhere (e.g., minimum expected loss decoding, smoothing formulas, neural networks, game tree analysis, and constraint programming). Although §4 and §5 have space to present only techniques for the semiring case, these can be generalized.

Our approach may be most closely related to deductive databases, which even in their heyday were apparently ignored by the CL community (except for Minnen, 1996). Deductive database systems permit inference rules that can derive new database facts from old ones.[5] They are essentially declarative logic programming languages (with restrictions or extensions) that are—or could be—implemented using efficient database techniques. Some implemented deductive databases such as CORAL (Ramakrishnan et al., 1994) and LOLA (Zukowski and Freitag, 1997) support aggregation (as in Dyna's +=, log+=, max=, ...), although only "stratified" forms of it that exclude unary CFG rule cycles.[6] Ross and Sagiv (1992) (and in a more restricted way, Kifer and Subrahmanian, 1992) come closest to our notion of attaching aggregable values to terms.

Among deductive or other database systems, Dyna is perhaps unusual in that its goal is not to support transactional databases or *ad hoc* queries, but rather to serve as an abstract layer for specifying an algorithm, such as a dynamic programming (DP) algorithm. Thus, the Dyna program already implicitly or explicitly specifies all queries that will be needed. This allows compilation into a hard-coded C++ implementation. The compiler's job is to support these queries by laying out and indexing the database re-

[3]Previous treatments of weighted deduction have used an agenda only for an unweighted parsing phase (Goodman, 1999) or for finding the single best parse (Nederhof, 2003). Our algorithm works in arbitrary semirings, including non-idempotent ones, taking care to avoid double-counting of weights and to handle side conditions.

[4]E.g., the inside algorithm in Fig. 1 falls into Goodman's framework, with $\langle \mathcal{W}, \oplus, \otimes \rangle = \langle \mathbb{R}_{\geq 0}, +, * \rangle$—the PLUSTIMES semiring. Because $\otimes$ distributes over $\oplus$ in a semiring, computing goal is equivalent to an aggregation over many separate parse trees. That is not the case for heterogeneous programs.

[5]Often they use some variant of the *unweighted* agenda-based algorithm, which is known in that community as "semi-naive bottom-up evaluation."

[6]An unweighted parser was implemented in an earlier version of LOLA (Specht and Freitag, 1995).

lations in memory[7] in a way that resembles hand-designed data structures for the algorithm in question. The compiler has many choices to make here; we ultimately hope to implement feedback-directed optimization, using profiled sample runs on typical data. For example, a sparse grammar should lead to different strategies than a dense one.

4 Computing Theorem Values

Fig. 1 specifies a set of equations but not how to solve them. Any declarative specification language must be backed up by a solver for the class of specifiable problems. In our continuing work to develop a range of compiler strategies for arbitrary Dyna programs, we have been inspired by the CL community's experience in building efficient parsers.

In this paper and in our current implementation, we give only the algorithms for what we call *weighted dynamic programs*, in which all axioms and theorems are variable-free. This means that a consequent may only contain variables that already appear elsewhere in the rule. We further restrict to semiring-weighted programs as in (Goodman, 1999). But with a few more tricks not given here, the algorithms can be generalized to a wider class of heterogeneous weighted logic programs.[8]

4.1 Desired properties

Computation is triggered when the user requests the value of one or more particular items, such as goal. Our algorithm must have several properties in order to substitute for manually written code.

Soundness. The algorithm cannot be guaranteed to terminate (since it is possible to write arbitrary Turing machines in Dyna). However, if it does terminate, it should return values from a valid model of the program, i.e., values that simultaneously satisfy all the equations expressed by the program.

Reasonable completeness. The computation should indeed terminate for programs of interest to the NLP community, such as parsing under a probabilistic grammar—even if the grammar has left recursion, unary rule cycles, or ϵ-productions. This appears to rule out pure top-down ("backward-chaining") approaches.

Efficiency. Returning the value of goal should do only as much computation as necessary. To return goal, one may not need to compute the values of *all* items.[9] In particular, finding the best parse should not require finding all parses (in contrast to Goodman (1999) and Zhou and Sato (2003)). Approximation techniques such as pruning and best-first search must also be supported for practicality.

```
1.  for each axiom $a$, set $agenda[a] :=$ value of axiom $a$
2.  while there is an item $a$ with $agenda[a] \neq \mathbf{0}$
3.      (* remove an item from the agenda and move its value to the chart *)
4.      choose such an $a$
5.      $\Delta := agenda[a];\ agenda[a] := \mathbf{0}$
6.      $old := chart[a];\ chart[a] := chart[a] \oplus \Delta$
7.      if $chart[a] \neq old$            (* only propagate actual changes *)
8.          (* compute new resulting updates and place them on the agenda *)
9.          for each inference rule "$c \mathrel{\oplus}= a_1 \otimes a_2 \otimes \cdots \otimes a_k$"
10.             for $i$ from 1 to $k$
11.                 for each way of instantiating the rule's variables
                    such that $a_i = a$
12.                     $agenda[c] \mathrel{\oplus}= \bigotimes_{j=1}^{k} \begin{cases} old & \text{if } j < i \text{ and } a_j = a \\ \Delta & \text{if } j = i \\ chart[a_j] & \text{otherwise} \end{cases}$
                        (* can skip this line if any multiplicand is $\mathbf{0}$ *)
```

Figure 3: Weighted agenda-based deduction in a semiring, without side conditions (see text).

4.2 The agenda algorithm

Our basic algorithm (Fig. 3) is a weighted agenda-based algorithm that works only with rules of the form $c \mathrel{\oplus}= a_1 \otimes a_2 \otimes \cdots \otimes a_k$. $\otimes$ must distribute over $\oplus$. Further, the default value for items (line 1 of Fig. 1) must be the semiring's zero element, denoted $\mathbf{0}$.[10]

Agenda-based deduction maintains two indexed data structures: the **agenda** and the **chart**. $chart[a]$ stores the current value of item a. The agenda holds future work that arises from assertions or from previous changes to the chart: $agenda[a]$ stores an incremental update to be added (using $\oplus$) to $chart[a]$ in future. If $chart[a]$ or $agenda[a]$ is not stored, it is

[7]Some relations might be left unmaterialized and computed on demand, with optional memoization and flushing of memos.

[8]Heterogeneous programs may propagate non-additive updates, which arbitrarily modify one of the inputs to an aggregation. Non-dynamic programs require non-ground items in the chart, complicating both storage and queries against the chart.

[9]This also affects completeness, as it sometimes enables the computation of goal to terminate even if the program as a whole contains some irrelevant non-terminating computation. Even in practical cases, the runtime of computing all items is often prohibitive, e.g., proportional to n^6 or worse for a dense tree-adjoining grammar or synchronous grammar.

[10]It satisfies $x \oplus \mathbf{0} = x, x \otimes \mathbf{0} = \mathbf{0}$ for all x. Also, this algorithm requires $\otimes$ to distribute over $\oplus$. Dyna's semantics requires $\oplus$ to be associative and commutative.

taken to be the default $\mathbf{0}$.

When item a is removed from the agenda, its chart weight is updated by the increment value. This change is then propagated to other items c, via rules of the form $c \oplus= \cdots$ with a on the right-hand-side. The resulting changes to c are placed back on the agenda and carried out only later.

The unweighted agenda-based algorithm (Shieber et al., 1995) may be regarded as the case where $\langle \mathcal{W}, \oplus, \otimes \rangle = \langle \{T, F\}, \vee, \wedge \rangle$. It has previously been generalized (Nederhof, 2003) to the case $\langle \mathcal{W}, \oplus, \otimes \rangle = \langle \mathbb{R}_{\geq 0}, \max, + \rangle$. In Fig. 3, we make the natural further generalization to any semiring.

How is this a further generalization? Since $\oplus$ (unlike $\vee$ and max) might not be idempotent, we must take care to avoid erroneous double-counting if the antecedent a combines with, or produces, another copy of itself.[11] For instance, if the input contains ϵ words, line 2 of Fig. 1 may get instantiated as constit("np",5,5) += rewrite("np","np","np") * constit("np",5,5) * constit("np",5,5). This is why we save the old values of *agenda*$[a]$ and *chart*$[a]$ as Δ and *old*, and why line 12 is complex.

4.3 Side conditions

We now extend Fig. 3 to handle Dyna's side conditions, i.e., rules of the form $c \oplus=$ *expression* whenever *boolean-expression*. We discuss only the simple side conditions treated in previous literature, which we write as $c \oplus= a_1 \otimes a_2 \otimes \cdots \otimes a_{k'}$ whenever $?b_{k'+1}$ & $\cdots$ & $?b_k$. Here, $?b_j$ is true or false according to whether there exists an *unweighted* proof of b_j.

Again, what is new here? Nederhof (2003) considers only max= with a uniform-cost agenda discipline (see §4.5), which guarantees that no item will be removed more than once from the agenda. We wish to support other cases, so we must take care that a second update to a_i will not retrigger rules of which a_i is a side condition.

For simplicity, let us reformulate the above rule as $c \oplus= a_1 \otimes a_2 \otimes \cdots \otimes a_{k'} \otimes ?b_{k'+1} \otimes \cdots \otimes ?b_k$, where $?b_i$ is now treated as having value $\mathbf{0}$ or $\mathbf{1}$ (the identity for $\otimes$) rather than false or true respectively.

[11] An agenda update that increases x by 0.3 will increase $r * x * x$ by $r * (0.6x + 0.09)$. Hence, the rule x += $r * x * x$ must propagate a new increase of that size to x, via the agenda.

We may now use Fig. 3, but now any a_j might have the form $?b_j$. Then in line 12, *chart*$[a_j]$ will be *chart*$[?b_j]$, which is defined as $\mathbf{1}$ or $\mathbf{0}$ according to whether *chart*$[b_j]$ is stored (i.e., whether b_j has been derived). Also, if $a_i = ?a$ at line 11 (rather than $a_i = a$), then Δ in line 12 is replaced by $\Delta ?$, where we have set $\Delta ? :=$ *chart*$[?a]$ at line 5.

4.4 Convergence

Whether the agenda algorithm halts depends on the Dyna program and the input. Like any other Turing-complete language, Dyna gives you enough freedom to write undesirable programs.

Most NLP algorithms do terminate, of course, and this remains true under the agenda algorithm. For typical algorithms, only finitely many different items (theorems) can be derived from a given finite input (set of axioms).[12] This ensures termination if one is doing unweighted deduction with $\langle \mathcal{W}, \oplus, \otimes \rangle = \langle \{T, F\}, \vee, \wedge \rangle$, since the test at line 7 ensures that no item is processed more than once.[13]

The same test ensures termination if one is searching for the best proof or parse with (say) $\langle \mathcal{W}, \oplus, \otimes \rangle = \langle \mathbb{R}_{\geq 0}, \min, + \rangle$, where values are negated log probabilities. Positive-weight cycles will not affect the min. (Negative-weight cycles, however, would correctly cause the computation to diverge; these do not arise with probabilities.)

If one is using $\langle \mathcal{W}, \oplus, \otimes \rangle = \langle \mathbb{R}_{\geq 0}, +, * \rangle$ to compute the total weight of all proofs or parses, as in the inside algorithm, then Dyna must solve a system of nonlinear equations. The agenda algorithm does this by iterative approximation (propagating updates around any cycles in the proof graph until numerical convergence), essentially as suggested by Stolcke (1995) for the case of Earley's algorithm.[14] Again, the computation may diverge.

[12] This holds for all Datalog programs, for instance.

[13] This argument does not hold if Dyna is used to express programs outside the semiring. In particular, one can write instances of SAT and other NP-hard constraint satisfaction problems by using cyclic rules *with negation* over finitely many boolean-valued items (Niemelä, 1998). Here the agenda algorithm can end up flipping values forever between false and true; a more general solver would have to be called in order to find a stable model of a SAT problem's equations.

[14] Still assuming the number of items is finite, one could in principle materialize the system of equations and call a dedicated numerical solver. In some special cases only a linear solver is needed: e.g., for unary rule cycles (Stolcke, 1995), or ϵ-cycles in FSMs (Eisner, 2002).

One can declare the conditions under which items of a particular type (constit or goal) should be treated as having converged. Then asking for the value of goal will run the agenda algorithm not until the agenda is empty, but only until *chart*[goal] has converged by this criterion.

4.5 Prioritization

The order in which items are chosen at line 4 does not affect the soundness of the agenda algorithm, but can greatly affect its speed. We implement the agenda as a priority queue whose priority function may be specified by the user.[15]

Charniak et al. (1998) and Caraballo and Charniak (1998) showed that, when seeking the best parse (using min= or max=), *best-first* parsing can be extremely effective. Klein and Manning (2003a) went on to describe admissible heuristics and an A* framework for parsing. For A* in our general framework, the priority of item a should be an estimate of the value of the best proof of goal that uses a. (This non-standard formulation is carefully chosen.[16]) If so, goal is guaranteed to converge the very first time it is selected from the priority-queue agenda.

Prioritizing "good" items first can also be useful in other circumstances. The inside-outside training algorithm requires one to find all parses, but finding the high-probability parses first allows one to ignore the rest by "early stopping."

In all these schemes (even A*), processing promising items as soon as possible risks having to reprocess them if their values change later. Thus, this strategy should be balanced against the "topological sort" strategy of waiting to process an item until its value has (probably) converged.[17] Ultimately we hope to *learn* priority functions that effectively balance these two strategies (especially in the context of early stopping).

[15]At present by writing a C++ function; ultimately within Dyna, by defining items such as priority(constit("s",0,3)).

[16]It is correct for proofs that incorporate two copies of a's value, or—more important—no copies of a's value because a is a side condition. Thus, it recognizes that a low-probability item must have *high* priority if it could be used as a side condition in a higher-probability parse (though this cannot happen for the side conditions derived by the magic templates transformation (§6)). Note also that a's own value (Nederhof, 2003) might not be an optimistic estimate, if negative weights are present.

[17]In parsing, for example, one often processes narrower constituents before wider ones. But such strategies do not always exist, or break down in the presence of unary rule cycles, or cannot be automatically found. Goodman's (1999) strategy of building all items and sorting them before computing any weights is wise only if one genuinely wants to build all items.

4.6 Matching, indexing, and interning

The crucial work in Fig. 3 occurs in the iteration over instantiated rules at lines 9–11. In practice, we restructure this triply nested loop as follows, where each line retains the variable bindings that result from the unification in the previous line:

```
9.  **for** each antecedent pattern $a_i$ that appears in some
    program rule $r$ and unifies with $a$
10.     **for** each way of simultaneously unifying $r$'s remaining antecedent patterns $a_1, \ldots a_{i-1}, a_{i+1}, \ldots a_k$
        with items that may have non-**0** value in the chart
11.         construct $r$'s consequent $c$    (* all vars are bound *)
```

Our implementation of line 9 tests a against all of the antecedent patterns at once, using a tree of simple "if" tests (generated by the Dyna-to-C++ compiler) to share work across patterns. As an example, $a =$ constit("np",3,8) will match two antecedents at line 3 of Fig. 1, but will fail to match in line 4. Because a is variable-free (for DPs), a full unification algorithm is not necessary, even though an antecedent pattern can contain repeated variables and nested subterms.

Line 10 rapidly looks up the rule's other antecedents using *indices* that are automatically maintained on the chart. For example, once constit("np",4,8) has matched antecedent 2 of line 3 of Fig. 1, the compiled code consults a maintained list of the chart constituents that start at position 8 (i.e., items of the form constit(Z,8,K) that have already been derived). Suppose one of these is constit("vp",8,15): then the code finds the rule's remaining antecedent by consulting a list of items of the form rewrite(X,"np","vp"). That leads it to construct consequents such as constit("s",4,15) at line 11.

By default, equal terms are represented by equal pointers. While this means terms must be "interned" when constructed (requiring hash lookup), it enforces structure-sharing and allows any term to be rapidly copied, hashed, or equality-tested without dereferencing the pointer.[18]

Each of the above paragraphs conceals many decisions that affect runtime. This presents future opportunities for feedback-directed optimization, where profiled runs on typical data influence the compiler.

[18]The compiled code provides garbage collection on the terms; this is important when running over large datasets.

5 Computing Gradients

The value of goal is a *function* of the axioms' values. If the function is differentiable, we may want to get its gradient with respect to its parameters (the axiom values), to aid in numerically optimizing it.

5.1 Gradients by symbolic differentiation

The gradient computation can be derived from the original by a program transformation. For each item a in the original program—in particular, for each axiom—the new program will also compute a new item $\mathsf{g}(a)$, whose value is $\partial\mathsf{goal}/\partial a$.

Thus, given weighted axioms, the new program computes both goal and $\nabla\mathsf{goal}$. An optimization algorithm such as conjugate gradient can use this information to tune the axiom weights to maximize goal. An alternative is the EM algorithm (Dempster et al., 1977) for probabilistic generative models such as PCFGs. Luckily the same program serves, since for such models, the E count (expected count) of an item a can be found as $a \cdot \mathsf{g}(a)/\mathsf{goal}$. In other words, the inside-outside algorithm has the same structure as computing the function and its gradient.

The GRADIENT transformation is simple. For example,[19] given a rule c += $a_1 * a_2 * \cdots * a_{k'}$ whenever $?b_{k'+1}$ & $\cdots$ & $?b_k$, we add a new rule $\mathsf{g}(a_i)$ += $\mathsf{g}(c) * a_1 * \cdots * a_{i-1} * a_{i+1} * \cdots * a_{k'}$ whenever $?a_i$, for each $i = 1, 2, ..., k'$. (The original rule remains, since we need inside values to compute outside values.) This strategy for computing the gradient $\partial\mathsf{goal}/\partial a$ via the chain rule is an example of automatic differentiation in the reverse mode (Griewank and Corliss, 1991), known in the neural network community as back-propagation.

5.2 Gradients by back-propagation

However, what if goal might be computed only approximately, by early stopping before convergence (§4.5)? To avoid confusing the optimizer, we want the *exact* gradient of the *approximate* function.

To do this, we "unwind" the computation of goal, *undoing* the value updates while building up the gradient values. The idea is to differentiate an "unrolled" version of the original computation (Williams and Zipser, 1989), in which an item at

[19]More generally, $\mathsf{g}(a_i) = \partial\mathsf{goal}/\partial a_i = \sum_c \partial\mathsf{goal}/\partial c \cdot \partial c/\partial a_i = \sum_c \mathsf{g}(c) \cdot \partial c/\partial a_i$ by the chain rule.

```
1.  for each $a$, $gchart[a] := 0$ and $gagenda[a] := 0$
        (* respectively hold $\partial\mathsf{goal}/\partial chart[a]$ and $\partial\mathsf{goal}/\partial agenda[a]$ *)
2.  $gchart[\mathsf{goal}] := 1$
3.  for each $\langle a, \Delta, old\rangle$ triple that was considered at line 8
    of Fig. 3, but in the reverse order                    (* $\Delta$ is agenda[a] *)
4.    $\Gamma := gchart[a]$                      (* will accumulate gagenda[a] here *)
5.    for each inference rule "$c$ += $a_1 * a_2 * \cdots * a_k$"
6.      for $i$ from 1 to $k$
7.        for each way of instantiating the rule's variables
          such that $a_i = a$
8.          for $h$ from 1 to $k$ such that $a_h$ is not a side cond.
                (* find $\partial\mathsf{goal}/\partial agenda[c] \cdot \partial agenda[c]/\partial(a_h$ factor) *)
9.            $\gamma := \prod_{j=1}^{k} \begin{cases} gagenda[c] & \text{if } j = h \\ old & \text{if } j \neq h \text{ and } j < i \text{ and } a_j = a \\ \Delta & \text{if } j \neq h \text{ and } j = i \\ chart[a_j] & \text{otherwise} \end{cases}$
10.           if $h \neq i$ then $gchart[a_h]$ += $\gamma$
11.           if $h \leq i$ and $a_h = a$ then $\Gamma$ += $\gamma$
12.   $gagenda[a] := \Gamma$
13.   $chart[a] := old$
14. return $gagenda$[a] for each axiom $a$
```

Figure 4: An efficient algorithm for computing $\nabla\mathsf{goal}$ (even when goal is an early-stopping approximation), specialized to the case $\langle \mathbb{W}, \oplus, \otimes\rangle = \langle \mathbb{R}, +, *\rangle$. The proof is suppressed for lack of space.

time t is considered to be a different variable (possibly with different value) than the same item at time $t + 1$. The reverse pass must recover earlier values. Our somewhat tricky algorithm is shown in Fig. 4.

At line 3, a stack is needed to remember the sequence of $\langle a, old, \Delta\rangle$ triples from the original computation.[20] It is a more efficient version of the "tape" usually used in automatic differentiation. For example, it uses $O(n^2)$ rather than $O(n^3)$ space for the CKY algorithm. The trick is that Fig. 3 does not record all its computations, but only its sequence of items. Fig. 4 then re-runs the inference rules to reconstruct the computations in an acceptable order.

This method is a generalization of Eisner's (2001) prioritized forward-backward algorithm for infinite-state machines. As Eisner (2001) pointed out, the tape created on the first forward pass can also be used to speed up later passes (i.e., after the numerical optimizer has adjusted the axiom weights).[21]

[20]If one is willing to risk floating-point error, then one can store only $\langle a, old\rangle$ on the stack and recover Δ as $chart[a] - old$. Also, $agenda[a]$ and $gagenda[a]$ can be stored in the same location, as they are only used during the forward and the backward pass, respectively.

[21]In brief, a later forward pass that chooses a at Fig. 3, line 4 according to the recorded tape order (1) is faster than using a priority queue, (2) avoids ordering-related discontinuities in the objective function as the axiom weights change, (3) can prune by skipping useless updates a that scarcely affected goal (e.g.,

constituents not in any good parse) by consulting *gagenda*$[a]$ values that the previous backward pass can have written onto the tape (overwriting Δ or *old*).

5.3 Parameter estimation

To support parameter training using these gradients, our implementation of Dyna includes a training module, DynaMITE. DynaMITE supports the EM algorithm (and many variants), supervised and unsupervised training of log-linear ("maximum entropy") models using quasi-Newton methods, and smoothing-parameter tuning on development data. As an object-oriented C++ library, it also facilitates rapid implementation of new estimation techniques (Smith and Eisner, 2004; Smith and Eisner, 2005).

6 Program Transformations

Another interest of Dyna is that its high-level specifications can be manipulated by mechanical source-to-source program transformations. This makes it possible to derive new algorithms from old ones. §5.1 already sketched the *gradient* transformation for finding ∇goal. We note a few other examples.

Bounding transformations generate a new program that computes upper or lower bounds on goal, via generic bounding techniques (Prieditis, 1993; Culberson and Schaeffer, 1998). The A* heuristics explored by Klein and Manning (2003a) can be seen as resulting from bounding transformations.

With John Blatz, we are also exploring transformations that can result in asymptotically more efficient computations of goal. Their unweighted versions are well-known in the logic programming community (Tamaki and Sato, 1984; Ramakrishnan, 1991). *Folding* introduces new intermediate items, perhaps exploiting the distributive law; applications include parsing speedups such as (Eisner and Satta, 1999), as well as well-known techniques for speeding up multi-way database joins, constraint programming, or marginalization of graphical models. *Unfolding* eliminates items; it can be used to specialize a parser to a particular grammar and then to eliminate unary rules. *Magic templates* introduce top-down filtering into the search strategy and can be used to derive Earley's algorithm (Minnen, 1996), to introduce left-corner filters, and to restrict FSM constructions to build only accessible states.

Finally, there are low-level optimizations. *Term* transformations restructure terms to change their layout in memory. We are also exploring the introduction of declarations that control which items use the agenda or are memoized in the chart. This can be used to support lazy or "on-the-fly" computation (Mohri et al., 1998) and asymptotic space-saving tricks (Binder et al., 1997).

7 Usefulness of the Implementation

7.1 Applications

The current Dyna compiler has proved indispensable in our own recent projects, in the sense that we would not have attempted many of them without it.

In some cases, we were experimenting with genuinely new algorithms not supported by any existing tool, as in our work on dependency-length-limited parsing (Eisner and Smith, 2005b) and loosely syntax-based machine translation (Eisner and D. Smith, 2005). (Dyna would have been equally helpful in the first author's earlier work on new algorithms for lexicalized and CCG parsing, syntactic MT, transformational syntax, trainable parameterized FSMs, and finite-state phonology.)

In other cases (Smith and Eisner, 2004; Smith and Smith, 2004; Smith et al., 2005), Dyna let us quickly replicate, tweak, and combine useful techniques from the literature. These techniques included unweighted FS morphology, conditional random fields (Lafferty et al., 2001), synchronous parsers (Wu, 1997; Melamed, 2003), lexicalized parsers (Eisner and Satta, 1999),[22] partially supervised training à la (Pereira and Schabes, 1992),[23] and grammar induction (Klein and Manning, 2002). These replications were easy to write and extend, and to train via §5.2.

7.2 Experiments

We compared the current Dyna compiler to hand-built systems on a variety of parsing tasks. These problems were chosen not for their novelty or interesting structure, but for the availability of existing well-tuned implementations.

Best parse. We compared a Dyna CFG parser to the Java parser of Klein and Manning (2003b),[24]

[22]Markus Dreyer's reimplementation of the complex Collins (1999) parser uses under 30 lines of Dyna.

[23]For example, lines 2–3 of Fig. 1 can be extended with whenever permitted(X,I,K).

[24]Neither uses heuristics from Klein and Manning (2003a).

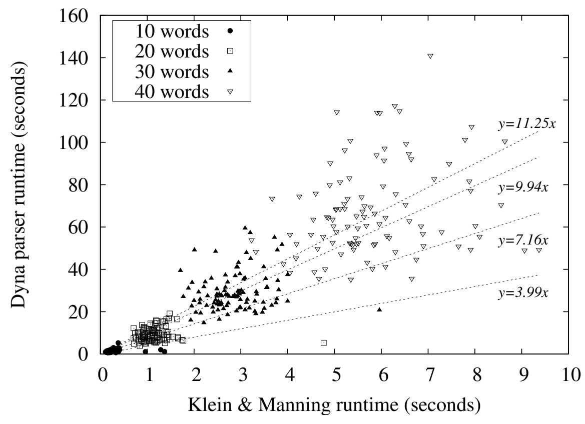

Figure 5: Dyna CKY parser vs. Klein & Manning hand-built parser, comparing runtime.

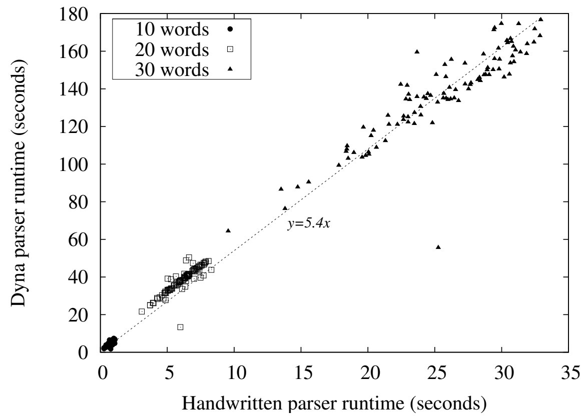

Figure 6: Dyna CKY parser vs. C++PARSE, a similar hand-built parser. The implementation differences amount to storage and indexing and give a consistent 5-fold speedup.

on the same grammar. Fig. 5 shows the results. Dyna's disadvantage is greater on longer sentences—probably because its greater memory consumption results in worse cache behavior.[25]

We also compared a Dyna CKY parser to our own hand-built implementation, C++PARSE. C++PARSE is designed like the Dyna parser but includes a few storage and indexing optimizations that Dyna does not yet have. Fig. 6 shows the 5-fold speedup from these optimizations on binarized-Treebank parsing with a large 119K-rule grammar. The sharp diagonal indicates that C++PARSE is simply a better-tuned version of the Dyna parser.

These optimizations and others are now being incorporated into the Dyna compiler, and are expected to provide similar speedups, putting Dyna's parser in the ballpark of the Klein & Manning parser. Importantly, these improvements will speed up existing Dyna programs through recompilation.

[25]Unlike Java, Dyna does not yet decide automatically when to perform garbage collection. In our experiment, garbage collection was called explicitly after each sentence and counted as part of the runtime (typically 0.25 seconds for 10-word sentences, 5 seconds for 40-word sentences).

	99%		99.99%	
uniform	89.3	(4.5)	90.3	(4.6)
after 1 EM iteration	82.9	(6.8)	85.2	(6.9)
after 2 EM iterations	77.1	(8.4)	79.1	(8.3)
after 3 EM iterations	71.6	(9.4)	73.7	(9.5)
after 4 EM iterations	66.8	(10.0)	68.8	(10.2)
after 5 iterations	62.9	(10.3)	65.0	(10.5)

Table 1: Early stopping. Each row describes a PCFG at a different stage of training; later PCFGs are sharper. The table shows the percentage of agenda runtime (mean across 1409 sentences, and standard deviation) required to get within 99% or 99.99% of the true value of goal.

Inside parsing. Johnson (2000) provides a C implementation of the inside-outside algorithm for EM training of PCFGs. We ran five iterations of EM on the WSJ10 corpus[26] using the Treebank grammar from that corpus. Dyna took 4.1 times longer.

Early stopping. An advantage of the weighted agenda discipline (§4.2) is that, with a reasonable priority function such as an item's inside probability, the inside algorithm can be stopped early with an estimate of goal's value. To measure the goodness of this early estimate, we tracked the progression of goal's value as each sentence was being parsed. In most instances, and especially after more EM iterations, the estimate was very tight long before all the weight had been accumulated (Table 1). This suggests that early stopping is a useful training speedup.

PRISM. The implemented tool most similar to Dyna that we have found is PRISM (Zhou and Sato, 2003), a probabilistic Prolog with efficient tabling and compilation. PRISM inherits expressive power from Prolog but handles only probabilities, not general semirings (or even side conditions).[27] In CKY parsing tests, PRISM was able to handle only a small fraction of the Penn Treebank ruleset (2,400 high-probability rules) and tended to crash on long sentences. Dyna is designed for real-world use: it consistently parses over 10$\times$ faster than PRISM and scales to full-sized problems.

IBAL (Pfeffer, 2001) is an elegant and powerful language for probabilistic modeling; it generalizes Bayesian networks in interesting ways.[28] Since

[26]Sentences with $\leq$10 words, stripping punctuation.

[27]Thus it can handle a subset of the cases described by Goodman (1999), again by building the whole parse forest.

[28]It might be possible to implement IBAL in Dyna (Pfeffer,

PCFGs and marginalization can be succinctly expressed in IBAL, we attempted a performance comparison on the task of the inside algorithm (Fig. 1). Unfortunately, IBAL's algorithm appears not to terminate if the PCFG contains any kind of recursion reachable from the start symbol.

8 Conclusions

Weighted deduction is a powerful theoretical formalism that encompasses many NLP algorithms (Goodman, 1999). We have given a bottom-up "inside" algorithm for general semiring-weighted deduction, based on a prioritized agenda, and a general "outside" algorithm that correctly computes weight gradients even when the inside algorithm is pruned.

We have also proposed a declarative language, Dyna, that replaces Prolog's Horn clauses with "Horn equations" over terms with values. Dyna can express more than the semiring-weighted dynamic programs treated in this paper. Our ongoing work concerns the full Dyna language, program transformations, and feedback-directed optimization.

Finally, we evaluated our first implementation of a Dyna-to-C++ compiler (download and documentation at `http://dyna.org`). We hope it will facilitate EMNLP research, just as FS toolkits have done for the FS case. It produces code that is slower than hand-crafted code but acceptably fast for our NLP research, where it has been extremely helpful.

Learning What to Talk About in Descriptive Games

Abstract

Text generation requires a planning module to select an object of discourse and its properties. This is specially hard in *descriptive games*, where a computer agent tries to describe some aspects of a game world. We propose to formalize this problem as a Markov Decision Process, in which an optimal message policy can be defined and learned through simulation. Furthermore, we propose *back-off policies* as a novel and effective technique to fight state dimensionality explosion in this framework.

1 Introduction

Traditionally, text generation systems are decomposed into three modules: the *application* module which manages the high-level task representation (state information, actions, goals, etc.), the *text planning* module which chooses messages based on the state of the application module, and the *sentence generation* module which transforms messages into sentences. The planning module greatly depends on the characteristics of both the application and the generation modules, solving issues in domain modelling, discourse and sentence planning, and to some degree lexical and feature selection (Cole et al., 1997). In this paper we concentrate on one of the most basic tasks that text planning needs to solve: selecting the message content, or more simply, choosing *what to talk about*.

Work on text-generation often assumes that an object or topic has been already chosen for discussion. This is reasonable for many applications, but in some cases choosing *what* to talk about can be harder than choosing *how* to. This is the case in the type of text generation applications that we are interested in: generating descriptive messages in computer games. In a modern computer game at any given moment there may be an enormous number of object properties that can be described, each with varying importance and consequences. The outcome of the game depends not only on the skill of the player, but also on the quality of the descriptive messages produced. We refer to such situations as *descriptive games*.

Our goal is to develop a strategy to choose the most interesting descriptive messages that a particular talker may communicate to a particular listener, given their context (i.e. their knowledge of the world and of each-other). We refer to this as *message planning*.

Developing a general framework for planning is very difficult because of the strong coupling between the planning and application modules. We propose to frame message planning as a Markov Decision Process (MDP) which encodes the environment, the information available to the *talker* and *listener*, the consequences of their communicative and non-communicative acts, and the constraints of the text generation module. Furthermore we propose to use Reinforcement Learning (RL) to learn the optimal message policy. We demonstrate the overall principle (Section 2) and then develop in more detail a computer game setting (Section 3).

One of the main weaknesses of RL is the problem of state dimensionality explosion. This problem is specially acute in message planning, since in typical situations there can be hundreds of thousands of potential messages. At the same time, the domain is highly structured. We propose to exploit this structure using a form of the back-off smoothing principle on the state space (Section 4).

1.1 Related Work

Our problem setting can be seen as a generalisation of the *content selection* problem in the generation of referring expressions in NLG. In the standard setting of this problem (see for example (van Deemter and Krahmer, to appear)) an algorithm needs to select the *distinguishing description* of an object in a scene. This description can be seen as a subset of scene properties which i) uniquely identifies a given target object, and ii) is optimal in some sense (minimal, psychologically plausible, etc.) van Deemter and Krahmer show that most content selection algorithms can be described as different cost functions over a particular graph representation of the scene. Minimising the cost of a subgraph leads to a distinguishing description.

Some aspects of our work generalise that of content selection: i) we consider the target object is unknown, ii) we consider scenes (i.e. world states) that are *dynamic* (i.e. they change over time) and *reactive* (i.e. utterances change the world), and iii) we consider listeners that have partial knowledge of the scene. This has important consequences. For example, the cost of a description cannot be directly evaluated; instead, we must *play the game*, that is, generate utterances and observe the rewards obtained over time. Also identical word-states may lead to different optimal messages, depending on the listener's partial knowledge. Other aspects of our work are very simplistic compared to current work in content selection, for example with respect to the use of negation and of properties that are boolean, relative or graded (van Deemter and Krahmer, to appear). We hope to incorporate these ideas into our work soon.

Probabilistic dialogue policies have been previously proposed for spoken dialogue systems (SDS) (see for example (Singh et al., 2002; Williams et al., 2005) and references therein). However, work in SDS focus mainly on coping with the noise and uncertainty resulting from speech recognition and sentence parsing. In this context MDPs are used to infer features and plan communicative strategies (modality, confusion, initiative, etc.) In our work we do not need to deal with uncertainty or parsing; our main concern is in the selection of the message content. In this sense our work is closer to (Henderson et al., 2005), where RL is used to train a SDS with very many states encoding message content.

Finally, with respect to the state-explosion problem in RL, related work can be found in the areas of multi-task learning and robot motion planning (Dietterich, 2000, and references therein). In these works the main concern is identifying the features that are relevant to specific sub-tasks, so that robots may learn multiple loosely-coupled tasks without incurring state-explosion. (Henderson et al., 2005) also addresses this problem in the context of SDS and proposes a semi-supervised solution. Our approach is related to these works, but it is different in that we assume that the feature structure is known in advance and has a very particular form amenable to a form of back-off regularisation.

2 Message planning

Let us consider an environment comprising a world with some objects and some agents, and some dynamics that govern their interaction. Agents can observe and memorize certain things about the world, can carry out actions and communicate with other agents. As they do so, they are rewarded or punished by the environment (e.g. if they find food, if the complete some goal, if they run out of energy, etc.)

The agents' actions are governed by a *policy*. We will consider separately the *physical action policy* (π), which decides which physical action to take given the state of the agent, and the *message action policy* (μ), which decides when to communicate, to whom, and what about. Our main concern in this paper will be to learn an optimal μ. Before we define this goal more precisely, we will introduce some notation.

A *property* is a set of *attribute-value pairs*. An *object* is a set of properties, with (at least) attributes Type and Location. A *domain* is a set of objects. Furthermore, we say that s' is a *sub-domain* of s if s' can be obtained by deleting property–value pairs from s (while enforcing the condition that remaining objects must have Type and Location). $\mathsf{Sub}(s)$ is the set containing s, all sub-domains of s, and the empty domain $\emptyset$.

A *world state* can be represented as a domain, noted s_W. Any partial view of the world state can also be represented as a domain $s \in \mathsf{Sub}(s_W)$. Similarly the content of any descriptive message about the world, noted m, can be represented as a partial view of it. An *agent* is the tuple:

$$A := \Big(s_A, \pi_A, \{\mu_{AA'}, s_{AA'}\}_{A' \neq A}\Big)$$

- $s_A \in \mathsf{Sub}(s_W)$: knowledge that A has about the state of the world.
- $s_{AA'} \in \mathsf{Sub}(s_A \cap s'_A)$: knowledge that A has about the knowledge that A' has about the world.
- $\pi_a := P(c|s_A)$ is the action policy of A, and c is a physical action.
- $\mu_{AA'} := P(m \in \mathcal{M}(s_A)|s_A, s_{AA'})$ is the message policy of A for sending messages to A', and $\mathcal{M}(s_A)$ are all valid messages at state s_A (discussed in Section 2.3).

When an agent A decides to send a message to A', it can use its knowledge of A' to choose messages effectively. For example, A will prefer to describe things that it knows A' does not know (i.e. not in $s_{AA'}$). This is the reason why the message policy μ_A depends on both s_A and $s_{AA'}$. After a message is sent (i.e. realised and uttered) the agent's will update their knowledge states $s_{A'}$, $s_{A'A}$ and $s_{AA'}$.

The question that we address in this paper is that of *learning an optimal message policy* $\mu_{AA'}$.

2.1 Talker's Markov Decision Process

We are going to formalize this problem as a standard Markov Decision Process (MDP). In general a MDP (Sutton and Barto, 1998) is defined over some set of states $\mathcal{S} := \{s_i\}_{i=1..K}$ and actions associated to every state, $\mathcal{A}(s_i) := \{a_{ij}\}_{j=1..N_i}$. The environment is governed by the state transition function $\mathcal{P}^a_{ss'} := P(s'|s,a)$. A policy determines the likelihood of actions at a given state: $\pi(s) := P(a|s)$. At each state transition a reward is generated from the reward function $\mathcal{R}^a_{ss'} := E\{r|s,s',a\}$.

MDPs allow us to define and find *optimal policies* which maximise the expected reward. Classical MDPs assume that the different functions introduced above are known and have some tractable analytical form. Reinforcement Learning (RL) in as extension of MDPs in which the environment function $\mathcal{P}^a_{ss'}$ is unknown or complex, and so the optimal policy needs to be learned online by directly interacting with the environment. There exist a number of algorithms to solve a RL problem, such as Q-Learning or SARSA (Sutton and Barto, 1998).

We can use a MDP to describe a full descriptive game, in which several agents interact with the world and communicate with each-other. To do so we would need to consider composite states containing s_W, $\{s_A\}_A$, and $\Big\{\{s_{AA'}\}_{A' \neq A}\Big\}_A$. Similarly, we need to consider composite policies containing $\{\pi_A\}_A$ and $\Big\{(\mu_{AA'})_{A' \neq A}\Big\}_A$. Finally, we would consider the many constrains in this model; for example: only physical actions affect the state of the world, only message actions affect believes, and only believe states can affect the choice of the agent's actions.

MDPs provide us with a principled way to deal with these elements and their relationships. However, dealing with the most general case results in models that are very cumbersome and which hide the conceptual simplicity of our approach. For this reason, we will limit ourselves in this paper to one of the simplest communication cases of interest: a single all-knowing talker, and a single listener completely observed by the talker. We will discuss later how this can be generalized.

2.2 The *Talking God* Setting

In the simplest case, an all-knowing agent A_0 sits in the background, without taking any physical actions, and uses its message policy (μ_{01}) to send messages to a *listener* agent A_1. The listener agent cannot talk back, but can interact with the environment using its physical action policy π_1. Rewards obtained by A_1 are shared by both agents. We refer to this setting as the *talking God* setting. Examples of such situations are common in games, for example when a computer character talks to its (computer) team-

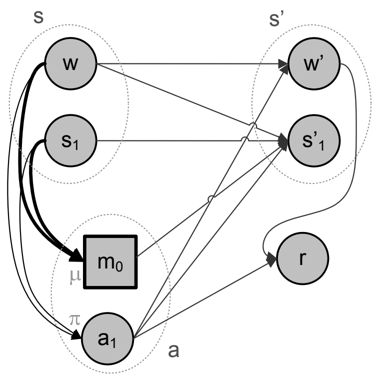

Figure 1: *Talking God* MDP.

mates, or when a mother-ship with full information of the ground sends a small simple robot to do a task. Another example would be that of a teacher talking to a learner, except that the teacher may not have full information of the learners head!

Since the talker is all-knowing, it follows that $s_0 = s_W$ and $s_{01} = s_1$. Furthermore, since the talker does not take physical actions, π_0 does not need to be defined. Similarly, since the listener does not talk we do not need to define μ_{10} or s_{10}. This case is depicted in Figure 1 as a graphical model. By grouping states and actions (dotted lines) we can see that this is can be modelled as a standard MDP. If all the probability distributions are known analytically, or if they can be sampled, optimal physical and message policies can be learnt (thick arrows).

Several generalizations of this model are possible. A straight forward generalization is to consider more than one listener agent. We can then choose to learn a single policy for all, or individual policies for each agent.

A second way to generalize the setting is to make the listeners mind only partially observable to the talker. In this case the talker continues to know the entire world ($s_0 = s_W$), but does not know exactly what the listener knows ($s_{01} \neq s_0$). This is more realistic in situations in which the listener cannot *talk back* to the talker, or in which the talkers mind is not observable. However, to model this we need a partially observable MDP (POMDP). Solving POMDPS is much harder than solving MDPs, but there have been models proposed for dialogue management (Williams et al., 2005).

In the more general case, the talker would have partial knowledge of the world and of the listener, and would itself act. In that case all agents are equal and can communicate as they evolve in the environment. The other agents minds are not directly observable, but we obtain information about them from their actions and their messages. This can all be in principle modelled by POMDPs in a straightforward manner, although solving these models is more involved. We are currently working towards doing so.

Finally, we note that all the above cases have dealt with worlds in which objects are static (i.e. information does not become obsolete), agents do not gain or communicate erroneous information, and communication itself is non-ambiguous and loss-less. This is a realistic scenario for text generation, and for communication between computer agents in games, but it is far removed from the spoken dialogue setting.

2.3 Generation Module and Valid Messages

Generating descriptive sentences of domains can be done in a number of ways, from template to feature-based systems (Cole et al., 1997). Our framework does not depend on a particular choice of generation module, and so we do not need to discuss this module. However, our message policy is not decoupled of the generation module; indeed, it would not make sense to develop a planning module which plans messages that cannot be realised! In our framework, the generation module is seen simply as a fixed and known *filter* over all possible the messages.

We formalize this by representing an agent's generation module as a function $\Gamma_A(m)$ mapping a message m to a NL sentence, or to $\emptyset$ if the module cannot fully realise m. The set of available messages to an agent A in state s_A is therefore: $\mathcal{M}(s_A) := \{m \,|\, m \in \mathsf{Sub}(s_A)\,,\ \Gamma_A(m) \neq \emptyset\}$.

3 A Simple Game Example

In this section we will use a simple computer game to demonstrate how the proposed framework can be used to learn message policies.

The game evolves in a grid-world. A mother-ship sends a *scout*, which will try to move from its

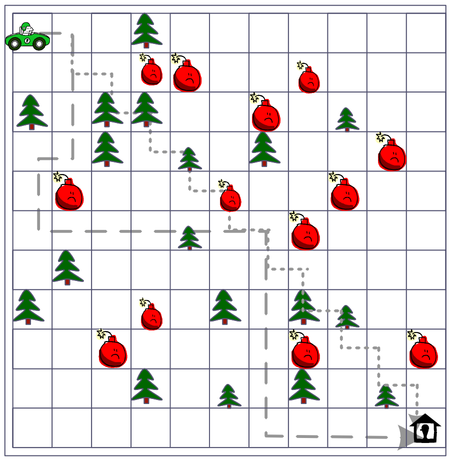

Figure 2: Example of a Simple Game Board.

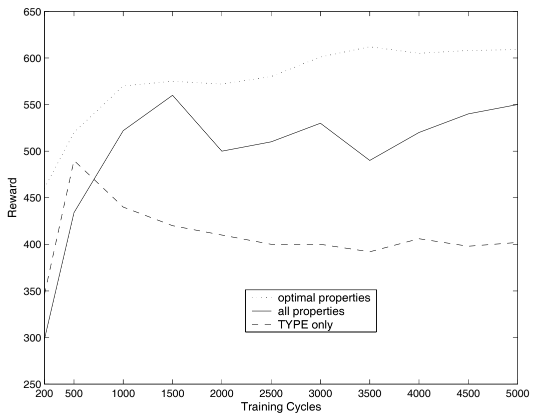

Figure 3: Simple Game Learning Results

State	**Best Action Learnt** *(and possible sentence realisation)*
{ TREE-BIG-LEFT }	∅ *-SILENCE-*
{ BOMB-BIG-FRONT }	BOMB-FRONT *There is a bomb in front of you*
{ TREE-SMALL-LEFT, TREE-BIG-RIGHT }	TREE-BIG-RIGHT *There is a big tree to your right*
{ BOMB-BIG-FRONT, BOMB-SMALL-LEFT, TREE-BIG-RIGHT, TREE-SMALL-BACK }	TREE-BIG-RIGHT *There is a big tree to your right*

Table 1: Examples of learnt actions.

starting position (top left corner) to a target (bottom right). There are two types of objects on the board, Type := {bomb, tree}, with a property Size := {big, small} in addition of Location. If a scout attempts to move into a big tree, the move is blocked; small trees have no effect. If a scout moves into a bomb the scout is destroyed and a new one is created at the starting position. Before every step the mother-ship may send a message to the scout. Then the scout moves one step (horizontal or vertical) towards the target choosing the shortest path which avoids hazards known by the scout (the A* algorithm is used for this). Initially scouts have no knowledge of the objects in the world; they gain this knowledge by stepping into objects or by receiving information from the mother-ship.

This is an instance of the talking god model discussed previously. The scout is the listener agent (A_1), and the mother-ship the talker (A_0). The scouts action policy π_1 is fixed (as described above), but we need to learn the message policy μ_{01}.

Rewards are associated with the results of physical actions: a high positive reward (1000) is assigned to reaching the destination, a large negative reward (-100) to stepping in a bomb, a medium negative reward (-10) to being blocked by a big tree, a small negative reward to every step (-1). Furthermore, sending a message has a small negative reward proportional to the number of attributes mentioned in the message (-2 per attribute, to discourage the talker from sending useless information). The message $\emptyset$ is given zero cost; this is done in order to learn when *not* to talk.

Learning is done as follows. We designed five maps of 11×11 cells, each with approximately 15 bombs and 20 trees of varying sizes placed in strategic locations to make the scouts task difficult (one of these maps is depicted in Figure 2; an A* path without any knowledge and one with full knowledge of the board are shown as dotted and dashed arrows respectively). A training epoch consists of randomly drawing one of these maps and running a single game until completion. The SARSA algorithm is used to learn the message policy, with $\epsilon = 0.1$ and $\gamma = 0.9$. The states s_W and s_1 are encoded to represent the location of objects surrounding the scout, relative to its direction (i.e. objects directly in front of the agent always receive the same location value). To speed up training, we only consider the 8 cells adjacent to the agent.

Figure 3 shows the results of these experiments. For comparison, we note that completing the game with a uniformly random talking policy results in an average reward of less than -3000 meaning that on average more than 30 scouts die before the target is reached. The dashed line indicates the reward obtained during training for a policy which does not use the size attribute, but only type and location. This policy effectively learns that both bombs and trees in front of the agent are to be communicated, resulting in an average reward of approximately 400, and reducing the average number of deaths to less than 2. The solid line represents the results obtained by a policy that is forced to use all attributes. Despite the increase in communication cost, this policy can distinguish between small and large trees, and so it increases the overall reward two-fold. Finally, the dotted line represents the results obtained by a policy that can choose whether to use or not the size attribute. This policy proves to be even more effective than the previous one; this means that it has learnt to use the size attribute only when it is necessary. Some optimal (state,action) pairs learnt for this policy are shown in Table 1. The first three show correctly learnt optimal actions. The last is an example of a wrongly learnt action, due to the state being rare.

These are encouraging results, since they demonstrate in practice how optimal policies may be learnt for message planning. However, it should be clear form this example that, as we increase the number of types, attributes and values, this approach will become unfeasible. This is discussed in the next section.

4 Back-Off Policies

One of the main problems when using RL in practical settings (and, more generally, using MDPs) is the exponential growth of the state space, and consequently of the learning time required. In our case, if there are M attributes, and each attribute p_i has $N(p_i)$ values, then there are $S = \prod_{i=1}^{M} N(p_i)$ possible sub-domains, and up to 2^S states in the state space. This exponential growth, unless addressed, will render MDP learning unfeasible.

NL domains are usually rich with structure, some of it which is known *a priori*. This is the case in text generation of descriptions for computer games, where we have many sources of information about the objects of discourse (i.e. world ontology, dynamics, etc.) We propose to tackle the problem of state dimensionality explosion by using this structure explicitly in the design of hierarchical policies.

We do so by borrowing the back-off smoothing idea from language models. This idea can be stated as: train a set of probability models, ordered by their specificity, and make predictions using the most specific model possible, but only if there is enough training data to support its prediction; otherwise, *back-off* to the next less-specific model available.

Formally, let us assume that for every state s we can construct a sequence of K embedded partial representations of increasing complexity, $(s_{[1]}, \ldots, s_{[k]}, \ldots, s_{[K]})$. Let us denote $\hat{\pi}_{[k]}$ a sequence of policies operating at each of the partial representation levels respectively, and let each of these policies have a *confidence measurement* $c_k(s)$ indicating the quality of the prediction at each state. Since k indicates increasingly complex, we require that $c_k(s) \geq c_{k'}(s)$ if $k < k'$. Then, the most specific policy we can use at state s can be written as:

$$k^*_s := \arg\max_k \{k \cdot \mathrm{sign}\,(c_k(s) - \theta)\} \qquad (1)$$

A back-off policy can be implemented by choosing, at every state s the most specific policy available:

$$\pi(s) = \hat{\pi}_{[k^*_s]}(s_{[k^*_s]}) \qquad (2)$$

We can use a standard off-policy learning algorithm (such as Q-learning or SARSA) to learn all the policies simultaneously. At every step, we draw an action using (2) and update all policies with the obtained reward[1]. Initially, the learning will be driven by high-level (simple) policies. More complex policies will kick-in progressively for those states that are encountered more often.

In order to implement back-off policies for our setting, we need to define a confidence function c_k. A simple confidence measure is the number of times the state $s_{[k]}$ has been previously encountered. This measure grows on average very quickly for small k states and slowly for high k states. Nevertheless, reoccurring similar states will have high visit counts

[1]An alternative view of back-off policies is to consider that a single complete policy is being learnt, but that actions are being drawn from regularised versions of this policy, where the regularisation is a back-off model on the features. We show this in Appendix I

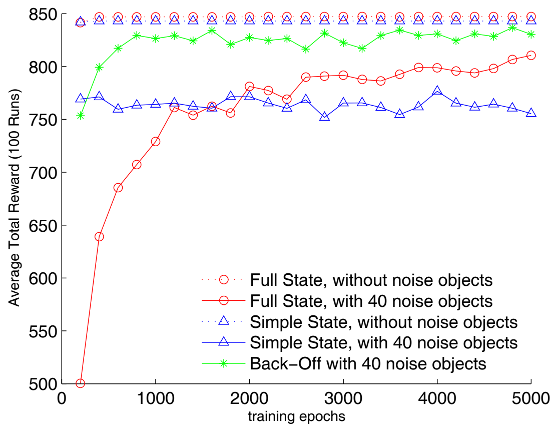

Figure 4: Back-Off Policy Simulation Results.

for all k values. This is exactly the kind of behaviour we require.

Furthermore, we need to choose a set of representations of increasing complexity. For example, in the case of n-gram models it is natural to choose as representations sequences of preceding words of increasing size. There are many choices open to us in our application domain. A natural choice is to order attribute types by their importance to the task. For example, at the simplest level of representation objects can be represented only by their type, at a second level by the type and colour, and at a third level by all the attributes. This same technique could be used to exploit ontologies and other sources of knowledge. Another way to create levels of representation of increasing detail is to consider different perceptual windows. For example, at the simplest level the agent can consider only objects directly in front of it, since these are generally the most important when navigating. At a second level we may consider also what is to the left and right of us, and finally consider all surrounding cells. This could be pursued even further by considering regions of increasing size.

4.1 Simulation Results

We present here a series of experiments based on the previous game setting, but further simplified to pinpoint the effect of dimensionality explosion, and how back-off policies can be used to mitigate it.

We modify the simple game of Section 3 as follows. First, we add a new object type, stone, and a new property Colour := {red, green}. We let all trees be green and big and all bombs red and small, and furthermore we fix their location (i.e. we use one map instead of five). Finally we change the world behaviour so that an agent that steps into a bomb receives the negative reward but does not die, it continues until it reaches the target. All these changes are done to reduce the variability of our learning baseline.

At every game we generate 40 stones of random location, size and colour. Stepping on stones has no physical effect to the scout and it generates the same reward as moving into an empty cell, but this is unknown to the talker and will need to be learnt. These stones are used as *noise* objects, which increase the size of the state space. When there are no noise objects, the number of possible states is $3^8 \approx 6.5K$ (the actual number of states will be much smaller since there is a single maze). Noise objects can take $2 \times 2 = 4$ possible forms, so the total number of states with noise objects is $(3+4)^8 \approx 6M$. Even with such a simplistic example we can see how drastic the state dimensionality problem is. Despite the fact that the noise objects do not affect the reward structure of our simple game, reinforcement learning will be drastically slowed down by them.

Simulation results[2] are shown in Figure 4. First let us look at the results obtained using the full state representation used in Section 3 (noted Full State). Solid and dotted lines represent runs obtained with and without noise objects. First note that learning without noise objects (dotted circles) occurs mostly within the first few epochs and settles after 250 epochs. When noise objects are added (solid circles) learning greatly slows down, taking over 5K epochs. This is a typical illustration of the effect that the number of states has on the speed of learning.

An obvious way to limit the number of states is to eliminate features. For comparison, we learned a simple representation policy with states encoding only the type of the object *directly in front* of the agent, ignoring its colour and all other locations (noted Simple State). Without noise, the performance (dotted triangles) is only slightly worse than that of the original policy. However, when noise objects

[2]Every 200 training epochs we run 100 validation epochs with $\epsilon = 0$. Only the average validation rewards are plotted.

are added (solid triangles) the training is no longer slowed down. In fact, with noise objects this policy outperforms the original policy up to epoch 1000: the performance lost in the representation is made up by the speed of learning.

We set up a back-off policy with $K = 3$ as follows. We use the Simple representation at $k = 1$, plus a second level of representation where we represent the colour as well as the type of the object in front of the agent, and finally the Full representation as the third level. As the c_k function we use state visit counts as discussed above and we set $\theta = 10$. Before reaching the full policy (level 3), this policy should progressively learn to avoid bombs and trees directly in front (level 1), then (level 2) not avoid small trees directly in front. We plot the performance of this back-off policy (stars) in Figure 4. We see that it attains very quickly the performance of the simple policy (in less than 200 epochs), but the continues to increase in performance settling within 500 epochs with a performance superior to that of the full state representation, and very close to that of the policies operating in the noiseless world.

Despite the small scale of this study, our results clearly suggest that back-off policies can be used effectively to control state dimensionality explosion when we have strong prior knowledge of the structure of the state space. Furthermore (and this may be very important in real applications such as game development) we find that back-off policies produce a *natural* to feel to the errors incurred while learning, since policies develop progressively in their complexity.

5 Conclusion

We have developed a formalism to learn interactively the most informative message content given the state of the listener and the world. We formalised this problem as a MDP and shown how RL may be used to learn message policies even when the environment dynamics are unknown. Finally, we have shown the importance of tackling the problem of state dimensionality explosion, and we have proposed one method to do so which exploits explicit *a priori* ontological knowledge of the task.

6 Appendix I

We show here that the expected reward for a partial policy π_k after an action a, noted $Q^{\pi_k}(s,a)$, can be obtained from the expected reward of the full policy $Q^{\pi}(s,a)$ and the conditional state probabilities $P(s|s_{[k]})$. We may use this to compute the expected risk of any partial policy $R^{\pi_k}(s)$ from the full policy.

Let $\mathcal{T}_k(s) := \left\{ s' \in \mathcal{S} \mid s'_{[k]} = s_{[k]} \right\}$ be the subset of full states which map to the same value of s. Given a state distribution $P(s)$ we can define distributions over partial states:

$$P(s_{[k]}, s_{[j]}) = \sum_{s' \in \mathcal{T}_k(s) \cap \mathcal{T}_j(s)} P(s') \quad . \tag{3}$$

Since $\sum_{s' \in \mathcal{T}_k(s)} P(s'|s_{[k]}) = 1$, we have $P(A|s_{[k]}) = \sum_{s' \in \mathcal{T}_k(s)} P(A|s')P(s'|s_{[k]})$, and so:

$$Q^{\pi_k}(s,a) = \sum_{s' \in \mathcal{T}_k(s)} P(s'|s_{[k]}) Q^{\pi}(s',a) \quad . \tag{4}$$

Using Question Series To Evaluate Question Answering System Effectiveness

Ellen M. Voorhees
National Institute of Standards and Technology
Gaithersburg, MD 20899

Abstract

The original motivation for using question series in the TREC 2004 question answering track was the desire to model aspects of dialogue processing in an evaluation task that included different question types. The structure introduced by the series also proved to have an important additional benefit: the series is at an appropriate level of granularity for aggregating scores for an effective evaluation. The series is small enough to be meaningful at the task level since it represents a single user interaction, yet it is large enough to avoid the highly skewed score distributions exhibited by single questions. An analysis of the reliability of the per-series evaluation shows the evaluation is stable for differences in scores seen in the track.

The development of question answering technology in recent years has been driven by tasks defined in community-wide evaluations such as TREC, NTCIR, and CLEF. The TREC question answering (QA) track started in 1999, with the first several editions of the track focused on factoid questions. A factoid question is a fact-based, short answer question such as *How many calories are there in a Big Mac?*. The track has evolved by increasing the type and difficulty of questions that are included in the test set. The task in the TREC 2003 QA track was a combined task that contained list and definition questions in addition to factoid questions (Voorhees, 2004). A list question asks for different instances of a particular kind of information to be returned, such as *List the names of chewing gums*. Answering such questions requires a system to assemble an answer from information located in multiple documents. A definition question asks for interesting information about a particular person or thing such as *Who is Vlad the Impaler?* or *What is a golden parachute?*. Definition questions also require systems to locate information in multiple documents, but in this case the information of interest is much less crisply delineated.

Like the NTCIR4 QACIAD challenge (Kato et al., 2004), the TREC 2004 QA track grouped questions into series, using the series as abstractions of information-seeking dialogues. In addition to modeling a real user task, the series are a step toward incorporating context-processing into QA evaluation since earlier questions in a series provide some context for the current question. In the case of the TREC series, each series contained factoid and list questions and had the target of a definition associated with it. Each question in a series asked for some information about the target. In addition, the final question in each series was an explicit "other" question, which was to be interpreted as "Tell me other interesting things about this target I don't know enough to ask directly". This last question was roughly equivalent to the definition questions in the TREC 2003 task.

This paper examines the efficacy of series-based QA evaluation, and demonstrates that aggregating scores over individual series provides a more meaningful evaluation than averages of individual question scores. The next section describes the question series that formed the basis of the TREC 2004 evaluation. Since TREC uses different evaluation protocols for different question types, the following section describes the way in which individual question types were evaluated. Section 3 contrasts the scores obtained by aggregating individual question scores by question type or by series, and shows the use of series leads to a reliable evaluation at differences in scores that are observed in practice.

1 Question Series

A question series as used in the TREC 2004 QA track consisted of several factoid questions, zero to two list questions, and exactly one Other question. Associated with each series was a definition target. The series a question belonged to, the order of the question in the series, and the type of each question (factoid, list, or Other) were all explicitly encoded in the XML format used to describe the test set. Example series (minus the XML tags) are shown in figure 1. A target was a person, an organization, or thing that was a plausible match for the scenario assumed for the task: that the questioner was an "average" adult reader of US newspapers who was looking for more information about a term encountered while reading the paper.

The TREC 2004 test set contains 65 series. Of the 65 targets, 23 are PERSONs, 25 are ORGANIZATIONs, and 17 are THINGs. The series contain a total of 230 factoid questions, 56 list questions, and 65 (one per target) Other questions. Each series contains at least four questions, counting the Other question, with most series containing five or six questions. The maximum number of questions in a series is ten.

Question series were also the fundamental structure used in the QACIAD challenge (Question Answering Challenge for Information Access Dialogue) of NTCIR4. However, there are some important differences between the QACIAD and TREC series. The QACIAD series model a more natural flow of questions in an information-seeking dialogue. Given other evaluation requirements (most questions need to have an answer in the source documents, answers to earlier questions should not be given in later questions, etc.), the series in the TREC test set are heavily edited versions of the series collected from the original information seekers. The resulting edited series appear as a stilted conversational style when viewed from the perspective of true dialogue, and the series do not reflect the full range of information requested in the original series. (For example, TREC requires list question answers to be concrete entities such as cities or book titles while the information seekers often asked for fuzzier information such as lists of descriptive qualities.) The QACIAD challenge contained two types of series, gathering series and browsing series. In a gathering series, all of the questions are related to a single target (that was not explicitly given in QACIAD), while questions in a browsing series can refer to unrelated targets. The TREC series are all gathering type series with the target explicitly given. Finally, the QACIAD series consist of list questions only, since factoid questions are treated as list questions with a single answer.

Systems participating in the TREC evaluation were required to process series independently from one another, and were required to process an individual series in question order. That is, systems were allowed to use questions and answers from earlier questions in a series to answer later questions in that same series, but could not "look ahead" and use later questions to help answer earlier questions. The series was the unit used to structure the test set, but there was no requirement for systems to process a series as a unit. Some systems appended the target to each of the questions in its series and then processed all resulting question strings independently as in earlier TREC evaluations. Per-series evaluation is still valid since the task to be evaluated is defined in terms of the series and is independent of how systems choose to process the questions.

Sixty-three runs from 28 participants were submitted to the TREC 2004 QA track.

2 Scoring Question Series

The evaluation protocol for individual questions depends on the type of the question. This section summarizes the protocols for the individual question types and for a series as a whole.

3	Hale Bopp comet		
	3.1	FACTOID	When was the comet discovered?
	3.2	FACTOID	How often does it approach the earth?
	3.3	LIST	In what countries was the comet visible on its last return?
	3.4	OTHER	
21	Club Med		
	21.1	FACTOID	How many Club Med vacation spots are there worldwide?
	21.2	LIST	List the spots in the United States.

	22.5	OTHER	

Figure 1: Sample question series from the test set. Series 3 has a THING as a target, series 21 has an ORGANIZATION as a target, and series 22 has a PERSON as a target.

2.1 Factoid questions

The system response for a factoid question is either exactly one [*doc-id*, *answer-string*] pair or the literal string 'NIL'. NIL is returned by a system when it believes there is no answer to the question in the document collection. Otherwise, *answer-string* is a string containing precisely an answer to the question, and *doc-id* is the id of a document in the collection that supports *answer-string* as an answer.

Each response was assigned exactly one of the following four judgments:

incorrect: the answer string does not contain a right answer or the answer is not responsive;

not supported: the answer string contains a right answer but the document returned does not support that answer;

not exact: the answer string contains a right answer and the document supports that answer, but the string contains more than just the answer or is missing bits of the answer;

correct: the answer string consists of exactly the right answer and that answer is supported by the document returned.

To be responsive, an answer string is required to contain appropriate units and to refer to the correct "famous" entity (e.g., the Taj Mahal casino is not responsive when the question asks about "the Taj Mahal"). NIL responses are correct only if there is no known answer to the question in the collection and are incorrect otherwise. NIL is correct for 22 of the 230 factoid questions in the test set

An individual factoid question has a binary score, 1 if the response is judged correct and 0 otherwise. The score for a set of factoid questions is accuracy, the fraction of questions in the set judged correct.

2.2 List questions

A list question can be thought of as a shorthand for asking the same factoid question multiple times. The set of all correct, distinct answers in the document collection that satisfy the factoid question is the correct answer for a list question.

A system's response for a list question is an unordered set of [*doc-id*, *answer-string*] pairs such that each *answer-string* is considered an instance of the requested type. Judgments of incorrect, unsupported, not exact, and correct are made for individual response pairs as in the factoid judging. The assessor is given one run's entire list at a time, and while judging for correctness also marks a set of responses as distinct. The assessor chooses an arbitrary member of the equivalent responses to be marked distinct, and the remainder are not marked as distinct. Only correct responses may be marked as distinct.

The final correct answer set for a list question is compiled from the union of the correct responses across all runs plus the instances the assessor found during question development. For the 55 list questions used in the evaluation (one list question was dropped because the assessor decided there were no correct answers during judging), the average number of answers per question is 8.8, with 2 as the smallest number of answers, and 41 as the maximum number of answers. A system's response to a list question was scored using instance precision (IP) and instance recall (IR) based on the list of known instances. Let S be the number of known instances, D be the number of correct, distinct responses returned by the system, and N be the total number of responses returned by the system. Then $IP = D/N$ and $IR = D/S$. Precision and recall were then combined using the F measure with equal weight given to recall and precision:

$$F = \frac{2 \times IP \times IR}{IP + IR}$$

The score for a set of list questions is the mean of the individual questions' F scores.

2.3 Other questions

The Other questions were evaluated using the same methodology as the TREC 2003 definition questions (Voorhees, 2003). A system's response for an Other question is an unordered set of [*doc-id*, *answer-string*] pairs as for list questions. Each string is presumed to be a facet in the definition of the series' target that had not yet been covered by earlier questions in the series. The requirement to not repeat information already covered by earlier questions in the series made answering Other questions somewhat more difficult than answering TREC 2003 definition questions.

Judging the quality of the systems' responses is done in two steps. In the first step, all of the answer strings from all of the systems' responses are presented to the assessor in a single list. Using these responses and the searches done during question development, the assessor creates a list of information nuggets about the target. An information nugget is an atomic piece of information about the target that is interesting (in the assessor's opinion) and is not part of an earlier question in the series or an answer to an earlier question in the series. An information nugget is atomic if the assessor can make a binary decision as to whether the nugget appears in a response. Once the nugget list is created for a target, the assessor marks some nuggets as vital, meaning that this information must be returned for a response to be good. Non-vital nuggets act as don't care conditions in that the assessor believes the information in the nugget to be interesting enough that returning the information is acceptable in, but not necessary for, a good response.

In the second step of judging the responses, an assessor goes through each system's response in turn and marks which nuggets appear in the response. A response contains a nugget if there is a conceptual match between the response and the nugget; that is, the match is independent of the particular wording used in either the nugget or the response. A nugget match is marked at most once per response—if the response contains more than one match for a nugget, an arbitrary match is marked and the remainder are left unmarked. A single [*doc-id*, *answer-string*] pair in a system response may match 0, 1, or multiple nuggets.

Given the nugget list and the set of nuggets matched in a system's response, the nugget recall of a response is the ratio of the number of matched nuggets to the total number of vital nuggets in the list. Nugget precision is much more difficult to compute since there is no effective way of enumerating all the concepts in a response. Instead, a measure based on length (in non-white space characters) is used as an approximation to nugget precision. The length-based measure starts with an initial allowance of 100 characters for each (vital or non-vital) nugget matched. If the total system response is less than this number of characters, the value of the measure is 1.0. Otherwise, the measure's value decreases as the length increases using the function $1 - \frac{length - allowance}{length}$. The final score for an Other question is computed as the F measure with nugget recall three times as important as nugget precision:

$$F(\beta = 3) = \frac{10 \times \text{precision} \times \text{recall}}{9 \times \text{precision} + \text{recall}}.$$

Note that the Other question for series S7 was mistakenly left unjudged, so the series was was removed from the TREC 2004 evaluation. This means final scores for runs were computed over 64 rather than 65 question series.

2.4 Per-series scores

In the TREC 2003 evaluation, the final score for a run was computed as a weighted average of the mean scores for different question types:

$$\begin{aligned}\text{FinalScore} &= .5\text{FactoidAccuracy} + .25\text{ListAveF}\\ &+ .25\text{DefinitionAveF}.\end{aligned}$$

Since each of the component scores ranges between 0 and 1, the final score is also in that range. The weights for the different components reflect the desire to emphasize factoid scores, since factoid technology is the most mature, while still allowing other components to affect the final score. The specific weights used match this general objective, but are otherwise arbitrary. No experiments have been run examining the effect of different weights on the stability of the final scores, but small perturbations in the weights should have little effect on the results.

An individual question series also contains a mixture of different question types, so the weighted average can be computed for an individual series rather than the test set as a whole. The mean of the per-series scores is then used as the final score for a run.

We use the same weighted average as above to compute the score for an individual series that contains all three question types, using only the scores for questions belonging to that series in the computation and using the Other question's score in place of the average of definition questions scores. For those series that did not contain any list questions, the score was computed as .67FactoidAccuracy + .33OtherF. Figure 2 shows the average per-series score for the best run for each of the top 10 groups that participated in TREC 2004.

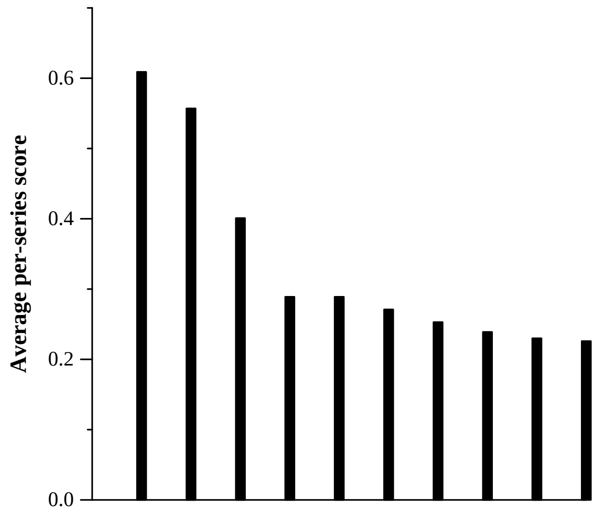

Figure 2: Average per-series scores for top ten QA track runs.

3 Analysis of Per-series Evaluation

The main purpose of evaluations such as TREC is to provide system builders with the information needed to improve their systems. An informative evaluation must be reliable (i.e., the results must be trustworthy) as well as capture salient aspects of the real user task. This section first examines the user task abstracted by the per-series evaluation, and then derives an empirical estimate of the reliability of the evaluation.

3.1 Modeling a User Task

The set of questions used to aggregate individual questions' scores determines the emphasis of a QA evaluation. In the TREC 2003 combined task there were no series but there were different question types, so question scores were first averaged by question type and then those averages were combined. This strategy emphasizes question-type analysis in that it is easy to compare different systems' abilities for the different question types. The QACIAD challenge contained only a single question type but introduced a series structure into the test set (Kato et al., 2004). In QACIAD, the scores were aggregated over the series and the series scores averaged. The QACIAD series were specifically constructed to be an abstraction of an information seeker's dialogue, and the aggregation of scores over series supports comparing different series types. For example, QACIAD results show browsing series to be more difficult than gathering series.

The TREC 2004 QA track contained both series structure and different question types, so individual question scores could be aggregated either by series or by question type. In general, the two methods of aggregation lead to different final scores. Aggregating by question type gives equal weight to

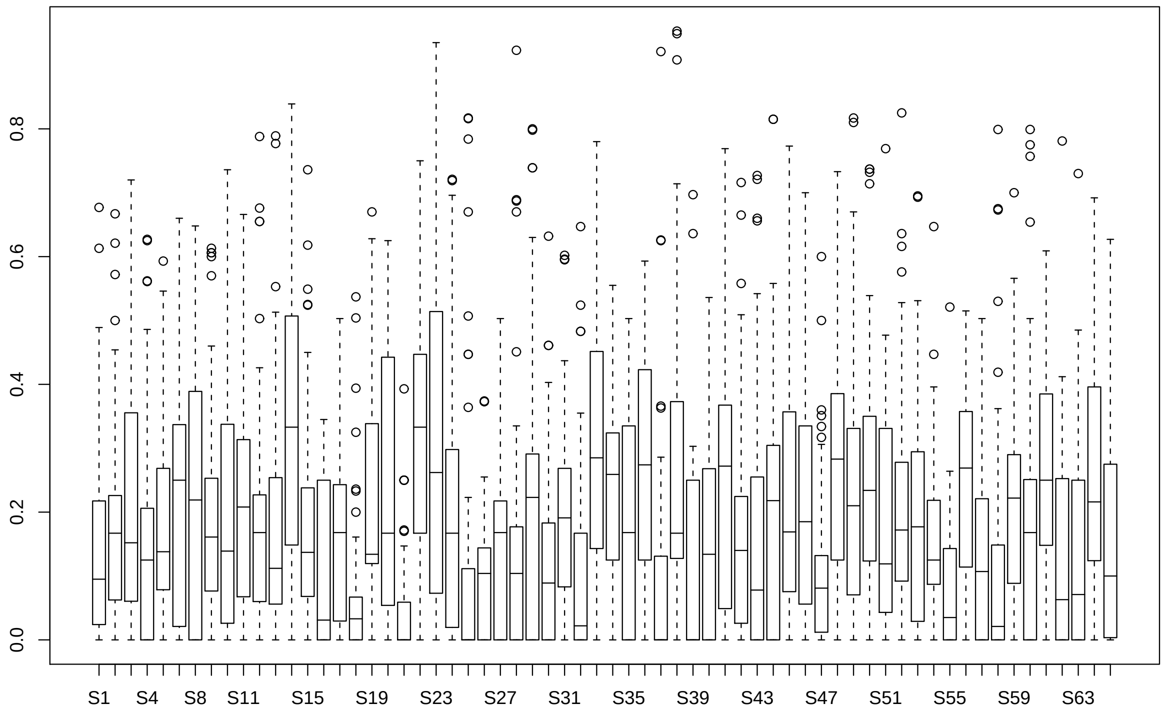

Figure 3: Box and whiskers plot of per-series scores across all TREC 2004 runs. The x-axis shows the series number and the y-axis the score.

each of the questions of the same type, while aggregating by series gives equal weight to each series. This is the same difference as between micro- and macro-averaging of document retrieval scores. For the set of runs submitted to TREC 2004, the absolute value of the final scores when aggregated by series were generally somewhat greater than the final scores when aggregated by question type, though it is possible for the question-type-aggregated score to be the greater of the two. The relative scores for different runs (i.e., whether one run was better than another) were usually, but not always, the same regardless of which aggregation method was used. The Kendall τ (Stuart, 1983) measure of correlation between the system rankings produced by sorting the runs by final score for each of the two aggregation methods was 0.971, where identical rankings would have a correlation of 1.0.

Despite the relatively minor differences in runs' final scores when aggregating by series or by question type, there is a strong reason to prefer the series aggregation. An individual series is small enough to be meaningful at the task level (it represents a single user's interaction) yet large enough for a series score to be meaningful. Figure 3 shows a box-and-whiskers plot of the per-series scores across all runs for each series. A box in the plot shows the extent of the middle half of the scores for that series, with the median score indicated by the line through the box. The dotted lines (the "whiskers") extend to a point that is 1.5 times the interquartile distance, or the most extreme score, whichever is less. Extreme scores that are greater than the 1.5 times the interquartile distance are plotted as circles. The plot shows that only a few series (S21, S25, S37, S39) have median scores of 0.0. This is in sharp contrast to the median scores of individual questions. For the TREC 2004 test set, 212 of the 230 factoid questions (92.2%) have a zero median, 39 of 55 list questions (70.9%) have a zero median, and 41 of 64 Other questions (64.1%) have a zero median.

Having a unit of evaluation that is at the appropriate level of granularity is necessary for meaningful results from the methodology used to assess the reliability of an evaluation. This methodology, described below, was originally created for document retrieval evaluations (Voorhees and Buckley, 2002) where the topic is the unit of evaluation. The distribution of scores across runs for an individual topic is much the same as the distribution of scores for the individual series as in figure 3. Score distributions that are heavily skewed toward zero make the evaluation look far more reliable than is likely to be the case since the reliability methodology computes a measure of the variability in scores.

3.2 Reliability

TREC uses comparative evaluations: one system is considered to be more effective than another if the evaluation score computed for the output of the first system is greater than the evaluation score computed for the output of the second system. Since all measurements have some (unknown) amount of error associated with them, there is always a chance that such a comparison can lead to the wrong result. An analysis of the reliability of an evaluation establishes bounds for how likely it is for a single comparison to be in error.

The reliability analysis uses the runs submitted to the track to empirically determine the relationship among the number of series in a test set, the observed difference in scores (δ) between two runs, and the likelihood that a single comparison of two runs leads to the correct conclusion. Once established, the relationship is used to derive the minimum difference in scores required for a certain level of confidence in the results given that there are 64 series in the test set.

The core of the procedure for establishing the relationship is comparing the effectiveness of a pair runs on two disjoint, equal-sized sets of series to see if the two sets disagree as to which of the runs is better. We define the error rate as the percentage of comparisons that have such a disagreement. Since the TREC 2004 track had 64 series, we can directly compute the error rate for test sizes up to 32 series. The smallest test set used is five series since fewer than five series in a test set is too noisy to be informative. By fitting curves to the values observed for test set sizes between 5 and 32, we can extrapolate the error rates to test sets up to 64 series.

When calculating the error rate, the difference between two runs' scores is categorized into a set of bins based on the size of the difference. The first bin contains runs with a difference of less than 0.01 (including no difference at all). The next bin contains runs whose difference is at least 0.01 but less than 0.02. The limits for the remaining bins increase by increments of 0.01.

Each test set size from 5 to 32 is treated as a separate experiment. Within an experiment, we randomly select two disjoint sets of series of the required size. We compute the average series score over both sets for all runs, then count the number of times we see a disagreement as to which run is better for all pairs of runs using the bins to segregate the counts by size of the difference in scores. The entire procedure is repeated 50 times (i.e., we perform 50 trials), with the counts of the number of disagreements kept as running totals over all trials. The ratio of the number of disagreements observed in a bin to the total number of cases that land in that bin is the error rate for the bin.

Figure 4 shows the error rate curves for five separate bins. In the figure the test set size is plotted on the x-axis and the error rate is plotted on the y-axis. The individual points in the graphs are the data points actually computed by the procedure above, while the lines are the best-fit exponential curve for the data points in the current bin and extrapolated to size 64. The top curve is for the bin with $0.01 \leq \delta < 0.02$ and the bottom curve for the bin with $0.05 \leq \delta < 0.06$; the intervening curves are for the intervening bins, in order with smaller δ's having larger error rates. An error rate no greater than 5%, requires a difference in scores of at least 0.05, which can be obtained with a test set of 47 series. Score differences of between 0.04 and 0.05 (the fourth curve) have an error rate slightly greater than 5% when there are 64 series in the test set.

Having established the minimum size of the difference in scores needed to be confident that two runs are actually different, it is also important to know whether differences of the required size actually occur in practice. If it is rare to observe a difference in scores as large as the minimum, then the evaluation will be reliable but insensitive. With 64 runs submitted to the TREC 2004 QA track, there are 1953 run pairs; 70% of the pairs have a difference in average per-series score that is at least 0.05. Many of the pairs in the remaining 30% are truly equivalent—for example, runs submitted by the same group that had very small differences in their processing. In figure 2, the difference in scores

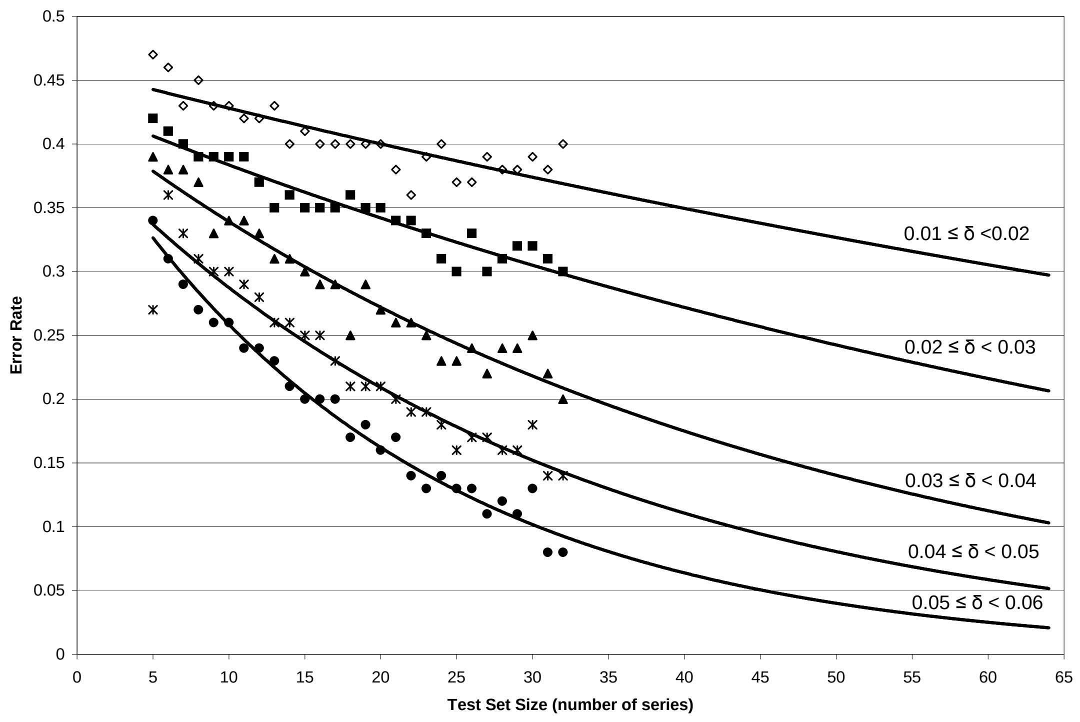

Figure 4: Extrapolated error rates for per-series scores for different test set sizes.

between each of the first three runs and its next closest run is greater than 0.05, while the next five runs are all within 0.05 of one another.

4 Conclusion

Question series have been introduced into recent question answering evaluations as a means of modeling dialogues between questioners and systems. The abstraction allows researchers to investigate methods for answering contextualized questions and for tracking (some forms of) the way objects are referred to in natural dialogues. The series have an important evaluation benefit as well. The individual series is at the correct level of granularity for aggregating scores for a meaningful evaluation. Unlike individual questions that have heavily skewed score distributions across runs, per-series score distributions resemble the distributions of per-topic scores in document retrieval evaluations. This allows the methodology developed for assessing the quality of a document retrieval evaluation to be meaningfully applied to the per-series evaluation. Such an analysis of the TREC 2004 QA track per-series evaluation shows the evaluation results to be reliable for differences in scores that are often observed in practice.

Abstract

We explore a hybrid approach for Chinese definitional question answering by combining deep linguistic analysis with surface pattern learning. We answer four questions in this study: 1) How helpful are linguistic analysis and pattern learning? 2) What kind of questions can be answered by pattern matching? 3) How much annotation is required for a pattern-based system to achieve good performance? 4) What linguistic features are most useful? Extensive experiments are conducted on biographical questions and other definitional questions. Major findings include: 1) linguistic analysis and pattern learning are complementary; both are required to make a good definitional QA system; 2) pattern matching is very effective in answering biographical questions while less effective for other definitional questions; 3) only a small amount of annotation is required for a pattern learning system to achieve good performance on biographical questions; 4) the most useful linguistic features are copulas and appositives; relations also play an important role; only some propositions convey vital facts.

1 Introduction

Due to the ever increasing large amounts of online textual data, learning from textual data is becoming more and more important. Traditional document retrieval systems return a set of relevant documents and leave the users to locate the specific information they are interested in. Question answering, which combines traditional document retrieval and information extraction, solves this problem directly by returning users the specific answers. Research in textual question answering has made substantial advances in the past few years (Voorhees, 2004).

Most question answering research has been focusing on factoid questions where the goal is to return a list of facts about a concept. Definitional questions, however, remain largely unexplored. Definitional questions differ from factoid questions in that the goal is to return the relevant "answer nuggets" of information about a query. Identifying such answer nuggets requires more advanced language processing techniques. Definitional QA systems are not only interesting as a research challenge. They also have the potential to be a valuable complement to static knowledge sources like encyclopedias. This is because they create definitions dynamically, and thus answer definitional questions about terms which are new or emerging (Blair-Goldensoha et al., 2004).

One success in factoid question answering is pattern based systems, either manually constructed (Soubbotin and Soubbotin, 2002) or machine learned (Cui et al., 2004). However, it is unknown whether such pure pattern based systems work well on definitional questions where answers are more diverse.

Deep linguistic analysis has been found useful in factoid question answering (Moldovan et al., 2002) and has been used for definitional questions (Xu et al., 2004; Harabagiu et al., 2003). Linguistic analysis is useful because full parsing captures long distance dependencies between the answers and the query terms, and provides more information for inference. However, merely linguistic analysis may not be enough. First, current state of the art linguistic analysis such as parsing, co-reference, and relation extraction is still far below human performance. Errors made in this stage will propagate and lower system accuracy. Second, answers to some types of definitional questions may have strong local dependencies that can be better captured by surface patterns. Thus we believe that combining linguistic analysis and pattern learning would be complementary and be beneficial to the whole system.

Work in combining linguistic analysis with patterns include Weischedel et al. (2004) and Jijkoun et al. (2004) where manually constructed patterns are used to augment linguistic features. However, manual pattern construction critically depends on the domain knowledge of the pattern designer and often has low coverage (Jijkoun et al., 2004). Automatic pattern derivation is more appealing (Ravichandran and Hovy, 2002).

In this work, we explore a hybrid approach to combining deep linguistic analysis with automatic pattern learning. We are interested in answering the following four questions for Chinese definitional question answering:

- How helpful are linguistic analysis and pattern learning in definitional question answering?
- If pattern learning is useful, what kind of question can pattern matching answer?
- How much human annotation is required for a pattern based system to achieve reasonable performance?
- If linguistic analysis is helpful, what linguistic features are most useful?

To our knowledge, this is the first formal study of these questions in Chinese definitional QA. To answer these questions, we perform extensive experiments on Chinese TDT4 data (Linguistic Data Consortium, 2002-2003). We separate definitional questions into biographical (Who-is) questions and other definitional (What-is) questions. We annotate some question-answer snippets for pattern learning and we perform deep linguistic analysis including parsing, tagging, name entity recognition, co-reference, and relation detection.

2 A Hybrid Approach to Definitional Question Answering

The architecture of our QA system is shown in Figure 1. Given a question, we first use simple rules to classify it as a “Who-is” or “What-is” question and detect key words. Then we use a HMM-based IR system (Miller et al., 1999) for document retrieval by treating the question keywords as a query. To speed up processing, we only use the top 1000 relevant documents. We then select relevant sentences among the returned relevant documents. A sentence is considered relevant if it contains the query keyword or contains a word that is co-referent to the query term. Coreference is determined using an information extraction engine, SERIF (Ramshaw et al., 2001). We then conduct deep linguistic analysis and pattern matching to extract candidate answers. We rank all candidate answers by predetermined feature ordering. At the same time, we perform redundancy detection based on n-gram overlap.

2.1 Deep Linguistic Analysis

We use SERIF (Ramshaw et al., 2001), a linguistic analysis engine, to perform full parsing, name entity detection, relation detection, and co-reference resolution. We extract the following linguistic features:

1. Copula: a copula is a linking verb such as “*is*” or “*become*”. An example of a copula feature is “*Bill Gates is the CEO of Microsoft*”. In this case, “*CEO of Microsoft*” will be extracted as an answer to “*Who is Bill Gates?*”. To extract copulas, SERIF traverses the parse trees of the sentences and extracts copulas based on rules. In Chinese, the rule for identifying a copula is the POS tag “*VC*”, standing for “*Verb Copula*”. The only copula verb in Chinese is “是”.

2. Apposition: appositions are a pair of noun phrases in which one modifies the other. For example, In “*Tony Blair, the British Prime Minister, ...*”, the phrase “*the British Prime Minister*” is in apposition to “*Blair*”. Extraction of appositive features is similar to that of copula. SERIF traverses the parse tree and identifies appositives based on rules. A detailed description of the algorithm is documented

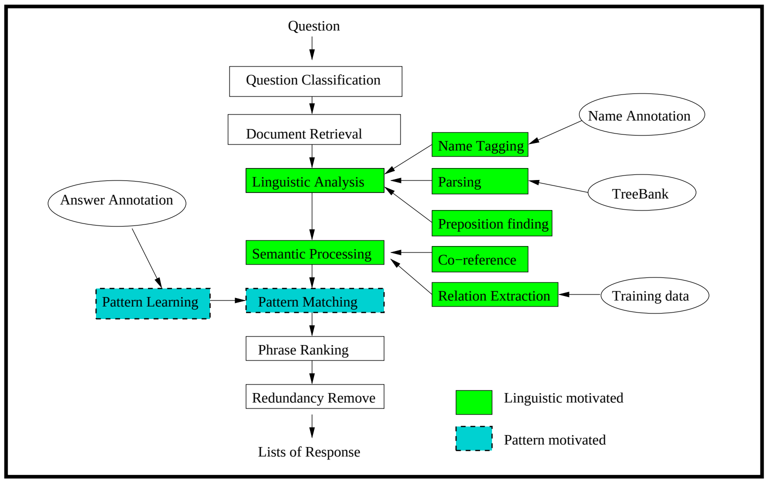

Figure 1: Question answering system structure

in (Ramshaw et al., 2001).

3. Proposition: propositions represent predicate-argument structures and take the form: *predicate(*$role_1$*:* arg_1*, ...,* $role_n$*:* arg_n*)*. The most common roles include logical subject, logical object, and object of a prepositional phrase that modifies the predicate. For example, "Smith went to Spain" is represented as a proposition, *went(logical subject: Smith, PP-to: Spain)*.

4. Relations: The SERIF linguistic analysis engine also extracts relations between two objects. SERIF can extract 24 binary relations defined in the ACE guidelines (Linguistic Data Consortium, 2002), such as spouse-of, staff-of, parent-of, management-of and so forth. Based on question types, we use different relations, as listed in Table 1.

Relations used for Who-Is questions
ROLE/MANAGEMENT, ROLE/GENERAL-STAFF, ROLE/CITIZEN-OF, ROLE/FOUNDER, ROLE/OWNER, AT/RESIDENCE, SOC/SPOUSE, SOC/PARENT, ROLE/MEMBER, SOC/OTHER-PROFESSIONAL
Relation used for What-Is questions
AT/BASED-IN, AT/LOCATED, PART/PART-OF

Table 1: Relations used in our system

Many relevant sentences do not contain the query key words. Instead, they contain words that are co-referent to the query. For example, in "*Yesterday UN Secretary General* **Anan** *Requested Every Side...,* **He** *said ...* ". The pronoun "He" in the second sentence refers to "Anan" in the first sentence. To select such sentences, we conduct co-reference resolution using SERIF.

In addition, SERIF also provides name tagging, identifying 29 types of entity names or descriptions, such as locations, persons, organizations, and diseases.

We also select complete sentences mentioning the term being defined as backup answers if no other features are identified.

The component performance of our linguistic analysis is shown in Table 2.

	Pre.	Recall	F
Parsing	0.813	0.828	0.820
Co-reference	0.920	0.897	0.908
Name-entity detection	0.765	0.753	0.759

Table 2: Linguistic analysis component performance for Chinese

2.2 Surface Pattern Learning

We use two kinds of patterns: manually constructed patterns and automatically derived patterns. A manual pattern is a commonly used linguistic expression that specifies aliases, super/subclass and membership relations of a term (Xu et al., 2004). For example, the expression "*tsunamis, also known as tidal waves*" gives an alternative term for tsunamis. We use 23 manual patterns for *Who-is* questions and 14 manual patterns for *What-is* questions.

We also classify some special propositions as manual patterns since they are specified by computational linguists. After a proposition is extracted, it is matched against a list of predefined predicates. If it is on the list, it is considered special and will be ranked higher. In total, we designed 22 special propositions for *Who-is* questions, such as 成为(become), 当选为(elected as), and 辞去(resign), 14 for *What-is* questions, such as 位于(located at), 创建于(created at), and 又称为(also known as).

However, it is hard to manually construct such patterns since it largely depends on the knowledge of the pattern designer. Thus, we prefer patterns that can be automatically derived from training data. Some annotators labeled question-answer snippets. Given a query question, the annotators were asked to highlight the strings that can answer the question. Though such a process still requires annotators to have knowledge of what can be answers, it does not require a computational linguist. Our pattern learning procedure is illustrated in Figure 2.

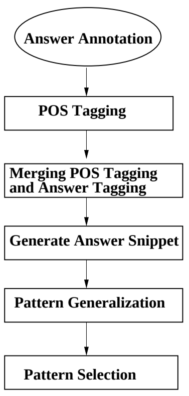

Figure 2: Surface Pattern Learning

Here we give an example to illustrate how pattern learning works. The first step is annotation. An example of Chinese answer annotation with English translation is shown in Figure 3. Question words are assigned the tag *QTERM*, answer words are tagged *ANSWER*, and all other words are assigned *BKGD*, standing for background words (not shown in the example to make the annotation more readable).

To obtain patterns, we conduct full parsing to obtain the full parse tree for a sentence. In our current

Chinese annotation: 到朝鲜进“行破冰之旅”的(美国国务卿 ANSWER)(奥尔布赖特 QTERM), 昨天同朝鲜领袖今正日进行历史性会谈

English translation: (U.S. Secretary of the State ANWER) (Albright QTERM), who visited North Korea for the “ice-breaking trip”, had a historical meeting with the leader of North Korea, Kim Jong Il.

Figure 3: Answer annotation example

patterns, we only use POS tagging information, but other higher level information could also be used. The segmented and POS tagged sentence is shown in Figure 4. Each word is assigned a POS tag as defined by the Penn Chinese Treebank guidelines.

(到 P)(朝 鲜 NR)(进 行 VV)(“ PU)(破 VV)(冰 NN)(之 旅 NN)(” PU)(的 DEC)(美 国 NR)(国 务 卿 NR)(奥 尔 NR)(布 赖 特 NR)(, PU) (昨 天 NT)(同 DT)(朝鲜 NR)(领袖 NR)(今正日 NN)(举行 VV)(历史性 JJ)(会谈 NN).

Figure 4: POS tagging

Next we combine the POS tags and the answer tags by appending these two tags to create a new tag, as shown in Figure 5.

(到 P/BKGD)(朝 鲜 NR/BKGD)(进 行 VV/BKGD)(“ PU/BKGD)(破 VV/BKGD)(冰 NN/BKGD)(之 旅 NN/BKGD)(” PU/BKGD)(的 DEC/BKGD)(美 国 NR/ANSWER)(国 务 卿 NR/ANSWER)(奥 尔 NR/QTERM)(布 赖 特 NR/QTERM)(, PU/BKGD) (昨 天 NT/BKGD)(同 DT/BKGD)(朝 鲜 NR/BKGD)(领 袖 NR/BKGD)(金正日 NN/BKGD)(进行 VV/BKGD)(历史性 JJ/BKGD)(会谈 NN/BKGD)

Figure 5: Combined POS and Answer tagging

We can then obtain an answer snippet from this training sample. Here we obtain the snippet *(美国国务卿 NR/ANSWER)(TERM)*.

We generalize a pattern using three heuristics (this particular example does not generalize). First, we replace all Chinese sequences longer than 3 characters with their POS tags, under the theory that long sequences are too specific. Second, we also replace NT (time noun, such as 昨天), DT (determiner, such as 这, 那), cardinals (CD, such as 一, 二, 三) and M (measurement word such as 年月日) with their POS tags. Third, we ignore adjectives.

After obtaining all patterns, we run them on the training data to calculate their precision and recall. We select patterns whose precision is above 0.6 and which fire at least 5 times in training data (parameters are determined with a held out dataset).

3 Experiments

3.1 Data Sets

We produced a list of questions and asked annotators to identify answer snippets from TDT4 data. To produce as many training answer snippets as possible, annotators were asked to label answers exhaustively; that is, the same answer can be labeled multiple times in different places. However, we remove duplicate answers for test questions since we are only interested in unique answers in evaluation.

We separate questions into two types, biographical (Who-is) questions, and other definitional questions (What-is). For "Who-is" questions, we used 204 questions for pattern learning, 10 for parameter tuning and another 42 questions for testing. For "What-is" questions, we used 44 for training and another 44 for testing.

3.2 Evaluation

The TREC question answering evaluation is based on human judgments (Voorhees, 2004). However, such a manual procedure is costly and time consuming. Recently, researchers have started automatic question answering evaluation (Xu et al., 2004; Lin and Demner-Fushman, 2005; Soricut and Brill, 2004). We use Rouge, an automatic evaluation metric that was originally used for summarization evaluation (Lin and Hovy, 2003) and was recently found useful for evaluating definitional question answering (Xu et al., 2004). Rouge is based on n-gram co-occurrence. An n-gram is a sequence of n consecutive Chinese characters.

Given a reference answer R and a system answer S, the Rouge score is defined as follows:

$$Rouge(R,S,N) = \sqrt[N]{\prod_{n=1}^{N} \frac{count_{match}(R,S,n)}{count(R,n)}}$$

where N is the maximum length of n-grams, $count_{match}(R,S,n)$ is the number of common n-grams of R and S, and $count(R,n)$ is the number of n-grams in R. If N is too small, stop words and bi-grams of such words will dominate the score; If N is too large, there will be many questions without answers. We select N to be 3, 4, 5 and 6.

To make scores of different systems comparable, we truncate system output for the same question by the same cutoff length. We score answers truncated at length L times that of the reference answers, where L is set to be 1, 2, and 3. The rationale is that people would like to read at least the same length of the reference answer. On the other hand, since the state of the art system answer is still far from human performance, it is reasonable to produce answers somewhat longer than the references (Xu et al., 2004).

In summary, we run experiments with parameters $N = 3,4,5,6$ and $L = 1,2,3$, and take the average over all of the 12 runs.

3.3 Overall Results

We set the pure linguistic analysis based system as the baseline and compare it to other configurations. Table 3 and Table 4 show the results on "*Who-is*" and "*What-is*" questions respectively. The baseline (Run 1) is the result of using pure linguistic features; Run 2 is the result of adding manual patterns to the baseline system; Run 3 is the result of using learned patterns only. Run 4 is the result of adding learned patterns to the baseline system. Run 5 is the result of adding both manual patterns and learned patterns to the system.

The first question we want to answer is how helpful the linguistic analysis and pattern learning are for definitional QA. Comparing Run 1 and 3, we can see that both pure linguistic analysis and pure pattern based systems achieve comparable performance; Combining them together improves performance (Run 4) for "who is" questions, but only slightly for "what is" questions. This indicates that linguistic analysis and pattern learning are complementary to each other, and both are helpful for biographical QA.

The second question we want to answer is what kind of questions can be answered with pattern matching. From these two tables, we can see that patterns are very effective in "*Who-is*" questions while less effective in "*What-is*" questions. Learned patterns improve the baseline from 0.3399 to 0.3860; manual patterns improve the baseline to 0.3657; combining both manual and learned patterns improve it to 0.4026, an improvement of **18.4%** compared to the baseline. However, the effect of patterns on "*What-is*" is smaller, with an improvement of only **3.5%**. However, the baseline performance on "*What-is*" is also much worse than that of "*Who-is*" questions. We will analyze the reasons in Section 4.3. This indicates that answering general definitional questions is much more challenging than answering biographical questions and deserves more research.

Run	Run description	Rouge
(1)	Baseline	0.3399
(2)	(1)+ manual patterns	0.3657
(3)	Learned patterns	0.3549
(4)	(1)+ learned patterns	0.3860
(5)	(2)+ learned patterns	0.4026

Table 3: Results on *Who-is* (Biographical) Questions

Run	Run description	Rouge
(1)	Baseline	0.2126
(2)	(1)+ manual patterns	0.2153
(3)	Learned patterns	0.2117
(4)	(1)+ learned patterns	0.2167
(5)	(2)+ learned patterns	0.2201

Table 4: Results on "*What-is*" (Other Definitional) Questions

4 Analysis

4.1 How much annotation is needed

The third question is how much annotation is needed for a pattern based system to achieve good performance. We run experiments with portions of training data on biographical questions, which produce different number of patterns. Table 5 shows the details of the number of training snippets used and the number of patterns produced and selected. The performance of different system is illustrated in Figure 6. With only 10% of the training data (549 snippets, about two person days of annotation), learned patterns achieve good performance of 0.3285, considering the performance of 0.3399 of a well tuned system with deep linguistic features. Performance saturates with 2742 training snippets (50% training, 10 person days annotation) at a Rouge score of 0.3590, comparable to the performance of a well tuned system with full linguistic features and manual patterns (Run 2 in Table 3). There could even be a slight, insignificant performance decrease with more training data because our sampling is sequential instead of random. Some portions of training data might be more useful than others.

	Training snippets	Patterns learned	Patterns selected
10% train	549	56	33
30% train	1645	144	88
50% train	2742	211	135
70% train	3839	281	183
90% train	4935	343	222
100% train	5483	381	266

Table 5: Number of patterns with different size of training data

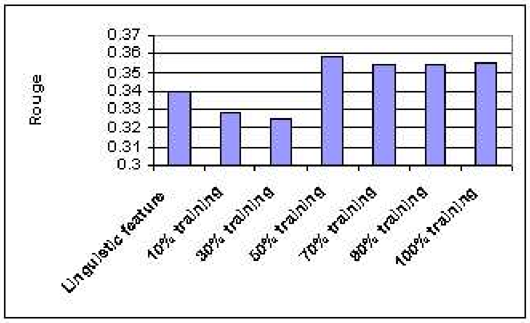

Figure 6: How much annotation is required (measured on biographical questions)

4.2 Contributions of different features

The fourth question we want to answer is: what features are most useful in definitional question answering? To evaluate the contribution of each individual feature, we turn off all other features and test the system on a held out data (10 questions). We calculate the coverage of each feature, measured by Rouge. We also calculate the precision of each feature with the following formula, which is very similar to Rouge except that the denominator here is based on system output $count(S, n)$ instead of reference $count(R, n)$. The notations are the same as those in Rouge.

$$Precision(R,S,N) = \sqrt[N]{\prod_{n=1}^{N} \frac{count_{match}(R,S,n)}{count(S,n)}}$$

Figure 7 is the precision-recall scatter plot of the features measured on "who is" questions. Interestingly, the learned patterns have the highest coverage and precision. The copula feature has the second highest precision; however, it has the lowest coverage. This is because there are not many copulas in the dataset. Appositive and manual pattern features have the same level of contribution. Surprisingly, the relation feature has a high coverage. This suggests that relations could be more useful if relation detection were more accurate; general propositions are not more useful than whole sentences since almost every sentence has a proposition, and since the high value propositions are identified by the lexical head of the proposition and grouped with the manual patterns.

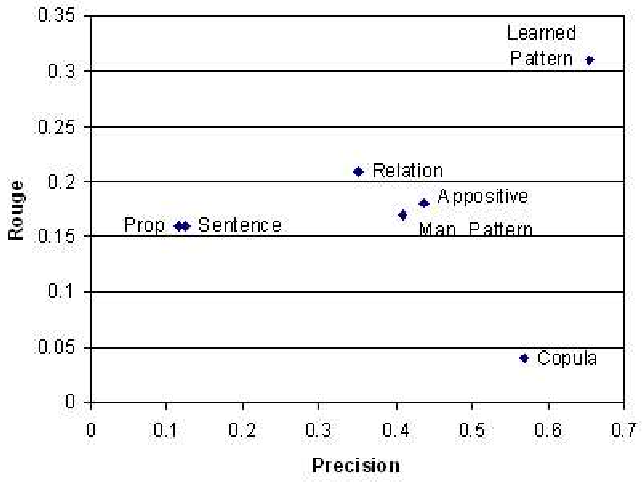

Figure 7: Feature precision recall scatter plot (measured on the biographical questions)

4.3 Who-is versus What-is questions

We have seen that "*What-is*" questions are more challenging than "*Who-is*" questions. We compare the precision and coverage of each feature for "*Who-is*" and "*What-is*" in Table 6 and Table 7. We see that although the precisions of the features are higher for "*What-is*", their coverage is too low. The most useful features for "*What-is*" questions are propositions and raw sentences, which are the worst two features for "*Who-is*". Basically, this means that most of the answers for "*What-is*" are from whole sentences. Neither linguistic analysis nor pattern matching works as efficiently as in biographical questions.

feature	who-is	what-is
copula	0.567	0.797
appositive	0.3460	0.3657
proposition	0.1162	0.1837
relation	0.3509	0.4422
sentence	0.1074	0.1556
learned patterns	0.6542	0.6858

Table 6: Feature Precision Comparison

feature	who-is	what-is
copula	0.055	0.049
appositive	0.2028	0.0026
proposition	0.2101	0.1683
relation	0.2722	0.043
sentence	0.1619	0.1717
learned patterns	0.3517	0.0860

Table 7: Feature Coverage Comparison

To identify the challenges of "*What-is*" questions, we conducted an error analysis. The answers for "*What-is*" are much more diverse and are hard to capture. For example, the reference answers for the question of "什么是国际空间站？/ What is the international space station?" include the weight of the space station, the distance from the space station to the earth, the inner structure of the space station, and the cost of its construction. Such attributes are hard to capture with patterns, and they do not contain any of the useful linguistic features we currently have (copula, appositive, proposition, relation). Identifying more useful features for such answers remains for future work.

5 Related Work

Ravichandran and Hovy (2002) presents a method that learns patterns from online data using some seed questions and answer anchors. The advantage is that it does not require human annotation. However, it only works for certain types of questions that have fixed anchors, such as “where was X born”. For general definitional questions, we do not know what the anchors should be. Thus we prefer using small amounts of human annotation to derive patterns. Cui et al. (2004) uses a similar approach for unsupervised pattern learning and generalization to soft pattern matching. However, the method is actually used for sentence selection rather than answer snippet selection. Combining information extraction with surface patterns has also seen some success. Jikoun et al. (2004) shows that information extraction can help improve the recall of a pattern based system. Xu et al. (2004) also shows that manually constructed patterns are very important in answering English definitional questions. Hildebrandt et al. (2004) uses manual surface patterns for target extraction to augment database and dictionary lookup. Blair-Goldensohn et al. (2004) apply supervised learning for definitional predicates and then apply summarization methods for question answering.

6 Conclusions and Future Work

We have explored a hybrid approach for definitional question answering by combining deep linguistic analysis and surface pattern learning. For the first time, we have answered four questions regarding Chinese definitional QA: deep linguistic analysis and automatic pattern learning are complementary and may be combined; patterns are powerful in answering biographical questions; only a small amount of annotation (2 days) is required to obtain good performance in a biographical QA system; copulas and appositions are the most useful linguistic features; relation extraction also helps.

Answering “*What-is*” questions is more challenging than answering “*Who-is*” questions. To improve the performance on “*What-is*” questions, we could divide “*What-is*” questions into finer classes such as organization, location, disease, and general substance, and process them specifically.

Our current pattern matching is based on simple POS tagging which captures only limited syntactic information. We generalize words to their corresponding POS tags. Another possible improvement is to generalize using automatically derived word clusters, which provide semantic information.

Enhanced Answer Type Inference from Questions using Sequential Models

Vijay Krishnan and **Sujatha Das** and **Soumen Chakrabarti**[*]
Computer Science and Engineering Department, IIT Bombay, India

Abstract

Question classification is an important step in factual question answering (QA) and other dialog systems. Several attempts have been made to apply statistical machine learning approaches, including Support Vector Machines (SVMs) with sophisticated features and kernels. Curiously, the payoff beyond a simple bag-of-words representation has been small. We show that most questions reveal their class through a short contiguous token subsequence, which we call its *informer span*. Perfect knowledge of informer spans can enhance accuracy from 79.4% to 88% using linear SVMs on standard benchmarks. In contrast, standard heuristics based on shallow pattern-matching give only a 3% improvement, showing that the notion of an informer is non-trivial. Using a novel multi-resolution encoding of the question's parse tree, we induce a Conditional Random Field (CRF) to identify informer spans with about 85% accuracy. Then we build a meta-classifier using a linear SVM on the CRF output, enhancing accuracy to 86.2%, which is better than all published numbers.

1 Introduction

An important step in factual question answering (QA) and other dialog systems is to classify the question (e.g., Who painted Olympia?) to the anticipated type of the answer (e.g., person). This step is called "question classification" or "answer type identification".

The answer type is picked from a hand-built taxonomy having dozens to hundreds of answer types (Harabagiu et al., 2000; Hovy et al., 2001; Kwok et al., 2001; Zheng, 2002; Dumais et al., 2002). QA systems can use the answer type to short-list answer tokens from passages retrieved by an information retrieval (IR) subsystem, or use the type together with other question words to inject IR queries.

Early successful QA systems used manually-constructed sets of rules to map a question to a type, exploiting clues such as the wh-word (who, where, when, how many) and the head of noun phrases associated with the main verb (what <u>is</u> the <u>tallest</u> *<u>mountain</u>* in . . .).

With the increasing popularity of statistical NLP, Li and Roth (2002), Hacioglu and Ward (2003) and Zhang and Lee (2003) used supervised learning for question classification on a data set from UIUC that is now standard[1]. It has 6 coarse and 50 fine answer types in a two-level taxonomy, together with 5500 training and 500 test questions. Webclopedia (Hovy et al., 2001) has also published its taxonomy with over 140 types.

The promise of a machine learning approach is that the QA system builder can now focus on designing features and providing labeled data, rather than coding and maintaining complex heuristic rule-bases. The data sets and learning systems quoted above have made question classification a well-defined and non-trivial subtask of QA for which algorithms can be evaluated precisely, isolating more complex factors at work in a complete QA system.

Prior work: Compared to human performance, the accuracy of question classifiers is not high. In all studies, surprisingly slim gains have resulted from sophisticated design of features and kernels.

Li and Roth (2002) used a Sparse Network of Winnows (SNoW) (Khardon et al., 1999). Their features included tokens, parts of speech (POS), chunks (non-overlapping phrases) and named entity (NE) tags. They achieved 78.8% accuracy for 50 classes, which improved to 84.2% on using an (unpublished, to our knowledge) hand-built dictionary of "semantically related words".

Hacioglu and Ward (2003) used linear support vector machines (SVMs) with question word 2-grams and error-correcting output codes (ECOC)—but no NE tagger or related word dictionary—to get 80.2–82% accuracy.

Zhang and Lee (2003) used linear SVMs with all possible question word q-grams, and obtained 79.2% accuracy. They went on to design an ingenious kernel on question parse trees, which yielded visible gains for the 6 coarse labels, but only "slight" gains for the 50 fine classes, because "the syntactic tree does not normally contain the information required to distinguish between the various fine categories within a coarse category".

Algorithm	6-class	50-class
Li and Roth, SNoW	(1)	78.8(2)
Hacioglu et al., SVM+ECOC	–	80.2–82
Zhang & Lee, LinearSVMq	87.4	79.2
Zhang & Lee, TreeSVM	90	–
SVM, "perfect" informer	**94.2**	**88**
SVM, CRF-informer	**93.4**	**86.2**

Table 1: Summary of % accuracy for UIUC data. (1) SNoW accuracy without the related word dictionary was not reported. With the related-word dictionary, it achieved 91%. (2) SNoW with a related-word dictionary achieved 84.2% but the other algorithms did not use it. Our results are summarized in the last two rows, see text for details.

Our contributions: We introduce the notion of the **answer type informer span** of the question (in §2): a short (typically 1–3 word) subsequence of question tokens that are adequate clues for question classification; e.g.: How much does an adult elephant *weigh*?

We show (in §3.2) that a simple linear SVM using features derived from human-annotated informer spans beats all known learning approaches. This confirms our suspicion that the earlier approaches suffered from a feature localization problem.

Of course, informers are useful only if we can find ways to automatically identify informer spans. Surprisingly, syntactic pattern-matching and heuristics widely used in QA systems are not very good at capturing informer spans (§3.3). Therefore, the notion of an informer is non-trivial.

Using a parse of the question sentence, we derive a novel set of multi-resolution features suitable for training a conditional random field (CRF) (Lafferty et al., 2001; Sha and Pereira, 2003). Our feature design paradigm may be of independent interest (§4). Our informer tagger is about 85–87% accurate.

We use a meta-learning framework (Chan and Stolfo, 1993) in which a linear SVM predicts the answer type based on features derived from the original question as well as the output of the CRF. This meta-classifier beats all published numbers on standard question classification benchmarks (§4.4). Table 1 (last two rows) summarizes our main results.

2 Informer overview

Our key insight is that a human can classify a question based on very few tokens gleaned from skeletal syntactic information. This is certainly true of the most trivial classes (*Who* wrote Hamlet? or *How many* dogs pull a sled at Iditarod?) but is also true of more subtle clues (How much does a rhino *weigh*?).

In fact, informal experiments revealed the surprising property that *only one* contiguous span of tokens is adequate for a human to classify a question. E.g., in the above question, a human does not even need the *how much* clue once the word *weigh* is available. In fact, "How much does a rhino *cost*?" has an identical syntax but a completely different answer type, not revealed by *how much* alone. The only exceptions to the single-span hypothesis are multi-function questions like "What is the *name* and *age* of . . .", which should be assigned to multiple answer types. In this paper we consider questions where one type suffices.

Consider another question with multiple clues: *Who* is the *CEO* of IBM? In isolation, the clue *who* merely tells us that the answer might be a person or country or organization, while *CEO* is perfectly precise, rendering *who* unnecessary. All of the above applies *a forteriori* to *what* and *which* clues, which are essentially uninformative on their own, as in "What is the *distance* between Pisa and Rome?"

Conventional QA systems use mild analysis on the wh-clues, and need much more sophistication on the rest of the question (e.g. inferring *author* from *wrote*, and even verb subcategorization). We submit that a single, minimal, suitably-chosen contiguous span of question token/s, defined as the **informer span** of the question, is adequate for question classification.

The informer span is very sensitive to the structure of clauses, phrases and possessives in the question, as is clear from these examples (informers italicized): "What is Bill Clinton's wife's *profession*", and "What *country*'s president was shot at Ford's Theater". The choice of informer spans also depends on the target classification system. Initially we wished to handle definition questions separately, and marked no informer tokens in "What is digitalis". However, *what is* is an excellent informer for the UIUC class `DESC:def` (description, definition).

3 The meta-learning approach

We propose a meta-learning approach (§3.1) in which the SVM can use features from the original question as well as its informer span. We show (§3.2) that human-annotated informer spans lead to large improvements in accuracy. However, we show (§3.3) that simple heuristic extraction rules commonly used in QA systems (e.g. head of noun phrase following wh-word) cannot provide informers that are nearly as useful. This naturally leads us to designing an informer tagger in §4.

Figure 1 shows our meta-learning (Chan and Stolfo, 1993) framework. The combiner is a linear multi-class one-vs-one SVM[2], as in the Zhang and Lee (2003) baseline. We did not use ECOC (Hacioglu and Ward, 2003) because the reported gain is less than 1%.

The word feature extractor selects unigrams and q-grams from the question. In our experience, $q = 1$ or $q = 2$ were best; if unspecified, all possible $q$grams were used. Through tuning, we also found that the SVM "C" parameter (used to trade between training data fit and model complexity) must be set to 300 to achieve their published baseline numbers.

3.1 Adding informer features

We propose two very simple ways to derive features from informers for use with SVMs. Initially, assume that perfect informers are known for all questions;

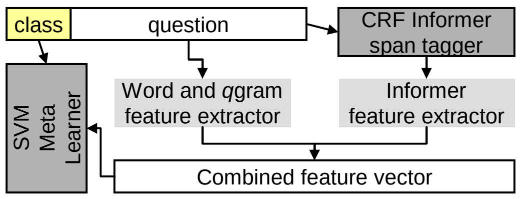

Figure 1: The meta-learning approach.

later (§4) we study how to predict informers.

Informer q-grams: This comprises of all word q-grams within the informer span, for all possible q. E.g., such features enable effective exploitation of informers like *length* or *height* to classify to the `NUMBER:distance` class in the UIUC data.

Informer q-gram hypernyms: For each word or compound within the informer span that is a WordNet noun, we add all hypernyms of all senses. The intuition is that the informer (e.g. *author*, *cricketer*, *CEO*) is often narrower than a broad question class (`HUMAN:individual`). Following hypernym links up to *person* via WordNet produces a more reliably correlated feature.

Given informers, other question words might seem useless to the classifier. However, retaining regular features from other question words is an excellent idea for the following reasons.

First, we kept word sense disambiguation (WSD) outside the scope of this work because WSD entails computation costs, and is unlikely to be reliable on short single-sentence questions. Questions like *How long* ... or *Which bank* ... can thus become ambiguous and corrupt the informer hypernym features. Additional question words can often help nail the correct class despite the feature corruption.

Second, while our CRF-based approach to informer span tagging is better than obvious alternatives, it still has a 15% error rate. For the questions where the CRF prediction is wrong, features from non-informer words give the SVM an opportunity to still pick the correct question class.

Word features: Based on the above discussion, one boolean SVM feature is created for every word q-gram over all question tokens. In experiments, we found bigrams ($q = 2$) to be most effective, closely followed by unigrams ($q = 1$). As with informers, we can also use hypernyms of regular words as SVM

[2]`http://www.csie.ntu.edu.tw/~cjlin/libsvm/`

features (marked “Question bigrams + hypernyms” in Table 2).

3.2 Benefits from “perfect” informers

We first wished to test the hypothesis that identifying informer spans to an SVM learner can improve classification accuracy. Over and above the class labels, we had two volunteers tag the 6000 UIUC questions with informer spans (which we call “perfect”—agreement was near-perfect).

Features	Coarse	Fine
Question trigrams	91.2	77.6
All question $q$grams	87.2	71.8
All question unigrams	88.4	78.2
Question bigrams	91.6	79.4
+informer q-grams	94.0	82.4
+informer hypernyms	**94.2**	**88.0**
Question unigrams + all informer	93.4	88.0
Only informer	92.2	85.0
Question bigrams + hypernyms	91.6	79.4

Table 2: Percent accuracy with linear SVMs, “perfect” informer spans, and various feature encodings.

Observe in Table 2 that the unigram baseline is already quite competitive with the best prior numbers, and exploiting perfect informer spans beats all known numbers. It is clear that both *informer q-grams* and *informer hypernyms* are very valuable features for question classification. The fact that no improvement was obtained with over *Question bigrams* using *Question hypernyms* highlights the importance of choosing a few relevant tokens as informers and designing suitable features on them.

Table 3 (columns b and e) shows the benefits from perfect informers broken down into broad question types. Questions with *what* as the trigger are the biggest beneficiaries, and they also form by far the most frequent category.

The remaining question, one that we address in the rest of the paper, is whether we can effectively and accurately automate the process of providing informer spans to the question classifier.

3.3 Informers provided by heuristics

In §4 we will propose a non-trivial solution to the informer-tagging problem. Before that, we must justify that such machinery is indeed required.

Some leading QA systems extract words very similar in function to informers from the parse tree of the question. Some (Singhal et al., 2000) pick the head of the first noun phrase detected by a shallow parser, while others use the head of the noun phrase adjoining the main verb (Ramakrishnan et al., 2004). Yet others (Harabagiu et al., 2000; Hovy et al., 2001) use hundreds of (unpublished to our knowledge) hand-built pattern-matching rules on the output of a full-scale parser.

A natural baseline is to use these extracted words, which we call “heuristic informers”, with an SVM just like we used “perfect” informers. All that remains is to make the heuristics precise.

How: For questions starting with *how*, we use the bigram starting with *how* unless the next word is a verb.

Wh: If the wh-word is not *how, what* or *which*, use the wh-word in the question as a separate feature.

WhNP: For questions having *what* and *which*, use the WHNP if it encloses a noun. WHNP is the Noun Phrase corresponding to the Wh-word, given by a sentence parser (see §4.2).

NP1: Otherwise, for *what* and *which* questions, the first (leftmost) noun phrase is added to yet another feature subspace.

Table 3 (columns c and f) shows that these already-messy heuristic informers do not capture the same signal quality as “perfect” informers. Our findings corroborate Li and Roth (2002), who report little benefit from adding head chunk features for the fine classification task.

Moreover, observe that using heuristic informer features *without* any word features leads to rather poor performance (column c), unlike using perfect informers (column b) or even CRF-predicted informer (column d, see §4). These clearly establish that the notion of an informer is nontrivial.

4 Using CRFs to label informers

Given informers are useful but nontrivial to recognize, the next natural question is, how can we learn to identify them automatically? From earlier sections, it is clear (and we give evidence later, see Table 5) that sequence and syntax information will be

important.

We will model informer span identification as a sequence tagging problem. An automaton makes probabilistic transitions between hidden states y, one of which is an "informer generating state", and emits tokens x. We observe the tokens and have to guess which were produced from the "informer generating state".

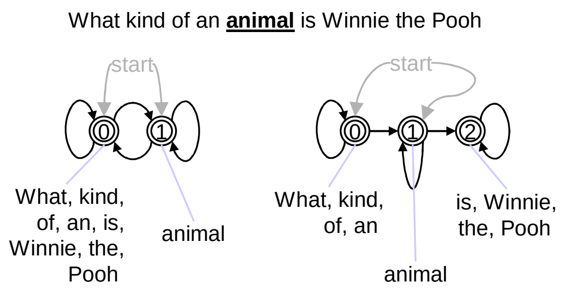
Hidden Markov models are extremely popular for such applications, but recent work has shown that conditional random fields (CRFs) (Lafferty et al., 2001; Sha and Pereira, 2003) have a consistent advantage over traditional HMMs in the face of many redundant features. We refer the reader to the above references for a detailed treatment of CRFs. Here we will regard a CRF as largely a black box[3].

To train a CRF, we need a set of state nodes, a transition graph on these nodes, and tokenized text where each token is assigned a state. Once the CRF is trained, it can be applied to a token sequence, producing a predicted state sequence.

[3]We used `http://crf.sourceforge.net/`

4.1 State transition models

We started with the common 2-state "in/out" model used in information extraction, shown in the left half of Figure 2. State "1" is the informer-generating state. Either state can be initial and final (double circle) states.



What kind of an **animal** is Winnie the Pooh
start
0

What, kind, of, an, is, Winnie, the, Pooh
animal
start
0
1
2
What, kind, of, an
is, Winnie, the, Pooh
animal

Figure 2: 2- and 3-state transition models.

The 2-state model can be myopic. Consider the question pair

A: What country is the largest producer of wheat?
B: Name the largest producer of wheat

The $i \pm 1$ context of *producer* is identical in A and B. In B, for want of a better informer, we would want *producer* to be flagged as the informer, although it might refer to a country, person, animal, company, etc. But in A, *country* is far more precise.

Any 2-state model that depends on positions $i \pm 1$ to define features will fail to distinguish between A and B, and might select both *country* and *producer* in A. As we have seen with heuristic informers, polluting the informer pool can significantly hurt SVM accuracy.

Therefore we also use the 3-state "begin/in/out" (BIO) model. The initial state cannot be "2" in the 3-state model; all states can be final. The 3-state model allows at most one informer span. Once the 3-state model chooses *country* as the informer, it is unlikely to stretch state 1 up to *producer*.

There is no natural significance to using four or more states. Besides, longer range syntax dependencies are already largely captured by the parser.

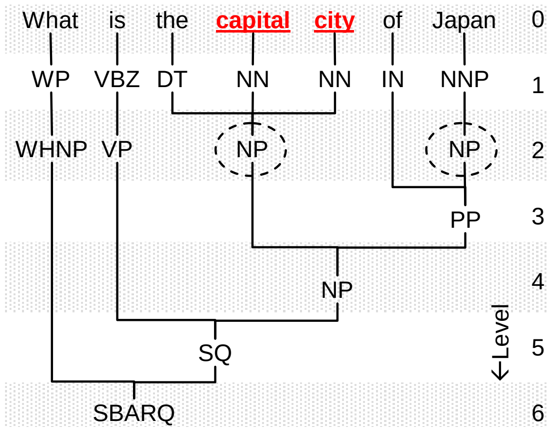

Figure 3: Stanford Parser output example.

4.2 Features from a parse of the question

Sentences with similar parse trees are likely to have the informer in similar positions. This was the intuition behind Zhang et al.'s tree kernel, and is also our starting point. We used the Stanford Lexicalized Parser (Klein and Manning, 2003) to parse the question. (We assume familiarity with parse tree notation for lack of space.) Figure 3 shows a sample parse tree organized in levels. Our first step was to translate the parse tree into an equivalent multi-resolution tabular format shown in Table 4.

i	1	2	3	4	5	6	7
y_i	0	0	0	1	1	2	2
x_i	What	is	the	capital	city	of	Japan
$\ell \downarrow$	Features for x_is						
1	WP,1	VBZ,1	DT,1	NN,1	NN,1	IN,1	NNP,1
2	WHNP,1	VP,1	NP,1	**NP**,1	NP,1	Null,1	**NP,2**
3	Null,1	Null,1	Null,1	Null,1	Null,1	PP,1	PP,1
4	Null,1	Null,1	NP,1	NP,1	NP,1	NP,1	NP,1
5	Null,1	SQ,1	SQ,1	SQ,1	SQ,1	SQ,1	SQ,1
6	SBARQ	SBARQ	SBARQ	SBARQ	SBARQ	SBARQ	SBARQ

Table 4: A multi-resolution tabular view of the question parse showing `tag` and `num` attributes. *capital city* is the informer span with $y = 1$.

Cells and attributes: A labeled question comprises the token sequence $x_i; i = 1, \ldots$ and the label sequence $y_i, i = 1, \ldots$ Each x_i leads to a column vector of observations. Therefore we use matrix notation to write down x: A table cell is addressed as $x[i, \ell]$ where i is the token position (column index) and ℓ is the level or row index, 1–6 in this example. (Although the parse tree can be arbitrarily deep, we found that using features from up to level $\ell = 2$ was adequate.)

Intuitively, much of the information required for spotting an informer can be obtained from the part of speech of the tokens and phrase/clause attachment information. Conversely, specific word information is generally sparse and misleading; the same word may or may not be an informer depending on its position. E.g., "What birds eat snakes?" and "What snakes eat birds?" have the same words but different informers. Accordingly, we observe two properties at each cell:

`tag`: The syntactic class assigned to the cell by the parser, e.g. $x[4, 2]$`.tag` = `NP`. It is well-known that POS and chunk information are major clues to informer-tagging, specifically, informers are often nouns or noun phrases.

`num`: Many heuristics exploit the fact that the first NP is known to have a higher chance of containing informers than subsequent NPs. To capture this positional information, we define `num` of a cell at $[i, \ell]$ as one plus the number of distinct contiguous chunks to the left of $[i, \ell]$ with `tag`s equal to $x[4, 2]$`.tag`. E.g., at level 2 in the table above, *the capital city* forms the first NP, while *Japan* forms the second NP. Therefore $x[7,2]\texttt{.num} = 2$.

In conditional models, it is notationally convenient to express features as functions on (x_i, y_i). To one unfamiliar with CRFs, it may seem strange that y_i is passed as an argument to features. At training time, y_i is indeed known, and at testing time, the CRF algorithm efficiently finds the most probable sequence of y_is using a Viterbi search. True labels are not revealed to the CRF at testing time.

Cell features `IsTag` and `IsNum`: E.g., the observation "$y_4 = 1$ and $x[4,2]\texttt{.tag} = \texttt{NP}$" is captured by the statement that "position 4 fires the feature $\texttt{IsTag}_{1,\texttt{NP},2}$" (which has a boolean value). There is an $\texttt{IsTag}_{y,t,\ell}$ feature for each (y, t, ℓ) triplet. Similarly, for every possible state y, every possible `num` value n (up to some maximum horizon), and every level ℓ, we define boolean features $\texttt{IsNum}_{y,n,\ell}$. E.g., position 7 fires the feature $\texttt{IsNum}_{2,2,2}$ in the 3-state model, capturing the statement "$x[7,2]\texttt{.num} = 2$ and $y_7 = 2$".

Adjacent cell features `IsPrevTag` and `IsNextTag`: Context can be exploited by a CRF by coupling the state at position i with observations at positions adjacent to position i (extending to larger windows did not help). To capture this, we use more boolean features: position 4 fires the feature $\texttt{IsPrevTag}_{1,\texttt{DT},1}$ because $x[3,1]\texttt{.tag} = \texttt{DT}$ and $y_4 = 1$. Position 4 also fires $\texttt{IsPrevTag}_{1,\texttt{NP},2}$ because $x[3,2]\texttt{.tag} = \texttt{NP}$ and $y_4 = 1$. Similarly we define a $\texttt{IsNextTag}_{y,t,\ell}$ feature for each possible (y, t, ℓ) triple.

State transition features `IsEdge`: Position i fires feature $\texttt{IsEdge}_{u,v}$ if $y_{i-1} = u$ and $y_i = v$. There is one such feature for each state-pair (u, v) allowed by the transition graph. In addition we have sentinel features $\texttt{IsBegin}_u$ and $\texttt{IsEnd}_u$ marking the beginning and end of the token sequence.

4.3 Informer-tagging accuracy

We study the accuracy of our CRF-based informer tagger wrt human informer annotations. In the next section we will see the effect of CRF tagging on question classification.

There are at least two useful measures of informer-tagging accuracy. Each question has a known set I_k of informer tokens, and gets a set of tokens I_c flagged as informers by the CRF. For each question, we can grant ourself a reward of 1 if $I_c = I_k$, and 0 otherwise. In §3.1, informers were regarded as a separate (high-value) bag of words. Therefore, overlap between I_c and I_k would be a reasonable predictor of question classification accuracy. We use the Jaccard similarity $|I_k \cap I_c| / |I_k \cup I_c|$. Table 5 shows the effect of using diverse feature sets.

Features used	Fraction $I_c = I_k$	Jaccard overlap
IsTag	0.368	0.396
+IsNum	0.474	0.542
+IsPrevTag+IsNextTag	0.692	0.751
+IsEdge+IsBegin+IsEnd	**0.848**	**0.867**

Table 5: Effect of feature choices.

- `IsTag` features are not adequate.
- `IsNum` features improve accuracy 10–20%.
- `IsPrevTag` and `IsNextTag` ("+Prev +Next") add over 20% of accuracy.
- `IsEdge` transition features help exploit Markovian dependencies and adds another 10–15% accuracy, showing that sequential models are indeed required.

Type	#Quest.	Heuristic Informers	2-state CRF	3-state CRF
what	349	57.3	68.2	83.4
which	11	77.3	83.3	77.2
when	28	75.0	98.8	100.0
where	27	84.3	100.0	96.3
who	47	55.0	47.2	96.8
how_*	32	90.6	88.5	93.8
rest	6	66.7	66.7	77.8
Total	500	62.4	71.2	86.7

Table 6: Effect of number of CRF states, and comparison with the heuristic baseline (Jaccard accuracy expressed as %).

Table 6 shows that the 3-state CRF performs much better than the 2-state CRF, especially on difficult questions with *what* and *which*. It also compares the Jaccard accuracy of informers found by the CRF vs. informers found by the heuristics described in §3.3. Again we see a clear superiority of the CRF approach.

Unlike the heuristic approach, the CRF approach is relatively robust to the parser emitting a somewhat incorrect parse tree, which is not uncommon. The heuristic approach picks the “easy” informer, *who*, over the better one, *CEO*, in “Who is the CEO of IBM”. Its bias toward the NP-head can also be a problem, as in “What country’s *president* . . .”.

4.4 Question classification accuracy

We have already seen in §3.2 that perfect knowledge of informers can be a big help. Because the CRF can make mistakes, the margin may decrease. In this section we study this issue.

We used questions with human-tagged informers (§3.2) to train a CRF. The CRF was applied back on the training questions to get informer predictions, which were used to train the 1-vs-1 SVM meta-learner (§3). Using CRF-tagged and not human-tagged informers may seem odd, but this lets the SVM learn and work around systematic errors in CRF outputs.

Results are shown in columns d and g of Table 3. Despite the CRF tagger having about 15% error, we obtained 86.2% SVM accuracy which is rather close to the the SVM accuracy of 88% with perfect informers.

The CRF-generated tags, being on the training data, might be more accurate that would be for unseen test cases, potentially misleading the SVM. This turns out not to be a problem: clearly we are very close to the upper bound of 88%. In fact, anecdotal evidence suggests that using CRF-assigned tags actually helped the SVM.

5 Conclusion

We presented a new approach to inferring the type of the answer sought by a well-formed natural language question. We introduced the notion of a span of *informer tokens* and extract it using a sequential graphical model with a novel feature representation derived from the parse tree of the question. Our approach beats the accuracy of recent algorithms, even ones that used max-margin methods with sophisticated kernels defined on parse trees.

An intriguing feature of our approach is that when an informer (*actor*) is narrower than the question class (*person*), we can exploit direct hypernymy connections like *actor* to *Tom Hanks*, if available. Existing knowledge bases like WordNet and Wikipedia, combined with intense recent work (Etzioni et al., 2004) on bootstrapping is-a hierarchies, can thus lead to potentially large benefits.

Acknowledgments: Thanks to Sunita Sarawagi for help with CRFs, and the reviewers for improving the presentation.

A Practically Unsupervised Learning Method to Identify Single-Snippet Answers to Definition Questions on the Web

Ion Androutsopoulos and **Dimitrios Galanis**
Department of Informatics
Athens University of Economics and Business
Patission 76, GR-104 34, Athens, Greece

Abstract

We present a practically unsupervised learning method to produce single-snippet answers to definition questions in question answering systems that supplement Web search engines. The method exploits on-line encyclopedias and dictionaries to generate automatically an arbitrarily large number of positive and negative definition examples, which are then used to train an SVM to separate the two classes. We show experimentally that the proposed method is viable, that it outperforms the alternative of training the system on questions and news articles from TREC, and that it helps the search engine handle definition questions significantly better.

1 Introduction

Question answering (QA) systems for document collections typically aim to identify in the collections text snippets (e.g., 50 or 250 characters long) or exact answers (e.g., names, dates) that answer natural language questions submitted by their users. Although they are commonly evaluated on newspaper archives, as in the TREC QA track, QA systems can also supplement Web search engines, to help them return snippets, as opposed to Web pages, that provide more directly the information users require.

Most current QA systems first classify the input question into one of several categories (e.g., questions asking for locations, persons, etc.), producing expectations for types of named entities that must be present in the answer (locations, person names, etc.). Using the question's terms as a query, an information retrieval (IR) system identifies relevant documents. Snippets of these documents are then selected and ranked, using criteria such as whether or not they contain the expected types of named entities, the percentage of the question's terms they contain, etc. The system then outputs the most highly-ranked snippets, or named entities therein.

The approach highlighted above performs poorly with definition questions (e.g., "What is gasohol?", "Who was Duke Ellington?"), because definition questions do not generate expectations for particular types of named entities, and they typically contain only a single term. Definition questions are particularly common; in the QA track of TREC-2001, where the distribution of question types reflected that of real user logs, 27% of the questions were requests for definitions. Of course, answers to many definition questions can be found in on-line encyclopedias and dictionaries.[1] There are always, however, new or less widely used terms that are not included in such resources, and this is also true for many names of persons and products. Hence, techniques to discover definitions in ordinary Web pages and other document collections are valuable. Definitions of this kind are often 'hidden' in oblique contexts (e.g., "He said that *gasohol, a mixture of gasoline and ethanol*, has been great for his business.").

In recent work, Miliaraki and Androutsopoulos (2004), hereafter M&A, proposed a method we call

[1]See, for example, Wikipedia (http://www.wikipedia.org/). WordNet's glosses are another on-line source of definitions.

DEFQA, which handles definition questions. The method assumes that a question preprocessor separates definition from other types of questions, and that in definition questions this module also identifies the term to be defined, called the *target term*.[2] The input to DEFQA is a (possibly multi-word) target term, along with the r most highly ranked documents that an IR system returned for that term. The output is a list of k 250-character snippets from the r documents, at least one of which must contain an acceptable short definition of the target term, much as in the QA track of TREC-2000 and TREC-2001.[3]

We note that since 2003, TREC requires definition questions to be answered by lists of *complementary* snippets, jointly providing a range of information nuggets about the target term (Voorhees, 2003). In contrast, here we focus on locating single-snippet definitions. We believe this task is still interesting and of practical use. For example, a list of single-snippet definitions accompanied by their source URLs is a good starting point for users of search engines wishing to obtain definitions. Single-snippet definitions can also be useful in information extraction, where the templates to be filled in often require short entity descriptions. We also note that the post-2003 TREC task has encountered evaluation problems, because it is difficult to agree on which nuggets should be included in the multi-snippet definitions (Hildebrandt et al., 2004). In contrast, our experimental results of Section 4 indicate strong inter-assessor agreement for single-snippet answers, suggesting that it is easier to agree upon what constitutes an acceptable single-snippet definition.

DEFQA relies on an SVM, which is trained to classify 250-character snippets that have the target term at their centre, hereafter called *windows*, as acceptable definitions or non-definitions.[4] To train the SVM, a collection of q training target terms is used; M&A used the target terms of definition questions from TREC-2000 and TREC-2001. The terms are submitted to an IR system, which returns the r most highly ranked documents per target term. The windows of the $q \cdot r$ resulting documents are tagged as acceptable definitions or non-definitions, and become the training instances of the SVM. At run time, when a definition question is submitted, the r top-ranked documents are obtained, their windows are collected, and for each window the SVM returns a score indicating how confident it is that the window is a definition. The k windows with the highest confidence scores are then reported to the user.

The SVM actually operates on vector representations of the windows, that comprise the verdicts or attributes of previous methods by Joho and Sanderson (2000) and Prager et al. (2002), as well as attributes corresponding to automatically acquired lexical patterns. On TREC-2000 and TREC-2001 data, M&A found that DEFQA clearly outperformed the original methods of Joho and Sanderson and Prager et al. Their best configuration answered correctly 73% of 160 definition questions in a cross-validation experiment with $k = 5$, $r = 50$, $q = 160$.

A limitation of DEFQA is that it cannot be trained easily on new document collections, because it requires the training windows to be tagged as definitions or non-definitions. In the experiments of M&A, there were 18,473 training windows. Tagging them was easy, because the windows were obtained from TREC questions and documents, and the TREC organizers provide Perl patterns that can be used to judge whether a snippet from TREC's documents is among the acceptable answers of a TREC question.[5] For non-TREC questions and document collections, however, where such patterns are unavailable, separating thousands of training windows into the two categories by hand is a laborious task.

In this paper, we consider the case where DEFQA is used as an add-on to a Web search engine. There are three training alternatives in this setting: (i) train DEFQA on TREC questions and documents; (ii) train DEFQA on a large collection of manually tagged training windows obtained from Web pages that the search engine returned for training target terms; or (iii) devise techniques to tag automatically the training windows of (ii). We have developed a technique along alternative (iii), which exploits on-

[2]Alternatively, the user can be asked to specify explicitly the question type and target term via a form-based interface.

[3]Definition questions were not considered in TREC-2002.

[4]See, for example, Scholkopf and Smola (2002) for information on SVMs. Following M&A, we use a linear SVM, as implemented by Weka's SMO class (http://www.cs.waikato.ac.nz/ml/weka/). The windows may be shorter than 250 characters, when the surrounding text is limited.

[5]The patterns' judgements are not always perfect, which introduces some noise in the training examples.

line encyclopedias and dictionaries. This allows us to generate and tag automatically an arbitrarily large number of training windows, in effect converting DEFQA to an unsupervised method. We show experimentally that the new unsupervised method is viable, that it outperforms alternative (i), and that it helps the search engine handle definition questions significantly better than on its own.

2 Attributes of DEFQA

DEFQA represents each window as a vector comprising the values of the following attributes:[6]

SN: The ordinal number of the window in the document, in our case Web page, it originates from. The intuition is that windows that mention the target term first in a document are more likely to define it.

WC: What percentage of the 20 words that are most frequent across all the windows of the target term are present in the particular window represented by the vector. A stop-list and a stemmer are applied first when computing WC.[7] In effect, the 20 most frequent words form a simplistic centroid of all the candidate answers, and WC measures how close the vector's window is to this centroid.

RK: The ranking of the Web page the window originates from, as returned by the search engine.

Manual patterns: 13 binary attributes, each signalling whether or not the window matches a different manually constructed lexical pattern (e.g., "*target*, a/an/the", as in "Tony Blair, the British prime minister"). The patterns are those used by Joho and Sanderson, and four more added by M&A. They are intended to perform well across text genres.

Automatic patterns: A collection of m binary attributes, each showing if the window matches a different automatically acquired lexical pattern. The patterns are sequences of n tokens ($n \in \{1, 2, 3\}$) that must occur either directly before or directly after the target term (e.g., "*target*, which is"). These patterns are acquired as follows. First, all the n-grams that occur directly before or after the target terms in the training windows are collected. The n-grams that have been encountered at least 10 times are considered candidate patterns. From those, the m patterns with the highest precision scores are retained, where *precision* is the number of training definition windows the pattern matches divided by the total number of training windows it matches. We set m to 200, the value that led to the best results in the experiments of M&A. The automatically acquired patterns allow the system to detect definition contexts that are not captured by the manual patterns, including genre-specific contexts.

M&A also explored an additional attribute, which carried the verdict of Prager et al.'s WordNet-based method (2002). However, they found the additional attribute to lead to no significant improvements, and, hence, we do not use it. We have made no attempt to extend the attribute set of M&A; for example, with attributes showing if the window contains the target term in italics, if the window is part of a list that looks like a glossary, or if the window derives from an authority Web page. We leave such extensions for future work. Our contribution is the automatic generation of training examples.

3 Generating training examples

When training DEFQA on windows from Web pages, a mechanism to tag the training windows as definitions or non-definitions is required. Rather than tagging them manually, we use a measure of how similar the wording of each training window is to the wording of definitions of the same target term obtained from on-line encyclopedias and dictionaries. This is possible because we pick training target terms for which there are several definitions in different on-line encyclopedias and dictionaries; hereafter we call these *encyclopedia definitions*.[8] Training windows whose wording is very similar to that of the corresponding encyclopedia definitions are tagged as definition windows (*positive examples*), while windows whose wording differs significantly from the encyclopedia definitions are tagged as non-definitions (*negative examples*). Training windows for which the similarity score does not indicate great similarity or dissimilarity to the wording of the encyclopedia definitions are excluded from DEFQA's

[6] SN and WC originate from Joho and Sanderson (2000).

[7] We use the 100 most frequent words of the British National Corpus as the stop-list, and Porter's stemmer.

[8] We use randomly selected entries from the index of http://www.encyclopedia.com/ as training terms, and Google's 'define:' feature, that returns definitions from on-line encyclopedias and dictionaries, to obtain the encyclopedia definitions.

training, as they cannot be tagged as positive or negative examples with sufficiently high confidence.

Note that encyclopedia definitions are used only to tag training windows. Once the system has been trained, it can be used to discover on ordinary Web pages definitions of terms for which there are no encyclopedia definitions, and indeed this is the main purpose of the system. Note also that we train DEFQA on windows obtained from Web pages returned by the search engine for training terms. This allows it to learn characteristics of the particular search engine being used; for example, what weight to assign to RK, depending on how much the search engine succeeds in ranking pages containing definitions higher. More importantly, it allows DEFQA to select lexical patterns that are indicative of definitions in Web pages, as opposed to patterns that are indicative of definitions in electronic encyclopedias and dictionaries. The latter explains why we do not train DEFQA directly on encyclopedia definitions; another reason is that DEFQA requires both positive and negative examples, while encyclopedia definitions provide only positive ones.

We now explain how we compute the similarity between a training window and the collection C of encyclopedia definitions for the window's target term. We first remove stop-words, punctuation, other non-alphanumeric characters and the target term from the training window, and apply a stemmer, leading to a new form W of the training window. We then compute the similarity of W to C as:

$$sim(W, C) = 1/|W| \cdot \Sigma_{i=1}^{|W|} sim(w_i, C)$$

where $|W|$ is the number of distinct words in W, and $sim(w_i, C)$ is the similarity of the i-th distinct word of W to C, defined as follows:

$$sim(w_i, C) = fdef(w_i, C) \cdot idf(w_i)$$

$fdef(w_i, C)$ is the percentage of definitions in C that contain w_i, and $idf(w_i)$ is the inverse document frequency of w_i in the British National Corpus (BNC):

$$idf(w_i) = 1 + log \frac{N}{df(w_i)}$$

N is the number of documents in BNC, and $df(w_i)$ the number of BNC documents where w_i occurs; if w_i does not occur in BNC, we use the lowest df score of BNC. $sim(w_i, C)$ is highest for words that occur in all the encyclopedia definitions and are used rarely in English. A training window with a large proportion of such words most probably defines the target term. More formally, given two thresholds t_+ and t_- with $t_- \leq t_+$, we tag W as a positive example if $sim(W, C) \geq t_+$, as a negative example if $sim(W, C) \leq t_-$, and we exclude it from the training of DEFQA if $t_- < sim(W, C) < t_+$. Hereafter, we refer to this method of generating training examples as the *similarity method*.

To select reasonable values for t_+ and t_-, we conducted a preliminary experiment for $t_- = t_+ = t$; i.e., both thresholds were set to the same value t and no training windows were excluded. We used $q = 130$ training target terms from TREC definition questions, for which we had multiple encyclopedia definitions. For each term, we collected the $r = 10$ most highly ranked Web pages.[9] To alleviate the class imbalance problem, whereby the positive examples (definitions) are much fewer than the negative ones (non-definitions), we kept only the first 5 windows from each Web page ($SN \leq 5$), based on the observation that windows with great SN scores are almost certainly non-definitions; we do the same in the training stage of all the experiments of this paper, and at run-time, when looking for windows to report, we ignore windows with $SN > 5$. From the resulting collection of training windows, we selected randomly 400 windows, and tagged them both manually and via the similarity method, with t ranging from 0 to 1. Figures 1 and 2 show the precision and recall of the similarity method on positive and negative training windows, respectively, for varying t. Here, *positive precision* is the percentage of training windows the similarity method tagged as positive examples (definitions) that were indeed positive; the true classes of the training windows were taken to be those assigned by the human annotators. *Positive recall* is the percentage of truly positive examples that the similarity method tagged as positive. *Negative precision* and *negative recall* are defined similarly.

Figures 1 and 2 indicate that there is no single threshold t that achieves both high positive precision and high negative precision. To be confident

[9] In all our experiments, we used the Altavista search engine.

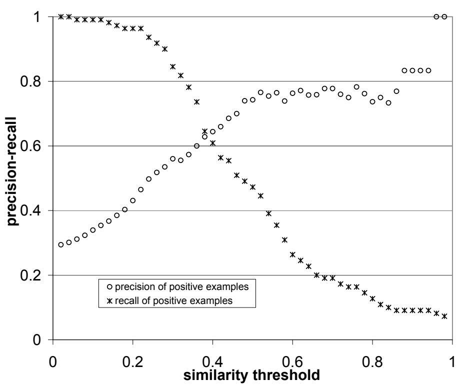

Figure 1: Positive precision and recall

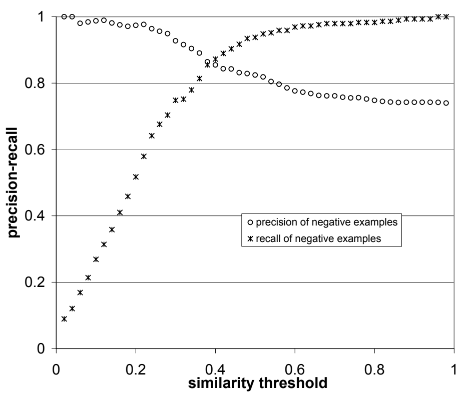

Figure 2: Negative precision and recall

that the training windows the similarity method will tag as positive examples are indeed positive (high positive precision), one has to set t close to 1; and to be confident that the training windows the similarity method will tag as negative examples are indeed negative (high negative precision), t has to be set close to 0. This is why we use two separate thresholds and discard the training windows whose similarity score is between t_- and t_+. Figures 1 and 2 also indicate that in both positive and negative examples the similarity method achieves perfect precision only at the cost of very low recall; i.e., if we insist that all the resulting training examples must have been tagged correctly (perfect positive and negative precision), the resulting examples will be very few (low positive and negative recall). There is also another consideration when selecting t_- and t_+: the ratio of positive to negative examples that the similarity method generates must be approximately the same as the true ratio before discarding any training windows, in order to avoid introducing an artificial bias in the training of DEFQA's SVM; the true ratio among the 400 training windows before discarding any windows was approximately $0.37 : 1$.

Based on the considerations above, in the remaining experiments of this paper we set t_+ to 0.5. In Figure 1, this leads to a positive precision of 0.72 (and positive recall 0.49), which does not improve much by adopting a larger t_+, unless one is willing to set t_+ at almost 1 at the price of very low positive recall. In the case of t_-, setting it to any value less than 0.34 leads to a negative precision above 0.9, though negative recall drops sharply as t_- approaches 0 (Figure 2). For example, setting t_- to 0.32, leads to 0.92 negative precision, 0.75 negative recall, and approximately the same positive to negative ratio ($0.31 : 1$) as the true observed ratio. In the experiments of Section 4, we keep t_+ fixed to 0.5, and set t_- to the value in the range $(0, 0.34)$ that leads to the positive to negative ratio that is closest to the true ratio we observed in the 400 windows.

The high negative precision we achieve (> 0.9) suggests that the resulting negative examples are almost always truly negative. In contrast, the lower positive precision (0.72) indicates that almost one in every four resulting positive examples is in reality a non-definition. This is a point where our similarity method needs to be improved; we return to this point in Section 6. Our experiments, however, show that despite this noise, the similarity method already outperforms the alternative of training DEFQA on TREC data. Note also that once the thresholds have been selected, we can generate automatically an arbitrarily large set of training examples, by starting with a sufficiently large number q of training terms to compensate for discarded training examples.

4 Evaluation

We tested two different forms of DEFQA. The first one, dubbed DEFQA^t, was trained on the $q = 160$ definition questions of TREC-2000 and TREC-2001 and the corresponding TREC documents, resulting in 3,800 training windows.[10] The second form of DE-

[10]For each question, the TREC organizers provide the 50 most highly ranked documents that an IR engine returned from the TREC document collection. We keep the top $r = 10$ of these documents, while M&A kept all 50. Furthermore, as discussed in Section 3, we retain up to the first 5 windows from each doc-

FQA, dubbed DEFQA^s, was trained via the similarity method, with $q = 480$ training target terms, leading to 7,200 training windows; as discussed in Section 3, one of the advantages of the similarity method is that one can generate an arbitrarily large set of training windows. As in the preliminary experiment of Section 3, r (Web pages per target term) was set to 10 in both systems. To simplify the evaluation and test DEFQA in a more demanding scenario, we set k to 1, i.e., the systems were allowed to return only one snippet per question, as opposed to the more lenient $k = 5$ in the experiments of M&A.

We also wanted a measure of how well DEFQA^t and DEFQA^s perform compared to a search engine on its own. For this purpose, we compared the performance of the two systems to that of a baseline, dubbed BASE^1, which always returns the first window of the Web page the search engine ranked first. In a search engine that highlights question terms in the returned documents, the snippet returned by BASE^1 is presumably the first snippet a user would read hoping to find an acceptable definition. To study how much DEFQA^t and DEFQA^s improve upon random behaviour, we also compared them to a second baseline, BASE^r, which returns a randomly selected window among the first five windows of all r Web pages returned by the search engine.

All four systems were evaluated on 81 unseen target terms. Their responses were judged independently by two human assessors, who had to mark each response as containing an acceptable short definition or not. As already pointed out, DEFQA^t and DEFQA^s consult encyclopedia definitions only during training, and at run time the systems are intended to be used with terms for which no encyclopedia definitions are available. During this evaluation, however, we deliberately chose the 81 test terms from the index of an on-line encyclopedia. This allowed us to give the encyclopedia's definitions to the assessors, to help them judge the acceptability of the single-snippet definitions the systems located on Web pages; many terms where related to, for example, medicine or biology, and without the encyclopedia's definitions the assessors would not be aware of their meanings. The following is a snippet returned correctly by DEFQA^s for 'genome':

discipline comparative genomics functional genomics bioinformatics the emergence of genomics as a discipline in 1920 , the term genome was proposed to denote the totality of all genes on all chromosomes in the nucleus of a cell . biology has...

while what follows is a non-definition snippet returned wrongly by BASE^1:

what is a genome national center for biotechnology information about ncbi ncbi at a glance a science primer databases...

The examples illustrate the nature of the snippets that the systems and assessors had to consider. The snippets often contain phrases that acted as links in the original pages, or even pieces of programming scripts that our rudimental preprocessing failed to remove. (We remove only HTML tags, and apply a simplistic tokenizer.) Nevertheless, in most cases the assessors had no trouble agreeing whether or not the resulting snippets contained acceptable short definitions. K_{Co} was 0.80, 0.81, 0.90, 0.89, and 0.86 in the assessment of the responses of DEFQA^s, DEFQA^t, BASE^r, BASE^1, and all responses, respectively, indicating strong inter-assessor agreement.[11] The agreement was slightly lower in DEFQA^s and DEFQA^t, because there were a few marginally acceptable or truncated definitions the assessors were uncertain about. There were also 4 DEFQA^s answers and 3 BASE^1 answers that defined secondary meanings of the target terms; e.g., apart from a kind of lizard, 'gecko' is also the name of a graphics engine, and 'Exodus' is also a programme for ex-offenders. Such answers were counted as wrong, though this may be too strict. With a larger k, there would be space to return both the main and secondary meanings, and the evaluation could require this.

Table 1 shows that DEFQA^s answered correctly approximately 6 out of 10 definition questions. This is lower than the score reported by M&A (73%), but remarkably high given that in our evaluation the systems were allowed to return only one snippet per question; i.e., the task was much harder than in M&A's experiments. DEFQA^s answered correctly more than twice as many questions as DEFQA^t, despite the fact that its training data contained a lot of noise. (Single-tailed difference-of-proportions tests show that all the differences of Table 1 are statisti-

ument. This is why we have fewer training windows than M&A.

[11]We follow the notation of Di Eugenio and Glass (2004). The $K_{S\&C}$ figures were identical. The $2 \cdot P(A) - 1$ figures were 0.80, 0.85, 0.95, 0.95, and 0.89 respectively.

	assessor 1	assessor 2	average
BASE^r	14.81 (12)	14.81 (12)	14.81 (12)
BASE^1	14.81 (12)	12.35 (10)	13.58 (11)
DEFQA^t	25.93 (21)	25.93 (21)	25.93 (21)
DEFQA^s	55.56 (45)	60.49 (49)	58.02 (47)

Table 1: Percentage of questions answered correctly

cally significant at $\alpha = 0.001$.) The superiority of DEFQA^s appears to be mostly due to its automatically acquired patterns. DEFQA^t too was able to acquire several good patterns (e.g., 'by *target*', 'known as *target*', '*target*, which is', '*target* is used in'), but its pattern set also comprises a large number of irrelevant n-grams; this had also been observed by M&A. In contrast, the acquired pattern set of DEFQA^s is much cleaner, with much fewer irrelevant n-grams, which is probably due to the largest, almost double, number of training windows. Furthermore, the pattern set of DEFQA^s contains many n-grams that are indicative of definitions on the Web. For example, many Web pages that define terms contain text of the form "What is a *target*? A *target* is…", and DEFQA^s has discovered patterns of the form 'what is a/an/the *target*', '? A/an/the *target*', etc. It has also discovered patterns like 'FAQ *target*', 'home page *target*', '*target* page' etc., that seem to be good indications of Web windows containing definitions.

Overall, DEFQA's process of acquiring lexical patterns worked better in DEFQA^s than in DEFQA^t, and we believe that the performance of DEFQA^s could be improved further by acquiring more than 200 patterns; we hope to investigate this in future work, along with an investigation of how the performance of DEFQA^s relates to q, the number of training target terms. Finally, note that the scores of both baselines are very poor, indicating that DEFQA^s performs significantly better than picking the first, or a random snippet among those returned by the search engine.

5 Related work

Definition questions have recently attracted several QA researchers. Many of the proposed approaches, however, rely on manually crafted patterns or heuristics to identify definitions, and do not employ learning algorithms (Liu et al., 2003; Fujii and Ishikawa, 2004; Hildebrandt et al., 2004; Xu et al., 2004).

Ng et al. (2001) use machine learning (C5 with boosting) to classify and rank candidate answers in a general QA system, but they do not treat definition questions in any special way; consequently, their worst results are for "What…?" questions, that presumably include definition questions. Ittycheriah and Roukos (2002) employ a maximum entropy model to rank candidate answers in a general-purpose QA system. Their maximum entropy model uses a very rich set of attributes, that includes 8,500 n-gram patterns. Unlike our work, their n-grams are five or more words long, they are coupled to two-word question prefixes, and, in the case of definition questions, they do not need to be anchored at the target term. The authors, however, do not provide separate performance figures for definition questions.

Blair-Goldensohn et al. (2003) focus on definition questions, but aim at producing coherent multi-snippet definitions, rather than single-snippet definitions. The heart of their approach is a component that uses machine learning (Ripper) to identify sentences that can be included in the multi-sentence definition. This component plays a role similar to that of our SVM, but it is intended to admit a larger range of sentences, and appears to employ only attributes conveying the ordinal number of the sentence in its document and the frequency of the target term in the sentence's context.

Since TREC-2003, several researchers have proposed ways to generate multi-snippet definitions (Cui et al., 2004; Fujii and Ishikawa, 2004; Hildebrandt et al., 2004; Xu et al., 2004). The typical approach is to locate definition snippets, much as in our work, and then report definition snippets that are sufficiently different; most of the proposals use some form of clustering to avoid reporting redundant snippets. Such methods could also be applied to DEFQA, to extend it to the post-2003 TREC task.

On-line encyclopedias and dictionaries have been used to handle definition questions in the past, but not as in our work. Hildebrandt et al. (2004) look up target terms in encyclopedias and dictionaries, and then, knowing the answers, try to find supporting evidence for them in the TREC document collection. Xu et al. (2004) collect from on-line encyclopedias and dictionaries words that co-occur with the target term; these words and their frequencies are then used as a centroid of the target term, and candidate answers are ranked by computing their similarity to the centroid. This is similar to our WC attribute.

Cui et al. (2004) also employ a form of centroid, comprising words that co-occur with the target term. The similarity to the centroid is taken into consideration when ranking candidate answers, but it is also used to generate training examples for a learning component that produces soft patterns, in the same way that we use the similarity method to produce training examples for the SVM. As in our work, the training examples that the centroid generates may be noisy, but the component that produces soft patterns manages to generalize over the noise. To the best of our knowledge, this is the only other unsupervised learning approach for definition questions that has been proposed. We hope to compare the two approaches experimentally in future work. For the moment, we can only point out that Cui et al.'s centroid approach generates only positive examples, while our similarity method generates both positive and negative ones; this allows us to use a principled SVM learner, as opposed to Cui et al.'s more ad hoc soft patterns that incorporate only positive examples.

6 Conclusions and future work

We presented an unsupervised method to learn to locate single-snippet answers to definition questions in QA systems that supplement Web search engines. The method exploits on-line encyclopedias and dictionaries to generate automatically an arbitrarily large number of positive and negative definition examples, which are then used to train an SVM to separate the two classes. We have shown experimentally that the proposed method is viable, that it outperforms training the QA system on TREC data, and that it helps the search engine handle definition questions significantly better than on its own.

We have already pointed out the need to improve the positive precision of the training examples. One way may be to combine our similarity method with Cui et al.'s centroids. We also plan to study the effect of including more automatically acquired patterns and using more training target terms. Finally, our method can be improved by including attributes for the layout and authority of Web pages.

Abstract

A content selection component determines which information should be conveyed in the output of a natural language generation system. We present an efficient method for automatically learning content selection rules from a corpus and its related database. Our modeling framework treats content selection as a collective classification problem, thus allowing us to capture contextual dependencies between input items. Experiments in a sports domain demonstrate that this approach achieves a substantial improvement over context-agnostic methods.

1 Introduction

Content selection is a fundamental task in concept-to-text generation (Reiter and Dale, 2000). A practical generation system typically operates over a large database with multiple entries that could potentially be included in a text. A content selection component determines what subset of this information to include in the generated document.

For example, consider the task of automatically generating game summaries, given a database containing statistics on Americal football. Table 1 shows an excerpt from such a database, and its corresponding game summary written by a journalist. A single football game is typically documented in hundreds of database entries — all actions, player positions, and scores are recorded, along with a wide range of comparative and aggregate statistics. Only a small fraction of this information is featured in a game summary. The content selection component aims to identify this subset.[1]

In existing generation systems the content selection component is manually crafted. Specifying content selection rules is, however, notoriously difficult, prohibitively so in large domains. It involves the analysis of a large number of texts from a domain-relevant corpus, familiarity with the associated database, and consultation with domain experts. Moreover, the task must be repeated for each domain anew.

This paper proposes a data-driven method for learning the content-selection component for a concept-to-text generation system. We assume that the learning algorithm is provided with a parallel corpus of documents and a corresponding database, in which database entries that should appear in documents are marked.

One possible approach is to formulate content selection as a standard binary classification task: predict whether an item is to be included on the basis of its attributes alone. In fact, this method is commonly used for content selection in text summarization (e.g., Kupiec et al., 1995). However, by treating each instance in isolation, we cannot guarantee that the selected database entries are related in a meaningful way, which is essential for the generation of a coherent text.

Rather than selecting each item separately, we propose a method for *collective content selection*, where all candidates are considered simultaneously for selection. Collective selection thereby allows us to explicitly optimize *coherence* in the generated

[1]The organization of the selected information and its surface realization is typically handled by other components of the generation system, which are outside the scope of this paper.

Passing					
PLAYER	CP/AT	YDS	AVG	TD	INT
Brunell	17/38	192	6.0	0	0
Garcia	14/21	195	9.3	1	0
...	...	...	...	...	...

Rushing					
PLAYER	REC	YDS	AVG	LG	TD
Suggs	22	82	3.7	25	1
...	...	...	...	...	...

Fumbles				
PLAYER	FUM	LOST	REC	YDS
Coles	1	1	0	0
Portis	1	1	0	0
Davis	0	0	1	0
Little	0	0	1	0
...	...	...	...	...

Suggs rushed for 82 yards and scored a touchdown in the fourth quarter, leading the Browns to a 17-13 win over the Washington Redskins on Sunday. **Jeff Garcia went 14-of-21 for 195 yards and a TD** for the Browns, who didn't secure the win until **Coles fumbled** with 2:08 left. The Redskins (1-3) can pin their third straight loss on going just 1-for-11 on third downs, mental mistakes and **a costly fumble by Clinton Portis**. **Brunell finished 17-of-38 for 192 yards**, but was unable to get into any rhythm because Cleveland's defense shut down Portis. The Browns faked a field goal, but holder Derrick Frost was stopped short of a first down. **Brunell then completed a 13-yard pass to Coles, who fumbled** as he was being taken down and Browns safety Earl Little recovered.

Table 1: Sample target game description and example of database entries; boldface indicates correspondences between the text and the database (CP/AT: completed out of attempted, YDS: yards, AVG: average, TD: touchdown, INT: interception, REC: received, LG: longest gain, FUM: fumble).

text: semantically related entries are often selected together. In essence, the algorithm seeks a subset of candidates that is consistent with the individual preferences of each candidate, and at the same time maximally satisfies contextual constraints. A graph-based formulation of this optimization problem allows us to find an exact, globally optimal solution, using a min-cut algorithm.

Collective content selection is particularly beneficial to generation systems that operate over relational databases. Rich structural information available in a database can be readily utilized to determine semantic relatedness between different database entries. For instance, we can easily find all actions (e.g., touchdowns and fumbles) associated with a specific player in a game, which could be relevant for generating a summary centered around an individual. We show how to utilize database relations for discovering meaningful contextual links between database entries.

We evaluate our collective content selection model in a sports domain. The proposed content selection component operates over a large database containing descriptive statistics about American football games. Our model yields a 10% increase in F-score, when compared to a standard classification approach, thus demonstrating the benefits of collective content selection on this complex domain. Furthermore, our results empirically confirm the contribution of discourse constraints for content selection.

In the following section, we provide an overview of existing work on content selection. Then, we define the learning task and introduce our approach for collective content selection. Next, we present our experimental framework and data. We conclude the paper by presenting and discussing our results.

2 Related Work

The generation literature provides multiple examples of content selection components developed for various domains (Kukich, 1983; McKeown, 1985; Sripada et al., 2001; Reiter and Dale, 2000). A common theme across different approaches is the emphasis on coherence: related information is selected "to produce a text that hangs together" (McKeown, 1985). Similarly, our method is also guided by coherence constraints. In our case these constraints are derived automatically, while in symbolic generation systems coherence is enforced by analyzing a large number of texts from a domain-relevant corpus and careful hand-crafting of content selection rules.

Duboue and McKeown (2003) were the first to propose a method for learning content selection rules automatically, thus going beyond mere corpus analysis. They treat content selection as a classification task. Given a collection of texts associated with a domain-specific database, their model learns whether a database entry should be selected for presentation or not. Their modeling approach uses an expressive feature space while considering database entries in isolation.

Similarly to Duboue and McKeown (2003), we view content selection as a classification task and learn selection rules from a database and its corresponding corpus. In contrast to them, we consider all database entries simultaneously, seeking a globally optimal selection. Thus, we avoid the need for extensive feature engineering by incorporating discourse constraints into the learning framework. In addition, we assess whether data-driven methods for content selection scale up to large databases with thousands of interrelated entries, by evaluating our model in a sports domain. Previous work (Duboue and McKeown, 2003) has tackled the content selection problem for biographical summaries, a simpler domain with fewer entities and interactions among them.

3 The Task

We assume that the content selection component takes as input a set of database entries.[2] Each entry has a type and a set of attributes associated with its type. For instance, the database shown in Table 1 contains entries of three types — `Passing`, `Rushing` and `Fumbles`. Two entries are of type `Passing`, and each of them has six attributes — `PLAYER`, `CP/AT`, `YDS`, `AVG`, `TD`, `INT`. In addition, each entry has a label that specifies whether it should be included in a generated text or not.

During the training process, the learning algorithm is provided with n sets of database entries, each associated with a label whose value is known. In practice, we only require a parallel corpus of game summaries and database entries — label values are derived automatically via alignment (see Section 4 for more details).

[2]A terminological note: a database entry is analogous to a row in a relational table; throughout this paper we use the terms entity and database entry interchangeably.

The goal of the content selection component is to select entries from a database, i.e., to determine whether their label values are 0 or 1. Under this formulation, content selection is restricted to information available in the database; there is no attempt to induce new facts through inference.

In the next section, we describe our learning framework, and explain how it is applied to the content selection task.

3.1 The Collective Classification Approach

Generation of a coherent text crucially depends on our ability to select entities that are related in a meaningful way (McKeown, 1985). A content selection component that considers every entity in isolation does not have any means to enforce this important discourse constraint. We therefore formulate content selection as a *collective classification* task, where all entities that belong to the same database (i.e., the same football game) are considered simultaneously. This framework thus enables us to enforce contextual constraints by selecting related entities.

When considered in isolation, some database entries are more likely to be selected than others. In the American football domain, for example, entries of type `Rushing` are often extracted if they yield a touchdown.[3] Other `Rushing` entries (e.g., which do not deliver scoring points) are typically omitted. In general, the attributes of an entry can provide useful cues for predicting whether it should be selected. Therefore, we can perform content selection by applying a standard classifier on each entry. In Section 3.2, we explain in more detail how such a classifier can be trained.

We can also decide about entity selection by analyzing how entities relate to each other in the database. For instance, in a game where both quarterbacks[4] score, it is fairly unorthodox to mention the passing statistics for only one of them. Label assignments in which either both quarterbacks are selected, or both of them are omitted should be there-

[3]A touchdown is the primary method of scoring in American football; a touchdown is worth six points and is accomplished by gaining legal possession of the ball in the opponent's end zone.

[4]A quarterback in American football is the leader of a team's offense. In most offenses his primary duty is passing the ball. Quarterbacks are typically evaluated on their passing statistics, including total yardage, completion ratio, touchdowns, and the ability to avoid interceptions.

fore preferred. This relation between quarterback passing statistics exemplifies one type of link that can hold between entities. Other link types may encode contextual constraints, for instance capturing temporal and locational information. (In Section 3.3, we describe a method for discovering link types which encapsulate meaningful contextual dependencies.) By taking into account links between related entities, a content selection component can enforce dependencies in the labeling of related entities.

Our goal is to select a subset of database entities that maximally satisfies linking constraints and is as consistent as possible with the individual preferences of each entity. Thus, content selection can be naturally stated as an optimization problem — we wish to find a label assignment that *minimizes* the cost of violating the above constraints.

Let C_+ and C_- be a set of selected and omitted entities, respectively; $ind_+(x)$ and $ind_-(x)$ are scores that capture the individual preference of x to be either selected or omitted, and $link_L(x,y)$ reflects the degree of dependence between the labels of x and y based on a link of type L. Thus, the optimal label assignment for database entries $x_1,\ldots,x_n$ will minimize:

$$\sum_{x \in C_+} ind_-(x) + \sum_{x \in C_-} ind_+(x) + \sum_L \sum_{\substack{x_i \in C_+ \\ x_j \in C_-}} link_L(x_i,x_j)$$

The first two elements in this expression capture the penalty for assigning entities to classes against their individual preferences. For instance, the penalty for selecting an entry $x \in C_+$ will equal $ind_-(x)$, i.e., x's individual preference of being ommitted. The third term captures a linking penalty for all pairs of entities (x_i,x_j) that are connected by a link of type L, and are assigned to different classes.

This formulation is similar to the energy minimization framework, which is commonly used in image analysis (Besag, 1986; Boykov et al., 1999) and has been recently applied in natural language processing (Pang and Lee, 2004). The principal advantages of this formulation lie in its computational properties. Despite seeming intractable — the number of possible subsets to consider for selection is exponential in the number of database entities — the inference problem has an exact solution. Provided that the scores $ind_+(x)$, $ind_-(x)$, and $link_L(x,y)$ are positive, we can find a globally optimal label assignment in polynomial time by computing a minimal cut partition in an appropriately constructed graph (Greig et al., 1989).

In the following we first discuss how individual preference scores are estimated. Next, we describe how to induce links and estimate their scores.

3.2 Computing Individual Preference Scores

The individual preference scores are estimated by considering the values of entity attributes, recorded in the database. The type and number of the attributes are determined by the entity type. Therefore, we separately estimate individual preference scores for each entity type. For example, individual scores for entities of type `Passing` are computed based on six attributes : `PLAYER`, `CP/AT`, `YDS`, `AVG`, `TD`, `INT` (see Table 1).

Considerable latitude is available when selecting a classifier for delivering the individual preference scores. In our experiments we used the publicly available BoosTexter system (Schapire and Singer, 2000). BoosTexter implements a boosting algorithm that combines many simple, moderately accurate categorization rules into a single, highly accurate rule. For each example, it outputs a prediction along with a weight whose magnitude indicates the classifier's confidence in the prediction. We thus set the individual preference scores to the weights obtained from BoosTexter. The weights range from -1 to 1; we obtained non-negative numbers, simply by adding 1.

It is important to note that BoosTexter is a fairly effective classifier. When applied to text categorization (Schapire and Singer, 2000), it outperformed a number of alternative classification methods, including Naive Bayes, decision trees, and k-nearest neighbor.

3.3 Link Selection and Scoring

The success of collective classification depends on finding links between entities with similar label preferences. In our application — concept-to-text generation, it is natural to define entity links in terms of their database relatedness. Since the underlying database contains rich structural information, we can explore a wide range of relations between database entities.

The problem here is finding a set of links that capture important contextual dependencies among many possible combinations. Instead of manually specifying this set, we propose a corpus-driven method for discovering links automatically. Automatic link induction can greatly reduce human effort. Another advantage of the method is that it can potentially identify relations that might escape a human expert and yet, when explicitly modeled, aid in content selection.

We induce important links by adopting a generate-and-prune approach. We first automatically create a large pool of candidate links. Next, we select only links with aconsistent label distributions.

Construction of Candidate Links An important design decision is the type of links that we allow our algorithm to consider. Since our ultimate goal is the generation of a coherent text, we wish to focus on links that capture semantic connectivity between database entities. An obvious manifestation of semantic relatedness is attribute sharing. Therefore, we consider links across entities with one or more shared attributes. An additional constraint is implied by computational considerations: our optimization framework, based on minimal cuts in graphs, supports only pairwise links, so we restrict our attention to binary relations.

We generate a range of candidate link types using the following template: For every pair of entity types E_i and E_j, and for every attribute k that is associated with both of them, create a link of type $L_{i,j,k}$. A pair of entities $\langle a,b \rangle$ is linked by $L_{i,j,k}$, if a is of type E_i, b is of type E_j and they have the same value for the attribute k. For example, a link that associates statistics on `Passing` and `Rushing` performed by the same player is an instantiation of the above with E_i = Rushing, E_j = Passing, and k = Player.

In a similar fashion, we construct link types that connect together entities with two or three attributes in common. Multiple pairs of entries can be connected by the same link type.

If the database consists of n entity types, and the number of attribute types is bounded by m, then the number of link types constructed by this process does not exceed $O(n^2(m + \binom{m}{2} + \binom{m}{3})) \approx O(n^2 m^3)$. In practice, this bound is much lower, since only a few attributes are shared among entity types. Links can be efficiently computed using SQL's `SELECT` operator.

Link Filtering Only a small fraction of the automatically generated link types will capture meaningful contextual dependencies. To filter out spurious links, we turn to the labels of the entities participating in each link. Only link types in which entities have a similar distribution of label values are selected from the pool of candidates.

We measure similarity in label distribution using the χ^2 test. This test has been successfully applied to similar tasks, such as feature selection in text classification (Rogati and Yang, 2002), and can be easily extended to our application. Given a binary link, our null hypothesis H_0 is that the labels of entities related by L are independent. For each link, we compute the χ^2 score over a 2-by-2 table that stores joint label values of entity pairs, computed across all database entries present in the training set. For links with $\chi^2 > \tau$, the null hypothesis is rejected, and the link is considered a valid discourse constraint. The value of τ is set to 3.84, which corresponds to a 5% level of statistical significance.

Link Weights The score of a link type L is defined as follows:

$$link_L(x,y) = \begin{cases} \lambda_L & if(x,y) \text{ are linked by L} \\ 0 & \text{otherwise} \end{cases}$$

We estimate link weights λ_L using simulated annealing. The goal is to find weight values that minimize an objective function, defined as the error rate on the development set[5] (see Section 4 for details). The individual scores and the link structure of the entities in the development set are predicted automatically using the models trained on the training set. Starting from a random assignment of weight values, we compute the objective function and generate new weight values using Parks' (1990) method. The procedure stops when no sufficient progress is observed in subsequent iterations.

4 Evaluation Framework

We apply the collective classification method just presented to the task of automatically learning content selection rules from a database containing football-related information. In this section, we first present the sport domain we are working with, and

[5]Our objective function cannot be optimized analytically. We therefore resort to heuristic search methods such as simulated annealing.

Entity Type	Attr	Inst	%Aligned	Entity Type	Attr	Inst	%Aligned
Defense	8	14,077	0.00	*Passing*	5	1,185	59.90
Drive	10	11,111	0.00	*Team comparison*	4	14,539	0.00
Play-by-Play	8	83,704	3.03	*Punt-returns*	8	940	5.74
Fumbles	8	2,937	17.78	*Punting*	9	950	0.87
Game	6	469	0.00	*Receiving*	8	6,337	11.19
Interceptions	6	894	45.05	*Rushing*	8	3,631	9.17
Kicking	8	943	26.93	*Scoring-sum*	9	3,639	53.34
Kickoff-returns	8	1,560	5.24	*Team*	3	4	0.00
Officials	8	464	0.00				

Table 2: Entity types and their attributes in the NFL database; percentage of database entries that are aligned to summary sentences.

describe how we collected a corpus for evaluating collective content selection. Next, we explain how we automatically obtained annotated data for training and testing our model.

Data As mentioned previously our goal is to generate descriptions of football games. The sports domain has enjoyed popularity among natural language generation practitioners (Robin, 1994; Tanaka-Ishii et al., 1998). The appeal is partly due to the nature of the domain — it exhibits several fixed patterns in content organization and is therefore amenable to current generation approaches. At the same time, it is complex enough to present challenges at almost all stages of the generation process.

We compiled a corpus of descriptions of football games from the web. More specifically, we obtained game summaries from the official site of the American National Football League[6] (NFL). We collected summaries for the 2003 and 2004 seasons. These are typically written by Associated Press journalists. The corpus consists of 468 texts in total (436,580 words). The average summary length is 46.8 sentences.

The site not only contains a summary for each game, but also a wealth of statistics describing the performance of individual players and their teams. It includes a scoring summary and a play-by-play summary giving details of the most important events in the game together with temporal (i.e., time remaining) and positional (i.e., location in the field) information. In sum, for each game the site offers a rich repository of tabulated information which we translated into a relational database. An excerpt of the database is shown in Table 1. Table 2 displays the entity types contained in our NFL database and lists the number of attributes (Attr) and instantiations (Inst) per type. The database contains 73,400 entries in total.

[6]See `http://www.nfl.com/scores`.

Alignment Recall that our collective classification method is supervised. The training instances are database entries and the class labels indicate whether an instance should be selected for presentation or not. We could obtain this information via manual annotation performed by domain experts. Instead, we opted for a less costly, automatic solution that yields large quantities of training and testing data. To infer which database entries correspond to sentences in the verbalized game summaries, we used a simple anchor-based alignment technique. In our domain, numbers and proper names appear with high frequency, and they constitute reliable anchors for alignment. Similar to previous work (Duboue and McKeown, 2003; Sripada et al., 2001), we employ a simple matching procedure that considers anchor overlap between entity attributes and sentence tokens.

Overall, the alignment procedure produced 7,513 pairs. 7.1% of the database entries were verbalized in our corpus and 31.7% of the corpus sentences had a database entry. Table 2 presents the proportion of database entries which are verbalized in our corpus, broken down by entity type (see %Aligned).

To evaluate the accuracy of this procedure, we compared our output with a gold-standard alignment produced by a domain expert. After analyzing the data from five games, the expert produced 52 alignment pairs; 47 of these pairs were identified

	Majority Baseline			Standard Classifier			Collective Classifier		
	Prec	Rec	F-score	Prec	Rec	F-score	Prec	Rec	F-score
Mean	29.40	68.19	40.09	44.88	62.23	49.75	**52.71**	**76.50**	**60.15**
Min	3.57	28.57	6.45	12.50	8.33	13.33	12.50	27.27	19.05
Max	57.14	100.00	65.12	76.92	100.00	75.00	100.00	100.00	100.00
Std Dev	10.93	15.75	12.25	15.36	18.33	13.98	21.29	18.93	19.66

Table 3: Results on content selection (precision, recall and F-score are averages over individual game summaries); comparison between the majority baseline, standard and collective classification.

by the automatic alignment. In addition, three pairs produced by the program did not match the gold-standard alignment. Thus, the automatic method achieved 94.0% precision and 90.4% recall.

Data Annotation For training and testing purposes, we only considered entity types for which alignments were observed in our corpus (e.g., `Fumbles`, `Interceptions`; see Table 2). Types without alignments can be trivially regarded as inappropriate for selection in the generated text. We considered database entries for which we found verbalizations in the corpus as positive instances (i.e., they should be selected); accordingly, non-verbalized entries were considered negative instances (i.e., they should not be selected). The overall dataset contained 105,792 instances (corresponding to 468 game summaries). Of these, 15% (68 summaries) were reserved for testing. We held out 1,930 instances (10 summaries) from the training data for development purposes.

5 Results

Our results are summarized in Table 3. We compare the performance of the collective classifier against a standard classifier. This can be done in our framework, simply by setting the link scores to zero. We also report the performance of a majority baseline. The latter was obtained by defaulting to the majority class for each entity type in the training data. As can be seen from Table 2, only for two relations — `Passing` and `Scoring-sum` — the majority class predicts that the corresponding database instances should be selected for presentation.

Our results confirm that a content selection component can be automatically engineered for the football domain. The collective classifier achieves an F-score of 60.15%. This result compares favorably with Duboue and McKeown (2003) whose best model has an F-score of 51.00% on a simpler domain. Our method has high recall (we want to avoid missing out information that should be presented in the output) but tends to overgenerate as demonstrated by the relatively moderate precision in Table 3. Erroneous content selection decisions could be remedied by other components later in the generation process. Alternatively, the obtained content selection rules could be further refined or post-processed by a domain expert. Finally, better classification performance should be possible with more expressive feature sets. As we can see from the weak performance of the standard classifier, attribute values of database entries may not be sufficiently strong predictors. Considering additional features tailored to the NFL domain could further enhance performance. However, feature selection is not one of the main objectives of this work.

Our results empirically validate the importance of discourse constraints for content selection (Table 4 illustrates examples of constraints that the model discovered). We observe that adding contextual information leads to a 10.4% F-score increase over the standard classifier. We used a paired t test to examine whether the differences are statistically significant. The collective model significantly outperforms the standard model on both precision (t = 4.824, $p < 0.01$) and recall (t = 8.445, $p < 0.01$). It is also significantly better than the majority baseline, both in terms of recall (t = 3.181, $p < 0.01$) and precision (t = 8.604, $p < 0.01$). The standard classifier performs significantly better than the majority baseline on precision (t = 7.043, $p < 0.01$) but worse on recall (t =-2.274, $p < 0.05$).

6 Conclusions and Future Work

In this paper we have presented a novel, data-driven method for automating content selection. Central

$\{\langle a,b\rangle \mid a \in Sum \wedge b \in Sum \wedge a.Quarter = b.Quarter\}$
$\{\langle a,b\rangle \mid a \in Sum \wedge b \in Play \wedge Sum.Player_1 = Play.Player_1 \wedge Sum.Action = Play.Action\}$
$\{\langle a,b\rangle \mid a \in Fumbles \wedge b \in Interceptions \wedge Fumbles.Player = Interceptions.Player\}$

Table 4: Examples of automatically derived links.

to our approach is the use of a collective classification model that captures contextual dependencies between input items. We show that incorporation of discourse constraints yields substantial improvement over context-agnostic methods. Our approach is linguistically grounded, computationally efficient, and viable in practical applications.

In the future, we plan to explore how to integrate more refined discourse models in the content selection process. Currently, we consider a limited set of contextual dependencies based on attribute similarity. Ideally, we would like to express more complex relations between items. For instance, we may want to represent disjunctive constraints, such as "at least one of the defense players should be mentioned in the summary." Such dependencies can be efficiently handled in a collective classification framework by using approximate probabilistic inference (Taskar et al., 2002). Another promising approach is the combination of our automatically acquired cross-entity links with domain knowledge.

Needless to say, content selection is one of several components within a working generation system. An interesting question is how to integrate our component into a generation pipeline, using feedback from other components to guide collective content selection.

Extracting Product Features and Opinions from Reviews

Ana-Maria Popescu and Oren Etzioni
Department of Computer Science and Engineering
University of Washington
Seattle, WA 98195-2350
{amp, etzioni}@cs.washington.edu

Abstract

Consumers are often forced to wade through many on-line reviews in order to make an informed product choice. This paper introduces OPINE, an unsupervised information-extraction system which mines reviews in order to build a model of important product features, their evaluation by reviewers, and their relative quality across products.

Compared to previous work, OPINE achieves 22% higher precision (with only 3% lower recall) on the feature extraction task. OPINE's novel use of *relaxation labeling* for finding the semantic orientation of words in context leads to strong performance on the tasks of finding opinion phrases and their polarity.

1 Introduction

The Web contains a wealth of opinions about products, politicians, and more, which are expressed in newsgroup posts, review sites, and elsewhere. As a result, the problem of "opinion mining" has seen increasing attention over the last three years from (Turney, 2002; Hu and Liu, 2004) and many others. This paper focuses on product reviews, though our methods apply to a broader range of opinions.

Product reviews on Web sites such as `amazon.com` and elsewhere often associate meta-data with each review indicating how positive (or negative) it is using a 5-star scale, and also rank products by how they fare in the reviews at the site. However, the reader's taste may differ from the reviewers'. For example, the reader may feel strongly about the quality of the gym in a hotel, whereas many reviewers may focus on other aspects of the hotel, such as the decor or the location. Thus, the reader is forced to wade through a large number of reviews looking for information about particular features of interest.

We decompose the problem of review mining into the following main subtasks:

I. Identify product features.
II. Identify opinions regarding product features.
III. Determine the polarity of opinions.
IV. Rank opinions based on their strength.

This paper introduces OPINE, an unsupervised information extraction system that embodies a solution to each of the above subtasks. OPINE is built on top of the KnowItAll Web information-extraction system (Etzioni et al., 2005) as detailed in Section 3.

Given a particular product and a corresponding set of reviews, OPINE solves the opinion mining tasks outlined above and outputs a set of *product features*, each accompanied by a list of *associated opinions* which are ranked based on strength (*e.g.*, "abominable" is stronger than "bad). This output information can then be used to generate various types of opinion summaries.

This paper focuses on the first 3 review mining subtasks and our contributions are as follows:

1. We introduce OPINE, a review-mining system whose novel components include the use of *relaxation labeling* to find the semantic orientation of words in the context of given product features and sentences.

2. We compare OPINE with the most relevant previous review-mining system (Hu and Liu, 2004) and find that OPINE's precision on the *feature extraction* task is 22% better though its recall is 3% lower on Hu's data sets. We show that 1/3 of this increase in precision comes from using OPINE's *feature assessment* mechanism on review data while the rest is due to Web PMI statistics.

3. While many other systems have used extracted opinion phrases in order to determine the polarity of sentences or documents, OPINE is the first to report its precision and recall on the tasks of *opinion phrase extraction* and *opinion phrase polarity determination* in the context of known product features and sentences. On the first task, OPINE has a precision of 79% and a recall of 76%. On the second task, OPINE has a precision of 86% and a recall of 89%.

Figure 1: **OPINE Overview.**

The remainder of this paper is organized as follows: Section 2 introduces the basic terminology, Section 3 gives an overview of OPINE, describes and evaluates its main components, Section 4 describes related work and Section 5 presents our conclusion.

2 Terminology

A *product class* (*e.g.*, Scanner) is a set of *products* (*e.g.*, Epson1200). OPINE extracts the following types of *product features*: *properties*, *parts*, *features of product parts*, *related concepts*, *parts* and *properties of related concepts* (see Table 1 for examples of such features in the Scanner domains). *Related concepts* are concepts relevant to the customers' experience with the main product (*e.g.*, the company that manufactures a scanner). The relationships between the main product and related concepts are typically expressed as verbs (*e.g.*, "Epson *manufactures* scanners") or prepositions ("scanners *from* Epson"). Features can be *explicit* ("good `scan quality`") or *implicit* ("good scans" implies good `ScanQuality`).

OPINE also extracts *opinion phrases*, which are adjective, noun, verb or adverb phrases representing customer opinions. Opinions can be *positive* or *negative* and vary in *strength* (*e.g.*, "fantastic" is stronger than "good").

3 OPINE Overview

This section gives an overview of OPINE (see Figure 1) and describes its components and their experimental evaluation.

Goal Given product class C with instances I and reviews R, OPINE's goal is to find a set of (feature, opinions) tuples $\{(f, o_i, ...o_j)\}$ s.t. $f \in F$ and $o_i, ...o_j \in O$, where:

a) F is the set of product class features in R.

b) O is the set of opinion phrases in R.

c) f is a feature of a particular product instance.

d) o is an opinion about f in a particular sentence.

d) the opinions associated with each feature f are ranked based on their strength.

Solution The steps of our solution are outlined in Figure 1 above. OPINE parses the reviews using MINIPAR (Lin, 1998) and applies a simple pronoun-resolution module to parsed review data. OPINE then uses the data to find *explicit* product features (E). OPINE's *Feature Assessor* and its use of Web PMI statistics are vital for the extraction of high-quality features (see 3.2). OPINE then identifies *opinion phrases* associated with features in E and finds their polarity. OPINE's novel use of relaxation-labeling techniques for determining the semantic orientation of potential opinion words in the context of given features and sentences leads to high precision and recall on the tasks of *opinion phrase extraction* and *opinion phrase polarity extraction* (see 3.3).

In this paper, we only focus on the extraction of explicit features, identifying corresponding customer opinions about these features and determining their polarity. We omit the descriptions of the opinion clustering, implicit feature generation and opinion ranking algorithms.

3.0.1 The KnowItAll System.

OPINE is built on top of KnowItAll, a Web-based, domain-independent information extraction system (Etzioni et al., 2005). Given a set of relations of interest, KnowItAll instantiates relation-specific generic extraction patterns into extraction rules which find candidate facts. KnowItAll's Assessor then assigns a probability to each candidate. The Assessor uses a form of *Point-wise Mutual Information* (PMI) between phrases that is estimated from Web search engine hit counts (Turney, 2001). It computes the PMI between each fact and *automatically generated discriminator phrases* (*e.g.*, "is a scanner" for the `isA()` relationship in the context of the `Scanner` class). Given fact f and discriminator d, the computed PMI score is:

$$\text{PMI}(f, d) = \frac{\text{Hits}(d + f)}{\text{Hits}(d) * \text{Hits}(f)}$$

The PMI scores are converted to binary features for a Naive Bayes Classifier, which outputs a probability associated with each fact (Etzioni et al., 2005).

3.1 Finding Explicit Features

OPINE extracts *explicit* features for the given product class from parsed review data. First, the system recursively identifies both the *parts* and the *properties* of the given product class and their parts and properties, in turn, continuing until no candidates are found. Then, the system finds *related concepts* as described in (Popescu et al., 2004) and extracts their parts and properties. Table 1 shows that each feature type contributes to the set of final features (averaged over 7 product classes).

Explicit Features	**Examples**	**% Total**
Properties	ScannerSize	7%
Parts	ScannerCover	52%
Features of Parts	BatteryLife	24%
Related Concepts	ScannerImage	9%
Related Concepts' Features	ScannerImageSize	8%

Table 1: **Explicit Feature Information**

In order to find parts and properties, OPINE first extracts the noun phrases from reviews and retains those with frequency greater than an experimentally set threshold. OPINE's *Feature Assessor*, which is an instantiation of KnowItAll's Assessor, evaluates each noun phrase by computing the PMI scores between the phrase and *meronymy discriminators* associated with the product class (*e.g.*, "of scanner", "scanner has", "scanner comes with", etc. for the `Scanner` class). OPINE distinguishes parts from properties using WordNet's IS-A hierarchy (which enumerates different kinds of properties) and morphological cues (*e.g.*, "-iness", "-ity" suffixes).

3.2 Experiments: Explicit Feature Extraction

In our experiments we use sets of reviews for 7 product classes (1621 total reviews) which include the publicly available data sets for 5 product classes from (Hu and Liu, 2004). Hu's system is the review mining system most relevant to our work. It uses association rule mining to extract *frequent* review noun phrases as features. Frequent features are used to find *potential opinion* words (only adjectives) and the system uses WordNet synonyms/antonyms in conjunction with a set of seed words in order to find actual *opinion* words. Finally, opinion words are used to extract associated *infrequent* features. The system only extracts *explicit* features.

On the 5 datasets in (Hu and Liu, 2004), OPINE's precision is 22% higher than Hu's at the cost of a 3% recall drop. There are two important differences between OPINE and Hu's system: a) OPINE's Feature Assessor uses PMI assessment to evaluate each candidate feature and b) OPINE incorporates Web PMI statistics in addition to review data in its assessment. In the following, we quantify the performance gains from a) and b).

a) In order to quantify the benefits of OPINE's Feature Assessor, we use it to evaluate the features extracted by Hu's algorithm on review data (**Hu+A/R**). The Feature Assessor improves Hu's precision by 6%.

b) In order to evaluate the impact of using Web PMI statistics, we assess OPINE's features first on reviews (**OP/R**) and then on reviews in conjunction with the Web (the corresponding methods are **Hu+A/R+W** and **OPINE**). Web PMI statistics increase precision by an average of 14.5%.

Overall, 1/3 of **OPINE**'s precision increase over Hu's system comes from using PMI assessment on reviews and the other 2/3 from the use of the Web PMI statistics.

In order to show that OPINE's performance is robust across multiple product classes, we used two sets of reviews downloaded from `tripadvisor.com` for Hotels and `amazon.com` for Scanners. Two annotators labeled a set of unique 450 OPINE extractions as *correct* or *incorrect*. The inter-annotator agreement was 86%. The extractions on which the annotators agreed were used to compute OPINE's precision, which was 89%. Furthermore, the annotators extracted explicit features from 800 review sentences (400 for each domain). The inter-annotator agreement was 82%. OPINE's recall on the set of 179 features on which both annotators agreed was 73%.

Data	**Explicit Feature Extraction: Precision**				
	Hu	**Hu+A/R**	**Hu+A/R+W**	**OP/R**	**OPINE**
D_1	*0.75*	+0.05	+0.17	+0.07	**+0.19**

Table 3: **Recall Comparison on the Explicit Feature-Extraction Task.** OPINE's recall is 3% lower than the recall of Hu's original system (precision level = 0.8). All results are reported with respect to Hu's.

3.3 Finding Opinion Phrases and Their Polarity

This subsection describes how OPINE extracts potential opinion phrases, distinguishes between opinions and non-opinions, and finds the *polarity* of each opinion in the context of its associated feature in a particular review sentence.

3.3.1 Extracting Potential Opinion Phrases

OPINE uses explicit features to identify potential opinion phrases. Our intuition is that an opinion phrase associated with a product feature will occur in its vicinity. This idea is similar to that of (Kim and Hovy, 2004) and (Hu and Liu, 2004), but instead of using a window of size k or the output of a noun phrase chunker, OPINE takes advantage of the syntactic dependencies computed by the MINIPAR parser. Our intuition is embodied by 10 *extraction rules*, some of which are shown in Table 4. If an explicit feature is found in a sentence, OPINE applies the extraction rules in order to find the heads of potential opinion phrases. Each head word together with its modifiers is returned as a potential opinion phrase[1].

Extraction Rules	**Examples**
if $\exists(M, NP = f) \rightarrow po = M$	(expensive) `scanner`
if $\exists(S = f, P, O) \rightarrow po = O$	`lamp` has (problems)
if $\exists(S, P, O = f) \rightarrow po = P$	I (hate) this `scanner`
if $\exists(S = f, P, O) \rightarrow po = P$	`program` (crashed)

Table 4: **Examples of Domain-independent Rules for the Extraction of Potential Opinion Phrases.** Notation: po=potential opinion, M=modifier, NP=noun phrase, S=subject, P=predicate, O=object. Extracted phrases are enclosed in parentheses. Features are indicated by the typewriter font. The equality conditions on the left-hand side use po's head.

Rule Templates	**Rules**
$dep(w, w')$	$m(w, w')$
$\exists v$ s.t. $dep(w, v), dep(v, w')$	$\exists v$ s.t. $m(w, v), o(v, w')$
$\exists v$ s.t. $dep(w, v), dep(w', v)$	$\exists v$ s.t. $m(w, v), o(w', v)$

Table 5: **Dependency Rule Templates For Finding Words w, w' with Related SO Labels** . OPINE instantiates these templates in order to obtain extraction rules. Notation: dep=dependent, m=modifier, o=object, v,w,w'=words.

OPINE examines the potential opinion phrases in order to identify the actual opinions. First, the system finds the semantic orientation for the lexical head of each potential opinion phrase. Every phrase whose head word has a *positive* or *negative* semantic orientation is then retained as an *opinion phrase*. In the following, we describe how OPINE finds the semantic orientation of words.

3.3.2 Word Semantic Orientation

OPINE finds the semantic orientation of a word w in the context of an associated feature f and sentence s. We restate this task as follows:

Task Given a set of *semantic orientation (SO) labels* ($\{positive, negative, neutral\}$), a set of reviews and a set of tuples (w, f, s), where w is a potential opinion word associated with feature f in sentence s, assign a SO label to each tuple (w, f, s).

For example, the tuple (*sluggish*, *driver*, "I am not happy with this sluggish driver") would be assigned a *negative* SO label.

Note: We use "word" to refer to a potential opinion word w and "feature" to refer to the word or phrase which represents the explicit feature f.

Solution OPINE uses the 3-step approach below:

1. Given the set of reviews, OPINE finds a SO label for each word w.

2. Given the set of reviews and the set of SO labels for words w, OPINE finds a SO label for each (w, f) pair.

[1]The (S,P,O) tuples in Table 4 are automatically generated from MINIPAR's output.

3. Given the set of SO labels for (w, f) pairs, OPINE finds a SO label for each (w, f, s) input tuple.

Each of these subtasks is cast as an *unsupervised collective classification* problem and solved using the same mechanism. In each case, OPINE is given a set of *objects* (words, pairs or tuples) and a set of *labels* (SO labels); OPINE then searches for a *global* assignment of labels to objects. In each case, OPINE makes use of *local constraints* on label assignments (*e.g.*, conjunctions and disjunctions constraining the assignment of SO labels to words (Hatzivassiloglou and McKeown, 1997)).

A key insight in OPINE is that the problem of searching for a *global* SO label assignment to words, pairs or tuples while trying to satisfy as many *local* constraints on assignments as possible is analogous to labeling problems in computer vision (*e.g.*, model-based matching). OPINE uses a well-known computer vision technique, *relaxation labeling* (Hummel and Zucker, 1983), in order to solve the three subtasks described above.

3.3.3 Relaxation Labeling Overview

Relaxation labeling is an unsupervised classification technique which takes as input:

a) a set of *objects* (*e.g.*, words)
b) a set of *labels* (*e.g.*, SO labels)
c) initial probabilities for each object's possible labels
d) the definition of an object o's *neighborhood* (a set of other objects which influence the choice of o's label)
e) the definition of *neighborhood features*
f) the definition of a *support function* for an object label

The influence of an object o's neighborhood on its label L is quantified using the *support function*. The support function computes the probability of the label L being assigned to o as a function of o's *neighborhood features*. Examples of features include the fact that a certain *local constraint* is satisfied (*e.g.*, the word $nice$ participates in the conjunction *and* together with some other word whose SO label is estimated to be *positive*).

Relaxation labeling is an iterative procedure whose output is an assignment of labels to objects. At each iteration, the algorithm uses an *update equation* to reestimate the probability of an object label based on its previous probability estimate and the features of its neighborhood. The algorithm stops when the global label assignment stays constant over multiple consecutive iterations.

We employ relaxation labeling for the following reasons: a) it has been extensively used in computer-vision with good results b) its formalism allows for many types of constraints on label assignments to be used simultaneously. As mentioned before, constraints are integrated into the algorithm as neighborhood features which influence the assignment of a particular label to a particular object.

OPINE uses the following sources of constraints:

a) *conjunctions* and *disjunctions* in the review text

b) manually-supplied *syntactic dependency rule templates* (see Table 5). The templates are automatically instantiated by our system with different dependency relationships (premodifier, postmodifier, subject, etc.) in order to obtain syntactic dependency rules which find words with related SO labels.

c) automatically derived *morphological relationships* (*e.g.*, "wonderful" and "wonderfully" are likely to have similar SO labels).

d) WordNet-supplied *synonymy, antonymy, IS-A* and *morphological* relationships between words. For example, *clean* and *neat* are synonyms and so they are likely to have similar SO labels.

Each of the SO label assignment subtasks previously identified is solved using a relaxation labeling step. In the following, we describe in detail how relaxation labeling is used to find SO labels for words in the given review sets.

3.3.4 Finding SO Labels for Words

For many words, a word sense or set of senses is used throughout the review corpus with a consistently positive, negative or neutral connotation (*e.g.*, "great", "awful", etc.). Thus, in many cases, a word w's SO label in the context of a feature f and sentence s will be the same as its SO label in the context of other features and sentences. In the following, we describe how OPINE's relaxation labeling mechanism is used to find a word's dominant SO label in a set of reviews.

For this task, a word's *neighborhood* is defined as the set of words connected to it through conjunctions, disjunctions and all other relationships previously introduced as sources of constraints.

RL uses an *update equation* to re-estimate the probability of a word label based on its previous probability estimate and the features of its neighborhood (see **Neighborhood Features**). At iteration m, let $q(w, L)_{(m)}$ denote the support function for label L of w and let $P(l(w) = L)_{(m)}$ denote the probability that L is the label of w. $P(l(w) = L)_{(m+1)}$ is computed as follows:

RL Update Equation (Rangarajan, 2000)

$$P(l(w) = L)_{(m+1)} = \frac{P(l(w) = L)_{(m)}(1 + \alpha q(w, L)_{(m)})}{\sum_{L'} P(l(w) = L')_{(m)}(1 + \alpha q(w, L')_{(m)})}$$

where $L' \in \{pos, neg, neutral\}$ and $\alpha > 0$ is an experimentally set constant keeping the numerator and probabilities positive. RL's output is an assignment of dominant SO labels to words.

In the following, we describe in detail the initialization step, the derivation of the support function formula and the use of neighborhood features.

RL Initialization Step OPINE uses a version of Turney's PMI-based approach (Turney, 2003) in order to derive the initial probability estimates ($P(l(w) = L)_{(0)}$) for a subset S of the words. OPINE computes a *SO score so(w)* for each w in S as the difference between the PMI of w with positive keywords (*e.g.*, "excellent") and the PMI of w with negative keywords (*e.g.*, "awful"). When $so(w)$ is small, or w rarely co-occurs with the keywords, w is classified as *neutral*. If $so(w) > 0$, then w is *positive*, otherwise w is negative. OPINE then uses the labeled S set in order to compute prior probabilities $P(l(w) = L)$, $L \in \{pos, neg, neutral\}$ by computing the ratio between the number of words in S labeled L and $|S|$. Such probabilities are used as initial probability estimates associated with the labels of the remaining words.

Support Function The support function computes the probability of each label for word w based on the labels of objects in w's neighborhood N.

Let $A_k = \{(w_j, L_j)|w_j \in N\}$, $0 < k \leq 3^{|N|}$ represent one of the potential assignments of labels to the words in N. Let $P(A_k)_{(m)}$ denote the probability of this particular assignment at iteration m. The *support* for label L of word w at iteration m is :

$$q(w, L)_{(m)} = \sum_{k=1}^{3^{|N|}} P(l(w) = L|A_k)_{(m)} * P(A_k)_{(m)}$$

We assume that the labels of w's neighbors are independent of each other and so the formula becomes:

$$q(w, L)_{(m)} = \sum_{k=1}^{3^{|N|}} P(l(w) = L|A_k)_{(m)} * \prod_{j=1}^{|N|} P(l(w_j) = L_j)_{(m)}$$

Every $P(l(w_j) = L_j)_{(m)}$ term is the estimate for the probability that $l(w_j) = L_j$ (which was computed at iteration m using the RL update equation).

The $P(l(w) = L|A_k)_{(m)}$ term quantifies the influence of a particular label assignment to w's neighborhood over w's label. In the following, we describe how we estimate this term.

Neighborhood Features

Each type of word relationship which constrains the assignment of SO labels to words (synonymy, antonymy, etc.) is mapped by OPINE to a neighborhood feature. This mapping allows OPINE to use simultaneously use multiple independent sources of constraints on the label of a particular word. In the following, we formalize this mapping.

Let T denote the type of a word relationship in R (synonym, antonym, etc.) and let $A_{k,T}$ represent the labels assigned by A_k to neighbors of a word w which are connected to w through a relationship of type T . We have $A_k = \bigcup_T A_{k,T}$ and

$$P(l(w) = L|A_k)_{(m)} = P(l(w) = L|\bigcup_T A_{k,T})_{(m)}$$

For each relationship type T, OPINE defines a *neighborhood feature* $f_T(w, L, A_{k,T})$ which computes $P(l(w) = L|A_{k,T})$, the probability that w's label is L given $A_{k,T}$ (see below). $P(l(w) = L|\bigcup_T A_{k,T})_{(m)}$ is estimated combining the information from various features about w's label using the sigmoid function $\sigma()$:

$$P(l(w) = L|A_k)_{(m)} = \sigma(\sum_{i=1}^{j} f_i(w, L, A_{k,i})_{(m)} * c_i)$$

where $c_0, ...c_j$ are weights whose sum is 1 and which reflect OPINE 's confidence in each type of feature.

Given word w, label L, relationship type T and neighborhood label assignment A_k, let N_T represent the subset of w's neighbors connected to w through a type T relationship. The feature f_T computes the probability that w's label is L given the labels assigned by A_k to words in N_T. Using Bayes's Law and assuming that these labels are independent given $l(w)$, we have the following formula for f_T at iteration m:

$$f_T(w, L, A_{k,T})_{(m)} = P(l(w) = L)_{(m)} * \prod_{j=1}^{|N_T|} P(L_j|l(w) = L)$$

$P(L_j|l(w) = L)$ is the probability that word w_j has label L_j if w_j and w are linked by a relationship of type T and w has label L. We make the simplifying assumption that this probability is constant and depends only of T, L and L', not of the particular words w_j and w. For each tuple (T, L, L_j), $L, L_j \in \{pos, neg, neutral\}$, OPINE builds a probability table using a small set of bootstrapped positive, negative and neutral words.

3.3.5 Finding (Word, Feature) SO Labels

This subtask is motivated by the existence of frequent words which change their SO label based on associated features, but whose SO labels in the context of the respective features are consistent throughout the reviews (*e.g.,* in the Hotel domain, "hot water" has a consistently positive connotation, whereas "hot room" has a negative one).

In order to solve this task, OPINE first assigns each (w, f) pair an initial SO label which is w's SO label. The system then executes a relaxation labeling step during which syntactic relationships between words and, respectively, between features, are used to update the default SO labels whenever necessary. For example, *(hot, room)* appears in the proximity of *(broken, fan)*. If "room"and "fan" are conjoined by *and*, this suggests that "hot" and "broken" have similar SO labels in the context of their respective features. If "broken" has a strongly negative semantic orientation, this fact contributes to OPINE's belief that "hot" may also be negative in this context. Since *(hot, room)* occurs in the vicinity of other such phrases (*e.g., stifling kitchen*), "hot" acquires a negative SO label in the context of "room".

3.3.6 Finding (Word, Feature, Sentence) SO Labels

This subtask is motivated by the existence of (w,f) pairs (*e.g., (big, room)*) for which w's orientation changes based on the sentence in which the pair appears (*e.g.,* " I hated the big, drafty room because I ended up freezing." vs. "We had a big, luxurious room".)

In order to solve this subtask, OPINE first assigns each (w, f, s) tuple an initial label which is simply the SO label for the (w, f) pair. The system then uses syntactic relationships between words and, respectively, features in order to update the SO labels when necessary. For example, in the sentence "I hated the big, drafty room because I ended up freezing.", "big" and "hate" satisfy condition 2 in Table 5 and therefore OPINE expects them to have similar SO labels. Since "hate" has a strong negative connotation, "big" acquires a negative SO label in this context.

In order to correctly update SO labels in this last step, OPINE takes into consideration the presence of *negation modifiers*. For example, in the sentence "I don't like a large scanner either", OPINE first replaces the *positive* (w, f) pair *(like, scanner)* with the *negative* labeled pair *(not like, scanner)* and then infers that "large" is likely to have a negative SO label in this context.

3.3.7 Identifying Opinion Phrases

After OPINE has computed the most likely SO labels for the head words of each potential opinion phrase in the context of given features and sentences, OPINE can extract opinion phrases and establish their polarity. Phrases whose head words have been assigned *positive* or *negative* labels are retained as *opinion phrases*. Furthermore, the polarity of an opinion phrase o in the context of a feature f and sentence s is given by the SO label assigned to the tuple $(head(o), f, s)$ (3.3.6 shows how OPINE takes into account negation modifiers).

3.4 Experiments

In this section we evaluate OPINE's performance on the following tasks: finding SO labels of words in the context of known features and sentences (*SO label extraction*); distinguishing between opinion and non-opinion phrases in the context of known features and sentences (*opinion phrase extraction*); finding the correct polarity of extracted opinion phrases in the context of known features and sentences (*opinion phrase polarity extraction*).

While other systems, such as (Hu and Liu, 2004; Turney, 2002), have addressed these tasks to some degree, OPINE is the first to report results. We first ran OPINE on 13841 sentences and 538 previously extracted features. OPINE searched for a SO label assignment for 1756 different words in the context of the given features and sentences. We compared OPINE against two baseline methods, **PMI++** and **Hu++**.

PMI++ is an extended version of (Turney, 2002)'s method for finding the SO label of a phrase (as an attempt to deal with context-sensitive words). For a given (word, feature, sentence) tuple, **PMI++** ignores the sentence, generates a phrase based on the word and the feature (*e.g., (clean, room)*: "clean room") and finds its SO label using PMI statistics. If unsure of the label, **PMI++** tries to find the orientation of the potential opinion word instead. The search engine queries use domain-specific keywords (*e.g.,* "scanner"), which are dropped if they lead to low counts.

Hu++ is a WordNet-based method for finding a word's context-independent semantic orientation. It extends Hu's adjective labeling method in a number of ways in order to handle nouns, verbs and adverbs in addition to adjectives and in order to improve coverage. Hu's method starts with two sets of positive and negative words and iteratively grows each one by including synonyms and antonyms from WordNet. The final sets are used to predict the orientation of an incoming word.

Type	PMI++		Hu++		OPINE	
	P	R	P	R	P	R
adj	0.73	0.91	+0.02	-0.17	**+0.07**	**-0.03**
nn	0.63	0.92	+0.04	-0.24	**+0.11**	**-0.08**
vb	0.71	0.88	+0.03	-0.12	**+0.01**	**-0.01**
adv	0.82	0.92	+0.02	-0.01	**+0.06**	**+0.01**
Avg	0.72	0.91	+0.03	-0.14	**+0.06**	**-0.03**

Table 6: **Finding SO Labels of Potential Opinion Words in the Context of Given Product Features and Sentences.** OPINE's precision is higher than that of **PMI++** and **Hu++**. All results are reported with respect to **PMI++** . Notation: adj=adjectives, nn=nouns, vb=verbs, adv=adverbs

3.4.1 Experiments: SO Labels

On the task of *finding SO labels for words in the context of given features and review sentences*, OPINE obtains higher precision than both baseline methods at a small loss in recall with respect to **PMI++**. As described below, this result is due in large part to OPINE's ability to handle context-sensitive opinion words.

We randomly selected 200 (word, feature, sentence) tuples for each word type (adjective, adverb, etc.) and obtained a test set containing 800 tuples. Two annotators assigned positive, negative and neutral labels to each tuple (the inter-annotator agreement was 78%). We retained the tuples on which the annotators agreed as the gold standard. We ran **PMI++** and **Hu++** on the test data and compared the results against OPINE's results on the same data.

In order to quantify the benefits of each of the three steps of our method for finding SO labels, we also compared OPINE with a version which only finds SO labels for words and a version which finds SO labels for words in the context of given features, but doesn't take into account given sentences. We have learned from this comparison that OPINE's precision gain over **PMI++** and **Hu++** is mostly due to to its ability to handle context-sensitive words in a large number of cases.

Although **Hu++** does not handle context-sensitive SO label assignment, its average precision was reasonable (75%) and better than that of **PMI++**. Finding a word's SO label is good enough in the case of strongly positive or negative opinion words, which account for the majority of opinion instances. The method's loss in recall is due to not recognizing words absent from WordNet (*e.g.*, "depth-adjustable") or not having enough information to classify some words in WordNet.

PMI++ typically does well in the presence of strongly positive or strongly negative words. Its high recall is correlated with decreased precision, but overall this simple approach does well. **PMI++**'s main shortcoming is misclassifying terms such as "basic" or "visible" which change orientation based on context.

3.4.2 Experiments: Opinion Phrases

In order to evaluate OPINE on the tasks of *opinion phrase extraction* and *opinion phrase polarity extraction in the context of known features and sentences*, we used a set of 550 sentences containing previously extracted features. The sentences were annotated with the opinion phrases corresponding to the known features and with the opinion polarity. We compared OPINE with **PMI++** and **Hu++** on the tasks of interest. We found that OPINE had the highest precision on both tasks at a small loss in recall with respect to **PMI++**. OPINE's ability to identify a word's SO label in the context of a given feature and sentence allows the system to correctly extract opinions expressed by words such as "big" or "small", whose semantic orientation varies based on context.

Measure	PMI++	Hu++	OPINE
OP Extraction: Precision	0.71	+0.06	**+0.08**
OP Extraction: Recall	0.78	-0.08	**-0.02**
OP Polarity: Precision	0.80	-0.04	**+0.06**
OP Polarity: Recall	0.93	+0.07	**-0.04**

Table 7: **Extracting Opinion Phrases and Opinion Phrase Polarity Corresponding to Known Features and Sentences.** OPINE's precision is higher than that of **PMI++** and of **Hu++**. All results are reported with respect to **PMI++**.

4 Related Work

The key components of OPINE described in this paper are the PMI feature assessment which leads to high-precision feature extraction and the use of relaxation-labeling in order to find the semantic orientation of potential opinion words. The review-mining work most relevant to our research is that of (Hu and Liu, 2004) and (Kobayashi et al., 2004). Both identify product features from reviews, but OPINE significantly improves on both. (Hu and Liu, 2004) doesn't assess candidate features, so its precision is lower than OPINE's. (Kobayashi et al., 2004) employs an iterative semi-automatic approach which requires human input at every iteration. Neither model explicitly addresses *composite* (feature of feature) or *implicit* features. Other systems (Morinaga et al., 2002; Kushal et al., 2003) also look at Web product reviews but they do not extract opinions about particular product features. OPINE's use of meronymy lexico-syntactic patterns is similar to that of many others, from (Berland and Charniak, 1999) to (Almuhareb and Poesio, 2004).

Recognizing the subjective character and polarity of words, phrases or sentences has been addressed by many authors, including (Turney, 2003; Riloff et al., 2003; Wiebe, 2000; Hatzivassiloglou and McKeown, 1997). Most recently, (Takamura et al., 2005) reports on the use of spin models to infer the semantic orientation of words. The paper's global optimization approach and use of multiple sources of constraints on a word's semantic orientation is similar to ours, but the mechanism differs and they currently omit the use of syntactic information. Subjective phrases are used by (Turney, 2002; Pang and Vaithyanathan, 2002; Kushal et al., 2003; Kim and Hovy, 2004) and others in order to classify reviews or sentences as positive or negative. So far, OPINE's focus has been on extracting and analyzing opinion phrases corresponding to specific features in specific sentences, rather than on determining sentence or review polarity.

5 Conclusion

OPINE is an unsupervised information extraction system which extracts fine-grained features, and associated opinions, from reviews. OPINE's use of the Web as a corpus helps identify product features with improved precision compared with previous work. OPINE uses a novel relaxation-labeling technique to determine the semantic orientation of potential opinion words in the context of the extracted product features and specific review sentences; this technique allows the system to identify customer opinions and their polarity with high precision and recall.

6 Acknowledgments

We would like to thank the KnowItAll project and the anonymous reviewers for their comments. Michael Gamon, Costas Boulis and Adam Carlson have also provided valuable feedback. We thank Minquing Hu and Bing Liu for providing their data sets and for their comments. Finally, we are grateful to Bernadette Minton and Fetch Technologies for their help in collecting additional reviews. This research was supported in part by NSF grant IIS-0312988, DARPA contract NBCHD030010, ONR grant N00014-02-1-0324 as well as gifts from Google and the Turing Center.

Abstract

This paper presents a new approach to phrase-level sentiment analysis that first determines whether an expression is neutral or polar and then disambiguates the polarity of the polar expressions. With this approach, the system is able to automatically identify the *contextual polarity* for a large subset of sentiment expressions, achieving results that are significantly better than baseline.

1 Introduction

Sentiment analysis is the task of identifying positive and negative opinions, emotions, and evaluations. Most work on sentiment analysis has been done at the document level, for example distinguishing positive from negative reviews. However, tasks such as multi-perspective question answering and summarization, opinion-oriented information extraction, and mining product reviews require sentence-level or even phrase-level sentiment analysis. For example, if a question answering system is to successfully answer questions about people's opinions, it must be able to pinpoint expressions of positive and negative sentiments, such as we find in the sentences below:

(1) African observers $generally\ approved^{+}$ of his victory while Western governments $denounced^{-}$ it.

(2) A succession of officers filled the TV screen to say they $supported^{+}$ the people and that the killings were "$not\ tolerable^{-}$."

(3) "We $don't\ hate^{+}$ the sinner," he says, "but we $hate^{-}$ the sin."

A typical approach to sentiment analysis is to start with a lexicon of positive and negative words and phrases. In these lexicons, entries are tagged with their a priori *prior polarity*: out of context, does the word seem to evoke something positive or something negative. For example, *beautiful* has a positive prior polarity, and *horrid* has a negative prior polarity. However, the *contextual polarity* of the phrase in which a word appears may be different from the word's prior polarity. Consider the underlined polarity words in the sentence below:

(4) Philip Clapp, president of the National Environment <u>Trust</u>, sums up <u>well</u> the general thrust of the reaction of environmental movements: "There is no <u>reason</u> at all to believe that the <u>polluters</u> are suddenly going to become <u>reasonable</u>."

Of these words, "Trust," "well," "reason," and "reasonable" have positive prior polarity, but they are not all being used to express positive sentiments. The word "reason" is negated, making the contextual polarity negative. The phrase "no reason at all to believe" changes the polarity of the proposition that follows; because "reasonable" falls within this proposition, its contextual polarity becomes negative. The word "Trust" is simply part of a referring expression and is not being used to express a sentiment; thus, its contextual polarity is neutral. Similarly for "polluters": in the context of the article, it simply refers to companies that pollute. Only "well" has the same prior and contextual polarity.

Many things must be considered in phrase-level sentiment analysis. Negation may be local (e.g., **not** *good*), or involve longer-distance dependencies such as the negation of the proposition (e.g., **does not** *look very good*) or the negation of the subject (e.g.,

no one *thinks that it's good*). In addition, certain phrases that contain negation words intensify rather than change polarity (e.g., **not only** *good but amazing*). Contextual polarity may also be influenced by modality (e.g., whether the proposition is asserted to be real (*realis*) or not real (*irrealis*) – *no reason at all to believe* is irrealis, for example); word sense (e.g., *Environmental* **Trust** versus *He has won the people's* **trust**); the syntactic role of a word in the sentence (e.g., **polluters** *are* versus *they are* **polluters**); and diminishers such as *little* (e.g., **little** *truth*, **little** *threat*). (See (Polanya and Zaenen, 2004) for a more detailed discussion of contextual polarity influencers.)

This paper presents new experiments in automatically distinguishing prior and contextual polarity. Beginning with a large stable of clues marked with prior polarity, we identify the contextual polarity of the phrases that contain instances of those clues in the corpus. We use a two-step process that employs machine learning and a variety of features. The first step classifies each phrase containing a clue as neutral or polar. The second step takes all phrases marked in step one as polar and disambiguates their contextual polarity (*positive*, *negative, both*, or *neutral*). With this approach, the system is able to automatically identify the contextual polarity for a large subset of sentiment expressions, achieving results that are significantly better than baseline. In addition, we describe new manual annotations of contextual polarity and a successful inter-annotator agreement study.

2 Manual Annotation Scheme

To create a corpus for the experiments below, we added contextual polarity judgments to existing annotations in the Multi-perspective Question Answering (MPQA) Opinion Corpus[1], namely to the annotations of *subjective expressions*[2]. A subjective expression is any word or phrase used to express an opinion, emotion, evaluation, stance, speculation, etc. A general covering term for such states is *private state* (Quirk et al., 1985). In the MPQA Corpus, subjective expressions of varying lengths are marked, from single words to long phrases.

For this work, our focus is on *sentiment expressions* – positive and negative expressions of emotions, evaluations, and stances. As these are types of subjective expressions, to create the corpus, we just needed to manually annotate the existing subjective expressions with their contextual polarity.

In particular, we developed an annotation scheme[3] for marking the contextual polarity of subjective expressions. Annotators were instructed to tag the polarity of subjective expressions as *positive*, *negative*, *both*, or *neutral*. The *positive* tag is for positive emotions (*I'm happy*), evaluations (*Great idea!*), and stances (*She supports the bill*). The *negative* tag is for negative emotions (*I'm sad*), evaluations (*Bad idea!*), and stances (*She's against the bill*). The *both* tag is applied to sentiment expressions that have both positive and negative polarity. The *neutral* tag is used for all other subjective expressions: those that express a different type of subjectivity such as speculation, and those that do not have positive or negative polarity.

Below are examples of contextual polarity annotations. The tags are in boldface, and the subjective expressions with the given tags are underlined.

(5) Thousands of coup supporters <u>celebrated</u> (**positive**) overnight, waving flags, blowing whistles ...

(6) The criteria set by Rice are the following: the three countries in question are <u>repressive</u> (**negative**) and <u>grave human rights violators</u> (**negative**) ...

(7) Besides, politicians refer to <u>good and evil</u> (**both**) only for purposes of intimidation and exaggeration.

(8) Jerome says the hospital <u>feels</u> (**neutral**) no different than a hospital in the states.

The annotators were asked to judge the contextual polarity of the sentiment that is ultimately being conveyed by the subjective expression, i.e., once the sentence has been fully interpreted. Thus, the subjective expression, *they have not succeeded, and*

[1]The MPQA Corpus is described in (Wiebe et al., 2005) and available at nrrc.mitre.org/NRRC/publications.htm.

[2]In the MPQA Corpus, subjective expressions are *direct subjective* expressions with *non-neutral expression intensity*, plus all the *expressive subjective elements*. Please see (Wiebe et al., 2005) for more details on the existing annotations in the MPQA Corpus.

[3]The annotation instructions are available at http://www.cs.pitt.edu/˜twilson.

will never succeed, was marked as positive in the sentence, *They have not succeeded, and will never succeed, in breaking the will of this valiant people*. The reasoning is that breaking the will of a valiant people is negative; hence, not succeeding in breaking their will is positive.

3 Agreement Study

To measure the reliability of the polarity annotation scheme, we conducted an agreement study with two annotators, using 10 documents from the MPQA Corpus. The 10 documents contain 447 subjective expressions. Table 1 shows the contingency table for the two annotators' judgments. Overall agreement is 82%, with a Kappa (κ) value of 0.72.

	Neutral	Positive	Negative	Both	Total
Neutral	123	14	24	0	161
Positive	16	73	5	2	96
Negative	14	2	167	1	184
Both	0	3	0	3	6
Total	153	92	196	6	447

Table 1: Agreement for Subjective Expressions (Agreement: 82%, κ: 0.72)

For 18% of the subjective expressions, at least one annotator used an *uncertain* tag when marking polarity. If we consider these cases to be borderline and exclude them from the study, percent agreement increases to 90% and Kappa rises to 0.84. Thus, the annotator agreement is especially high when both are certain. (Note that all annotations are included in the experiments described below.)

4 Corpus

In total, 15,991 subjective expressions from 425 documents (8,984 sentences) were annotated with contextual polarity as described above. Of these sentences, 28% contain no subjective expressions, 25% contain only one, and 47% contain two or more. Of the 4,247 sentences containing two or more subjective expressions, 17% contain mixtures of positive and negative expressions, and 62% contain mixtures of polar (positive/negative/both) and neutral subjective expressions.

The annotated documents are divided into two sets. The first (66 documents/1,373 sentences/2,808 subjective expressions) is a development set, used for data exploration and feature development. We use the second set (359 documents/7,611 sentences/13,183 subjective expressions) in 10-fold cross-validation experiments, described below.

5 Prior-Polarity Subjectivity Lexicon

For the experiments in this paper, we use a lexicon of over 8,000 *subjectivity clues*. Subjectivity clues are words and phrases that may be used to express private states, i.e., they have subjective usages (though they may have objective usages as well). For this work, only single-word clues are used.

To compile the lexicon, we began with a list of subjectivity clues from (Riloff and Wiebe, 2003). The words in this list were grouped in previous work according to their reliability as subjectivity clues. Words that are subjective in most contexts were marked strongly subjective (*strongsubj*), and those that may only have certain subjective usages were marked weakly subjective (*weaksubj*).

We expanded the list using a dictionary and a thesaurus, and also added words from the General Inquirer positive and negative word lists (General-Inquirer, 2000) which we judged to be potentially subjective. We also gave the new words reliability tags, either *strongsubj* or *weaksubj*.

The next step was to tag the clues in the lexicon with their prior polarity. For words that came from positive and negative word lists (General-Inquirer, 2000; Hatzivassiloglou and McKeown, 1997), we largely retained their original polarity, either *positive* or *negative*. We assigned the remaining words one of the tags *positive*, *negative*, *both* or *neutral*.

By far, the majority of clues, 92.8%, are marked as having either positive (33.1%) or negative (59.7%) prior polarity. Only a small number of clues (0.3%) are marked as having both positive and negative polarity. 6.9% of the clues in the lexicon are marked as neutral. Examples of these are verbs such as *feel*, *look*, and *think*, and intensifiers such as *deeply*, *entirely*, and *practically*. These words are included because, although their prior polarity is neutral, they are good clues that a sentiment is being expressed (e.g., **feels** *slighted*, **look** *forward to*). Including them increases the coverage of the system.

6 Experiments

The goal of the experiments described below is to classify the contextual polarity of the expressions that contain instances of the subjectivity clues in our lexicon. What the system specifically does is give each clue instance its own label. Note that the system does not try to identify expression boundaries. Doing so might improve performance and is a promising avenue for future research.

6.1 Definition of the Gold Standard

We define the gold standard used to train and test the system in terms of the manual annotations described in Section 2.

The gold standard class of a clue instance that is not in a subjective expression is *neutral*: since the clue is not even in a subjective expression, it is not contained in a sentiment expression.

Otherwise, if a clue instance appears in just one subjective expression (or in multiple subjective expressions with the same contextual polarity), then the class assigned to the clue instance is the class of the subjective expression(s). If a clue appears in at least one positive and one negative subjective expression (or in a subjective expression marked as *both*), then its class is *both*. If it is in a mixture of negative and neutral subjective expressions, its class is *negative*; if it is in a mixture of positive and neutral subjective expressions, its class is *positive*.

6.2 Performance of a Prior-Polarity Classifier

An important question is how useful prior polarity alone is for identifying contextual polarity. To answer this question, we create a classifier that simply assumes that the contextual polarity of a clue instance is the same as the clue's prior polarity, and we explore the classifier's performance on the development set.

This simple classifier has an accuracy of 48%. From the confusion matrix given in Table 2, we see that 76% of the errors result from words with non-neutral prior polarity appearing in phrases with neutral contextual polarity.

6.3 Contextual Polarity Disambiguation

The fact that words with non-neutral prior polarity so frequently appear in neutral contexts led us to adopt a two-step approach to contextual polarity disambiguation. For the first step, we concentrate on whether clue instances are neutral or polar in context (where *polar in context* refers to having a contextual polarity that is positive, negative or both). For the second step, we take all clue instances marked as polar in step one, and focus on identifying their contextual polarity. For both steps, we develop classifiers using the BoosTexter AdaBoost.HM (Schapire and Singer, 2000) machine learning algorithm with 5000 rounds of boosting. The classifiers are evaluated in 10-fold cross-validation experiments.

		Prior-Polarity Classifier				
		Neut	Pos	Neg	Both	Total
Gold	Neut	798	784	698	4	2284
	Pos	81	371	40	0	492
	Neg	149	181	622	0	952
	Both	4	11	13	5	33
	Total	1032	1347	1373	9	3761

Table 2: Confusion matrix for the prior-polarity classifier on the development set.

6.3.1 Neutral-Polar Classification

The neutral-polar classifier uses 28 features, listed in Table 3.

Word Features: *Word context* is a bag of three word tokens: the previous word, the word itself, and the next word. The *prior polarity* and *reliability class* are indicated in the lexicon.

Modification Features: These are binary relationship features. The first four involve relationships with the word immediately before or after: if the word is a noun preceded by an adjective, if the preceding word is an adverb other than *not*, if the preceding word is an intensifier, and if the word itself is an intensifier. A word is considered an intensifier if it appears in a list of intensifiers and if it precedes a word of the appropriate part-of-speech (e.g., an intensifier adjective must come before a noun).

The *modify* features involve the dependency parse tree for the sentence, obtained by first parsing the sentence (Collins, 1997) and then converting the tree into its dependency representation (Xia and Palmer, 2001). In a dependency representation, every node in the tree structure is a surface word (i.e., there are no abstract nodes such as NP or VP). The edge between a parent and a child specifies the grammatical relationship between the two words. Figure 1 shows

Word Features	Sentence Features	Structure Features
word token	strongsubj clues in current sentence: count	in subject: binary
word part-of-speech	strongsubj clues in previous sentence: count	in copular: binary
word context	strongsubj clues in next sentence: count	in passive: binary
prior polarity: positive, negative, both, neutral	weaksubj clues in current sentence: count	
reliability class: strongsubj or weaksubj	weaksubj clues in previous sentence: count	
Modification Features	weaksubj clues in next sentence: count	Document Feature
preceeded by adjective: binary	adjectives in sentence: count	document topic
preceeded by adverb (other than not): binary	adverbs in sentence (other than not): count	
preceeded by intensifier: binary	cardinal number in sentence: binary	
is intensifier: binary	pronoun in sentence: binary	
modifies strongsubj: binary	modal in sentence (other than will): binary	
modifies weaksubj: binary		
modified by strongsubj: binary		
modified by weaksubj: binary		

Table 3: Features for neutral-polar classification

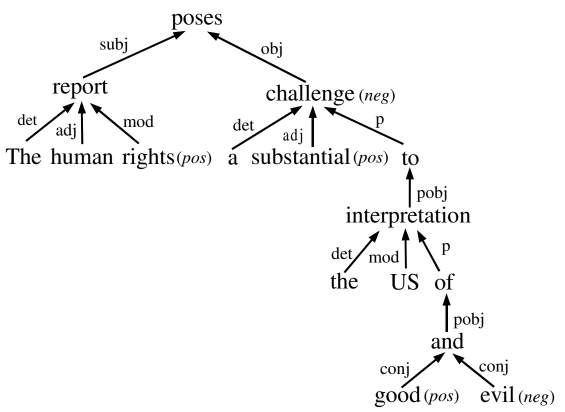

Figure 1: The dependency tree for the sentence *The human rights report poses a substantial challenge to the US interpretation of good and evil.* Prior polarity is marked in parentheses for words that match clues from the lexicon.

an example. The *modifies strongsubj/weaksubj* features are true if the word and its parent share an *adj*, *mod* or *vmod* relationship, and if its parent is an instance of a clue from the lexicon with strongsubj/weaksubj reliability. The *modified by strongsubj/weaksubj* features are similar, but look for relationships and clues in the word's children.

Structure Features: These are binary features that are determined by starting with the word instance and climbing up the dependency parse tree toward the root, looking for particular relationships, words, or patterns. The *in subject* feature is true if we find a *subj* relationship. The *in copular* feature is true if *in subject* is false and if a node along the path is both a main verb and a copular verb. The *in passive* features is true if a passive verb pattern is found on the climb.

Sentence Features: These are features that were found useful for sentence-level subjectivity classification by Wiebe and Riloff (2005). They include counts of strongsubj and weaksubj clues in the current, previous and next sentences, counts of adjectives and adverbs other than *not* in the current sentence, and binary features to indicate whether the sentence contains a pronoun, a cardinal number, and a modal other than *will*.

Document Feature: There is one document feature representing the topic of the document. A document may belong to one of 15 topics ranging from specific (e.g., the 2002 presidential election in Zimbabwe) to more general (e.g., economics) topics.

Table 4 gives neutral-polar classification results for the 28-feature classifier and two simpler classifiers that provide our baselines. The first row in the table lists the results for a classifier that uses just one feature, the word token. The second row shows the results for a classifier that uses both the word token and the word's prior polarity as features. The results for the 28-feature classifier are listed in the last row. The 28-feature classifier performs significantly better (1-tailed t-test, $p \leq .05$) than the two simpler classifiers, as measured by accuracy, polar F-measure, and neutral F-measure ($\beta = 1$). It has an accuracy of 75.9%, with a polar F-measure of 63.4 and a neutral F-measure of 82.1.

Focusing on the metrics for polar expressions, it's interesting to note that using just the word token as a feature produces a classifier with a precision slightly better than the 28-feature classifier, but with a recall that is 20% lower. Adding a feature for the prior

Word Features
word token
word prior polarity: positive, negative, both, neutral
Polarity Features
negated: binary
negated subject: binary
modifies polarity: positive, negative, neutral, both, notmod
modified by polarity: positive, negative, neutral, both, notmod
conj polarity: positive, negative, neutral, both, notmod
general polarity shifter: binary
negative polarity shifter: binary
positive polarity shifter: binary

Table 6: Features for polarity classification

polarity improves recall so that it is only 4.4% lower, but this hurts precision, which drops to 4.2% lower than the 28-feature classifier's precision. It is only with all the features that we get the best result, good precision with the highest recall.

The clues in the prior-polarity lexicon have 19,506 instances in the test set. According to the 28-feature neutral-polar classifier, 5,671 of these instances are polar in context. It is these clue instances that are passed on to the second step in the contextual disambiguation process, polarity classification.

6.3.2 Polarity Classification

Ideally, this second step in the disambiguation process would be a three-way classification task, determining whether the contextual polarity is positive, negative or both. However, although the majority of neutral expressions have been filtered out by the neutral-polar classification in step one, a number still remain. So, for this step, the polarity classification task remains four-way: positive, negative, both, and neutral.

Table 6 lists the features used by the polarity classifier. *Word token* and *word prior polarity* are unchanged from the neutral-polar classifier. *Negated* is a binary feature that captures whether the word is being locally negated: its value is true if a negation word or phrase is found within the four preceeding words or in any of the word's children in the dependency tree, and if the negation word is not in a phrase that intensifies rather than negates (e.g., *not only*). The *negated subject* feature is true if the subject of the clause containing the word is negated.

The *modifies polarity*, *modified by polarity*, and *conj polarity* features capture specific relationships between the word instance and other polarity words it may be related to. If the word and its parent in the dependency tree share an *obj*, *adj*, *mod*, or *vmod* relationship, the *modifies polarity* feature is set to the prior polarity of the word's parent (if the parent is not in our prior-polarity lexicon, its prior polarity is set to neutral). The *modified by polarity* feature is similar, looking for *adj*, *mod*, and *vmod* relationships and polarity clues within the word's children. The *conj polarity* feature determines if the word is in a conjunction. If so, the value of this feature is its sibling's prior polarity (as above, if the sibling is not in the lexicon, its prior polarity is neutral). Figure 1 helps to illustrate these features: *modifies polarity* is negative for the word "substantial," *modified by polarity* is positive for the word "challenge," and *conj polarity* is negative for the word "good."

The last three polarity features look in a window of four words before, searching for the presence of particular types of polarity influencers. *General polarity shifters* reverse polarity (e.g., *little* truth, *little* threat). *Negative polarity shifters* typically make the polarity of an expression negative (e.g., *lack* of understanding). *Positive polarity shifters* typically make the polarity of an expression positive (e.g., *abate* the damage).

The polarity classification results for this second step in the contextual disambiguation process are given in Table 5. Also listed in the table are results for the two simple classifiers that provide our baselines. The first line in Table 5 lists the results for the classifier that uses just one feature, the word token. The second line shows the results for the classifier that uses both the word token and the word's prior polarity as features. The last line shows the results for the polarity classifier that uses all 10 features from Table 6.

Mirroring the results from step one, the more complex classifier performs significantly better than the simpler classifiers, as measured by accuracy and all of the F-measures. The 10-feature classifier achieves an accuracy of 65.7%, which is 4.3% higher than the more challenging baseline provided by the word + prior polarity classifier. Positive F-measure is 65.1 (5.7% higher); negative F-measure is 77.2 (2.3% higher); and neutral F-measure is 46.2 (13.5% higher).

Focusing on the metrics for positive and negative expressions, we again see that the simpler classifiers

	Acc	Polar Rec	Polar Prec	Polar F	Neut Rec	Neut Prec	Neut F

AB2	modifies polarity, modified by polarity
AB3	conj polarity
AB4	general, negative, and positive polarity shifters

Table 7: Features for polarity classification

take turns doing better or worse for precision and recall. Using just the word token, positive precision is slightly higher than for the 10-feature classifier, but positive recall is 11.6% lower. Add the prior polarity, and positive recall improves, but at the expense of precision, which is 12.6% lower than for the 10-feature classifier. The results for negative expressions are similar. The word-token classifier does well on negative recall but poorly on negative precision. When prior polarity is added, negative recall improves but negative precision drops. It is only with the addition of the polarity features that we achieve both higher precisions and higher recalls.

To explore how much the various polarity features contribute to the performance of the polarity classifier, we perform four experiments. In each experiment, a different set of polarity features is excluded, and the polarity classifier is retrained and evaluated. Table 7 lists the features that are removed for each experiment.

The only significant difference in performance in these experiments is neutral F-measure when the modification features (AB2) are removed. These ablation experiments show that the combination of features is needed to achieve significant results over baseline for polarity classification.

7 Related Work

Much work on sentiment analysis classifies documents by their overall sentiment, for example determining whether a review is positive or negative (e.g., (Turney, 2002; Dave et al., 2003; Pang and Lee, 2004; Beineke et al., 2004)). In contrast, our experiments classify individual words and phrases. A number of researchers have explored learning words and phrases with *prior* positive or negative polarity (another term is *semantic orientation*) (e.g., (Hatzivassiloglou and McKeown, 1997; Kamps and Marx, 2002; Turney, 2002)). In contrast, we begin with a lexicon of words with established prior polarities, and identify the *contextual polarity* of phrases in which instances of those words appear in the corpus. To make the relationship between that task and ours clearer, note that some word lists used to evaluate methods for recognizing prior polarity are included in our prior-polarity lexicon (General Inquirer lists (General-Inquirer, 2000) used for evaluation by Turney, and lists of manually identified positive and negative adjectives, used for evaluation by Hatzivassiloglou and McKeown).

Some research classifies the sentiments of sentences. Yu and Hatzivassiloglou (2003), Kim and Hovy (2004), Hu and Liu (2004), and Grefenstette et al. (2001)[4] all begin by first creating prior-polarity lexicons. Yu and Hatzivassiloglou then assign a sentiment to a sentence by averaging the prior semantic orientations of instances of lexicon words in the sentence. Thus, they do not identify the contextual polarity of individual phrases containing clues, as we

[4]In (Grefenstette et al., 2001), the units that are classified are fixed windows around named entities rather than sentences.

do in this paper. Kim and Hovy, Hu and Liu, and Grefenstette et al. multiply or count the prior polarities of clue instances in the sentence. They also consider local negation to reverse polarity. However, they do not use the other types of features in our experiments, and they restrict their tags to *positive* and *negative* (excluding our *both* and *neutral* categories). In addition, their systems assign one sentiment per sentence; our system assigns contextual polarity to individual expressions. As seen above, sentences often contain more than one sentiment expression.

Nasukawa, Yi, and colleagues (Nasukawa and Yi, 2003; Yi et al., 2003) classify the contextual polarity of sentiment expressions, as we do. Thus, their work is probably most closely related to ours. They classify expressions that are about specific items, and use manually developed patterns to classify polarity. These patterns are high-quality, yielding quite high precision, but very low recall. Their system classifies a much smaller proportion of the sentiment expressions in a corpus than ours does.

8 Conclusions

In this paper, we present a new approach to phrase-level sentiment analysis that first determines whether an expression is neutral or polar and then disambiguates the polarity of the polar expressions. With this approach, we are able to automatically identify the *contextual polarity* for a large subset of sentiment expressions, achieving results that are significantly better than baseline.

Abstract

Recent systems have been developed for sentiment classification, opinion recognition, and opinion analysis (e.g., detecting polarity and strength). We pursue another aspect of opinion analysis: identifying the sources of opinions, emotions, and sentiments. We view this problem as an information extraction task and adopt a hybrid approach that combines Conditional Random Fields (Lafferty et al., 2001) and a variation of AutoSlog (Riloff, 1996a). While CRFs model source identification as a sequence tagging task, AutoSlog learns extraction patterns. Our results show that the combination of these two methods performs better than either one alone. The resulting system identifies opinion sources with 79.3% precision and 59.5% recall using a head noun matching measure, and 81.2% precision and 60.6% recall using an overlap measure.

1 Introduction

In recent years, there has been a great deal of interest in methods for automatically identifying opinions, emotions, and sentiments in text. Much of this research explores sentiment classification, a text categorization task in which the goal is to classify a document as having positive or negative polarity (e.g., Das and Chen (2001), Pang et al. (2002), Turney (2002), Dave et al. (2003), Pang and Lee (2004)). Other research efforts analyze opinion expressions at the sentence level or below to recognize opinions, their polarity, and their strength (e.g., Dave et al. (2003), Pang and Lee (2004), Wilson et al. (2004), Yu and Hatzivassiloglou (2003), Wiebe and Riloff (2005)). Many applications could benefit from these opinion analyzers, including product reputation tracking (e.g., Morinaga et al. (2002), Yi et al. (2003)), opinion-oriented summarization (e.g., Cardie et al. (2004)), and question answering (e.g., Bethard et al. (2004), Yu and Hatzivassiloglou (2003)).

We focus here on another aspect of opinion analysis: automatically identifying the sources of the opinions. Identifying opinion sources will be especially critical for opinion-oriented question-answering systems (e.g., systems that answer questions of the form "How does [X] feel about [Y]?") and opinion-oriented summarization systems, both of which need to distinguish the opinions of one source from those of another.[1]

The goal of our research is to identify direct and indirect sources of opinions, emotions, sentiments, and other *private states* that are expressed in text. To illustrate the nature of this problem, consider the examples below:

S1: <u>Taiwan-born voters</u> favoring independence...

[1]In related work, we investigate methods to identify the opinion expressions (e.g., Riloff and Wiebe (2003), Wiebe and Riloff (2005), Wilson et al. (2005)) and the nesting structure of sources (e.g., Breck and Cardie (2004)). The *target* of each opinion, i.e., what the opinion is directed towards, is currently being annotated manually for our corpus.

S2: According to the report, the human rights record in China is horrendous.

S3: International officers believe that the EU will prevail.

S4: International officers said US officials want the EU to prevail.

In S1, the phrase "Taiwan-born voters" is the direct (i.e., first-hand) source of the "favoring" sentiment. In S2, "the report" is the direct source of the opinion about China's human rights record. In S3, "International officers" are the direct source of an opinion regarding the EU. The same phrase in S4, however, denotes an indirect (i.e., second-hand, third-hand, etc.) source of an opinion whose direct source is "US officials".

In this paper, we view *source identification* as an information extraction task and tackle the problem using sequence tagging and pattern matching techniques simultaneously. Using syntactic, semantic, and orthographic lexical features, dependency parse features, and opinion recognition features, we train a linear-chain Conditional Random Field (CRF) (Lafferty et al., 2001) to identify opinion sources. In addition, we employ features based on automatically learned extraction patterns and perform feature induction on the CRF model.

We evaluate our hybrid approach using the NRRC corpus (Wiebe et al., 2005), which is manually annotated with direct and indirect opinion source information. Experimental results show that the CRF model performs well, and that both the extraction patterns and feature induction produce performance gains. The resulting system identifies opinion sources with 79.3% precision and 59.5% recall using a head noun matching measure, and 81.2% precision and 60.6% recall using an overlap measure.

2 The Big Picture

The goal of information extraction (IE) systems is to extract information about events, including the participants of the events. This task goes beyond Named Entity recognition (e.g., Bikel et al. (1997)) because it requires the recognition of role relationships. For example, an IE system that extracts information about corporate acquisitions must distinguish between the company that is doing the acquiring and the company that is being acquired. Similarly, an IE system that extracts information about terrorism must distinguish between the person who is the perpetrator and the person who is the victim. We hypothesized that IE techniques would be well-suited for source identification because an opinion statement can be viewed as a kind of speech event with the source as the agent.

We investigate two very different learning-based methods from information extraction for the problem of opinion source identification: graphical models and extraction pattern learning. In particular, we consider Conditional Random Fields (Lafferty et al., 2001) and a variation of AutoSlog (Riloff, 1996a). CRFs have been used successfully for Named Entity recognition (e.g., McCallum and Li (2003), Sarawagi and Cohen (2004)), and AutoSlog has performed well on information extraction tasks in several domains (Riloff, 1996a). While CRFs treat source identification as a sequence tagging task, AutoSlog views the problem as a pattern-matching task, acquiring symbolic patterns that rely on both the syntax and lexical semantics of a sentence. We hypothesized that a combination of the two techniques would perform better than either one alone.

Section 3 describes the CRF approach to identifying opinion sources and the features that the system uses. Section 4 then presents a new variation of AutoSlog, *AutoSlog-SE*, which generates IE patterns to extract sources. Section 5 describes the hybrid system: we encode the IE patterns as additional features in the CRF model. Finally, Section 6 presents our experimental results and error analysis.

3 Semantic Tagging via Conditional Random Fields

We defined the problem of opinion source identification as a sequence tagging task via CRFs as follows. Given a sequence of tokens, $x = x_1 x_2 ... x_n$, we need to generate a sequence of tags, or labels, $y = y_1 y_2 ... y_n$. We define the set of possible label values as `'S'`, `'T'`, `'-'`, where `'S'` is the first token (or Start) of a source, `'T'` is a non-initial token (i.e., a conTinuation) of a source, and `'-'` is a token that is not part of any source.[2]

A detailed description of CRFs can be found in

[2]This is equivalent to the IOB tagging scheme used in syntactic chunkers (Ramshaw and Marcus, 1995).

Lafferty et al. (2001). For our sequence tagging problem, we create a linear-chain CRF based on an undirected graph $G = (V, E)$, where V is the set of random variables $Y = \{Y_i | 1 \leq i \leq n\}$, one for each of n tokens in an input sentence; and $E = \{(Y_{i-1}, Y_i) | 1 < i \leq n\}$ is the set of $n - 1$ edges forming a linear chain. For each sentence x, we define a non-negative clique potential $\exp(\sum_{k=1}^{K} \lambda_k f_k(y_{i-1}, y_i, x))$ for each edge, and $\exp(\sum_{k=1}^{K'} \lambda'_k f'_k(y_i, x))$ for each node, where $f_k(...)$ is a binary feature indicator function, λ_k is a weight assigned for each feature function, and K and K' are the number of features defined for edges and nodes respectively. Following Lafferty et al. (2001), the conditional probability of a sequence of labels y given a sequence of tokens x is:

$$P(y|x) = \frac{1}{Z_x} \exp\left(\sum_{i,k} \lambda_k\, f_k(y_{i-1}, y_i, x) + \sum_{i,k} \lambda'_k\, f'_k(y_i, x)\right) \tag{1}$$

$$Z_x = \sum_{y} \exp\left(\sum_{i,k} \lambda_k\, f_k(y_{i-1}, y_i, x) + \sum_{i,k} \lambda'_k\, f'_k(y_i, x)\right) \tag{2}$$

where Z_x is a normalization constant for each x. Given the training data D, a set of sentences paired with their correct `'ST-'` source label sequences, the parameters of the model are trained to maximize the conditional log-likelihood $\prod_{(x,y) \in D} P(y|x)$. For inference, given a sentence x in the test data, the tagging sequence y is given by $\text{argmax}_{y'} P(y'|x)$.

3.1 Features

To develop features, we considered three properties of opinion sources. First, the sources of opinions are mostly noun phrases. Second, the source phrases should be semantic entities that can bear or express opinions. Third, the source phrases should be directly related to an opinion expression. When considering only the first and second criteria, this task reduces to named entity recognition. Because of the third condition, however, the task requires the recognition of opinion expressions and a more sophisticated encoding of sentence structure to capture relationships between source phrases and opinion expressions.

With these properties in mind, we define the following features for each token/word x_i in an input sentence. For pedagogical reasons, we will describe some of the features as being multi-valued or categorical features. In practice, however, all features are binarized for the CRF model.

Capitalization features We use two boolean features to represent the capitalization of a word: `all-capital`, `initial-capital`.

Part-of-speech features Based on the lexical categories produced by GATE (Cunningham et al., 2002), each token x_i is classified into one of a set of coarse part-of-speech tags: noun, verb, adverb, wh-word, determiner, punctuation, etc. We do the same for neighboring words in a $[-2, +2]$ window in order to assist noun phrase segmentation.

Opinion lexicon features For each token x_i, we include a binary feature that indicates whether or not the word is in our *opinion lexicon* — a set of words that indicate the presence of an opinion. We do the same for neighboring words in a $[-1, +1]$ window. Additionally, we include for x_i a feature that indicates the opinion subclass associated with x_i, if available from the lexicon. (e.g., "bless" is classified as "moderately subjective" according to the lexicon, while "accuse" and "berate" are classified more specifically as "judgments".) The lexicon is initially populated with approximately 500 opinion words [3] from (Wiebe et al., 2002), and then augmented with opinion words identified in the training data. The training data contains manually produced phrase-level annotations for all expressions of opinions, emotions, etc. (Wiebe et al., 2005). We collected all content words that occurred in the training set such that at least 50% of their occurrences were in opinion annotations.

Dependency tree features For each token x_i, we create features based on the parse tree produced by the Collins (1999) dependency parser. The purpose of the features is to (1) encode structural information, and (2) indicate whether x_i is involved in any grammatical relations with an opinion word. Two pre-processing steps are required before features can be constructed:

[3] Some words are drawn from Levin (1993); others are from Framenet lemmas (Baker et al. 1998) associated with communication verbs.

1. **Syntactic chunking.** We traverse the dependency tree using breadth-first search to identify and group syntactically related nodes, producing a flatter, more concise tree. Each syntactic "chunk" is also assigned a grammatical role (e.g., `subject`, `object`, `verb modifier`, `time`, `location`, `of-pp`, `by-pp`) based on its constituents. Possessives (e.g., "Clinton's idea") and the phrase "according to X" are handled as special cases in the chunking process.

2. **Opinion word propagation.** Although the opinion lexicon contains only content words and no multi-word phrases, actual opinions often comprise an entire phrase, e.g., *"is really willing"* or *"in my opinion"*. As a result, we mark as an opinion the entire chunk that contains an opinion word. This allows each token in the chunk to act as an opinion word for feature encoding.

After syntactic chunking and opinion word propagation, we create the following dependency tree features for each token x_i:

- the grammatical role of its chunk
- the grammatical role of x_{i-1}'s chunk
- whether the parent chunk includes an opinion word
- whether x_i's chunk is in an argument position with respect to the parent chunk
- whether x_i represents a constituent boundary

Semantic class features We use 7 binary features to encode the semantic class of each word x_i: `authority`, `government`, `human`, `media`, `organization_or_company`, `proper_name`, and `other`. The `other` class captures 13 semantic classes that cannot be sources, such as `vehicle` and `time`.

Semantic class information is derived from named entity and semantic class labels assigned to x_i by the Sundance shallow parser (Riloff, 2004). Sundance uses named entity recognition rules to label noun phrases as belonging to named entity classes, and assigns semantic tags to individual words based on a semantic dictionary. Table 1 shows the hierarchy that Sundance uses for semantic classes associated with opinion sources. Sundance is also used to recognize and instantiate the source extraction patterns that are learned by AutoSlog-SE, which is described in the next section.

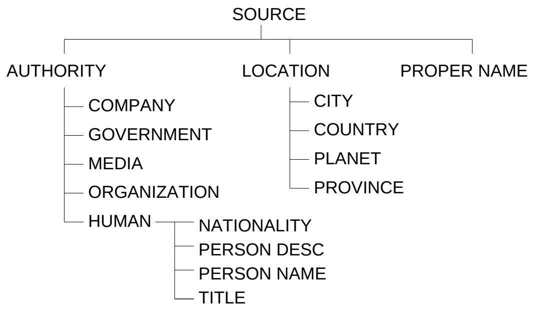

Figure 1: The semantic hierarchy for opinion sources

4 Semantic Tagging via Extraction Patterns

We also learn patterns to extract opinion sources using a statistical adaptation of the AutoSlog IE learning algorithm. AutoSlog (Riloff, 1996a) is a supervised extraction pattern learner that takes a training corpus of texts and their associated answer keys as input. A set of heuristics looks at the context surrounding each answer and proposes a lexico-syntactic pattern to extract that answer from the text. The heuristics are not perfect, however, so the resulting set of patterns needs to be manually reviewed by a person.

In order to build a fully automatic system that does not depend on manual review, we combined AutoSlog's heuristics with statistics from the annotated training data to create a fully automatic supervised learner. We will refer to this learner as AutoSlog-SE (Statistically Enhanced variation of AutoSlog). AutoSlog-SE's learning process has three steps:

Step 1: AutoSlog's heuristics are applied to every noun phrase (NP) in the training corpus. This generates a set of extraction patterns that, collectively, can extract every NP in the training corpus.

Step 2: The learned patterns are augmented with selectional restrictions that semantically constrain the types of noun phrases that are legitimate extractions for opinion sources. We used the semantic classes shown in Figure 1 as selectional restrictions.

Step 3: The patterns are applied to the training corpus and statistics are gathered about their extractions. We count the number of extractions that match annotations in the corpus (correct extractions) and the number of extractions that do not match annotations (incorrect extractions). These counts are then used to estimate the probability that the pattern will extract an opinion source in new texts:

$$P(\text{source} \mid \text{pattern}_i) = \frac{\text{correct sources}}{\text{correct sources} + \text{incorrect sources}}$$

This learning process generates a set of extraction patterns coupled with probabilities. In the next section, we explain how these extraction patterns are represented as features in the CRF model.

5 Extraction Pattern Features for the CRF

The extraction patterns provide two kinds of information. `SourcePatt` indicates whether a word activates any source extraction pattern. For example, the word *"complained"* activates the pattern *"<subj> complained"* because it anchors the expression. `SourceExtr` indicates whether a word is extracted by any source pattern. For example, in the sentence "President Jacques Chirac frequently complained about France's economy", the words "President", "Jacques", and "Chirac" would all be extracted by the *"<subj> complained"* pattern.

Each extraction pattern has frequency and probability values produced by AutoSlog-SE, hence we create four IE pattern-based features for each token x_i: `SourcePatt-Freq`, `SourceExtr-Freq`, `SourcePatt-Prob`, and `SourceExtr-Prob`, where the frequency values are divided into three ranges: {0, 1, 2+} and the probability values are divided into five ranges of equal size.

6 Experiments

We used the Multi-Perspective Question Answering (MPQA) corpus[4] for our experiments. This corpus consists of 535 documents that have been manually annotated with opinion-related information including direct and indirect sources. We used 135 documents as a tuning set for model development and feature engineering, and used the remaining 400 documents for evaluation, performing 10-fold cross validation. These texts are English language versions of articles that come from many countries and cover many topics.[5]

We evaluate performance using 3 measures: overlap match (OL), head match (HM), and exact match (EM). OL is a lenient measure that considers an extraction to be correct if it overlaps with any of the annotated words. HM is a more conservative measure that considers an extraction to be correct if its head matches the head of the annotated source. We report these somewhat loose measures because the annotators vary in where they place the exact boundaries of a source. EM is the strictest measure that requires an exact match between the extracted words and the annotated words. We use three evaluation metrics: recall, precision, and F-measure with recall and precision equally weighted.

6.1 Baselines

We developed three baseline systems to assess the difficulty of our task. *Baseline-1* labels as sources all phrases that belong to the semantic categories `authority`, `government`, `human`, `media`, `organization_or_company`, `proper_name`. Table 1 shows that the precision is poor, suggesting that the third condition described in Section 3.1 (opinion recognition) does play an important role in source identification. The recall is much higher but still limited due to sources that fall outside of the semantic categories or are not recognized as belonging to these categories. *Baseline-2* labels a noun phrase as a source if any of the following are true: (1) the NP is the subject of a verb phrase containing an opinion word, (2) the NP follows *"according to"*, (3) the NP contains a possessive and is preceded by an opinion word, or (4) the NP follows *"by"* and attaches to an opinion word. *Baseline-2*'s heuristics are designed to address the first and the third conditions in Section 3.1. Table 1 shows that *Baseline-2* is substantially better than *Baseline-1*. *Baseline-3*

[4]The MPQA corpus can be freely obtained at http://nrrc.mitre.org/NRRC/publications.htm.

[5]This data was obtained from the Foreign Broadcast Information Service (FBIS), a U.S. government agency.

		Recall	Prec	F1
Baseline-1	OL	77.3	28.8	42.0
	HM	71.4	28.6	40.8
	EM	65.4	20.9	31.7
Baseline-2	OL	62.4	60.5	61.4
	HM	59.7	58.2	58.9
	EM	50.8	48.9	49.8
Baseline-3	OL	49.9	72.6	59.2
	HM	47.4	72.5	57.3
	EM	44.3	58.2	50.3
Extraction Patterns	OL	48.5	81.3	60.8
	HM	46.9	78.5	58.7
	EM	41.9	70.2	52.5
CRF: basic features	OL	56.1	81.0	66.3
	HM	55.1	79.2	65.0
	EM	50.0	72.4	59.2
CRF: basic + IE pattern features	OL	59.1	82.4	68.9
	HM	58.1	80.5	67.5
	EM	52.5	73.3	61.2
CRF-FI: basic features	OL	57.7	80.7	67.3
	HM	56.8	78.8	66.0
	EM	51.7	72.4	60.3
CRF-FI: basic + IE pattern features	OL	60.6	81.2	69.4
	HM	59.5	79.3	68.0
	EM	54.1	72.7	62.0

Table 1: Source identification performance table

labels a noun phrase as a source if it satisfies both *Baseline-1* and *Baseline-2*'s conditions (this should satisfy all three conditions described in Section 3.1). As shown in Table 1, the precision of this approach is the best of the three baselines, but the recall is the lowest.

6.2 Extraction Pattern Experiment

We evaluated the performance of the learned extraction patterns on the source identification task. The learned patterns were applied to the test data and the extracted sources were scored against the manual annotations.[6] Table 1 shows that the extraction patterns produced lower recall than the baselines, but with considerably higher precision. These results show that the extraction patterns alone can identify nearly half of the opinion sources with good accuracy.

[6]These results were obtained using the patterns that had a probability $> .50$ and frequency > 1.

6.3 CRF Experiments

We developed our CRF model using the MALLET code from McCallum (2002). For training, we used a Gaussian prior of 0.25, selected based on the tuning data. We evaluate the CRF using the *basic features* from Section 3, both with and without the IE pattern features from Section 5. Table 1 shows that the CRF with basic features outperforms all of the baselines as well as the extraction patterns, achieving an F-measure of 66.3 using the OL measure, 65.0 using the HM measure, and 59.2 using the EM measure. Adding the IE pattern features further increases performance, boosting recall by about 3 points for all of the measures and slightly increasing precision as well.

CRF with feature induction. One limitation of log-linear function models like CRFs is that they cannot form a decision boundary from conjunctions of existing features, unless conjunctions are explicitly given as part of the feature vector. For the task of identifying opinion sources, we observed that the model could benefit from conjunctive features. For instance, instead of using two separate features, HUMAN and PARENT-CHUNK-INCLUDES-OPINION-EXPRESSION, the conjunction of the two is more informative.

For this reason, we applied the CRF feature induction approach introduced by McCallum (2003). As shown in Table 1, where CRF-FI stands for the CRF model with feature induction, we see consistent improvements by automatically generating conjunctive features. The final system, which combines the basic features, the IE pattern features, and feature induction achieves an F-measure of 69.4 (recall=60.6%, precision=81.2%) for the OL measure, an F-measure of 68.0 (recall=59.5%, precision=79.3%) for the HM measure, and an F-measure of 62.0 (recall=54.1%, precision=72.7%) for the EM measure.

6.4 Error Analysis

An analysis of the errors indicated some common mistakes:

- Some errors resulted from error propagation in our subsystems. Errors from the sentence boundary detector in GATE (Cunningham et al., 2002) were especially problematic because they caused the Collins parser to fail, resulting in no dependency tree information.

• Some errors were due to complex and unusual sentence structure, which our rather simple feature encoding for CRF could not capture well.

• Some errors were due to the limited coverage of the opinion lexicon. We failed to recognize some cases when idiomatic or vague expressions were used to express opinions.

Below are some examples of errors that we found interesting. Doubly underlined phrases indicate incorrectly extracted sources (either false positives or false negatives). Opinion words are singly underlined.

False positives:

(1) Actually, these three countries do have one common denominator, i.e., that their values and policies do not agree with those of the United States and none of them are on good terms with the United States.

(2) Perhaps this is why Fidel Castro has not spoken out against what might go on in Guantanamo.

In (1), "their values and policies" seems like a reasonable phrase to extract, but the annotation does not mark this as a source, perhaps because it is somewhat abstract. In (2), "spoken out" is negated, which means that the verb phrase does not bear an opinion, but our system failed to recognize the negation.

False negatives:

(3) And for this reason, too, they have a moral duty to speak out, as Swedish Foreign Minister Anna Lindh, among others, did yesterday.

(4) In particular, Iran and Iraq are at loggerheads with each other to this day.

Example (3) involves a complex sentence structure that our system could not deal with. (4) involves an uncommon opinion expression that our system did not recognize.

7 Related Work

To our knowledge, our research is the first to automatically identify opinion sources using the MPQA opinion annotation scheme. The most closely related work on opinion analysis is Bethard et al. (2004), who use machine learning techniques to identify propositional opinions and their holders (sources). However, their work is more limited in scope than ours in several ways. Their work only addresses propositional opinions, which are "localized in the propositional argument" of certain verbs such as "believe" or "realize". In contrast, our work aims to find sources for all opinions, emotions, and sentiments, including those that are not related to a verb at all. Furthermore, Berthard et al.'s task definition only requires the identification of direct sources, while our task requires the identification of both direct and indirect sources. Bethard et al. evaluate their system on manually annotated FrameNet (Baker et al., 1998) and PropBank (Palmer et al., 2005) sentences and achieve 48% recall with 57% precision.

Our IE pattern learner can be viewed as a cross between AutoSlog (Riloff, 1996a) and AutoSlog-TS (Riloff, 1996b). AutoSlog is a supervised learner that requires annotated training data but does not compute statistics. AutoSlog-TS is a weakly supervised learner that does not require annotated data but generates coarse statistics that measure each pattern's correlation with relevant and irrelevant documents. Consequently, the patterns learned by both AutoSlog and AutoSlog-TS need to be manually reviewed by a person to achieve good accuracy. In contrast, our IE learner, AutoSlog-SE, computes statistics directly from the annotated training data, creating a fully automatic variation of AutoSlog.

8 Conclusion

We have described a hybrid approach to the problem of extracting sources of opinions in text. We cast this problem as an information extraction task, using both CRFs and extraction patterns. Our research is the first to identify both direct and indirect sources for all types of opinions, emotions, and sentiments.

Directions for future work include trying to increase recall by identifying relationships between opinions and sources that cross sentence boundaries, and relationships between multiple opinion expressions by the same source. For example, the fact that a coreferring noun phrase was marked as a source in one sentence could be a useful clue for extracting the source from another sentence. The probability or the strength of an opinion expression may also play a useful role in encouraging or suppressing source extraction.

Abstract

This research is aimed at the problem of disambiguating toponyms (place names) in terms of a classification derived by merging information from two publicly available gazetteers. To establish the difficulty of the problem, we measured the degree of ambiguity, with respect to a gazetteer, for toponyms in news. We found that 67.82% of the toponyms found in a corpus that were ambiguous in a gazetteer lacked a local discriminator in the text. Given the scarcity of human-annotated data, our method used unsupervised machine learning to develop disambiguation rules. Toponyms were automatically tagged with information about them found in a gazetteer. A toponym that was ambiguous in the gazetteer was automatically disambiguated based on preference heuristics. This automatically tagged data was used to train a machine learner, which disambiguated toponyms in a human-annotated news corpus at 78.5% accuracy.

1 Introduction

Place names, or toponyms, are ubiquitous in natural language texts. In many applications, including Geographic Information Systems (GIS), it is necessary to interpret a given toponym mention as a particular entity in a geographical database or gazetteer. Thus the mention "Washington" in "He visited Washington last year" will need to be interpreted as a reference to either the city Washington, DC or the U.S. state of Washington, and "Berlin" in "Berlin is cold in the winter" could mean Berlin, New Hampshire or Berlin, Germany, among other possibilities. While there has been a considerable body of work distinguishing between a toponym and other kinds of names (e.g., person names), there has been relatively little work on resolving which place and what kind of place given a classification of kinds of places in a gazetteer. Disambiguated toponyms can be used in a GIS to highlight a position on a map corresponding to the coordinates of the place, or to draw a polygon representing the boundary.

In this paper, we describe a corpus-based method for disambiguating toponyms. To establish the difficulty of the problem, we began by quantifying the degree of ambiguity of toponyms in a corpus with respect to a U.S. gazetteer. We then carried out a corpus-based investigation of features that could help disambiguate toponyms. Given the scarcity of human-annotated data, our method used unsupervised machine learning to develop disambiguation rules. Toponyms were automatically tagged with information about them found in a gazetteer. A toponym that was ambiguous in the gazetteer was automatically disambiguated based on preference heuristics. This automatically tagged data was used to train the machine learner. We compared this method with a supervised machine learning approach trained on a corpus annotated and disambiguated by hand.

Our investigation targeted toponyms that name cities, towns, counties, states, countries or national capitals. We sought to classify each toponym as a *national capital*, a *civil political/administrative region*, or a *populated place* (administration unspecified). In the vector model of GIS, the type of place crucially determines the geometry chosen to represent it (e.g., point, line or polygon) as well as any reasoning about geographical inclusion. The class of the toponym can be useful in "grounding" the toponym to latitude and longitude coordinates,

Entry Number	Toponym	U.S. County	U.S. State	Lat-Long (dddmmss)	Elevation (ft. above sea level)	Class
110	Acton	Middlesex	Massachusetts	422906N-0712600W	260	Ppl (populated place)
111	Acton	Yellowstone	Montana	455550N-1084048W	3816	Ppl
112	Acton	Los Angeles	California	342812N-1181145W	2720	Ppl

Table 1. Example GNIS entries for an ambiguous toponym

but it can also go beyond grounding to support spatial reasoning. For example, if the province is merely grounded as a point in the data model (e.g., if the gazetteer states that the centroid of a province is located at a particular latitude-longitude) then without the class information, the inclusion of a city within a province can't be established. Also, resolving multiple cities or a unique capital to a political region mentioned in the text can be a useful adjunct to a map that lacks political boundaries or whose boundaries are dated.

It is worth noting that our classification is more fine-grained than efforts like the EDT task in Automatic Content Extraction[1] program (Mitchell and Strassel 2002), which distinguishes between toponyms that are a Facility "Alfredo Kraus Auditorium", a Location "the Hudson River", and Geo-Political Entities that include territories "U.S. heartland", and metonymic or other derivative place references "Russians", "China (offered)", "the U.S. company", etc. Our classification, being gazetteer based, is more suited to GIS-based applications.

2 Quantifying Toponym Ambiguity

2.1 Data

We used a month's worth of articles from the New York Times (September 2001), part of the English Gigaword (LDC 2003). This corpus consisted of 7,739 documents and, after SGML stripping, 6.51 million word tokens with a total size of 36.4MB). We tagged the corpus using a list of place names from the USGS Concise Gazetteer (GNIS). The resulting corpus is called MAC1, for "Machine Annotated Corpus 1". GNIS covers cities, states, and counties in the U.S., which are classified as "civil" and "populated place" *geographical entities.* A *geographical entity* is an entity on the Earth's surface that can be represented by some geometric specification in a GIS; for example, as a point, line or polygon. GNIS also covers 53 other types of geo-entities, e.g., "valley," "summit", "water" and "park." GNIS has 37,479 entries, with 27,649 distinct toponyms, of which 13,860 toponyms had multiple entries in the GNIS (i.e., were ambiguous according to GNIS). Table 1 shows the entries in GNIS for an ambiguous toponym.

2.2 Analysis

Let E be a set of elements, and let F be a set of features. We define a feature g in F to be a *disambiguator* for E iff for all pairs $<e_x, e_y>$ in E X E, $g(e_x) \neq g(e_y)$ and neither $g(e_x)$ nor $g(e_y)$ are null-valued. As an example, consider the GNIS gazetteer in Table 1, let F = {U.S. County, U.S. State, Lat-Long, and Elevation}. We can see that each feature in F is a disambiguator for the set of entries E = {110, 111, 112}.

Let us now characterize the mapping between texts and gazetteers. A string s1 in a text is said to be a *discriminator within a window w* for another string s2 no more than w words away if s1 matches a disambiguator d for s2 in a gazetteer. For example, "MT" is a discriminator within a window 5 for the toponym "Acton" in "Acton, MT," since "MT" occurs within a ±5-word window of "Acton" and matches, via an abbreviation, "Montana", the value of a GNIS disambiguator U.S. State (here the tokenized words are "Acton", ",", and "MT").

A trie-based lexical lookup tool (called LexScan) was used to match each toponym in GNIS against the corpus MAC1. Of the 27,649 distinct toponyms

[1] www.ldc.upenn.edu/Projects/ACE/

in GNIS, only 4553 were found in the corpus (note that GNIS has only U.S. toponyms). Of the 4553 toponyms, 2911 (63.94%) were “bare” toponyms, lacking a local discriminator within a ±5-word window that could resolve the name.

Of the 13,860 toponyms that were *ambiguous* according to GNIS, 1827 of them were found in MAC1, of which only 588 had discriminators within a ±5-word window (i.e., discriminators which matched gazetteer features that disambiguated the toponym). Thus, **67.82%** of the 1827 toponyms found in MAC1 that were ambiguous in GNIS lacked a discriminator.

This 67.82% proportion is only an estimate of true toponym ambiguity, even for the sample MAC1. There are several sources of error in this estimate: (i) World cities, capitals and countries were not yet considered, since GNIS only covered U.S. toponyms. (ii) In general, a single feature (e.g., County, or State) may not be sufficient to disambiguate a set of entries. It is of course possible for two different places named by a common toponym to be located in the same county in the same state. However, there were no toponyms with this property in GNIS. (iii) A string in MAC1 tagged by GNIS lexical lookup as a toponym may not have been a place name at all (e.g., “Lord Acton lived …”). Of the toponyms that were spurious, most were judged by us to be common words and person names. This should not be surprising, as 5341 toponyms in GNIS are also person names according to the U.S. Census Bureau[2] (iv) LexScan wasn’t perfect, for the following reasons. First, it sought only exact matches. Second, the matching relied on expansion of standard abbreviations. Due to non-standard abbreviations, the number of true U.S. toponyms in the corpus likely exceeded 4553. Third, the matches were all case-sensitive: while case-insensitivity caused numerous spurious matches, case-sensitivity missed a more predictable set, i.e. all-caps dateline toponyms or lower-case toponyms in Internet addresses.

Note that the 67.82% proportion is just an estimate of *local* ambiguity. Of course, there are often non-local discriminators (outside the ±5-word windows); for example, an initial place name reference could have a local discriminator, with subsequent references in the article lacking local discriminators while being *coreferential* with the initial reference. To estimate this, we selected cases where a toponym was discriminated on its first mention. In those cases, we counted the number of times the toponym was repeated in the same document without the discriminator. We found that **73%** of the repetitions lacked a local discriminator, suggesting an important role for coreference (see Sections 4 and 5).

3 Knowledge Sources for Automatic Disambiguation

To prepare a toponym disambiguator, we required a gazetteer as well as corpora for training and testing it.

3.1 Gazetteer

To obtain a gazetteer that covered worldwide information, we harvested countries, country capitals, and populous world cities from two websites ATLAS[3] and GAZ[4], to form a consolidated gazetteer (WAG) with four features G1,..,G4 based on geographical inclusion, and three classes, as shown in Table 2. As an example, an entry for Aberdeen could be the following feature vector: G1=United States, G2=Maryland, G3=Harford County, G4=Aberdeen, CLASS=ppl.

We now briefly discuss the merging of ATLAS and GAZ to produce WAG. ATLAS provided a simple list of countries and their capitals. GAZ recorded the country as well as the population of 700 cities of at least 500,000 people. If a city was in both sources, we allowed two entries but ordered them in WAG to make the more specific type (e.g. “capital”) the default sense, the one that LexScan would use. Accents and diacritics were stripped from WAG toponyms by hand, and aliases were associated with standard forms. Finally, we merged GNIS state names with these, as well as abbreviations discovered by our abbreviation expander.

3.2 Corpora

We selected a corpus consisting of 15,587 articles from the complete Gigaword Agence France

[2] www.census.gov/genealogy/www/freqnames.html

[3] . www.worldatlas.com

[4] www.worldgazetteer.com

Presse, May 2002. LexScan was used to tag, insensitive to case, all WAG toponyms found in this corpus, with the attributes in Table 2. If there were multiple entries in WAG for a toponym, LexScan only tagged the preferred sense, discussed below. The resulting tagged corpus, called MAC-DEV,

Tag Attribute	Description
CLASS	**Civil** (Political Region or Administrative Area, e.g. Country, Province, County), **Ppl** (Populated Place, e.g. City, Town), **Cap** (Country Capital, Provincial Capital, or County Seat)
G1	Country
G2	Province (State) or Country-Capital
G3	County or Independent City
G4	City, Town (Within County)

Table 2: WAG Gazetteer Attributes

Corpus	Size	Use	How Annotated
MAC1	6.51 million words with 61,720 place names (4553 distinct) from GNIS	Ambiguity Study (Gigaword NYT Sept. 2001) (Section 2)	LexScan of all senses, no attributes marked
MAC-DEV	5.47 million words with 124,175 place names (1229 distinct) from WAG	Development Corpus (Gigaword AFP May 2002) (Section 4)	LexScan using attributes from WAG, with heuristic preference
MAC-ML	6.21 million words with 181,866 place names (1322 distinct) from WAG	Machine Learning Corpus (Gigaword AP Worldwide January 2002) (Section 5)	LexScan using attributes from WAG, with heuristic preference
HAC	83,872 words with 1275 place names (435 distinct) from WAG.	Human Annotated Corpus (from TimeBank 1.2, and Gigaword NYT Sept. 2001 and June 2002) (Section 5)	LexScan using WAG, with attributes and sense being manually corrected

Table 4. Top 10 terms disambiguating toponym classes

was used as a development corpus for feature exploration. To disambiguate the sense for a toponym that was ambiguous in WAG, we used two preference heuristics. First, we searched

MAC1 for two dozen highly frequent ambiguous toponym strings (e.g., "Washington", etc.), and observed by inspection which sense predominated in MAC1, preferring the predominant sense for each of these frequently mentioned toponyms. For example, in MAC1, "Washington" was predominantly a Capital. Second, for toponyms outside this most frequent set, we used the following specificity-based preference: *Cap.* > *Ppl* > *Civil*. In other words, we prefer the more specific sense; since there are a smaller number of Capitals than Populated places, we prefer Capitals to Populated Places.

For machine learning, we used the Gigaword Associated Press Worldwide January 2002 (15,999 articles), tagged in the same way by LexScan as MAC-DEV was. This set was called MAC-ML. Thus, MAC1, MAC-DEV, and MAC-ML were all generated automatically, without human supervision.

For a blind test corpus with human annotation, we opportunistically sampled three corpora: MAC1, TimeBank 1.2[5] and the June 2002 New York Times from the English Gigaword, with the first author tagging a random 28, 88, and 49 documents respectively from each. Each tag in the resulting human annotated corpus (HAC) had the WAG attributes from Table 2 with manual correction of all the WAG attributes. A summary of the corpora, their source, and annotation status is shown in Table 3.

4 Feature Exploration

We used the tagged toponyms in MAC-DEV to explore useful features for disambiguating the classes of toponyms. We identified single-word terms that co-occurred significantly with classes within a k-word window (we tried k= ±3, and k=±20). These terms were scored for pointwise mutual information (MI) with the classes. Terms with average tf.idf of less than 4 in the collection were filtered out as these tended to be personal pronouns, articles and prepositions.

To identify which terms helped select for particular classes of toponyms, the set of 48 terms whose MI scores were above a threshold (-11, chosen by inspection) were filtered using the student's t-statistic, based on an idea in (Church and Hanks 1991). The t-statistic was used to compare the distribution of the term with one class of toponym to its distribution with other classes to assess whether the underlying distributions were significantly different with at least 95% confidence. The results are shown in Table 4, where scores for a term that occurred jointly in a window with at least one other class label are shown in bold. A t-score > 1.645 is a significant difference with 95% confidence. However, because joint evidence was scarce, we eventually chose not to eliminate Table 4 terms such as 'city' (t =1.19) as features for machine learning. Some of the terms were significant disambiguators between only one pair of classes, e.g. 'yen,' 'attack,' and 'capital,' but we kept them on that basis.

Feature Name	**Description**
Abbrev	Value is *true* iff the toponym is abbreviated.
AllCaps	Value is *true* iff the toponym is all capital letters.
Left/Right Pos{1,.., k}	Values are the ordered tokens up to *k* positions to the left/right
WkContext	Value is the *set* of MI collocated terms found in windows of ± *k* tokens (to the left and right)
TagDiscourse	Value is the *set* of CLASS values represented by all toponyms from the document: e.g., the set {*civil, capital, ppl*}
CorefClass	Value is the CLASS if any for a prior mention of a toponym in the document, or *none*

Table 5. Features for Machine Learning

Based on the discovered terms in experiments with different window sizes, and an examination of MAC1 and MAC-DEV, we identified a final set of features that, it seemed, might be useful for machine learning experiments. These are shown in Table 5. The features *Abbrev* and *Allcaps* describe evidence internal to the toponym:

[5] www.timeml.org

an abbreviation may indicate a state (Mass.), territory (N.S.W.), country (U.K.), or some other *civil* place; an all-caps toponym might be a *capital* or *ppl* in a dateline. The feature sets *LeftPos* and *RightPos* target the ±*k* positions in each window as ordered tokens, but note that only windows with a MI term are considered. The domain of *WkContext* is the window of ±k tokens around a toponym that contains a MI collocated term.

We now turn to the global discourse-level features. The domain for *TagDiscourse* is the whole document, which is evaluated for the set of toponym classes present: this information may reflect the discourse topic, e.g. a discussion of U.S. sports teams will favor mentions of cities over states or capitals. The feature *CorefClass* implements a one sense per discourse strategy, motivated by our earlier observation (from Section 2) that 73% of subsequent mentions of a toponym that was discriminated on first mention were expressed without a local discriminator.

5 Machine Learning

The features in Table 5 were used to code feature vectors for a statistical classifier. The results are shown in Table 6. As an example, when the Ripper classifier (Cohen 1996) was trained on MAC-ML with a window of *k*= ±3 word tokens, the predictive accuracy when tested using cross-validation MAC-ML was 88.39% ±0.24 (where 0.24 is the standard deviation across 10 folds).

		Accuracy on Test Set			
		Window = ±3		**Window = ±20**	
Training Set	**Test Set**	**Predictive Accuracy**	**Recall, Precision, F-measure**	**Predictive Accuracy**	**Recall, Precision, F-measure**
MAC-ML	MAC-ML *(cross-validation)*	**88.39** ± 0.24 (*Civ.* 65.0)	*Cap* r70 p88 f78 *Civ.* r94 p90 f92 *Ppl* r87 p82 f84 Avg. r84 p87 **f85**	80.97 ± 0.33 (*Civ.* 57.1)	*Cap* r61 p77 f68 *Civ.* r83 p86 f84 *Ppl* r81 p72 f76 Avg. r75 p78 f76

Table 6. Machine Learning Accuracy

The majority class (**Civil**) had the predictive accuracy shown in parentheses. (When tested on a different set from the training set, cross-validation wasn't used). Ripper reports a confusion matrix for each class; Recall, Precision, and F-measure for these classes are shown, along with their average across classes.

In all cases, Ripper is significantly better in predictive accuracy than the majority class. When testing using cross-validation on the same machine-annotated corpus as the classifier was trained on, performance is comparable across corpora, and is in the high 80%, e.g., **88.39** on MAC-ML (k=±3). Performance drops substantially when we train on machine-annotated corpora but test on the human-annotated corpus (HAC) (the unsupervised approach), or when we both train and test on HAC (the supervised approach). The noise in the auto-generated classes in the machine-annotated corpus is a likely cause for the lower accuracy of the unsupervised approach. The poor performance of the supervised approach can be attributed to the lack of human-annotated training data: HAC is a small, 83,872-word corpus.

Rule Description (Window = ±3)	**Coverage of Examples in Testing (Accuracy)**
If not AllCaps(P) and Right-Pos1(P,'SINGLE_QUOTE') and Civil ∈ TagDiscourse Then Civil(P).	5/67 (100%)
If not AllCaps(P) and Left-Pos1(P, *southern*) and Civil ∈ TagDiscourse Then Civil(P).	13/67 (100%)

Table 7. Sample Rules Learnt by Ripper

TagDiscourse was a critical feature; ignoring it during learning dropped the accuracy nearly 9 percentage points. This indicates that prior mention of a class increases the likelihood of that class. (Note that when inducing a rule involving a set-valued feature, Ripper tests whether an element is a member of that set-valued feature, selecting the test that maximizes information gain for a set of examples.) Increasing the *window size* only lowered accuracy when tested on the same corpus (using cross-validation); for example, an increase from ±3 words to ±20 words (intervening sizes are not shown for reasons of space) lowered the PA by 5.7 percentage points on MAC-DEV. However, increasing the *training set size* was effective, and this increase was more substantial for larger window sizes: combining MAC-ML with MAC-DEV improved accuracy on HAC by about 4.5% for *k*= ±3, but an increase of 13% was seen for *k* =±20. In addition, F-measure for the classes was steady or increased. As Table 6 shows, this was largely due to the increase in recall on the non-majority classes. The best performance when training Ripper on the machine-annotated MAC-DEV+MAC-ML and testing on the human-annotated corpus HAC was 78.30.

Another learner we tried, the SMO support-vector machine from WEKA (Witten and Frank 2005), was marginally better, showing **81.0** predictive accuracy training and testing on MAC-DEV+MAC-ML (ten-fold cross-validation, k=±20) and **78.5** predictive accuracy training on MAC-DEV+MAC-ML and testing on HAC (k=±20). Ripper rules are of course more transparent: example rules learned from MAC-DEV are shown in Table 7, along with their coverage of feature vectors and accuracy on the test set HAC.

6 Related Work

Work related to toponym tagging has included harvesting of gazetteers from the Web (Uryupina 2003), hand-coded rules to place name disambiguation, e.g., (Li et al. 2003) (Zong et al. 2005), and machine learning approaches to the problem, e.g., (Smith and Mann 2003). There has of course been a large amount of work on the more general problem of word-sense disambiguation, e.g., (Yarowsky 1995) (Kilgarriff and Edmonds 2002). We discuss the most relevant work here.

While (Uryupina 2003) uses machine learning to induce gazetteers from the Internet, we merely download and merge information from two popular Web gazetteers. (Li et al. 2003) use a statistical approach to tag place names as a LOCation class. They then use a heuristic approach to location normalization, based on a combination of hand-coded pattern-matching rules as well as discourse features based on co-occurring toponyms (e.g., a document with "Buffalo", "Albany" and "Rochester" will likely have those toponyms disambiguated to New York state). Our *TagDiscourse* feature is more coarse-grained. Finally, they assume one sense per discourse in their rules, whereas we use it as a feature *CorefClass* for use in learning. Overall, our approach is based on unsupervised machine learning, rather than hand-coded rules for location normalization.

(Smith and Mann 2003) use a "minimally supervised" method that exploits as training data toponyms that are found locally disambiguated, e.g., "Nashville, Tenn."; their disambiguation task is to identify the state or country associated with the toponym in test data that has those disambiguators stripped off. Although they report 87.38% accuracy on news, they address an easier problem than ours, since: (i) our earlier local ambiguity estimate suggests that as many as two-thirds of the gazetteer-ambiguous toponyms may be excluded from their test on news, as they would lack local discriminators (ii) the classes our tagger uses (Table 3) are more fine-grained. Finally, they use one sense per discourse as a bootstrapping strategy to expand the machine-annotated data, whereas in our case *CorefClas*s is used as a feature.

Our approach is distinct from other work in that it firstly, attempts to quantify toponym ambiguity, and secondly, it uses an unsupervised approach based on learning from noisy machine-annotated corpora using publicly available gazetteers.

7 Conclusion

This research provides a measure of the degree of of ambiguity with respect to a gazetteer for toponyms in news. It has developed a toponym disambiguator that, when trained on entirely machine annotated corpora that avail of easily available Internet gazetteers, disambiguates toponyms in a human-annotated corpus at 78.5% accuracy.

Our current project includes integrating our disambiguator with other gazetteers and with a geovisualization system. We will also study the effect of other window sizes and the combination of this unsupervised approach with minimally-supervised approaches such as (Brill 1995) (Smith and Mann 2003). To help mitigate against data sparseness, we will cluster terms based on stemming and semantic similarity.

A Semantic Approach to Recognizing Textual Entailment

Marta Tatu and **Dan Moldovan**
Language Computer Corporation
Richardson, TX 75080, USA
marta,moldovan@languagecomputer.com

Abstract

Exhaustive extraction of semantic information from text is one of the formidable goals of state-of-the-art NLP systems. In this paper, we take a step closer to this objective. We combine the semantic information provided by different resources and extract new semantic knowledge to improve the performance of a *recognizing textual entailment* system.

1 Recognizing Textual Entailment

While communicating, humans use different expressions to convey the same meaning. Therefore, numerous NLP applications, such as, Question Answering, Information Extraction, or Summarization require computational models of language that recognize if two texts semantically overlap. Trying to capture the major inferences needed to understand equivalent semantic expressions, the PASCAL Network proposed the *Recognizing Textual Entailment* (RTE) challenge (Dagan et al., 2005). Given two text fragments, the task is to determine if the meaning of one text (the entailed hypothesis, H) can be inferred from the meaning of the other text (the entailing text, T).

Given the wide applicability of this task, there is an increased interest in creating systems which detect the semantic entailment between two texts. The systems that participated in the Pascal RTE challenge competition exploit various inference elements which, later, they combine within statistical models, scoring methods, or machine learning frameworks. Several systems (Bos and Markert, 2005; Herrera et al., 2005; Jijkoun and de Rijke, 2005; Kouylekov and Magnini, 2005; Newman et al., 2005) measured the word overlap between the two text strings. Using either statistical or WordNet's relations, almost all systems considered lexical relationships that indicate entailment. The degree of similarity between the syntactic parse trees of the two texts was also used as a clue for entailment by several systems (Herrera et al., 2005; Kouylekov and Magnini, 2005; de Salvo Braz et al., 2005; Raina et al., 2005). Several groups used logic provers to show the entailment between T and H (Bayer et al., 2005; Bos and Markert, 2005; Fowler et al., 2005; Raina et al., 2005) and some of them made use of world knowledge axioms to increase the logic prover's power of inference (Bayer et al., 2005; Bos and Markert, 2005; Fowler et al., 2005).

In this paper, we describe a novel technique which employs a set of *semantic axioms* in its attempt to exhaustively extract semantic knowledge from texts. In order to show the contribution that our semantic information extraction method brings, we append it as an additional module to an already existing system that participated in the RTE challenge. Our system (Fowler et al., 2005), first, transforms the text T and the hypothesis H into semantically enhanced logic forms, and, then, the integrated logic prover tries to prove or disprove the entailment using a set of world-knowledge axioms (*die of blood loss* $\rightarrow$ *bleed to death*), linguistic rewriting rules which break down complex syntactic structures, like coordinating conjunctions, and WordNet-based lexical chains axioms (*buy/VB/1* $\rightarrow$ *pay/VB/1*).

2 Approach

We believe that a logic-based semantic approach is highly appropriate for the RTE task[1]. Text T semantically entails H if its meaning logically implies the meaning of H. Because the set of semantic relations encoded in a text represents its meaning, we need to identify all the semantic relations that hold between the constituents of T and, subsequently, between the constituents of H to understand the meaning of each text. It should be noted that state-of-the-art semantic parsers extract only some of the semantic relations encoded in a given text. To complete this information, we need semantic axioms that augment the extracted knowledge and, thus, provide a better coverage of the text's semantics. Once we gather this information, we state that text T entails hypothesis H if and only if we find similar relations between a concept from T and a semantically analogous concept from H. By analogous concepts, we mean identical concepts, or words connected by a chain of SYNONYMY, HYPERNYMY or morphological derivation relations in WordNet.

Because the set of semantic elements identified by a semantic parser does not necessarily convey the complete meaning of a sentence, we shall use a set of semantic axioms to infer the missing pieces of information. By combining two semantic relations or by using the FrameNet's frame elements identified in a given text, we derive new semantic information.

In order to show if T entails H, we analyze their meanings. Our approach to semantic entailment involves the following stages:

1. We convert each text into logic form (Moldovan and Rus, 2001). This conversion includes part-of-speech tagging, parse tree generation, and name entity recognition.

2. Using our semantic parser, we identify some of the semantic relations encoded in the analyzed texts. We note that state-of-the-art semantic parsers cannot discover all the semantic relations conveyed implicitly or explicitly by the text. This problem compromises our system's performance. To obtain the complete set of semantic relations that represents the meaning of the given texts, we introduce a new step in our algorithm.

3. We add *semantic axioms* to the already created set of world knowledge, NLP, and WordNet-based lexical chain (Moldovan and Novischi, 2002) axioms that assist the logic prover in its search for proofs. We developed semantic axioms that show how two semantic relations can be combined. This will allow the logic prover to combine, whenever possible, semantic instances in order to infer new semantic relationships. The instances of relations that participate in semantic combinations can be either provided by the text or annotated between WordNet synsets. We also exploit other sources of semantic information from the text. For example, the frames encoded in the text sentence provide information which complements the meaning given by the semantic relations. Our second type of axioms derive semantic relations between the frame elements of a given FrameNet frame.

We claim that the process of applying the semantic axioms, given the semantic relations detected by a semantic parser, will capture the complete semantic information expressed by a text fragment. In this paper, we show the usefulness of this procedure for the RTE task, but we are convinced that it can be used by any system which plans to extract the entire semantic information from a given text.

4. We load the COGEX logic prover (Moldovan et al., 2003) which operates by "reductio ad absurdum" with H's negated form and T's predicates. These clauses are weighted in the order in which they should be chosen to participate in the search. To ensure that H will be the last clause to participate, we assign it the largest value. The logic prover searches for new inferences that can be made using the smallest weight clauses. It also assigns a value to each inference based on the axiom it used to derive it. This process continues until the set of clauses is empty. If a refutation is found, the proof is complete. If a contradiction cannot be found, then the predicate arguments are relaxed and, if the argument relaxation fails, then predicates are dropped until a proof by refutation is found. Its score will be computed by deducting points for each argument relaxation and predicate removal. If this value falls below a threshold, then T does not entail H. Otherwise, the (T, H) pair is a true entailment.

We present a textual entailment example to show the steps of our approach. This proof will not

Table 1: Entailment proof example. Table 2 lists the semantic relations and their abbreviations. Sections 3.2 and 4.1 will detail the semantics behind the axioms $T_{Axiom_1}, T_{Axiom_2}, T_{Axiom_3}, T_{Axiom_4}$, and H_{Axiom_1}.

make use of any world knowledge axioms. Let the text T be *John and his son, George, emigrated with Mike, John's uncle, to US in 1969* and the entailed hypothesis H *George and his relative, Mike, came to America*. Our system transforms each text into its corresponding semantically enhanced logic form ($\mathcal{LF}_T$ and $\mathcal{LF}_H$ in Table 1). Then, the logic prover uses the newly added semantic axioms to derive extra semantic information from T and H (for example, *George* and *Mike* are relatives, but T does not explicitly specify this), after another preprocessing step which identifies the frame elements of each frame encoded in the two texts ($T_{Departing}$, $T_{Kinship}$, $H_{Arriving}$, $H_{Kinship}$). In our example, the axioms T_{Axiom_1} and T_{Axiom_2} denote the *symmetry* and the *transitivity* of the KINSHIP relation. T_{Axiom_3}, T_{Axiom_4} and H_{Axiom_1} are the frame-related axioms used by the logic prover. The $T_{Semantics}$ and $H_{Semantics}$ rows (Table 1) summarize the meaning of T and H. We note that half of these semantic instances were extracted using the semantic axioms. Once the lexical chains between the concepts in T and the ones from H are computed, the entailment becomes straightforward. We represented, graphically, the meaning of the two texts in Figure 1. We also show the links between the analogous concepts that help prove the entailment.

In the coming sections of the paper, we detail the process of semantic axiom generation. We start with a summary of the axioms that combine two semantic relations.

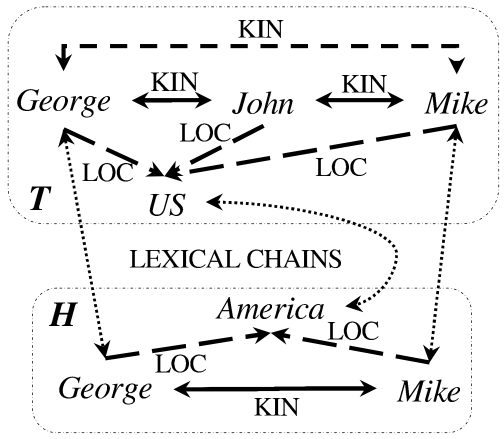

Figure 1: $T_{Semantics}$ and $H_{Semantics}$. The solid arrows represent the relations identified by the semantic parser. The dotted arrows symbolize the lexical chains between concepts in T and their analogous concepts in H (US_T and $America_H$ belong to the same WordNet synset). The dash arrows denote the relations inferred by combining two semantic relations. The long dash arrows indicate the relations between frame elements.

3 Semantic Calculus

3.1 Semantic relations

For this study, we adopt a revised version of the semantic relation set proposed by (Moldovan et al., 2004). Table 2 enumerates the semantic relations that we consider[2].

[2]See (Moldovan et al., 2004) for definitions and examples.

Table 2: The set of semantic relations

3.2 Combinations of two semantic relations

Our goal is to devise semantic axioms for combinations of two relations, R_1 and R_2, by observing the semantic connection between the w_1 and w_3 words for which there exists at least one other word, w_2, such that $R_1(w_1, w_2)$ and $R_2(w_2, w_3)$ hold true[3].

Harabagiu and Moldovan (1998) tackled the problem of semantic combinations, for the first time. Their set of relations included the WordNet1.5 annotations and 12 relationships derived from the WordNet glosses[4]. In our research, unlike (Harabagiu and Moldovan, 1998), the semantic combinations use the relations identified in text with a rather minimal contribution from the WordNet relations.

Harabagiu and Moldovan (1998) also investigate the number of possible semantic combinations. Based on their properties, we can have up to eight combinations between any two semantic relations and their inverses, not counting the combinations between a semantic relation and itself[5]. For instance, given an asymmetric relation and a symmetric one which share the same part-of-speech for their arguments, we can produce four combinations. ISA $\circ$ ANT, ISA^{-1} $\circ$ ANT, ANT $\circ$ ISA, and ANT $\circ$ ISA^{-1} are the four possible distinct combinations between HYPERNYMY and ANTONYMY. "$\circ$" symbolizes the semantic composition between two relations compatible with respect to the part-of-speech of their arguments: for any two concepts, w_1 and w_3, $(R_i \circ R_j)(w_1, w_3)$ if and only if $\exists w_2$, a third concept, such that $R_i(w_1, w_2)$ and $R_j(w_2, w_3)$ hold. By R^{-1}, we denote the inverse of relation R: if $R(x, y)$, then $R^{-1}(y, x)$.

While analyzing the combinations, we observed some regularities within the semantic composition process. For example, $R_1^{-1} \circ R_2^{-1} = (R_2 \circ R_1)^{-1}$ for any, not necessarily distinct, semantic relations R_1 and R_2[6]. If one of the relations is symmetric ($R^{-1} = R$), the statement is still valid. Using $(R^{-1})^{-1} = R$ and the previous equality, we can reduce by half the number of semantic combinations that we have to compute for $R_1 \neq R_2$.

We plan to create a 40×40 matrix with all the possible combinations between any two semantic relations from the set we consider. Theoretically, we can have up to 27,556 semantic combinations, but only 25.79% of them are possible[7] (for example, MNR(r, v) and SYN(n, n) cannot be combined). Many combinations are not semantically significant either because they are very rare, like, KIN(n, n) $\circ$ TMP(n, v), or because they do not result into one of the 40 relations, for instance, PAH(a, n) $\circ$ AGT(n, v)[8]. We identified two approaches to the problem mentioned above. The first tries to fill one matrix cell at a time in a consecutive manner. The second approach tries to solve the semantic combinations we come upon in text corpora. As a result, we analyzed the RTE development corpus and we devised rules for some of the $R_i \circ R_j$ combinations that we encountered. We validated these axioms by man-

[3] $R(x, y)$ indicates that relation R holds between x and y.

[4] This set includes the AGENT, OBJECT, INSTRUMENT, BENEFICIARY, PURPOSE, ATTRIBUTE, REASON, STATE, LOCATION, THEME, TIME, and MANNER relations.

[5] Harabagiu and Moldovan (1998) lists the exact number of possible combinations for several WordNet relations and part-of-speech classes.

[6] The equality holds only if the two composition terms exist.

[7] On average, each semantic relation has 2.075 pairs of arguments. For example, SRC can connect two nouns (*US investor*), or an adjective and a noun (*American investor*) and, depending on its arguments, SRC will participate in different combinations. Out of the 27,556 combinations, only 7,109 are syntactically possible.

[8] n, v, a, and r stand for *noun*, *verb*, *adjective*, and *adverb*, respectively. As an example, $R(n, n)$ means that relation R can connect two nouns.

LOCATION ∘ PART-WHOLE = LOCATION (LOCATION(x, l_1) $\wedge$ PART-WHOLE(l_1, l_2) $\rightarrow$ LOCATION(x, l_2))
Example: John lives in Dallas, Texas.
LOCATION$(John, Dallas)$ and PART-WHOLE$(Dallas, Texas)$ imply that LOCATION$(John, Texas)$.
ISA ∘ ATTRIBUTE = ATTRIBUTE (ISA(x, y) $\wedge$ ATTRIBUTE(y, a) $\rightarrow$ ATTRIBUTE(x, a))
Example: Mike is a rich man.
If ISA$(Mike, man)$ and ATTRIBUTE$(man, rich)$, then ATTRIBUTE$(Mike, rich)$.
Similar statements can be made for other "attributes": LOCATION, TIME, SOURCE, etc.
ISA ∘ LOCATION = LOCATION (ISA(x, y) $\wedge$ LOCATION(y, l) $\rightarrow$ LOCATION(x, l))
Example: The man in the car, George, is an old friend of mine.
ISA$(George, man)$ and LOCATION(man, car) $\rightarrow$ LOCATION$(George, car)$
KINSHIP ∘ KINSHIP = KINSHIP (KINSHIP(x, y) $\wedge$ KINSHIP(y, z) $\rightarrow$ KINSHIP(x, z))
See example in Section 2.
THEME ∘ ISA^{-1} = THEME (THEME(e, y) $\wedge$ ISA(x, y) $\rightarrow$ THEME(e, x))
Example: Yesterday, John ate some fruits: an apple and two oranges.
THEME$(eat, fruit)$ $\wedge$ ISA$(apple, fruit)$ $\rightarrow$ THEME$(eat, apple)$
THEME ∘ PART-WHOLE^{-1} = THEME (THEME(e, y) $\wedge$ PART-WHOLE(x, y) $\rightarrow$ THEME(e, x))
Example: Five Israelis, including two children, were killed yesterday.
THEME$(kill, Israeli)$ $\wedge$ PART-WHOLE$(child, Israeli)$ $\rightarrow$ THEME$(kill, child)$
Similar statements can be made for all the thematic roles: AGENT, EXPERIENCER, INSTRUMENT, CAUSE, LOCATION, etc.
AGENT ∘ ISA^{-1} = AGENT (AGENT(e, y) $\wedge$ ISA(x, y) $\rightarrow$ AGENT(e, x))
AGENT ∘ PART-WHOLE^{-1} = AGENT (AGENT(e, y) $\wedge$ PART-WHOLE(x, y) $\rightarrow$ AGENT(e, x))

Table 3: Examples of semantic combination axioms

ually checking all the LA Times corpus (w_1, w_3) pairs which satisfy $(R_i \circ R_j)(w_1, w_3)$. We have identified 64 semantic axioms that show how semantic relations can be combined. These axioms use relations such as PART-WHOLE, ISA, LOCATION, ATTRIBUTE, or AGENT. We listed several example rules in Table 3. The 64 axioms can be applied independent of the concepts involved in the semantic composition. We have also identified rules that can be applied only if the concepts that participate satisfy a certain condition or if the relations are of a certain type. For example, LOC ∘ LOC = LOC only if the LOC relation shows inclusion (*John is in the car in the garage* $\rightarrow$ LOC$(John, garage)$. *John is near the car behind the garage* $\not\rightarrow$ LOC$(John, garage)$).

4 FrameNet Can Help

The Berkeley FrameNet project[9] (Baker et al., 1998) is a lexicon-building effort based on the theory of *frame semantics* which defines the meanings of lexical units with respect to larger conceptual structures, called frames. Individual lexical units point to specific frames and establish a binding pattern to specific elements within the frame. FrameNet describes the underlying frames for different lexical units and examines sentences related to the frames using the BNC corpus. The result is an XML database that contains a set of frames, a set of frame elements for each frame, and a set of frame annotated sentences.

[9]http://framenet.icsi.berkeley.edu

4.1 Frame-based semantic axioms

With respect to a given target, the frame elements contribute to the understanding of the sentence. But they only link each argument to the target word (for example, THM$(theme, target)$ or AGT$(theme, target)$, LOC$(place, target)$, etc.). Often enough, we can find relations between the frame elements of a given frame. These new instances of semantic relations take as arguments the frame elements of a certain frame, when they are expressed in the text. For example, given the DEPARTING frame, we can say that the origin of the *theme* is the *source* (SRC$(theme, source)$) and that the new location of the *theme* is the *goal* frame element (LOC$(theme, goal)$). Moreover, if the text specifies the *cotheme* frame element, then we can make similar statements about it (SRC$(cotheme, source)$ and LOC$(cotheme, goal)$). These new relation instances increase the semantic information that can be derived from text.

So far, we manually inspected 54 frames and analyzed the relationships between their frame elements by examining their definitions and the annotated corpus provided with the FrameNet data. For each frame, we retained only the rules independent of the

CLOTHING_PARTS_F → PW($subpart, clothing$)
CLOTHING_PARTS_F → PW($material, subpart$) *Example:* “Hello, Hank” they said from the depths of the [fur]$_{Material}$ [collars]$_{Subpart,Target}$ of [their]$_{Wearer}$ [coats]$_{Clothing}$. PW($fur, collar$) and PW($collar, coat$)
CLOTHING_F → PAH($descriptor, garment$) ∨ PAH($descriptor, material$) *Example:* She didn’t bring heels with her so she decided on [gold]$_{Descriptor}$ [leather]$_{Material}$ [flip-flops]$_{Garment,Target}$. PAH($gold, leather$) ∨ PAH($gold, flip - flop$)
KINSHIP_F → KIN($ego, alter$) *Example:* The new subsidiary is headed by [Rupert Soames]$_{Alter}$, [son]$_{Target}$ [of the former British Ambassador to France and EC vice-president]$_{Ego}$. KIN(*Rupert Soames*, *the former British Ambassador to France and EC vice-president*)
GETTING_F → POS($recipient, theme$)
GETTING_F → ¬ POS($source, theme$) (only if the *source* is a person) *Example:* In some cases, [the BGS libraries]$_{Recipient}$ had [obtained]$_{Target}$ [copies of theses]$_{Theme}$ [from the authors]$_{Source}$ [by purchase or gift]$_{Means}$, and no loan records were available for such copies. POS(*the BGS libraries*, *copies of theses*) and ¬ POS($authors$, *copies of theses*)
GETTING_F → SRC($theme, source$) (if the *source* is not a person) *Example:* He also said that [Iran]$_{Recipient}$ [acquired]$_{Target}$ [fighter-bomber aircraft]$_{Theme}$ [from countries other than the USA and the Soviet Union]$_{Source}$. SRC(*fighter-bomber aircraft*, *countries other than the USA and the Soviet Union*)

Table 4: Frames-related semantic rules

frame’s lexical units. We identified 132 semantic axioms that hold in most cases[10]. We show some examples in Table 4.

4.2 Context importance

There are cases when the rules that we identified should not be applied. Let’s examine the sentence *John intends to leave the kitchen*. If we consider only the DEPARTING frame and its corresponding rules, without looking at the context, then our conclusions (¬ LOC($John, kitchen$) and SRC($John, kitchen$)) will be false. This sentence states an intention of motion, not the actual action. Therefore, our semantic axioms apply only when the context they are in, allows it. To overcome this problem, we do not apply the axioms for target words found in planning contexts, contexts related to beliefs, intentions, desires, etc. As an alternative, we keep track of plans, intentions, desires, etc. and, if, later on, we confirm them, then we apply the semantic axioms. Also, when we analyze a sentence, the frame whose rules we apply needs to be chosen carefully. For example, in the sentence [*A boat*]$_{Agent}$ [*carrying*]$_{Target}$ [*would-be Moroccan illegal emigrants*]$_{Theme}$ [*from UK*]$_{Path\_start}$ [*to Spain*]$_{Path\_end}$ *sank in the Strait of Gibraltar on June 8*, the CARRYING frame’s axioms do not apply. The boat nor the emigrants reach Spain (the *path_end* of the motion) because the boat sank. Here, the rules given by *sink.v*’s frame should be given priority over the *carry.v*’s rules. We can generalize and conclude that, given a sentence that contains more than one target (therefore, maybe multiple frames), the dominant frame, the one whose rules should be applied, is the frame given by the predicative verb. In the previous sentence, the dominant frame is the one given by *sink.v* and its rules should be applied before the axioms of the CARRYING frame. It should be noted that some of the axioms semantically related to the CARRYING frame still apply (for example, SRC($emigrants, UK$) or SRC($boat, UK$)). Unlike LOC($emigrants, Spain$), the previous relations do not conflict with the semantics given by *sink.v* and its location (*the Strait of Gibraltar*).

5 Experimental Results

5.1 The RTE data

The benchmark corpus for the RTE task consists of seven subsets with a 50%-50% split between the positive entailment examples and the negative ones. Each subgroup corresponds to a different NLP application: Information Retrival (IR), Comparable Documents (CD), Reading Comprehension (RC), Question Answering (QA), Information Extraction (IE), Machine Translation (MT), and Paraphrase Acquisition (PP). The RTE data set includes 1367 English (T, H) pairs from the news domain (political, eco-

[10]Section 4.2 lists some exception cases.

Semantic Axioms	**CD**		**IE**		**IR**		**MT**		**PP**		**QA**		**RC**	
	T	**F**	**T**	**F**	**T**	**F**	**T**	**F**	**T**	**F**	**T**	**F**	**T**	**F**
Test data (%)														
applied to all Ts	13.33	21.33	26.66	10	6.66	4.44	11.66	10	8	0	15.38	7.69	21.43	17.14
applied to all Hs	1.33	9.33	5	10	0	0	1.66	1.66	8	0	1.53	0	0	1.43
solution for (T, H)	9.33	0	20	0	4.44	0	10	1.66	0	0	10.77	1.53	10	5.71
Development data (%)														
applied to all Ts	22	27.08	34.28	5.71	8.57	8.57	18.51	18.51	5.12	9.3	28.88	0	9.61	9.8
applied to all Hs	4	8.33	5.71	2.85	0	2.85	7.4	3.7	0	0	2.22	0	0	1.96
solution for (T, H)	10	2.08	22.85	5.71	5.71	2.85	18.51	3.7	2.56	0	20	0	7.69	0

Table 5: The impact of the semantic axioms on each NLP application data set. **T** and **F** stand for *True* and *False* entailments, respectively.

nomical, etc.). The development set consists of 567 examples and the test set contains the remaining 800 pairs.

5.2 Semantic axiom applicability

We measured the applicability of our set of semantic rules, by counting the number of times they extract new semantic information from text. Table 6 shows, in percentages, the coverage of the semantic axioms when applied to the texts T and the hypotheses H. We also show the number of times the semantic rules solve a (T, H) entailment without employing any other type of axioms.

Semantic Axioms	**True**	**False**	**Overall** (True and False)
Test data (%)			
applied to all Ts	15.75	11.75	13.75
applied to all Hs	2.00	3.74	2.87
both Ts and Hs	8.87	7.75	8.31
solution for (T, H)	10.25	1.50	5.87
Development data (%)			
applied to all Ts	18.02	11.26	14.64
applied to all Hs	2.47	2.81	2.65
both Ts and Hs	10.25	7.04	8.64
solution for (T, H)	12.36	1.76	7.05

Table 6: Applicability on the RTE data

Clearly, because the texts T convey much more information than H, they are the ones that benefit the most from our semantic axioms. The hypotheses H are more straightforward and a semantic parser can extract all their semantic information. Also, the rules tend to solve more positive (T, H) entailments. Because there are seven subsets corresponding to different NLP applications that make up the RTE data, we analyzed the contribution of our semantic axioms to each of the seven tasks. Table 5 shows the axioms' impact on each type of data. The logic-based approach proves to be useful to tasks like Information Extraction, Reading Comprehension, or Comparable Documents, and it doesn't seem to be the right choice for the more lexical-orientated applications like Paraphrase Acquisition, Machine Translation, and Information Retrieval.

5.3 RTE performance

To show the impact of our semantic axioms, we measured the contribution they bring to a system that participated in the RTE challenge. The ACC and F columns (Table 7) show the performance of the system before and after we added our semantic rules to the list of axioms needed by the logic prover.

Task	**Original**		**Enhanced**	
	ACC	F	ACC	F
Test-IR	.478	.472	.5	.505
Test-CD	.78	.736	.847	.819
Test-RC	.514	.558	.6	.636
Test-QA	.485	.481	.523	.537
Test-IE	.483	.603	.575	.687
Test-MT	.542	.444	.567	.49
Test-PP	.45	.585	.44	.576
Test	.551	.561	.604	.621
Development	.63	.619	.718	.714

Table 7: The accuracy(ACC) and f-measure(F) performance values of our system

The results show that richer semantic connectivity between text concepts improve the performance of a semantic entailment system. The overall accuracy increases with around 5% on the test data and almost 8% on the development set. We obtained performance improvements for all application settings, except for the Paraphrase Acquisition task. For this application, we obtained the smallest axiom coverage (Table 5). The impact of the semantic axioms on each NLP application data set correlates with the improvement that the addition of the rules brought to the system's accuracy.

Our error analysis showed that the system did not take full advantage of our semantic axioms, because the semantic parser did not identify all the semantic relations needed as building blocks by the axioms. We noticed a significant decrease in the logic prover's usage of world-knowledge axioms.

6 Conclusion

In this paper, we present a logic-based semantic approach for the *recognizing textual entailment* task. The system participating in the RTE competition used a set of world-knowledge, NLP, and lexical chain-based axioms and an in-house logic prover which received as input the logic forms of the two texts enhanced with semantic relation instances. Because the state-of-the-art semantic parsers cannot extract the complete semantic information encoded in text, the need for *semantic calculus* in NLP became evident. We introduce *semantic axioms* that either combine two semantic instances or label relations between the frame elements of a given frame. Preliminary statistical results show that incorporating semantic rules into the logic prover can double the semantic connectivity between the concepts of the analyzed text. Our process of identifying more semantic instances leads to a smaller dependency of the logic-based RTE system on world knowledge axioms, while improving its overall accuracy.

Abstract

In this paper, we describe an integrated approach to entity mention detection that yields a monolithic, almost language independent system. It is *optimal* in the sense that all categorical constraints are simultaneously considered. The system is compact and easy to develop and maintain, since only a single set of features and classifiers are needed to be designed and optimized. It is implemented using one-versus-all support vector machine (SVM) classifiers and a number of feature extractors at several linguistic levels. SVMs are well known for their ability to handle a large set of overlapping features with theoretically sound generalization properties. Data sparsity might be an important issue as a result of a large number of classes and relatively moderate training data size. However, we report results that the integrated system performs as good as a pipelined system that decomposes the problem into a few smaller subtasks. We conduct all our experiments using ACE 2004 data, evaluate the systems using ACE metrics and report competitive performance.

1 Introduction

The entity-relation (ER) model (Chen, 1976) views the physical world as a collection of entities with complex relationships. Automatic extraction of this model from raw text is important for creating a knowledge base (such as relational databases, marked-up text etc.) that can be used to achieve better end-to-end performances in several natural language processing (NLP) applications including information retrieval, question answering and machine translation. For example, in a typical QA system this knowledge base can be used to facilitate extraction of answers and retrieval of relevant documents.

Entities and relations in a document can be mentioned in several different ways. For example, a person entity, e.g. **Bill Clinton**, can be expressed in many different ways such as *The President*, *President Clinton*, *Mr. Clinton*, *he*, *him* etc. Similarly, one can express a geo-political entity, e.g. **United States**, as *his country* or another person entity, e.g. **Hillary Clinton**, as *his wife*, and their relation to the entity **Bill Clinton** as "president-of" and "family", respectively. It is clear that the detection of these mentions is the first crucial step for the extraction of the ER model to populate a database or an ontology.

Extraction of entities and their relationships is usually done in a pipelined system that first identifies entity mentions, next resolves mentions into unique entities (co-reference) and finally finds relations among them (Florian et al., 2004; Kambhatla, 2004). In that architecture, the errors in the first stage propagate and reduce the performance of subsequent stages; namely, co-reference resolver, that clusters all different mentions of an entity into a unique entity, and relation finder, that links entities according to their relationships. In fact, the subtask of entity mention detection itself is a very challeng-

Table 1: Categorical structure of entities in ACE program

Entity Mention				
Entity			Mention	
Type	Sub-Type	Class	Type	Role

ing subtask since respective expressions can have relatively complex syntactic and categorical ("semantic") structures. That is, entity mentions in a body of text can occur in relatively complex embedded constructs with many attributes. Table 1 illustrates the categorical structure of an entity mention as specified in the Automatic Content Extraction (ACE) program run by NIST (ACE, 2004). Compared to the previous years the number of entity types and subtypes is greater.

The following segment of a sentence provides a typical example of the annotation:

[The [[Jordanian] military] spokesman] added ...

For simplicity, the entity mention attributes are excluded. The annotation clearly shows the embedded structure of entity mentions. We identify three entity mentions as *The Jordanian military spokesman*, *Jordanian military* and *Jordanian*.

Due to its complex nature, it is not uncommon that the mention detection task itself is also divided into a number of smaller sub-tasks. However, in this paper, we adopt an integrated classification approach to this problem that yields a monolithic structure. This allows all attributes, which define the categorical ("semantic") structure of a mention, to be jointly considered. The system has the ability to achieve better performance in principle provided that there is "enough" data to train, is easier to maintain and develop, and has a single set of features and classifiers to be engineered. All possible class labels are obtained by filling in the values of each attribute in the label **etype_subtype_class_mtype_role**, where, to avoid confusion, **etype** and **mtype** are used to denote entity and mention types, respectively.

Our data representation requires segmenting documents into sentences and then tokenizing sentences into words and punctuation. Each word is then assigned a label depending on its role in the mention. This data representation reduces the problem to a tagging task. For each token in focus, we create a number of features at lexical, syntactic and semantic levels. Additionally, we augment those features using features from external resources (e.g. named entity taggers, gazetteers, wordnet). We train a number of one-versus-all classifiers (Allwein et. al, 2000) using SVMs (Vapnik, 1995; Burges, 1998). During testing, classification of each token is performed in a greedy left-to-right manner using a finite-size sliding context window centered at the token in focus (Kudo and Matsumato, 2000).

This approach yields a large number of classes and a large number of overlapping features. We used a machine learning framework based on SVM classification since a large number of classes (in a one-versus-all set-up) and a large number of overlapping features can be easily handled with good generalization properties. We argue that data sparsity and computational complexity is not as severe as it might be expected in the other machine learning methods that are based on maximum likelihood parameter estimation. In other words, we claim that the large set of classification labels and training data sparseness are not major drawbacks. To provide evidence for this we also consider an approach that divides the task into relatively simpler tasks with considerably smaller numbers of labels. The approach yields a pipelined structure in which the decisions in earlier stages are used in later stages. We report results that the integrated approach performs similar to, and in some cases, even slightly better than the pipelined structure.

We also implement a novel post-processing scheme based on an entity base (EB) created from the tagged test data. This is motivated by the fact that an entity is identically referenced several times in a document. However, depending on the capitalization information of the entity mention and context in which it occurs, the entity can be missed at several positions in the document. A simple postprocessing algorithm that checks untagged tokens with low confidence against the EB is implemented. In doing so, it is highly likely that some of those missed entities could be identified. This is expected to reduce misses at the expense of false alarms. We report results that support our expectation.

The paper is organized as follows. Section 2 describes the ACE 2004 data used for training and evaluation. In Section 3, the problem is explained

Table 2: ACE 2004 corpus statistics for English and Chinese text.

Language	Train	Test
English	˜ 150K words	˜ 50K words
Chinese	˜ 150K words	˜ 50K words

and its data representation is introduced. Section 4 describes the general system architecture, that consists of a number of feature extractors, a (machine-learned) classifier and a simple post processor. In section 5, the features used for both English and Chinese systems are described. In section 6, we describe an alternative pipelined system. A novel post processing algorithm is introduced in section 7. Section 8 reports experimental results. Concluding remarks are made in the final section.

2 ACE Data

The ACE 2004 corpus consists of various text annotated for entities and relations. This corpus was created by the Linguistic Data Consortiom (LDC) in three languages: English, Chinese and Arabic (with support from the ACE program that began in 1999). Resources for data are newswire reports and broadcast news programs. Table 2 gives train and test statistics of this corpus for English and Chinese languages. Both languages have almost the same amount of data for both training and evaluation.

3 Problem Description and Data Representation

As shown in Table 1, an entity mention is characterized along 5 dimensions; namely *etype, sub-type class, mtype* and *role*. The ACE program specifies seven entity types; *person, organization, geo-political, location, facility, vehicle, weapon*. All entity types except *person* are further divided into several sub-types. For example, *organization* has *government, commercial, educational, non-profit* and *other* as its sub-types. The *class* attribute describes the kind of reference the entity mention makes to the entity in the world by taking one of the values {*generic, specific, negative, under-specified*} . Entity mentions are further characterized according to linguistic types of references as name (proper noun), nominal (common noun), pronominal (pronoun) and premodifier. The *role* of entity mention applies only to *geo-political* entities indicating the role of the entity in the context of the mention as one of *person, location, organization* and *geo-political*. For further details the reader is referred to (ACE, 2004)

All entity mentions in the original data are XML tagged with their respective attributes. In addition to the full extent of mentions, mention heads are also tagged. Referring to the previous example, the entity mention "The Jordanian military spokesman" which refers to a PERSON has the word "spokesman" as its head. Similarly, the entity mention "Jordanian military" which refers to an ORGANIZATION has the word "military" as its head. If one reduces the problem of entity mention detection to the detection of its head, the nature of the problem changes and the annotation of data becomes flat;

The [**GPE** Jordanian] [**ORG** military] [**PER** spokesman] .....

This allows us to consider the problem as a tagging/chunking problem and describe each word as beginning (B) an entity mention, inside (I) an entity mention or outside (O) an entity mention (Ramhsaw and Marcus, 1995; Sang and Veenstra, 1999). However, we believe that the information regarding the embedded structure in which the heads of entities occur is also useful for subsequent stages of an IE system including inference of relations among heads occurring in the same embedded construct. So, in addition to the IOB tags we introduce bracketing tags that might partially recover the embedded structure surrounding the heads. We refer to the following simple example

[Javier Trevino] was [the campaign manager for [the [ruling party] candidate [Fox] beat]].

to illustrate our tokenwise vertical representation:

#SNT_BEG#

Javier	B-PER_NAM
Trevino	I-PER_NAM
was	O

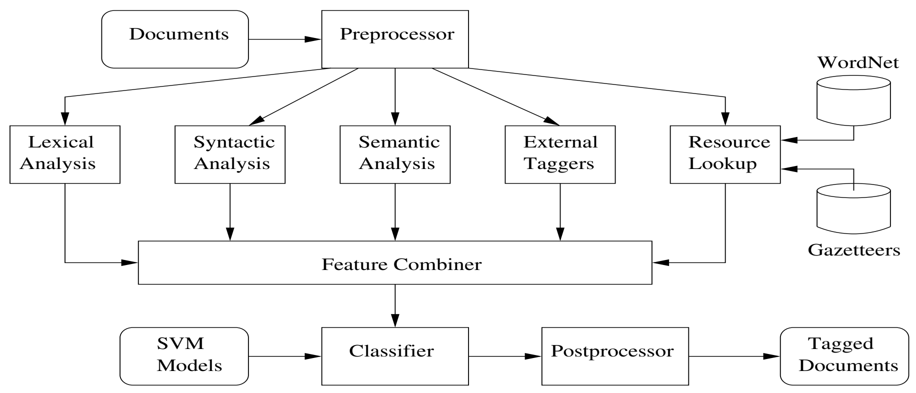

Figure 1: System Architecture

the	(*
campaign	*
manager	B-PER_NOM
for	*
the	(*
ruling	*
party	B-ORG_NOM
candidate	B-PER_NOM
Fox	B-PER_NAM
beat	*))
.	O
#SNT_END#	

If one does not use the bracketing representation, all non-head tokens will be labeled as ”Outside”. We believe that it is useful to discriminate the tokens that take part in mentions from those that do not occur in mentions.

4 General System Architecture

The general system block diagram is illustrated in Figure 1. It consists of a pre-processor, several feature extractors, a classifier and a post-processing module. Although the architecture is language independent, there are some minor language specific differences in some modules depending on the nature of the language and availability of resources for that language. In the following, we briefly describe both English and Chinese systems and indicate differences between them.

In the English system, the pre-processor segments the documents into sentences. It also includes a caser that restores the capitalization information of text without case (e.g. broadcast news) and a tokenizer that separates contractions and punctuation from words. Tokenized sentences are then processed at different linguistic levels to create features. At this stage, we employ a lexical pattern analyzer, part-of-speech tagger, a base phrase chunker, a syntactic parser, a dependency analyzer, look-up interfaces to external knowledge sources, and external small scale named entity taggers trained on different genres of text with different machine learning algorithms. All features are combined and then input to a classifier based on one-versus-all SVM classifiers. Finally, we perform simple post-processing to make sure that the final bracketing information is consistent.

The POS tagger and BP chunker are trained in-house using the Penn TreeBank. The syntactic parser is the Charniak parser which has models trained on the Penn TreeBank. The dependency analyzer performs dependency analysis using a set of head rules. The software was generously made available to us by the University of Maryland. The look-up interface to external knowledge sources such as WordNet or gazetteers is implemented using simple pattern matching.

In the Chinese system, the pre-processor is slightly different from that of the English system. It (obviously) does not need a caser and considers single Chinese characters as the minimal units of processing. It jointly segments a document into sentences and words. Then, it passes both word and sentence segmentation information to the subsequent stages along with Chinese characters. The SVM-based joint sentence/word segmenter is trained using the Chinese TreeBank (CTB). Linguistic analysis at different levels is performed in a manner similar to the analysis in the English system. In the Chinese system, the CTB is used to train a SVM-based POS tagger and BP chunker. The syntactic parser is trained on the CTB using Dan Bikel's parser. Dependency analysis is performed as in the English system using a set of Chinese head rules. Several in-house external taggers are trained using SVMs and different corpora. We have used only gazetteers for chinese as external knowledge sources.

5 Features

The following features are used in the English system:

- **tokens**: words in their original and all lower-cased forms
- **n-grams**: token prefixes and suffixes of length less than and equal to four
- **lexical patterns**: indicate case information (all lower-case, mixed case, first letter capital, all upper-case), is_hyphen, type (numeral, alphanumeral, alpha, other)
- **Part of Speech tags**
- **BP Positions**: The position of a token in a BP using the IOB representation (e.g. B-NP, I-NP, O etc.)
- **Clause tags**: The tags that mark token positions in a sentence with respect to clauses. (e.g *S)*S) marks a position that two clauses end)
- **Named entities-1**: The IOB tags of named entities. There are four categories; LOC, ORG, PERSON and MISC. A SVM-based tagger which is trained on CoNLL 2003 shared task data is used.
- **Named entities-2**: IOB tags of named entities found by the Identifinder (Bikel et. al, 1999); a HMM-based named entity tagger with 29 classes
- **Named entities-3**: IOB tags from a named entity tagger trained on MUC-6 and MUC-7 data using only the entity classes PERSON, LOCATION and ORGANIZATION.
- **Gazetteer labels**: indicate the name of the list to which the token belongs. Simple pattern matching is employed here.
- **WordNet categories**: concepts or class names in the WordNet 2.0 hypernym hierarchy rooted at "entity" concept. We trace hypernym hierarchies of the two most frequent senses of tokens that are tagged as nouns (NN, NNS, NNP etc.) to the top concepts. We count the number of concepts (that match to ACE entity types and subtypes) that occur in the hypernym hierarchy indicating that *token* is a (kind of) *concept*. The concepts (i.e entity/types/subtypes) with the maximum counts in the top two senses are selected as features (can also be considered as "maybe" labels)
- **Syntactic tags**: patterns of non-terminals and brackets that indicate the position of tokens in syntactic trees.
- **Head words**: words that the tokens depend
- **POS of Head words**:
- **main verb**: the verb at which the dependency parse tree is rooted.
- **Relations**: the grammatical and semantic relations between tokens and their heads.
- **Head word flag**: indicates whether the token plays a role of head in the sentence.

The features used in the Chinese system are

- **tokens**: Chinese characters
- **token positions**: IOB tags that indicate position of characters in words
- **Part of Speech tags**: POS tags of words to which tokens (characters) belong
- **BP Positions**: The position of a token in a BP using the IOB representation (e.g. B-NP, I-NP, O etc.)
- **Named entities-1**: IOB tags of two type of entities; *location* and *person*. A SVM based tagger trained on part of the Sinica corpus from Taiwan is used to generate these features.

- **Named entities-2**: IOB tags of named entities: person, location, organization etc. Another SVM based tagger trained on the People Daily data from mainland of China.

- **Gazetteer labels**: indicate the name of the list to which the token belongs. Simple pattern matching is employed here. Examples are labels that indicate Chinese last name, foreign person last name, first name etc.

- **Syntactic labels**: base phrase chunk labels and paths in syntactic trees

- **Head words**: as determined by Chinese dependency analysis

- **POS of Head words**:

- **Relations**: the grammatical and semantic relations between tokens and their heads.

6 A Pipelined System

As mentioned earlier the structure of entity mention categories is very complex. Considering all attributes together yields a large number of classes. One can argue that the large number of classes and data sparsity is an important issue here that it might have significant effect on performance. However, several attempts to divide the task into simpler subtasks have failed to yield a system with a better performance than that of the integrated system. In this section, we describe one such system.

The system consists of three stages in cascade: (i) entity mention extent detector, , (ii) mention type detector and (iii) entity type, subtype and mention role detector. Referring to the earlier example, the data representation in terms of class labels at each level is as follows:

#SNT_BEG#

Javier	(*	B-NAM	PER
Trevino	*)	I-NAM	PER
was	O	O	O
the	(*	O	O
campaign	*	O	O
manager	*	B-NOM	PER
for	*	O	O
the	(*	O	O
ruling	(*	O	O
party	*)	B-NOM	ORG
candidate	*)	B-NOM	PER
Fox	*	B-NAM	PER
beat	*))	O	O
.	O	O	O

#SNT_END#

where the second column is for the extent labels of mentions in bracketed representation, the third column is for the mention type labels in IOB representation and the last column is for the type labels (subtype and role labels are omitted for the sake of simplicity) of entity mentions in plain representation.

The pipelined system operates as follows. First it detects embedding structure of mention extents. Using that information the second stage identifies the type of mentions. In the final stage, the system identifies entity types, subtypes and mention roles using information (as features within context) from previous stages. Finally we combine all information into entity mention attributes and resolve inconsistencies by simple postprocessing.

Here, we have not done any feature selection specific to each stage. Instead we used the same features in all stages. One can argue that this is not the optimal set up for a cascaded system; separate feature design and selection should be made for each stage. Also we acknowledge that there are several other ways of dividing the task into smaller, simpler subtasks. Although we have not explored all possible pipelined architectures with all possible feature selections , we conjecture that the data sparsity is not as big an issue in SVMs as expected to be in the other machine learning algorithms based on maximum likelihood parameter estimation such as those based on maximum entropy (ME) or conditional random fields (CRF) frameworks.

7 A Novel Post-Processing Method

In our experiments, we have consistently observed that the identical mentions of a unique entity are missed depending on the missing capitalization information, unseen context and errors in feature extraction. For example, although the *name* mention of *person* “Eminem” is captured at several positions in the document, the entity mention “eminem” is missed, probably, due to its missing capitalization.

Table 3: Statistics on ACE 2004 data.

Language	Train Samples	Test Samples	# Joint Classes	# Pipelined Classes		
				Extent	MType	EType-SubTypey-Role
English	˜ 167K	˜ 61K	384	24	9	93
Chinese	˜ 307K	˜ 105K	374	15	7	95

As a solution we propose a post-processing method that is based on an entity base (EB) created from the tagged text. We populate the EB with all entity mentions (particularly with those that have *name* values) identified in the text. After we create the EB, we tag the text again by case insensitive pattern matching. We determine all tagged tokens that were initially left untagged or tagged with a different label by the SVM classifier. Using the SVM output (distance from separating hyperplane) as a confidence measure, we accept or reject the new tag based on a preselected threshold.

8 Experiments and Results

In this section, we describe the experiments conducted and results obtained using the ACE 2004 data. The number of training and test examples, which are words/punctuations in English and characters in Chinese, are summarized in Table 3. The number of classes in the joint task and in each pipelined subtask are also included.

In the first set of experiments we evaluated our integrated system and investigated the performance with respect to broad classes of features introduced in section 5, by adding one group of features at a time. Grouping of features into broad classes were done as follows:

- baseline features: tokens
- lexical features: POS, lexical patterns
- syntactic features: base phrase chunks, syntactic tree features
- "semantic" features: heads and grammatical relations
- external features: features from external resources; e.g. wordnet, gazetteers, other entity taggers etc.

Table 4: English system performance with respect to broad classes of features; lex: lexical features, syn: syntactic features, sem: "semantic" features, ext: external features, F_{uw}: unweighted F-score, F_w: weighted F-score, ACE: ACE value.

Feature class	F_{uw}	F_w	ACE
baseline (tokens)	56.5	54.8	36.1
baseline+lex	76.8	86.7	75.6

baseline+lex+syn+sem	77.1	87.8	77.6
baseline+lex+syn+sem+ext	82.0	90.7	82.9

The results are summarized in Table 4 and Table 5 for both English and Chinese systems. Both unweighted and weighted F-scores, and also ACE values are reported. It is interesting to note that significant gains were achieved by simple lexical and external features when they are added. The degree of improvement by using computationally intensive syntactic and dependency analysis is marginal. This might partly be due to the type of features derived from parse trees and partly due to the mismatch of the genre of text to the text on which the syntactic chunker and parser is trained. Since the dependency analysis is based on the syntactic analysis using a set of head rules, the extracted dependency based features might also be inaccurate. Although we observed moderate improvement for English, those features slightly hurt the performance of the Chinese system. This is because of the fact that the Chinese syntactic parser performs relatively worse than the English syntactic parser.

Table 6 presents the integrated and pipelined system performances using all features extracted for English and Chinese. Post-processing results are also included. It shows notable performance improvement with the recovery of many misses by post-processing. It should be noted that, in the pipelined architecture the post-processing is performed twice; at both mention and entity levels.

Table 5: Chinese system performance with respect to broad classes of features; lex: lexical features, syn: syntactic features, sem: "semantic" features, ext: external features, F_{uw}: unweighted F-score, F_w: weighted F-score, ACE: ACE value.

baseline+lex+syn+sem	74.8	83.6	70.8
baseline+lex+syn+sem+ext	78.4	86.8	76.1

9 Conclusions

We have discussed the significance of the entity mention detection in ER model extraction from raw text and presented the complex syntactic and categorical structure of the entity mentions specified in the ACE program. We have explored different ways of representing the problem and implemented two architecturally different (supervised) machine-learning based systems to accomplish the task; namely, a monolithic system and a cascaded system. We have described those systems in detail and empirically compared them. Both systems have achieved comparable performances on English text. However, the integrated system has achived moderately better performance on Chinese text. We have argued that it is easier to develop and maintain the monolithic system since it has a single set of features and classifiers to be tuned. We believe that the performance levels achieved at mid 80s (in ACE values) for English and at upper 70s for Chinese, using only the ACE data, are competitive. We have introduced a post-processing algorithm based on an entity base created during the testing. It has worked very well for both languages to recover several missed entity mentions and considerably improved the performance.

Abstract

We present a system for deciding whether a given sentence can be inferred from text. Each sentence is represented as a directed graph (extracted from a dependency parser) in which the nodes represent words or phrases, and the links represent syntactic and semantic relationships. We develop a learned graph matching approach to approximate entailment using the amount of the sentence's semantic content which is contained in the text. We present results on the Recognizing Textual Entailment dataset (Dagan et al., 2005), and show that our approach outperforms Bag-Of-Words and TF-IDF models. In addition, we explore common sources of errors in our approach and how to remedy them.

1 Introduction

A fundamental stumbling block for several NLP applications is the lack of robust and accurate semantic inference. For instance, question answering systems must be able to recognize, or infer, an answer which may be expressed differently from the query. Information extraction systems must also be able recognize the variability of equivalent linguistic expressions. Document summarization systems must generate succinct sentences which express the same content as the original document. In Machine Translation evaluation, we must be able to recognize legitimate translations which structurally differ from our reference translation.

One sub-task underlying these applications is the ability to *recognize* semantic entailment; whether one piece of text follows from another. In contrast to recent work which has successfully utilized logic-based abductive approaches to inference (Moldovan et al., 2003; Raina et al., 2005b), we adopt a graph-based representation of sentences, and use graph matching approach to measure the semantic overlap of text. Graph matching techniques have proven to be a useful approach for tractable approximate matching in other domains including computer vision. In the domain of language, graphs provide a natural way to express the dependencies between words and phrases in a sentence. Furthermore, graph matching also has the advantage of providing a framework for structural matching of phrases that would be difficult to resolve at the level of individual words.

2 Task Definition and Data

We describe our approach in the context of the 2005 Recognizing Textual Entailment (RTE) Challenge (Dagan et al., 2005), but note that our approach easily extends to other related inference tasks. The system presented here was one component of our research group's 2005 RTE submission (Raina et al., 2005a) which was the top-ranking system according to one of the two evaluation metrics.

In the 2005 RTE domain, we are given a set of pairs, each consisting of two parts: 1) the *text*, a

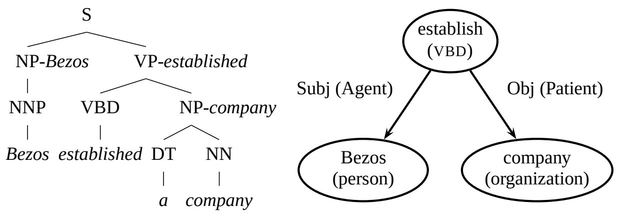

Figure 1: An example parse tree and the corresponding dependency graph. Each phrase of the parse tree is annotated with its head word, and the parenthetical edge labels in the dependency graph correspond to semantic roles.

small passage,[1] and the *hypothesis*, a single sentence. Our task is to decide if the hypothesis is "entailed" by the text. Here, "entails" does not mean strict *logical* implication, but roughly means that a competent speaker with basic world-knowledge would be happy to conclude the hypothesis given the text. This criterion has an aspect of relevance logic as opposed to material implication: while various additional background information may be needed for the hypothesis to follow, the text must substantially support the hypothesis.

Despite the informality of the criterion and the fact that the available world knowledge is left unspecified, human judges show extremely good agreement on this task – 3 human judges independent of the organizers calculated agreement rates with the released data set ranging from 91–96% (Dagan et al., 2005). We believe that this in part reflects that the task is fairly natural to human beings. For a flavor of the nature (and difficulty) of the task, see Table 1.

We give results on the data provided for the RTE task which consists of 567 development pairs and 800 test pairs. In both sets the pairs are divided into 7 tasks – each containing roughly the same number of entailed and not-entailed instances – which were used as both motivation and means for obtaining and constructing the data items. We will use the following toy example to illustrate our representation and matching technique:

Text: In 1994, Amazon.com was founded by Jeff Bezos.
Hypothesis: Bezos established a company.

[1]Usually a single sentence, but occasionally longer.

3 Semantic Representation

3.1 The Need for Dependencies

Perhaps the most common representation of text for assessing content is "Bag-Of-Words" or "Bag-of-N-Grams" (Papineni et al., 2002). However, such representations lose syntactic information which can be essential to determining entailment. Consider a Question Answer system searching for an answer to *When was Israel established?* A representation which did not utilize syntax would probably enthusiastically return an answer from (the 2005 RTE text): *The National Institute for Psychobiology in Israel was established in 1979.*

In this example, it's important to try to match relationships as well as words. In particular, any answer to the question should preserve the dependency between *Israel* and *established*. However, in the proposed answer, the expected dependency is missing although all the words are present.

Our approach is to view sentences as graphs between words and phrases, where dependency relationships, as in (Lin and Pantel, 2001), are characterized by the path between vertices.

Given this representation, we judge entailment by measuring not only how many of the *hypothesis* vertices are matched to the *text* but also how well the relationships between vertices in the hypothesis are preserved in their textual counterparts. For the remainder of the section we outline how we produce graphs from text, and in the next section we introduce our graph matching model.

3.2 From Text To Graphs

Starting with raw English text, we use a version of the parser described in (Klein and Manning, 2003), to obtain a parse tree. Then, we derive a dependency tree representation of the sentence using a slightly modified version of Collins' head propagation rules (Collins, 1999), which make main verbs not auxiliaries the head of sentences. Edges in the dependency graph are labeled by a set of hand-created `tgrep` expressions. These labels represent "surface" syntax relationships such as `subj` for subject and `amod` for adjective modifier, similar to the relations in *Minipar* (Lin and Pantel, 2001). The dependency graph is the basis for our graphical representation, but it is enhanced in the following ways:

Task	Text	Hypothesis	Entailed
Question Answer (QA)	Prince Charles was previously married to Princess Diana, who died in a car crash in Paris in August 1997.	Prince Charles and Princess Diana got married in August 1997.	False
Machine Translation (MT)	Sultan Al-Shawi, a.k.a the Attorney, said during a funeral held for the victims, ”They were all children of Iraq killed during the savage bombing.”.	The Attorney, said at the funeral, ”They were all Iraqis killed during the brutal shelling.”.	True
Comparable Documents (CD)	Napster, which started as an unauthorized song-swapping Web site, has transformed into a legal service offering music downloads for a monthly fee.	Napster illegally offers music downloads.	False
Paraphrase Recognition (PP)	Kerry hit Bush hard on his conduct on the war in Iraq.	Kerry shot Bush.	False
Information Retrieval (IR)	The country's largest private employer, Wal-Mart Stores Inc., is being sued by a number of its female employees who claim they were kept out of jobs in management because they are women.	Wal-Mart sued for sexual discrimination.	True

Table 1: Some Textual Entailment examples. The last three demonstrate some of the harder instances.

1. Collapse Collocations and Named-Entities: We "collapse" dependency nodes which represent named entities (e.g., *Jeff Bezos* in Figure fig-example) and also collocations listed in WordNet, including verbs and their adjacent particles (e.g., *blow_off* in *He blew off his work*) .

2. Dependency Folding: As in (Lin and Pantel, 2001), we found it useful to fold certain dependencies (such as modifying prepositions) so that modifiers became labels connecting the modifier's governor and dependent directly. For instance, in the text graph in Figure 2, we have changed *in* from a word into a relation between its head verb and the head of its NP complement.

3. Semantic Role Labeling: We also augment the graph representation with Probank-style semantic roles via the system described in (Toutanova et al., 2005). Each predicate adds an arc labeled with the appropriate semantic role to the head of the argument phrase. This helps to create links between words which share a deep semantic relation not evident in the surface syntax. Additionally, modifying phrases are labeled with their semantic types (e.g., *in 1991* is linked by a *Temporal* edge in the text graph of Figure 2), which should be useful in Question Answering tasks.

4. Coreference Links: Using a co-rereference resolution tagger, `coref` links are added throughout the graph. These links allowed connecting the referent entity to the vertices of the referring vertex. In the case of multiple sentence texts, it is our only "link" in the graph between entities in the two sentences.

For the remainder of the paper, we will refer to the text as T and hypothesis as H, and will speak of them in graph terminology. In addition we will use H_V and H_E to denote the vertices and edges, respectively, of H.

4 Entailment by Graph Matching

We take the view that a hypothesis is entailed from the text when the cost of matching the hypothesis graph to the text graph is low. For the remainder of this section, we outline a general model for assigning a match cost to graphs.

For hypothesis graph H, and text graph T, a *matching* M is a mapping from the vertices of H to those of T. For vertex v in H, we will use $M(v)$ to denote its "match" in T. As is common in statistical machine translation, we allow nodes in H to map to fictitious NULL vertices in T if necessary. Suppose the cost of matching M is Cost(M). If $\mathcal{M}$ is the set of such matchings, we define the cost of matching H to T to be

$$\text{MatchCost}(H,T) = \min_{M \in \mathcal{M}} \text{Cost}(M) \qquad (1)$$

Suppose we have a model, VertexSub$(v, M(v))$, which gives us a cost in $[0,1]$, for substituting vertex v in H for $M(v)$ in T. One natural cost model is to use the normalized cost for each of the vertex substitutions in M:

$$\text{VertexCost}(M) = \frac{1}{Z}\sum_{v \in H_V} w(v)\text{VertexSub}(v, M(v)) \tag{2}$$

Here, $w(v)$ represents the weight or relative importance for vertex v, and $Z = \sum_{v \in H_V} w(v)$ is a normalization constant. In our implementation, the weight of each vertex was based on the part-of-speech tag of the word or the type of named entity, if applicable. However, there are several other possibilities including using TF-IDF weights for words and phrases.

Notice that when $\text{Cost}(M)$ takes the form of (2), computing $\text{MatchCost}(H, T)$ is equivalent to finding the minimal cost bipartite graph-matching, which can be efficiently computed using linear programming.

We would like our cost-model to incorporate some measure of how relationships in H are preserved in T under M. Ideally, a matching should preserve all local relationships; i.e, if $v \rightarrow v' \in H_E$, then $M(v) \rightarrow M(v') \in T_E$. When this condition holds for all edges in H, H is isomorphic to a subgraph of T.

What we would like is an *approximate* notion of isomorphism, where we penalize the distortion of each edge relation in H. Consider an edge $e = (v, v') \in H_E$, and let $\phi_M(e)$ be the path from $M(v)$ to $M(v')$ in T.

Again, suppose we have a model, $\text{PathSub}(e, \phi_M(e))$ for assessing the "cost" of substituting a direct relation $e \in H_E$ for its counterpart, $\phi_M(e)$, under the matching. This leads to a formulation similar to (2), where we consider the normalized cost of substituting each edge relation in H with a path in T:

$$\text{RelationCost}(M) = \frac{1}{Z}\sum_{e \in H_E} w(e)\text{PathSub}(e, \phi_M(e)) \tag{3}$$

where $Z = \sum_{e \in H_E} w(e)$ is a normalization constant. As in the vertex case, we have weights for each hypothesis edge, $w(e)$, based upon the edge's label; typically subject and object relations are more important to match than others. Our final matching cost is given by a convex mixture of

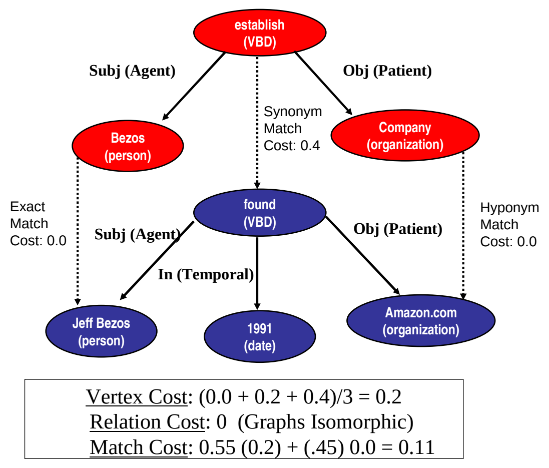

Figure 2: Example graph matching ($\alpha = 0.55$) for example pair. Dashed lines represent optimal matching.

the vertex and relational match costs: $\text{Cost}(M) = \alpha\text{VertexCost}(M) + (1 - \alpha)\text{RelationCost}(M)$.

Notice that minimizing $\text{Cost}(M)$ is computationally hard since if our PathSub model assigns zero cost only for preserving edges, then $\text{RelationCost}(M) = 0$ if and only if H is isomorphic to a subgraph of T. Since subgraph isomophism is an NP-complete problem, we cannot hope to have an efficient exact procedure for minimizing the graph matching cost. As an approximation, we can efficiently find the matching M^* which minimizes $\text{VertexCost}(\cdot)$; we then perform local greedy hill-climbing search, beginning from M^*, to approximate the minimal matching. The allowed operations are changing the assignment of any hypothesis vertex to a text one, and, to avoid ridges, swapping two hypothesis assignments

5 Node and Edge Substitution Models

In the previous section we described our graph matching model in terms of our VertexSub model, which gives a cost for substituting one graph vertex for another, and PathSub, which gives a cost for substituting the path relationship between two paths in one graph for that in another. We now outline these models.

5.1 Vertex substitution cost model

Our $\text{VertexSub}(v, M(v))$ model is based upon a sliding scale, where progressively higher costs are given based upon the following conditions:

- **Exact Match**: v and $M(v)$ are identical words/ phrases.
- **Stem Match**: v and $M(v)$'s stems match or one is a derivational form of the other; e.g., matching *coaches* to *coach*.
- **Synonym Match:** v and $M(v)$ are synonyms according to *WordNet* (Fellbaum, 1998). In particular we use the top 3 senses of both words to determine synsets.
- **Hypernym Match:** v is a "kind of" $M(v)$, as determined by *WordNet*. Note that this feature is asymmetric.
- **WordNet Similarity:** v and $M(v)$ are similar according to `WordNet::Similarity` (Pedersen et al., 2004). In particular, we use the measure described in (Resnik, 1995). We found it useful to only use similarities above a fixed threshold to ensure precision.
- **LSA Match:** v and $M(v)$ are distributionally similar according to a freely available Latent Semantic Indexing package,[2] or for verbs similar according to *VerbOcean* (Chklovski and Pantel, 2004).
- **POS Match:** v and $M(v)$ have the same part of speech.
- **No Match:** $M(v)$ is NULL.

Although the above conditions often produce reasonable matchings between text and hypothesis, we found the recall of these lexical resources to be far from adequate. More robust lexical resources would almost certainly boost performance.

5.2 Path substitution cost model

Our PathSub$(v \rightarrow v', M(v) \rightarrow M(v'))$ model is also based upon a sliding scale cost based upon the following conditions:

- **Exact Match:** $M(v) \rightarrow M(v')$ is an en edge in T with the same label.
- **Partial Match:** $M(v) \rightarrow M(v')$ is an en edge in T, not necessarily with the same label.
- **Ancestor Match:** $M(v)$ is an ancestor of $M(v')$. We use an exponentially increasing cost for longer distance relationships.

[2]Available at `http://infomap.stanford.edu`

- **Kinked Match:** $M(v)$ and $M(v')$ share a common parent or ancestor in T. We use an exponentially increasing cost based on the maximum of the node's distances to their least common ancestor in T.

These conditions capture many of the common ways in which relationships between entities are distorted in semantically related sentences. For instance, in our system, a partial match will occur whenever an edge type differs in detail, for instance use of the preposition *towards* in one case and *to* in the other. An ancestor match will occur whenever an indirect relation leads to the insertion of an intervening node in the dependency graph, such as matching *John is studying French farming* vs. *John is studying French farming practices*.

5.3 Learning Weights

Is it possible to learn weights for the relative importance of the conditions in the VertexSub and PathSub models? Consider the case where match costs are given only by equation (2) and vertices are weighted uniformly ($w(v) = 1$). Suppose that $\Phi(v, M(v))$ is a vector of features[3] indicating the cost according to each of the conditions listed for matching v to $M(v)$. Also let w be weights for each element of $\Phi(v, M(v))$. First we can model the substitution cost for a given matching as:

$$\text{VertexSub}(v, M(v)) = \frac{\exp\left(w^T \Phi(v, M(v))\right)}{1 + \exp\left(w^T \Phi(v, M(v))\right)}$$

Letting $s(\cdot)$ be the 1-sigmoid function used in the right hand side of the equation above, our final matching cost as a function of w is given by

$$c(H, T; w) = \min_{M \in \mathcal{M}} \frac{1}{|H_V|} \sum_{v \in H} s(w^T \Phi(v, M(v))) \tag{4}$$

Suppose we have a set of text/hypothesis pairs, $\{(T^{(1)}, H^{(1)}), \ldots, (T^{(n)}, H^{(n)})\}$, with labels $y^{(i)}$ which are 1 if $H^{(i)}$ is entailed by $T^{(i)}$ and 0 otherwise. Then we would like to choose w to minimize costs for entailed examples and maximize it for non-entailed pairs:

[3]In the case of our "match" conditions, these features will be binary.

$$\ell(w) = \sum_{i:y^{(i)}=1} \log c(H^{(i)}, T^{(i)}; w) + \sum_{i:y^{(i)}=0} \log(1 - c(H^{(i)}, T^{(i)}; w))$$

Unfortunately, $\ell(w)$ is not a convex function. Notice that the cost of each matching, M, implicitly depends on the current setting of the weights w. It can be shown that since each $c(H,T;w)$ involves minimizing $M \in \mathcal{M}$, which depends on w, it is not convex. Therefore, we can't hope to globally optimize our cost functions over w and must settle for an approximation.

One approach is to use coordinate ascent over M and w. Suppose that we begin with arbitrary weights and given these weights choose $M^{(i)}$ to minimize each $c(H^{(i)}, T^{(i)}; w)$. Then we use a relaxed form of the cost function where we use the matchings found in the last step:

$$\hat{c}(H^{(i)}, T^{(i)}; w) = \frac{1}{|H_V|} \sum_{v \in H} s(w^T \Phi(v, M^{(i)}(v)))$$

Then we maximize w with respect to $\ell(w)$ with each $c(\cdot)$ replaced with the cost-function $\hat{c}(\cdot)$. This step involves only logistic regression. We repeat this procedure until our weights converge.

To test the effectiveness of the above procedure we compared performance against baseline settings using a random split on the development set. Picking each weight uniformly at random resulted in 53% accuracy. Setting all weights identically to an arbitrary value gave 54%. The procedure above, where the weights are initialized to the same value, resulted in an accuracy of 57%. However, we believe there is still room for improvement since carefully-hand chosen weights results in comparable performance to the learned weights on the final test set. We believe this setting of learning under matchings is a rather general one and could be beneficial to other domains such as Machine Translation. In the future, we hope to find better approximation techniques for this problem.

6 Checks

One systematic source of error coming from our basic approach is the implicit assumption of upwards monotonicity of entailment; i.e., if T entails H then adding *more* words to T should also give us a sentence which entails H. This assumption, also made by other recent abductive approaches (Moldovan et al., 2003), does not hold for several classes of examples. Our formalism does not at present provide a general solution to this issue, but we include special case handling of the most common types of cases, which we outline below.[4] These checks are done after graph matching and assume we have stored the minimal cost matching.

Negation Check

Text: Clinton's book is not a bestseller

Hypothesis: Clinton's book is a bestseller

To catch such examples, we check that each hypothesis verb is not matched to a text word which is negated (unless the verb pairs are antonyms) and vice versa. In this instance, the *is* in H, denoted by *is*$_H$, is matched to *is*$_T$ which has a negation modifier, *not*$_T$, absent for *is*$_H$. So the negation check fails.

Factive Check

Text: Clonaid claims to have cloned 13 babies worldwide.

Hypothesis: Clonaid has cloned 13 babies.

Non-factive verbs (*claim*, *think*, *charged*, etc.) in contrast to factive verbs (*know*, *regret*, etc.) have sentential complements which do not represent true propositions. We detect such cases, by checking that each verb in H that is matched in T does not have a non-factive verb for a parent.

Superlative Check

Text: The Osaka World Trade Center is the tallest building in Western Japan.

Hypothesis: The Osaka World Trade Center is the tallest building in Japan.

In general, superlative modifiers (*most*, *biggest*, etc.) invert the typical monotonicity of entailment and must be handled as special cases. For any noun n with a superlative modifier (part-of-speech JJS) in H, we must ensure that all modifier relations of $M(n)$ are preserved in H. In this example, *building*$_H$ has a superlative modifier *tallest*$_H$, so we must ensure that each modifier relation of *Japan*$_T$, a noun

[4]All the examples are actual, or slightly altered, RTE examples.

Method	Accuracy	CWS
Random	50.0%	0.500
Bag-Of-Words	49.5%	0.548
TF-IDF	51.8%	0.560
GM-General	56.8%	0.614
GM-ByTask	56.7%	0.620

Table 2: Accuracy and confidence weighted score (CWS) for test set using various techniques.

dependent of *building*$_T$, has a *Western*$_T$ modifier not in H. So its fails the superlative check.

Additionally, during error analysis on the development set, we spotted the following cases where our VertexSub function erroneously labeled vertices as similar, and required special case consideration:

- **Antonym Check:** We consistently found that the `WordNet::Similarity` modules gave high-similarity to antonyms.[5] We explicitly check whether a matching involved antonyms and reject unless one of the vertices had a negation modifier.
- **Numeric Mismatch:** Since numeric expressions typically have the same part-of-speech tag (CD), they were typically matched when exact matches could not be found. However, mismatching numerical tokens usually indicated that H was not entailed, and so pairs with a numerical mismatch were rejected.

7 Experiments and Results

For our experiments we used the devolpement and test sets from the Recognizing Textual Entailment challenge (Dagan et al., 2005). We give results for our system as well as for the following systems:

- Bag-Of-Words: We tokenize the text and hypothesis and strip the function words, and stem the resulting words. The cost is given by the fraction of the hypothesis not matched in the text.
- TF-IDF: Similar to Bag-Of-Words except that there is a tf.idf weight associated with each hypothesis word so that more "important" words are higher weight for matching.

[5]This isn't necessarily incorrect, but is simply not suitable for textual inference.

Task	GM-General		GM-ByTask	
	Accuracy	CWS	Accuracy	CWS
CD	72.0%	0.742	76.0%	0.771
IE	55.9%	0.583	55.8%	0.595
IR	52.2%	0.564	51.1%	0.572
MT	50.0%	0.497	43.3%	0.489
PP	58.0%	0.741	58.0%	0.746
QA	53.8%	0.537	55.4%	0.556
RC	52.1%	0.539	52.9%	0.523

Table 3: Accuracy and confidence weighted score (CWS) split by task on the RTE test set.

We also present results for two graph matching (GM) systems. The GM-General system fits a single global threshold from the development set. The GM-ByTask system fits a different threshold for each of the tasks.

Our results are summarized in Table 2. As the result indicates, the task is particularly hard; all RTE participants scored between 50% and 60% in terms of overall accuracy (Dagan et al., 2005). Nevevertheless, both GM systems perform better than either Bag-Of-Words or TF-IDF. CWS refers to Confidence Weighted Score (also known as average precision). This measure is perhaps a more insightful measure, since it allows the inclusion of a ranking of answers by confidence and assesses whether you are correct on the pairs that you are most confident that you know the answer to. To assess CWS, our n answers are sorted in decreasing order by the confidence we return, and then for each i, we calculate a_i, our accuracy on our i most confident predictions. Then CWS $= \frac{1}{n}\sum_{i=1}^{n} a_i$.

We also present results on a per-task basis in Table 3. Interestingly, there is a large variation in performance depending on the task.

8 Conclusion

We have presented a learned graph matching approach to approximating textual entailment which outperforms models which only match at the word level, and is competitive with recent weighed abduction models (Moldovan et al., 2003). In addition, we explore problematic cases of nonmonotonicity in entailment, which are not naturally handled by either subgraph matching or the so-called "logic form"

Abstract

"Bootstrapping" methods for learning require a small amount of supervision to seed the learning process. We show that it is sometimes possible to eliminate this last bit of supervision, by trying many candidate seeds and selecting the one with the most plausible outcome. We discuss such "strapping" methods in general, and exhibit a particular method for strapping word-sense classifiers for ambiguous words. Our experiments on the Canadian Hansards show that our unsupervised technique is significantly more effective than picking seeds by hand (Yarowsky, 1995), which in turn is known to rival supervised methods.

1 Introduction

Some of NLP's most interesting problems have to do with unsupervised learning. Human language learners are able to discover word senses, grammatical genders, morphological systems, grammars, discourse registers, and so forth. One would like to build systems that discover the same linguistic patterns in raw text. For that matter, one would also like to discover patterns in bilingual text (for translation), in document collections (for categorization and retrieval), and in other data that fall outside the scope of humans' language learning.

There are relatively few successful methods for fully unsupervised learning from raw text. For example, the EM algorithm (Dempster et al., 1977) extracts the "wrong" patterns or gets stuck in local maxima.

One of the most promising avenues in recent years has been the use of "minimally supervised" methods. Such methods are initialized with some sort of "seed" that grows into a full classifier (or generative model). We say that a seed is "fertile" if it grows into a classifier (or model) that performs well on some desired criterion.

Ordinarily, it is up to a human to choose a seed that he or she intuitively expects to be fertile. While this may be easy when building a single classifier, it is prohibitive when building many classifiers. For example, we may wish to build

- word-sense classifiers for all words of a language (e.g., to get sharper lexical translation probabilities in a machine translation system)
- named-entity extractors for many languages
- new clusters or classifiers every day (for an evolving document collection)
- new clusters or classifiers every minute (for the document sets retrieved by *ad hoc* queries)
- many distinct classifiers that correspond to different views of the data[1]

Even when building a single classifier, a human may not know how to pick a good seed when working with an unfamiliar language or sublanguage, or when trying to induce less intuitive hidden variables, such as grammar rules or fine-grained senses. And there is no reason to expect humans to have good intuitions about seeds for mining non-linguistic data such as consumer purchasing records.

This paper considers how to remove this last element of supervision. Our idea is to guess a number of plausible seeds, build a classifier for each one, and then try to determine which of the seeds have grown successfully.

For example, to discover the two senses of the English word *drug*, we grow 200 classifiers (from different seeds) that attempt to partition instances of *drug* into two classes. We have no *direct* supervision about which of the resulting partitions corresponds to the true sense distinction. Instead, we rely on clues that tend to signal that a seed was fertile and led to a good partition. The clues are not specific to the word *drug*, but they may have been demonstrated to be good clues in general for successfully grown word sense disambiguators.

Demonstrated how? If we consider more than one clue, we may need some data to learn which clues to trust, and their relative weights. Our method is unsupervised in the conventional sense, as it obtains a classifier for *drug* with no supervision about *drug*. However, to learn what good classifiers generally look like[2] for this task, we first use

[*]We thank David Yarowsky for advice on the choice of data and for the *plant*/*tank* dataset.

[1]A word token or document can be characterized by a 20-bit vector, corresponding to its classifications by 20 different binary classifiers. These vectors are detailed abstract representations of the words or documents. They can be clustered, or all their bits can be included as potentially relevant features in another task.

[2]Ando and Zhang (2005) independently used this phrase, for a *semi-supervised, cross-task* learner that differs from our *unsupervised, cross-instance* learner. Both their work and ours try to transfer knowledge to a target problem from many artificial supervised "auxiliary problems," which are generated from unlabeled data (e.g., our pseudoword disambiguation problems). However, in their "structural learning," the target problem is *supervised* (if inadequately), and the auxiliary problems (supervised instances of a *different* task) are a source of useful *hidden features for the classifier*. In our "strapping," the target task is *unsupervised*, and the auxiliary problems (supervised instances

supervised data for a few *other* ambiguous words—or ambiguous pseudowords, a kind of artificial data where supervision comes for free. This supervision's effect on *drug* might be called *cross-instance learning*.

To take another metaphor, minimally supervised learning is often called "bootstrapping." Our goal is to allow a method to pull itself up by its own bootstraps[3] even when it has none. It places its stocking feet in anything handy, pulls on what it hopes to be sturdy straps, and checks to see how high it got.

We dub this family of methods "bootstrapping without the boot," or "strapping" for short. The name is meant to evoke "bagging" and "boosting"—other methods that train and combine multiple classifiers of the same form. However, we are careful to point out that strapping, unlike those theoretically motivated methods, is an *unsupervised* learning technique (in the sense explained above). The clusters or other hidden variables extracted by the winning classifier may or may not be the ones that one had hoped to find. Designing a strapping algorithm for a particular task requires more art than designing a supervised learner: one must invent not only appropriate features for classifying the data, but also appropriate clues for identifying "successful" classifiers.

2 Bootstrapping

To show where strapping might be useful, we briefly review a range of successful bootstrapping work. We consider different *tasks*. Given an *instance* of the task and a *seed* s for that instance, one bootstraps a classifier C_s that can classify *examples* of the task instance.

2.1 The Yarowsky algorithm

Yarowsky (1995) sparked considerable interest in bootstrapping with his successful method for word sense disambiguation. An instance of this task involves a homonymous word such as *drug*. A seed for the instance is a pair of words that are strongly associated, respectively, with the two senses of *drug*, such as (*trafficking*, *therapy*). An example is a token of *drug*.

For our purposes, a bootstrapping method can be regarded almost as a black box. However, we review the details of the Yarowsky algorithm to illustrate how bootstrapping is possible, and why some seeds are better than others. We will use these intuitions later in designing a method to strap the Yarowsky algorithm on a new instance—i.e., a method for *automatically* choosing seeds that discover a true sense distinction.

A learned classifier for the instance *drug* is an ordered decision list of contextual features (such as the presence of *dealer* nearby) that strongly indicate one or the other sense of *drug*. Given a sample token of *drug*, the classifier picks a sense according to the single highest-ranked feature that is present in the token's context.

To bootstrap a decision-list classifier from a seed, Yarowsky starts with all examples of *drug* that can be classified by using the seed words as the only features. These few examples are used as supervised data to train a longer decision list, which includes the seed words and any other features that suffice to distinguish these examples with high confidence. This longer decision list can now classify further examples, which are used to train a new and even longer decision list, and so on.

Yarowsky's method works if it can maintain high accuracy as it gradually increases its coverage. A precise classifier at iteration t tends to accurately classify new examples. This tends to produce a still-accurate classifier with greater coverage at iteration $t + 1$.

The method fails if the initial classifier is inaccurate (i.e., if the two seed words do not accurately pick out examples of the two senses). It may also fail if at some point, by bad luck on sparse data, the process learns some inappropriate features. If the classifier at iteration t is sufficiently polluted by bad features, the classifier at iteration $t + 1$ will start trying to distinguish examples that do *not* correspond to different senses, which may lead to even worse classifiers on subsequent iterations. However, some alternative seed may have escaped this bad luck by sprouting a different set of examples.

2.2 A Few Other Applications of Bootstrapping

Inspired by Yarowsky, Blum and Mitchell (1998) built a classifier for the task of web page classification.[4] They considered only one instance of this task, namely distinguishing course home pages from other web pages at a computer science department. Their seed consisted of 3 positive and 9 negative examples. Strapping a web page classifier would mean identifying seeds that lead to other "natural classes" of web pages. Strapping may be useful for unsupervised text categorization in general.

Riloff et al. (2003) learned lists of subjective nouns in English, seeding their method with 20 high-frequency, strongly subjective words. This seed set was chosen manually from an automatically generated list of 850 can-

of the *same* task) are a source of *clues for a meta-classifier* that chooses among classifiers grown from different seeds. In short, their auxiliary problems help train the target classifier directly, while ours help train only a simple meta-classifier that chooses among many unsupervised target classifiers. We use far fewer auxiliary problems but ours must be instances of the target task.

[3]The reference is to Baron Munchausen, a fictional 18th-century adventurer who rescued himself from a pit in this way. It is distinct from the "bootstrap" in non-parametric statistics.

[4]More precisely, they bootstrapped *two* Naive Bayes classifiers—one that looked at page content and the other that looked at links to the page. This "co-training" approach has become popular. It was also used by the Cucerzan and Yarowsky papers below, which looked at "internal" and "external" features of a phrase.

didate words. Strapping their method would identify subjective nouns in other languages, or other "natural classes" of English words.

Query expansion in IR searches for more documents "similar to" a designated relevant document. This problem too might be regarded as searching for a natural class—a small subset of documents that share some property of the original document—and approached using iterative bootstrapping. The seed would specify the original document *plus* one or two additional words or documents initially associated with the "relevant" and/or "irrelevant" classes. Strapping would guess various different seeds that extended the original document, then try to determine which seeds found a *cohesive* "relevant set."

Collins and Singer (1999) bootstrapped a system for classifying phrases in context. Again, they considered only one instance of this task: classifying English proper names as persons, organizations, or locations. Their seed consisted of 7 simple rules ("that *New York, California,* and *U.S.* are locations; that any name containing *Incorporated* is an organization; and that *I.B.M.* and *Microsoft* are organizations"). Strapping such a classifier would automatically discover named-entity classes in a different language, or other phrase classes in English.

Cucerzan and Yarowsky (1999) built a similar system that identified proper names as well as classifying them. Their seed consisted of a list of 40 to 300 names. Large seeds were not necessary for precision but did help recall.

Cucerzan and Yarowsky (2003) classified masculine vs. feminine nouns. They experimented with several task instances, namely different Indo-European languages. In each instance, their seed consisted of up to 30 feminine and 30 masculine words (e.g., *girl, princess, father*).

Many more papers along these lines could be listed. A rather different task is grammar induction, where a task instance is a corpus of text in some language, and the learned classifier is a parser. Following Chomsky (1981), we suggest that it may be possible to seed a grammar induction method with a small number of facts about the word order of the language: the basic clause order (SVO, SOV, etc.), whether pronominal subjects may be omitted (Chomsky's "*pro*-drop" parameter), etc. These facts can for example be used to construct a starting point for the inside-outside algorithm (Baker, 1979), which like other EM algorithms is highly sensitive to starting point. In a strapping method, one would guess a number of different seeds and evaluate the learned grammars on likelihood, entropy (Wang et al., 2002), correlation with semantics, or plausibility on other linguistic grounds that were not considered by the likelihood or the prior.

3 Strapping

Given a seed s for some task instance, let C_s denote the classifier grown from s. Let $f(s)$ denote the true fertility of a seed s, i.e., the performance of C_s measured against some set of correct answers for this instance. In general, we do not know the correct answers and hence do not know $f(s)$. That is why we are doing *unsupervised* learning.

Strapping relies on two *estimates* of $f(s)$. Let $g(s)$ be a quick estimate that considers only superficial features of the seed s. $h(s)$ is a more careful estimate that can be computed once C_s has been grown.

The basic method for strapping a classifier for a new task instance is very simple:

1. Quickly select a set S of candidate seeds such that $g(s)$ is high.
2. For each seed $s \in S$, learn a classifier C_s and measure $h(s)$.
3. Choose the seed $\hat{s} \in S$ that maximizes $h(\hat{s})$.
4. Return $C_{\hat{s}}$.

Variants on this method are obviously possible. For example, instead of returning a single classifier $C_{\hat{s}}$, one might use classifier combination to combine several classifiers C_s that have high $h(s)$.

It is clearly important that g and h be good estimates of f. Can data help us design g and h? Unfortunately, f is not known in an unsupervised setting. However, if one can get a few *supervised* instances of the same task, then one can select g and h so $g(s)$ and $h(s)$ approximate $f(s)$ for various seeds s for *those* instances, where $f(s)$ can be measured directly. The same g and h can then be used for *unsupervised* learning on all *new* task instances.

3.1 Selecting Candidate Seeds

The first step in strapping a classifier is to select a set S of seeds to try. For strapping to work, it is crucial that this set contain a fertile seed. How can this be arranged? Different strategies are appropriate for different problems and bootstrapping methods.

- Sometimes a simple heuristic $g(s)$ can help identify plausibly fertile seeds, as in the pseudocode above. In strapping the Yarowsky algorithm, we hope to find seeds $s = (x, y)$ such that x and y are strongly associated with different senses of the ambiguous target word. We choose $s = (x, y)$ such that x and y were never observed in the same sentence, but each of x and y has high pointwise mutual information with the ambiguous target word and appeared with it at least 5 times.
- If the space of possible seeds is small, it may be possible to try many or all of them. In grammar induction, for example, perhaps seeding with a few basic word order facts is enough. There are not so many basic word orders to try.

- Some methods have many fertile seeds—so many that a small random sample (perhaps filtered by $g(s)$) is likely to include at least one. We rely on this for the Yarowsky algorithm. If the target word is a true homonym, there exist many words x associated strongly with the first sense, and many words y associated strongly with the second sense. It is not difficult to stumble into a fertile seed $s = (x, y)$, just as it is not difficult for a human to think of one.[5]
- If fertile seeds are few and far between, one could abandon the use of a candidate set S selected by $g(s)$, and directly use general-purpose search methods to look for a seed whose predicted fertility $h(s)$ is high.

  For example, one could use genetic algorithms to breed a population of seeds with high $h(s)$. Or after evaluating several candidate seeds to obtain $h(s_1), h(s_2), \ldots h(s_k)$, one could perform a regression analysis that predicts $h(s)$ from superficial features of s, and use this regression function (a kind of $g(s)$ that is specific to the task instance) to pick s_{k+1}.

Strapping may be harder in cases like gender induction: it is hard to stumble into the kind of detailed seed used by Cucerzan and Yarowsky (2003). However, we suspect that fertile seeds exist that are much smaller than their lists of 50–60 words. While their large hand-crafted seed is sure to work, a handful of small seeds (each consisting of a *few* supposedly masculine and feminine words) might be likely to contain at least one that is fertile.[6] That would be sufficient, assuming we have a way to guess which seed in the handful is most fertile. That issue is at the core of strapping, and we now turn to it.

3.2 Clues for Evaluating Bootstrapped Classifiers

Once we have identified a candidate seed s and built the classifier C_s, we must evaluate whether C_s "looks like" the kind of classifier that tends to do well on our task.

This evaluation function $h(s)$ is task-specific. It may consider features of C_s, the growth trajectory of C_s, or the relation between C_s and other classifiers.

For concretness, we consider the Yarowsky method for word-sense disambiguation (WSD). How can we tell if a seed $s = (x, y)$ was fertile, without using even a small validation set to judge C_s? There are several types of *clues* to fertility, which may be combined into a meta-classifier that identifies fertile seeds.

Judge the result of classification with C_s: Even without a validation set, the result of running C_s on the training corpus can be validated in various ways, using independent plausibility criteria that were *not* considered by the bootstrapping learner.

- Is the classification reasonably balanced? (If virtually all examples of the target word are labeled with the same sense, then C_s has not found a sense distinction.)
- When a document contains multiple tokens of the target word, are all examples labeled with the same sense? This property tends to hold for correct classifiers (Gale et al., 1992a), at least for homonyms.
- True word senses usually correlate with document or passage topic. Thus, choose a measure of similarity between documents (e.g., the cosine measure in TF/IDF space). Does the target word tend to have the same sense in a document and in its nearby neighbors?
- True word senses may also improve performance on some task. Is the perplexity of a language model much reduced by knowing whether sense x or sense y (according to C_s) appeared in the current context? (This relates to the previous point.) Likewise, given a small bilingual text that has been automatically (and perhaps poorly) word-aligned, is it easier to predict how the target word will translate when we know its sense (according to C_s)?

Judge the internal structure of C_s: Does C_s look like a typical supervised decision list for word-sense disambiguation? For instance, does it contain many features with high log-likelihood ratios? (If a true sense distinction was discovered, we would expect *many* contextual features to correlate strongly with the predicted sense.)

Look at the process whereby C_s was learned: Does the bootstrapping run that starts from s look like a typical bootstrapping run from a fertile seed? For example, did it rapidly add many new examples with high confidence? Once new examples were classified, did their classifications remain stable rather than switching back and forth?

Judge the robustness of learning with seed s: Train several versions of C_s, as in ensemble methods (but unsupervised), by restricting each to a random subset of the data, or a subset of the available features. Do these versions tend to *agree* on how to classify the data? If not, seed s does not reliably find true (or even false) classes.

Judge the agreement of C_s with other classifiers: Are there several other classifiers $C_{s'}$ that agree strongly with C_s on examples that they both classify? If the sense

[5]Alignment methods in machine translation rely even more heavily on this property. While they begin with a small translation lexicon, they are sufficiently robust to the choice of this initial seed (lexicon) that it suffices to construct a single seed by crude automatic means (Brown et al., 1990; Melamed, 1997). Human supervision (or strapping) is unnecessary.

[6]This is particularly likely if one favors function words (in particular determiners and pronouns), which are strong indicators of gender. Cucerzan and Yarowsky used only content words because they could be extracted from bilingual dictionaries.

distinction is real, then many different seeds should be able to find it.

3.3 Training the Evaluation Function $h(s)$

Many of the above clues are necessary but not sufficient. For example, a learned classification may be robust without being a sense distinction. We therefore define $h(s)$ from a combination of several clues.

In general, $h(s)$ is a classifier or regression function that attempts to distinguish fertile from infertile seeds, given the clues. As mentioned earlier, we train its free parameters (e.g., coefficients for linear regression) on a few *supervised* instances of the task. These supervised instances allow us to measure the fertility $f(s)$ of various seeds, and thus to model the behavior of fertile versus infertile seeds. The presumption is that these behavior patterns will generalize to new seeds.

3.4 Training $h(s)$ on Artificial Data

Optionally, to avoid the need for any human annotation at all, the supervised task instances used to train $h(s)$ may be *artificial* instances, whose correct classifications are known without annotation.

In the case of word-sense disambiguation, one can automatically construct ambiguous *pseudowords* (Gale et al., 1992c; Schütze, 1998) by replacing all occurences of two words or phrases with their conflation. For example, *banana* and *wine* are replaced everywhere by *banana-wine*. The original, unconflated text serves as a supervised answer key for the artificial task of disambiguating *banana-wine*.

Traditionally, pseudowords are used as cheap test data to evaluate a disambiguation system. Our idea is to use them as cheap development data to tune a system. In our case, they tune a few free parameters of $h(s)$, which says what a good classifier for this task looks like. Pseudowords should be plausible instances of the task (Gaustad, 2001; Nakov and Hearst, 2003): so it is deliberate that *banana* and *wine* share syntactic and semantic features, as senses of real ambiguous words often do.

Cheap "pseudo-supervised" data are also available in some other strapping settings. For grammar induction, one could construct an artificial probabilistic grammar at random, and generate text from it. The task of recovering the grammar from the text then has a known answer.

4 Experiments

4.1 Unsupervised Training/Test Data

Our experiments focused on the original Yarowsky algorithm. We attempted to strap word-sense classifiers, using English data only, for English words whose French translations are ambiguous. This has obvious benefits for training an English-to-French MT system: separate parameters can be learned for the two senses of *drug*.[7]

Gale et al. (1992b) identified six such words in the Canadian Hansards, a parallel sentence-aligned corpus of parliamentary debate in English and French: *drug, duty, land, language, position, sentence*. We extracted all examples of each word from the 14-million-word English portion of the Hansards.[8] Note that this is considerably smaller than Yarowsky's (1995) corpus of 460 million words, so bootstrapping will not perform as well, and may be more sensitive to the choice of seed.

Because we are doing unsupervised learning, we both trained and tested these 6 words on the English Hansards. We used the French portion of the Hansards only to create a gold standard for evaluating our results.[9] If an English sentence containing *drug* is paired with a French sentence that contains exactly one of *médicament* or *drogue*, we take that as an infallible indicator of its sense.

4.2 Comparing Classifiers

Suppose binary classifier 1 assigns class "+" to a of n examples; binary classifier 2 assigns class "+" to b of the same n examples. Let e be the number of examples where the classifiers agree (both "+" or both "–").

An unsupervised classifier's polarity is arbitrary: classifier 1's "+" may correspond to classifier 2's "–". So we define the *overlap* as $E = \max(e, n - e)$, to reflect the best polarity.

To evaluate a learned classifier, we measure its overlap with the true classification. The statistical significance is the probability that this level of overlap would be reached by chance under independent classifications given the values a, b, n:

$$p = \sum_{\substack{\max(a+b-n,0) \,\le\, c \,\le\, \lfloor (a+b-E)/2 \rfloor \\ \text{or} \\ \lceil (a+b-(n-E))/2 \rceil \,\le\, c \,\le\, \min(a,b)}} \binom{a}{c} \binom{n-a}{b-c} \Big/ \binom{n}{b}$$

Also, we can measure the *agreement* between any two learned classifiers as $-(\log p)/n$. Note that a classifier that strongly favors one sense will have low agreement with other classifiers.

[7]To hedge against the possibility of misclassification, one could interpolate with non-sense-specific parameters.

[8]We are not certain that our version of the Hansards is identical to that in (Gale et al., 1992b).

[9]By contrast, Gale et al. (1992b) used the French portion as a source of training supervision. By contrast, we will assume that we do *not* have a large bilingual text such as the Hansards. We train only on the English portion of the Hansards, ignoring the French. This mimics the situation where we must construct an MT system with very little bilingual text. By first discovering word senses in unsupervised monolingual data (for either language), we can avoid incorrectly mixing up two senses of *drug* in our translation model.

4.3 Generating Candidate Seeds (via $g(s)$)

For each target word t, we chose candidate seeds $s = (x, y)$ with a high score $g(s)$, where $g(s) = \mathrm{MI}(t, x) + \mathrm{MI}(t, y)$, provided that $c(x, y) = 0$ and $c(t, x) \geq 5$ and $c(t, y) \geq 5$ and $1/9 < c(t, x)/c(t, y) < 9$.[10]

The set S of 200 seeds for t was constructed by repeatedly adding the top-scoring unused seed to S, except that to increase the variety of words, we disallowed a seed $s = (x, y)$ if x or y already appeared 60 times in S.

4.4 Hand-Picked Seeds

To compare, we chose two seeds by hand for each t.

The *casually* hand-picked seed was chosen by intuition from the list of 200 automatically generated seeds. This took about 2 minutes (per seed).

The *carefully* hand-picked seed was not limited to this list, and took up to 10 minutes to choose, in a data-guided fashion. We first looked at some supervised example sentences to understand the desired translational sense distinction, and then for each sense chose the highest-MI word that both met some stringent subjective criteria and appeared to retrieve an appropriate initial set of examples.

4.5 The Bootstrapping Classifier

Our approximate replication of Yarowsky's algorithm used only a small set of features:

- Original and lemmatized form of the word immediately preceding the target word t.
- Original and lemmatized form of the word immediately following t.
- Original and lemmatized form of the *content* words that appear in the same sentence as t.

We used the seed to provisionally classify any token of the target word that appeared in a sentence with exactly one of the two seed words. This formed our initial "training set" of disambiguated tokens. At each iteration of the algorithm, we trained a decision list on the current training set. We then used the decision list to reclassify all k tokens in the current training set, and also to augment the training set by classifying the *additional* $\max(50, k/10)$ tokens on which the decision list was most confident.[11]

[10] $c(x, y)$ counts the sentences containing both x and y. MI(t, x) $= \log c(t, x)c()/c(t)c(x)$ is pointwise mutual information.

[11] Such a token has some feature with high log-likelihood ratio, i.e., it strongly indicates one of the senses in the current training set. We smoothed using the method of (Yarowsky, 1996): when a feature has been observed with only one sense, its log-likelihood ratio is estimated as a linear function of the number of occurrences of the seen sense. Function words are smoothed with a different linear coefficient than content words, in order to discount their importance. We borrowed the actual coefficients from (Yarowsky, 1996), though we could have learned them.

4.6 Development Data (for tuning $h(s)$)

Before turning to the unsupervised Hansards, we tuned our fertility estimator $h(s)$ to identify good seeds on development data—i.e., on other, supervised task instances.

In the *supervised* condition, we used just 2 additional task instances, *plant* and *tank*, each with 4000 hand-annotated instances drawn from a large balanced corpus (Yarowsky, 1995).

In the *pseudo-supervised* condition, we used *no hand-annotated data*, instead constructing 10 artificial supervised task instances (section 3.4) from the English portion of the Hansards. To facilitate cross-instance learning, we tried to construct these pseudowords to behave something like our ambiguous test words.[12] Given a test word t, we randomly selected a seed (x, y) from its candidate list (section 4.3), excluding any that contained function words.[13] Our basic idea was to conflate x and y into a pseudoword x-y. However, to get a pseudoword with only two senses, we tried to focus on the particular senses of x and y that were selected by t. We constructed about 500 pseudoword tokens by using only x and y tokens that appeared in sentences that contained t, or in sentences resembling those under a TF-IDF measure. We repeated this process twice per test word to obtain 12 pseudowords. We then discarded the 2 pseudowords for which no seed beat baseline performance, reasoning that they were ill-chosen and unlike real ambiguous words.[14]

4.7 Clues to Fertility

For each seed s for each development or test target word, we measured a few clues $h_1(s), h_2(s) \ldots h_6(s)$ that we hoped might correlate with fertility. (In future work, we plan to investigate more clues inspired by section 3.2.)

- The *agreeability* of C_s with (some of) the other 199 classifiers:

$$\left(\frac{1}{199} \sum_{s' \neq s} \mathrm{agr}(C_s, C_{s'})^\gamma \right)^{1/\gamma}$$

  The agreement agr($C_s, C_{s'}$) was defined in section 4.2. We tried 4 values for γ (namely 1, 2, 5, 10), each resulting in a different feature.

[12] We used collocates of t. Perhaps better yet would be words that are distributionally similar to t (appear in same contexts). Such words tend to be syntactically and semantically like t.

[13] For an unknown language or domain, a lexicon of function words could be constructed automatically (Katz, 1996).

[14] Thus we discarded *alcohol-trafficking* and *addicts-alcohol*; note that these were indeed ill-chosen (difficult) since both words unluckily corresponded to the *same* sense of *drug*. This left us with *bound-constituents, customs-pray, claims-value, claims-veterans, culture-unparliamentary, english-learn, competitive-party, financial-party, death-quote, death-page.*

- The *robustness* of the seed, defined by the agreement of C_s with 10 variant classifiers $C_s^{(k)}$ that were trained with the same seed but under different conditions:

$$\frac{1}{10}\sum_{k=1}^{10} \text{agr}(C_s, C_s^{(k)})$$

  We simply trained each classifier $C_s^{(k)}$ on a random subset of the n test examples, chosen by sampling n times with replacement.[15]

- The *confidence* of C_s on its own training data: its average confidence over the n training tokens, minus the *classifier skew*.

  The decision list's confidence on a token is the log-likelihood ratio of the single feature used to classify that token. It has the form $|\log(c/d)|$ (perhaps smoothed) and was previously used to select data while bootstrapping C_s. Subtracting the skew, $|\log(a/(n-a))|$,[16] gives a measurement ≥ 0. It corrects for confidence that arises from the classifier's overall bias, leaving only the added value of the relevant contextual feature.

4.8 Tuning $h(s)$ and Strapping New Classifiers

For each of the 2 words or 10 pseudowords t in our development set (see section 4.6), we ranked its 200 seeds s by their true fertility $f(s)$. We then ran support vector regression[17] to learn a single linear function, $h(s) = \vec{w} \cdot$ (clue vector for C_s), that predicts the fertilities of all $2 \cdot 200$ or $10 \cdot 200$ seeds.[18]

Then, for each of our 6 Hansards test instances (section 4.1), we used $h(s)$ to pick the *top*-ranked of 200 seeds.[19] It took about 3 hours total to strap classifiers for all 6 instances, using about 40 machines and unoptimized Perl code on the 14-million-word Hansards. For each of the 6 instances, this involved selecting 200 candidate seeds, bootstrapping 11 classifiers $C_s, C_s^{(1)}, \ldots C_s^{(10)}$ from each seed, and choosing a particular C_s to return.

4.9 Results

Our results are in Table 1. On both development and test instances of the task, $g(s)$ proposed seeds with a good range of fertilities. The correlation of predicted with actual fertility on test data averaged an outstanding 85%.

Despite having no knowledge of the desired senses, strapping significantly beat human selection in *all 24* of the possible comparisons between a hand-picked seed (casual or careful) and a strapped seed (chosen by an $h(s)$ tuned on supervised or pseudo-supervised instances).

The $h(s)$ tuned on annotated *plant/tank* actually chose the *very best* of the 200 seeds in 4 of the 6 instances. The $h(s)$ tuned on artificial pseudowords did nearly as well, in 2 of 6 instances identifying the very best seed, and in 5 of 6 instances ranking it among its top 3 choices.

We conclude that our unsupervised clues to fertility actually work. Furthermore, combining clues via regression was wise, as it tended to work better than any single clue. Somewhat better regression weights for the WSD task were learned from 2 out-of-domain hand-annotated words than from 10 in-domain artificial pseudowords.

5 Open Questions

The work reported here raises many interesting questions for future research.

In the WSD task, we have only considered word types with two unrelated senses (homonyms). A more general problem is to determine when a word type is ambiguous at all, and if so, how many coarse-grained or fine-grained senses it has. Strapping seems naturally suited to this problem, since it aims to discover when a sense distinction grown from some seed is a *true* sense distinction.

Then we would like to know how well strapping generalizes to additional bootstrapping scenarios. Our WSD strapping experiments were successful using only a subset of the techniques proposed in section 3. Generalizing to other tasks may require other techniques for selecting and evaluating candidate seeds, and perhaps combining the resulting classifiers.

An interesting question is whether strapping can be used in an active learning context. Active learning is a kind of bootstrapping method that periodically requires new seeds: it turns to the user whenever it gets confused. Perhaps some of these seeds can be guessed nondeterministically and the guesses evaluated automatically, with or without user confirmation.

Finally, there may be theoretical guarantees about strapping when something is known about the data. When $h(s)$ is trained to estimate $f(s)$ well on some supervised instances, there may be guarantees about how strapping will perform on unsupervised instances drawn

[15]We eliminated duplicates, perhaps unfortunately.

[16]As before, a and $n - a$ are the numbers of tokens that C_s classifies as "+" and "–" respectively. Thus the skew is the log-likelihood ratio of the decision list's "baseline" feature.

[17]We used cross-validation among the 10 development pseudowords to choose the options to SVM*light* (Joachims, 1999): a linear kernel, a regularization parameter of 0.3, and a dependent variable of $10^{f(s)} \in [1, 10]$ rather than $f(s) \in [0, 1]$, which placed somewhat more emphasis on modeling the better seeds. Our development objective function was the average over the 10 pseudowords of the Spearman rank-order correlation between $h(s)$ and $f(s)$.

[18]We augmented the clue vector with binary clues of the form $t =$ *plant*, $t =$ *tank*, etc. The regression weight of such a clue is a learned bias term that models the inherent difficulty of the task instance t (which varies greatly by t). This allows the other regression features to focus on the quality of the seed *given* t.

[19]We do not have a clue $t = \ldots$ for this test instance. The resulting lack of a bias term may subtract a constant from the predicted fertilities—but that does not affect the ranking of seeds.

Table 1: [See section 4.9 for highlights.] Accuracy (as percentage) and rank (in parentheses) of bootstrapped classifiers for variously chosen seeds, some of which are shown. * denotes statistically significant agreement with the truth (section 4.2, $p < 0.01$). † denotes a seed having significantly better agreement with the truth than does the better of the hand-picked seeds (McNemar's test, $p < 0.03$). In each column, the best performance for an automatic or manual seed appears in **boldface**. The "most …" lines use no tuning, the "plant/tank" line tunes $h(s)$ on 2 supervised instances, and the subsequent lines tune $h(s)$ on 10 pseudoword instances. The last line gives the Spearman rank-order correlation between seeds' predicted fertilities $h(s)$ and their actual fertilities $f(s)$.

from the same source (cross-instance learning). Even in the fully unsupervised case, it may be possible to prove that if the data were generated from a particular kind of process (e.g., a Gaussian mixture), then a certain strapping algorithm can recover the hidden variables.

6 Conclusions

In this paper, we showed that it is sometimes possible—indeed, preferable—to eliminate the initial bit of supervision in "bootstrapping" algorithms such as the Yarowsky (1995) algorithm for word sense disambiguation. Our "strapping" approach tries many candidate seeds as starting points and evaluates them automatically. The evaluation function can be tuned if desired on other task instances, perhaps artificially constructed ones. It can then be used wherever human guidance is impractical.

We applied the method to unsupervised disambiguation of English words in the Canadian Hansards, as if for English-French translation. Our results (see section 4.9 for several highlights) show that our automatic "strapped" classifiers consistently outperform the classifiers bootstrapped from manually, knowledgeably chosen seeds.

Differentiating Homonymy and Polysemy in Information Retrieval

Christopher Stokoe

christopher.stokoe@sunderland.ac.uk

Abstract

Recent studies into Web retrieval have shown that word sense disambiguation can increase retrieval effectiveness. However, it remains unclear as to the minimum disambiguation accuracy required and the granularity with which one must define word sense in order to maximize these benefits. This study answers these questions using a simulation of the effects of ambiguity on information retrieval. It goes beyond previous studies by differentiating between homonymy and polysemy. Results show that retrieval is more sensitive to polysemy than homonymy and that, when resolving polysemy, accuracy as low as 55% can potentially lead to increased performance.

1 Introduction

Lexical ambiguity refers to words that share the same orthography but have different meanings (word senses). It can be sub-divided into two distinct types, homonymy and polysemy. Homonymy describes when two senses of a given word (or derivation) are distinct. Typically, they are separated by etymology and are therefore entirely unrelated in meaning. One classic example (Kilgarriff, 1992) is '*bat*' as in an airborne mammal (from the Middle English word '*bakke'* meaning flying rodent) vs. '*bat*' as in an instrument used in the game of cricket (from the Celtic for stick or cudgel). There is no underlying relationship between these two meanings which have come about independently from differing root languages. Alternatively, polysemy describes where two senses of a word are related in that they share membership of a subsuming semantic classification. Consider the word '*mouth*' as in a part of the body vs. '*mouth*' as in the outlet of a river. Both meanings are subsumed by a higher concept (in this case they both describe an opening). Homonymy and polysemy are differentiated in most dictionaries by the major (homonyms) and minor (polysemes) entries for a given word. Where a lexical resource is described in terms of granularity a coarse-grained approach only differentiates between homonymy whereas a fine-grained approach also considers polysemy.

The use of word sense disambiguation in Information Retrieval (IR) has been an active field of study for the past 30 years. Despite several failures (described in Sanderson, 2000) recent studies have begun to show increased retrieval effectiveness, particularly in Web retrieval. However, two key questions remain: (1) to what accuracy must disambiguation be performed in order to show increased retrieval effectiveness and (2) to what level of granularity should disambiguation be performed in order to maximize these gains? This study answers these questions by simulating the impact of ambiguity and its subsequent resolution on retrieval effectiveness.

2 Related Work

The motivation for this research is taken from recent studies (section 2.1) which have demonstrated increased retrieval effectiveness by accounting for word sense. The methodology is derived from previous studies (section 2.2) which model the impact that ambiguity and its subsequent resolution have on IR.

2.1 Accounting for Sense in IR

One of the first studies to show increased retrieval effectiveness through resolving ambiguity was Schütze and Pederson (1995). They used clustering to discriminate between alternate uses of a word. The clusters they produced were apparently fine-grained, although it is not clear if this observation was made with reference to a particular lexical resource. In terms of the accuracy to which they could discriminate meaning, a limited evaluation using a 10 word sample demonstrated accuracy approaching 90%. Results showed that retrieval effectiveness increased when documents were indexed by cluster as opposed to raw terms. Performance further increased when a word in the collection was assigned membership of its three most likely clusters. However, it is not clear if assigning multiple senses leads to coarser granularity or simply reduces the impact of erroneous disambiguation.

Stokoe et al. (2003) showed increased retrieval effectiveness through fine-grained disambiguation where a word occurrence in the collection was assigned one of the sense definitions contained in WordNet. The accuracy of their disambiguation was reported at 62% based on its performance over a large subset of SemCor (a collection of manually disambiguated documents). It remains unclear how accuracy figures produced on different collections can be compared. Stokoe et al. (2003) did not measure the actual performance of their disambiguation when it was applied to the WT10G (the IR collection used in their experiments). This highlights the difficulty involved in quantifying the effects of disambiguation within an IR collection given that the size of modern collections precludes manual disambiguation.

Finally, Kim et al. (2004) showed gains through coarse-grained disambiguation by assigning all nouns in the WT10G collection (section 3) membership to 25 top level semantic categories in WordNet (for more detail about the composition of WordNet see section 4). The motivation behind coarse-grained disambiguation in IR is that higher accuracy is achieved when only differentiating between homonyms. Several authors (Sanderson, 2000; Kim et al., 2004) postulate that fine-grained disambiguation may not offer any benefits over coarse-grained disambiguation which can be performed to a higher level of accuracy.

2.2 The Effects of Ambiguity on IR

The studies described in section 2.1 provide empirical evidence of the benefits of disambiguation. Unfortunately, they do not indicate the minimum accuracy or the optimal level of granularity required in order to bring about these benefits. Perhaps more telling are studies which have attempted to quantify the effects of ambiguity on IR.

Sanderson (1994) used pseudowords to add additional ambiguity to an IR collection. Pseudowords (Gale et al., 1992) are created by joining together randomly selected constituent words to create a unique term that has multiple controlled meanings. Sanderson (1994) offers the example of "*banana/kalashnikov*". This new term features two pseudosenses '*banana*' and '*kalashnikov*' and is used to replace any occurrences of the constituent words in the collection, thus introducing additional ambiguity. In his study, Sanderson experimented with adding ambiguity to the Reuters collection. Results showed that even introducing large amounts of additional ambiguity (size 10 pseudowords - indicating they had 10 constituents) had very little impact on retrieval effectiveness. Furthermore, attempts to resolve this ambiguity with less than 90% accuracy proved extremely detrimental.

Sanderson (1999) acknowledged that pseudowords are unlike real words as the random selection of their constituents ensures that the pseudosenses produced are unlikely to be related, in effect only modeling homonymy. Several studies (Schütze, 1998; Gaustad, 2001) suggest that this failure to model polysemy has a significant impact. Disambiguation algorithms evaluated using pseudowords show much better performance than when subsequently applied to real words. Gonzalo et al. (1998) cite this failure to model related senses in order to explain why their study into the effects of ambiguity showed radically different results to Sanderson (1994). They performed known item retrieval on 256 manually disambiguated documents and showed increased retrieval effectiveness where disambiguation was over 60% accurate. Whilst Sanderson's results no longer fit the empirical data, his pseudoword methodology does allow us to explore the effects of ambiguity without the overhead of manual disambiguation. Gaustad (2001) highlighted that the challenge lies in adapting pseudowords to account for polysemy.

Krovetz (1997) performed the only study to date which has explicitly attempted to differentiate between homonymy and polysemy in IR. Using the Longmans dictionary he grouped related senses based on any overlap that existed between two sense definitions for a given word. His results support the idea that grouping together related senses can increase retrieval effectiveness. However, the study does not contrast the relative merits of this technique against fine-grained approaches, thus highlighting that the question of granularity remains open. Which is the optimal approach? Grouping related senses or attempting to make fine-grained sense distinctions?

3 Experimental Setup

The experiments in this study use the WT10G corpus (Hawking and Craswell, 2002), an IR web test collection consisting of 1.69 million documents. There are two available Query / Relevance Judgments sets each consisting of 50 queries. This study uses the TREC 10 Web Track Ad-Hoc query set (NIST topics 501 – 550). The relevance judgments for these queries were produced using pooling based on the top 100 ranked documents retrieved by each of the systems that participated in the TREC 10 Web Track.

Initially the author produced an index of the WT10G and performed retrieval on this unmodified collection in order to measure baseline retrieval effectiveness. The ranking algorithm was length normalized TF.IDF (Salton and McGill, 1983) which is comparable to the studies in section 2. Next, two modified versions of the collection were produced where additional ambiguity in the form of pseudowords had been added. The first used pseudowords created by selecting constituent pseudosenses which are unrelated, thus introducing additional homonymy. The second used a new method of generating pseudowords that exhibit polysemy (the methodology is described in section 4.1). Contrasting retrieval performance over these three indexes quantifies the relative impact of both homonymy and polysemy on retrieval effectiveness. The final step was to measure the effects of attempting to resolve the additional ambiguity which had been added to the collection. In order to do this, the author simulated disambiguation to varying degrees of accuracy and measured the impact that this had on retrieval effectiveness.

4 Methodology

To date only Nakov and Hearst (2003) have looked into creating more plausible pseudowords. Working with medical abstracts (MEDLINE) and the controlled vocabulary contained in the MESH hierarchy they created pseudosense pairings that are related. By identifying pairs of MESH subject categories which frequently co-occurred and selecting constituents for their pseudowords from these pairings they produced a disambiguation test collection. Their results showed that category based pseudowords provided a more realistic test data set for disambiguation, in that evaluation using them more closely resembled real words. The challenge in this study lay in adapting these ideas for open domain text.

4.1 Pseudoword Generation

This study used WordNet (Miller et al., 1990) to inform the production of pseudowords. WordNet (2.0) is a hierarchical semantic network developed at Princeton University. Concepts in WordNet are represented by synsets and links between synsets represent hypernmy (subsumes) and hyponymy (subsumed) relationships in order to form a hierarchical structure. A unique word sense consists of a lemma and the particular synset in which that lemma occurs. WordNet is a fine-grained lexical resource and polysemy can be derived to varying degrees of granularity by traversing the link structure between synsets (figure 1).

Figure 1. A Subsection of the Noun Hierarchy in WordNet

An important feature of pseudowords is the number of constituents as this controls the amount of additional ambiguity created. A feature of all previous studies is that they generate pseudowords with a uniform number of constituents, e.g. size 2, size 5 or size 10, thus introducing uniform levels of additional ambiguity. It is clear that such an approach does not reflect real words given that they do not exhibit uniform levels of ambiguity. The approach taken in this study was to generate pseudowords where the number of constituents was variable. As each of the pseudowords in this study contain one query word from the IR collection then the number of constituents was linked directly to the number of senses of that word contained in WordNet. This effectively doubles the level of ambiguity expressed by the original query word. If a query word was not contained in WordNet then this was taken to be a proper name and exempted from the process of adding ambiguity. It was felt that to destroy any unambiguous proper names, which might act to anchor a query, would dramatically overstate the effects of ambiguity in terms of the IR simulation. The average size of the pseudowords produced in these experiments was 6.4 pseudosenses.

When producing the traditional pseudoword based collection the only modification to Sanderson's (1994) approach (described in section 2), other than the variable size, involved formalizing his observation that the constituent words were unlikely to be related. Given access to WordNet it was possible to guarantee that this is the case by rejecting constituents which could be linked through its inheritance hierarchy. This ensures that the pseudowords produced only display homonymy.

In order to produce pseudowords that model polysemy it was essential to devise a method for selecting constituents that have the property of relatedness. The approach taken was to deliberately select constituent words that could be linked to a sense of the original query word through WordNet. Thus the additional ambiguity added to the collection models any underlying relatedness expressed by the original senses of the query word. Pseudowords produced in this way will now be referred to as root pseudowords as this reflects that the ambiguity introduced is modeled around one root constituent. Consider the following worked example for the query "How are tornadoes formed?" After the removal of stopwords we are left with '*tornadoes*' and '*formed*' each of which is then transformed into a root pseudoword. The first step involves identifying any potential senses of the target word from WordNet. If we consider the word '*tornado*' it appears in two synsets:

> *1. tornado, twister -- (a localized and violently destructive windstorm occurring over land characterized by a funnel-shaped cloud extending toward the ground)*
>
> *2. crack, tornado -- (a purified and potent form of cocaine that is smoked rather than snorted)*

For each sense of the target word the system expands WordNet's inheritance hierarchy to produce a directed graph of its hypernyms. Figure 2 shows an example of this graph for the first sense of the word '*tornado*'. In order to ensure a related sense pair the system builds a pool of words which are subsumed by concepts contained in this graph. This is generated by recursively moving up the hierarchy until the pool contains at least one viable candidate. For a candidate to be viable it must meet the following criteria:

1) It must exist in the IR collection.
2) It must not be part of another pseudoword.
3) It can not be linked (through WordNet) to another constituent of the pseudoword.

The pool for sense 1 of '*tornado*' consists of [*hurricane*|*typhoon*], one of which is selected at random.

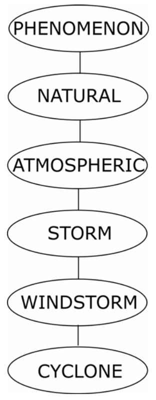

Figure 2. A Graph of the Hypernyms for the First Sense of the Word '*tornado*'

This process is repeated for each noun and verb sense of the query word. In this example there is one remaining sense of the word '*tornado*' - a slang term used to refer to the drug crack cocaine. For this sense the system produced a pool consisting of [*diacetylemorphine*|*heroin*]. Once all senses of the query word have been expanded the resulting pseudoword, '*tornadoes/hurricane/heroin*', is then used to replace all occurrences of its constituents within the collection. Through this process the system produces pseudowords with pseudosense pairings which have subsuming relationships, e.g. '*tornadoes/hurricane*' are subsumed by the higher category of '*cyclone*' whilst '*tornadoes/heroin*' are subsumed by the higher semantic category of '*hard_drug*'.

4.2 Pseudo-disambiguation

In order to perform pseudo-disambiguation the unmodified collection acts as a gold standard model answer. Through reducing each instance of a pseudoword back to one of its constituent components this models the selection process made by a disambiguation system. Obviously, the correct pseudosense for a given instance is the original word which appeared at that point in the collection. Variable levels of accuracy are introduced using a weighted probability model where the correct pseudosense for a given test instance is seeded with a fixed probability equivalent to the desired accuracy being simulated. When a disambiguation error is simulated one of the incorrect pseudosenses is selected randomly.

5 Results

The first set of results (section 5.1) addresses the question of granularity by quantifying the impact that adding either additional homonymy or polysemy has on retrieval effectiveness. The second set of results (section 5.2) looks at the question of disambiguation accuracy by simulating the impact that varied levels of accuracy have on retrieval effectiveness.

5.1 Homonymy vs. Polysemy

Let us first consider the impact of adding additional homonymy. Figure 3 graphs precision across the 11 standard points of recall for retrieval from both the baseline collection and one where additional homonymy has been added. Note that the introduction of additional homonymy brings about a small drop in retrieval effectiveness. With regard to the single value measures contained in table 1, this is a decrease of 2.5% in terms of absolute R-Precision (average precision after the total number of known relevant documents in the collection has been retrieved). This is a relative decrease of 14.3%. Similar drops in both precision@10 (precision after the first 10 documents retrieved) and average precision are also seen.

Next let us consider retrieval effectiveness over the root pseudoword collection where additional polysemy has been added (figure 4). Note that the introduction of additional polysemy has a more substantive impact upon retrieval effectiveness. In terms of R-Precision this decrease is 5.3% in absolute terms, a relative decrease of 30% compared to baseline retrieval from the unmodified collection. In addition, an even larger decrease in precision@10 occurs where the introduction of additional polysemy brings about a 7% drop in retrieval effectiveness.

In terms of the relative effects of homonymy and polysemy on retrieval effectiveness then note that adding additional polysemy has over double the impact of adding homonymy. This provides a clear indication that the retrieval process is more substantially affected by polysemy than homonymy.

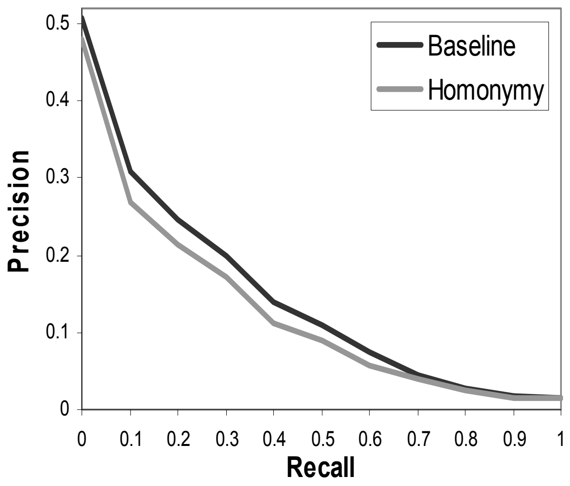

Figure 3. Precision across the 11 Standard Points of Recall for the Baseline and the Collection Containing Additional Homonymy

	R-Precision	Precision @10	Avg. Precision
Baseline	0.1732	0.2583	0.1334
Homonymy	0.1485	0.2208	0.1145
Polysemy	0.1206	0.1875	0.0951

Table 1. R-Precision, Precision@10 and Average Precision for all Three Versions of the Collection

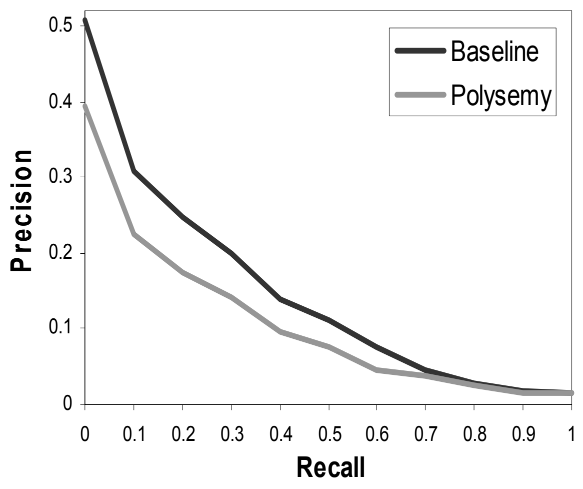

Figure 4. Precision across the 11 Standard Points of Recall for the Baseline and the Collection Containing Additional Polysemy

5.2 The Impact of Disambiguation

We now address the second part of the research question: to what accuracy should disambiguation be performed in order to enhance retrieval effectiveness? Figure 5 plots the impact, in terms of R-Precision, of performing disambiguation to varying degrees of accuracy after additional homonymy has been added to the collection. The dotted line represents the breakeven point, with R-Precision below this line indicating reduced performance as a result of disambiguation. Results show that where additional homonymy has been added to the collection disambiguation accuracy at or above 76% is required in order for disambiguation to be of benefit. Performing disambiguation which is less than 76% accurate leads to lower performance than if the additional homonymy had been left unresolved.

Moving on to consider the root pseudoword collection (figure 6) note that the breakeven point is only 55% where additional polysemy has been added. Consider that the results in section 5.1 showed that the introduction of additional polysemy had over double the impact of introducing additional homonymy. This is reflected in the relative effects of disambiguation in that the breakeven point is considerably lower for polysemy than homonymy.

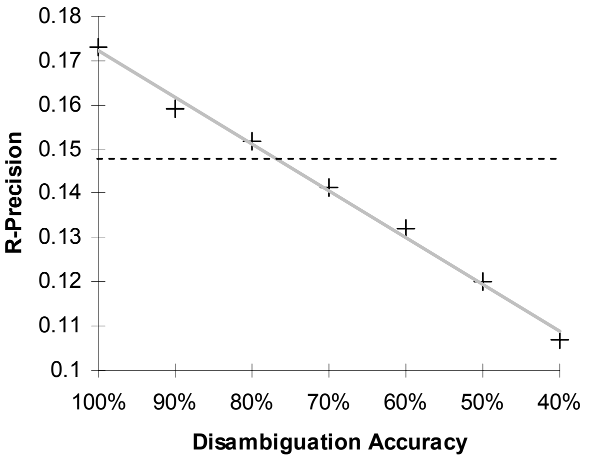

Figure 5. The Impact of Disambiguation on Effectiveness after the Addition of Homonymy

(Note the dashed line is the breakeven point)

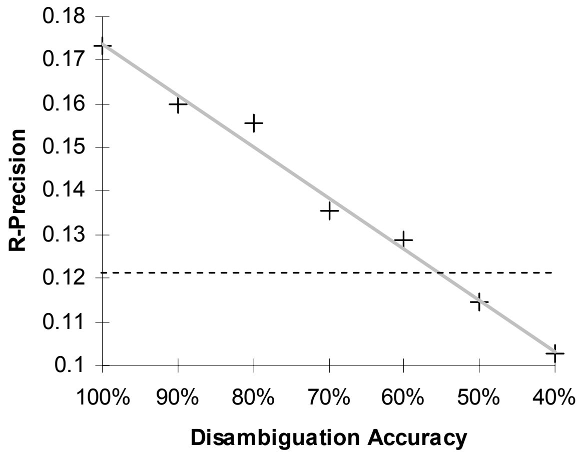

Figure 6. The Impact of Disambiguation on Effectiveness after the Addition of Polysemy

(Note the dashed line is the breakeven point)

6 Discussion

The results in section 5.1 show that retrieval effectiveness is more sensitive to polysemy than homonymy. One explanation for this can be hypothesized from previous studies (Krovetz and Croft, 1992; Sanderson and Van Rijsbergen, 1999) which highlight the importance of co-occurrence between query words. Where two (or more) words appear together in a query, statistical retrieval inherently performs some element of disambiguation. However, in the case of a word with many closely related senses, co-occurrence between query words may not be sufficient for a given sense to become apparent. This is particularly exasperated in Web retrieval given that the average query length in these experiments was 2.9 words. Clearly, the inherent disambiguation performed by statistical IR techniques is sensitive to polysemy in the same way as systems which explicitly perform disambiguation.

With regard to disambiguation accuracy and IR (section 5.2) these experiments establish that performance gains begin to occur where disambiguation is between 55% and 76%. Where within this range the actual breakeven point lies is dependent on the granularity of the disambiguation and the balance between polysemy and homonymy in a given collection. Consider that coarse-grained disambiguation is frequently advocated on the basis that it can be performed more accurately. Whilst this is undoubtedly true these results suggest that homonymy has to be resolved to a much higher level of accuracy than polysemy in order to be of benefit in IR.

It would seem prudent to consider the results of this study in relation to the state-of-the-art in disambiguation. At Senseval-3 (Mihalcea et al., 2004) the top systems were considered to have reached a ceiling, in terms of performance, at 72% for fine-grained disambiguation and 80% for coarse-grained. When producing the English language test collections the rate of agreement between humans performing manual disambiguation was approximately 74%. This suggests that machine disambiguation has reached levels comparable to the performance of humans. In parallel with this the IR community has begun to report increased retrieval effectiveness through explicitly performing disambiguation to varying levels of granularity.

A final point of discussion is the way in which we simulate disambiguation both in this study and those previously (Sanderson, 1994; Gonzalo et al., 1998). There is growing evidence (Leacock et al., 1998; Agirre and Martinez, 2004) to suggest that simulating uniform rates of accuracy and error across both words and senses may not reflect the performance of modern disambiguation systems. Supervised approaches are known to exhibit inherent bias that exists in their training data. Examples include Zipf's law (Zipf, 1949) which denotes that a small number of words make up a large percentage of word use and Krovetz and Croft's (1992) observation that one sense of a word accounts for the majority of all use. It would seem logical to presume that supervised systems show their best performance over the most frequent senses of the most frequent words in their training data. Not enough is known about the potential impact of these biases to allow for them to be incorporated into this simulation. Still, it should be noted that Stokoe et al. (2003) utilized frequency statistics in their disambiguator and that a by-product of Schütze and Pederson's (1992) approach was that they eliminated infrequently observed senses. There is supporting evidence from Sanderson and Van Rijsbergen (1999) to suggest that accounting for this frequency bias is in some way advantageous. Therefore, it is worth considering that simulating a uniform accuracy and error rate across all words and senses might actually offer a pessimistic picture of the potential for disambiguation and IR. Whilst this merits further study, the focus of this research was contrasting the relative effects of two types of ambiguity and both models were subject to the same uniform disambiguation.

7 Conclusions

This study has highlighted that retrieval systems are more sensitive to polysemy than homonymy. This leads the author to conclude that making fine-grained sense distinctions can offer increased retrieval effectiveness in addition to any benefits brought about by coarse-grained disambiguation. It also emphasises that although coarse-grained disambiguation can be performed to a higher degree of accuracy, this might not directly translate to increased IR performance compared to fine-grained approaches. This is in contrast to current thinking which suggests that coarse-grained approaches are more likely to bring about retrieval performance because of their increased accuracy.

In terms of disambiguation accuracy and increased retrieval effectiveness, results show potential benefits where accuracy is as low as 55% when dealing with just polysemy and rises to 76% when dealing with just homonymy. Obviously this study has simulated two extremes (polysemy or homonymy) and the exact point where performance increases will occur is likely to be dependent on the interaction between homonymy and polysemy in a given query.

With regard to simulation a more empirical exploration of the ideas expressed in this work would be desirable. However, the size of modern IR test collections dictates that future studies will need to rely more heavily on simulation. Therefore, until such time that a significant manually disambiguated IR collection exists pseudowords remain an interesting way to explore the effects of ambiguity within a large collection. The challenge lies in producing pseudowords that better model real words.

Unsupervised Large-Vocabulary Word Sense Disambiguation with Graph-based Algorithms for Sequence Data Labeling

Rada Mihalcea
Department of Computer Science
University of North Texas
rada@cs.unt.edu

Abstract

This paper introduces a graph-based algorithm for sequence data labeling, using random walks on graphs encoding label dependencies. The algorithm is illustrated and tested in the context of an unsupervised word sense disambiguation problem, and shown to significantly outperform the accuracy achieved through individual label assignment, as measured on standard sense-annotated data sets.

1 Introduction

Many natural language processing tasks consist of labeling sequences of words with linguistic annotations, e.g. word sense disambiguation, part-of-speech tagging, named entity recognition, and others. Typical labeling algorithms attempt to formulate the annotation task as a traditional learning problem, where the correct label is *individually* determined for each word in the sequence using a learning process, usually conducted independent of the labels assigned to the other words in the sequence. Such algorithms do not have the ability to encode and thereby exploit dependencies across labels corresponding to the words in the sequence, which potentially limits their performance in applications where such dependencies can influence the selection of the correct set of labels.

In this paper, we introduce a graph-based sequence data labeling algorithm well suited for such natural language annotation tasks. The algorithm simultaneously annotates all the words in a sequence by exploiting relations identified among word labels, using random walks on graphs encoding label dependencies. The random walks are mathematically modeled through iterative graph-based algorithms, which are applied on the label graph associated with the given sequence of words, resulting in a stationary distribution over label probabilities. These probabilities are then used to simultaneously select the most probable set of labels for the words in the input sequence.

The annotation method is illustrated and tested on an unsupervised word sense disambiguation problem, targeting the annotation of all open-class words in unrestricted text using information derived exclusively from dictionary definitions. The graph-based sequence data labeling algorithm significantly outperforms the accuracy achieved through individual data labeling, resulting in an error reduction of 10.7%, as measured on standard sense-annotated data sets. The method is also shown to exceed the performance of other previously proposed unsupervised word sense disambiguation algorithms.

2 Iterative Graphical Algorithms for Sequence Data Labeling

In this section, we introduce the iterative graphical algorithm for sequence data labeling. The algorithm is succinctly illustrated using a sample sequence for a generic annotation problem, with a more extensive illustration and evaluation provided in Section 3.

Given a sequence of words $W = \{w_1, w_2, ..., w_n\}$, each word w_i with corresponding admissible labels $L_{w_i} = \{l^1_{w_i}, l^2_{w_i}, ..., l^{N_{w_i}}_{w_i}\}$, we define a label graph G = (V,E) such that there is a vertex $v \in V$ for every possible label $l^j_{w_i}$, $i = 1..n$, $j = 1..N_{w_i}$. Dependencies between pairs of labels are represented as directed or indirected edges $e \in E$, defined over the set of vertex pairs $V \times V$. Such label dependencies can be learned from annotated data, or derived by other means, as illustrated later. Figure 1 shows an example of a graph-

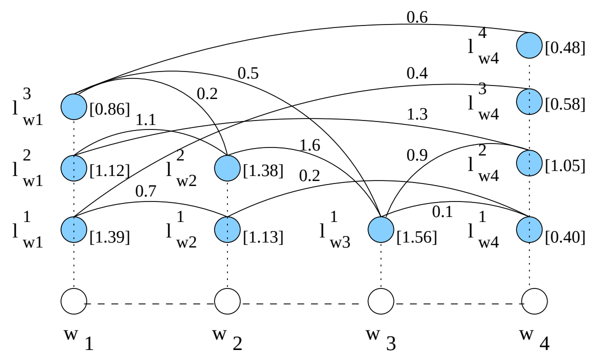

Figure 1: Sample graph built on the set of possible labels (shaded nodes) for a sequence of four words (unshaded nodes). Label dependencies are indicated as edge weights. Scores computed by the graph-based algorithm are shown in brackets, next to each label.

ical structure derived over the set of labels for a sequence of four words. Note that the graph does not have to be fully connected, as not all label pairs can be related by a dependency.

Given such a label graph associated with a sequence of words, the likelihood of each label can be recursively determined using an iterative graph-based ranking algorithm, which runs over the graph of labels and identifies the importance of each label (vertex) in the graph. The iterative graphical algorithm is modeling a random walk, leading to a stationary distribution over label probabilities, represented as scores attached to vertices in the graph. These scores are then used to identify the most probable label for each word, resulting in the annotation of all the words in the input sequence. For instance, for the graph drawn in Figure 1, the word w_1 will be assigned with label $l^1_{w_1}$, since the score associated with this label (1.39) is the maximum among the scores assigned to all admissible labels associated with this word.

A remarkable property that makes these iterative graphical algorithms appealing for sequence data labeling is the fact that they take into account global information recursively drawn from the entire graph, rather than relying on local vertex-specific information. Through the random walk performed on the label graph, these iterative algorithms attempt to collectively exploit the dependencies drawn between *all* labels in the graph, which makes them superior to other approaches that rely only on local information, individually derived for each word in the sequence.

2.1 Graph-based Ranking

The basic idea implemented by an iterative graph-based ranking algorithm is that of “voting” or “recommendation”. When one vertex links to another one, it is basically casting a vote for that other vertex. The higher the number of votes that are cast for a vertex, the higher the importance of the vertex. Moreover, the importance of the vertex casting a vote determines how important the vote itself is, and this information is also taken into account by the ranking algorithm.

While there are several graph-based ranking algorithms previously proposed in the literature, we focus on only one such algorithm, namely PageRank (Brin and Page, 1998), as it was previously found successful in a number of applications, including Web link analysis, social networks, citation analysis, and more recently in several text processing applications.

Given a graph $G = (V, E)$, let $In(V_a)$ be the set of vertices that point to vertex V_a (predecessors), and let $Out(V_a)$ be the set of vertices that vertex V_a points to (successors). The PageRank score associated with the vertex V_a is then defined using a recursive function that integrates the scores of its predecessors:

$$P(V_a) = (1 - d) + d * \sum_{V_b \in In(V_a)} \frac{P(V_b)}{|Out(V_b)|} \qquad (1)$$

where d is a parameter that is set between 0 and 1[1].

This vertex scoring scheme is based on a random walk model, where a walker takes random steps on the graph G, with the walk being modeled as a Markov process – that is, the decision on what edge to follow is solely based on the vertex where the walker is currently located. Under certain conditions, this model converges to a stationary distribution of probabilities, associated with vertices in the graph. Based on the Ergodic theorem for Markov chains (Grimmett and Stirzaker, 1989), the algorithm is guaranteed to converge if the graph is both aperiodic and irreducible. The first condition is achieved for any graph that is a non-bipartite graph, while the second condition holds for any strongly connected graph – property achieved by PageRank through the random jumps introduced by the $(1 - d)$ factor. In matrix notation, the PageRank vector of stationary probabilities is the principal eigenvector for the matrix A_{row}, which is obtained from the adjacency matrix A representing the graph, with all rows normalized to sum to 1: ($P = A^T_{row} P$).

Intuitively, the stationary probability associated with a vertex in the graph represents the probability

[1]The typical value for d is 0.85 (Brin and Page, 1998), and this is the value we are also using in our implementation.

of finding the walker at that vertex during the random walk, and thus it represents the importance of the vertex within the graph. In the context of sequence data labeling, the random walk is performed on the label graph associated with a sequence of words, and thus the resulting stationary distribution of probabilities can be used to decide on the most probable set of labels for the given sequence.

2.2 Ranking on Weighted Graphs

In a weighted graph, the decision on what edge to follow during a random walk is also taking into account the weights of outgoing edges, with a higher likelihood of following an edge that has a larger weight. The weighted version of the ranking algorithm is particularly useful for sequence data labeling, since the dependencies between pairs of labels are more naturally modeled through weights indicating their strength, rather than binary $0/1$ values. Given a set of weights w_{ab} associated with edges connecting vertices V_a and V_b, the weighted PageRank score is determined as:

$$WP(V_a) = (1-d)+d \sum_{V_b \in In(V_a)} \frac{w_{ba}}{\sum_{V_c \in Out(V_b)} w_{bc}} WP(V_b) \quad (2)$$

2.3 Algorithm for Sequence Data Labeling

Given a sequence of words with their corresponding admissible labels, the algorithm for sequence data labeling seeks to identify a graph of label dependencies on which a random walk can be performed, resulting in a set of scores that can be used for label assignment. Algorithm 1 shows the pseudocode for the labeling process. The algorithm consists of three main steps: (1) construction of label dependencies graph; (2) label scoring using graph-based ranking algorithms; (3) label assignment.

First, a weighted graph of label dependencies is built by adding a vertex for each admissible label, and an edge for each pair of labels for which a dependency is identified. A maximum allowable distance can be set ($MaxDist$), indicating a constraint over the distance between words for which a label dependency is sought. For instance, if $MaxDist$ is set to 3, no edges will be drawn between labels corresponding to words that are more than three words apart, counting all running words. Label dependencies are determined through the $Dependency$ function, whose definition depends on the application and type of resources available (see Section 2.4).

Next, scores are assigned to vertices using a graph-based ranking algorithm. Current experiments are based on PageRank, but other ranking algorithms can be used as well.

Algorithm 1 Graph-based Sequence Data Labeling

Input: Sequence $W = \{w_i | i = 1..N\}$
Input: Admissible labels $L_{w_i} = \{l^t_{w_i} | t = 1..N_{w_i}\}$,$i = 1..N$
Output: Sequence of labels $L = \{l_{w_i} | i = 1..N\}$, with label l_{w_i} corresponding to word w_i from the input sequence.

Build graph G of label dependencies

```
 1: for $i = 1$ to $N$ do
 2:   for $j = i + 1$ to $N$ do
 3:     if $j - i > MaxDist$ then
 4:       $break$
 5:     end if
 6:     for $t = 1$ to $N_{w_i}$ do
 7:       for $s = 1$ to $N_{w_j}$ do
 8:         $weight \leftarrow Dependency(l^t_{w_i}, l^s_{w_j}, w_i, w_j)$
 9:         if $weight > 0$ then
10:           $AddEdge(G, l^t_{w_i}, l^s_{w_j}, weight)$
11:         end if
12:       end for
13:     end for
14:   end for
15: end for
```

Score vertices in G

```
 1: repeat
 2:   for all $V_a \in Vertices(G)$ do
 3:     $WP(V_a) = (1 - d) + d*$
          $\sum_{V_b \in In(V_a)} w_{ba} WP(V_b) / \sum_{V_c \in Out(V_b)} w_{bc}$
 4:   end for
 5: until convergence of scores $WP(V_a)$
```

Label assignment

```
 1: for $i = 1$ to $N$ do
 2:   $l_{w_i} \leftarrow argmax\{WP(l^t_{w_i}) | t = 1..N_{w_i}\}$
 3: end for
```

Finally, the most likely set of labels is determined by identifying for each word the label that has the highest score. Note that all admissible labels corresponding to the words in the input sequence are assigned with a score, and thus the selection of two or more most likely labels for a word is also possible.

2.4 Label Dependencies

Label dependencies can be defined in various ways, depending on the application at hand and on the knowledge sources that are available. If an annotated corpus is available, dependencies can be defined as label co-occurrence probabilities approximated with frequency counts $P(l^t_{w_i}, l^s_{w_j})$, or as conditional probabilities $P(l^t_{w_i} | l^s_{w_j})$. Optionally, these dependencies can be lexicalized by taking into account the corresponding words in the sequence, e.g. $P(l^t_{w_i} | l^s_{w_j}) \times P(w_i | l^t_{w_i})$. In the absence of an annotated corpus, dependencies can be derived by other means, e.g. part-of-speech probabilities can be approximated from a raw corpus as in (Cutting et al., 1992), word-sense dependencies can be derived as definition-based similarities, etc. Label dependencies are set as weights on the arcs drawn between corresponding labels. Arcs can be directed or undirected for joint probabilities or similarity measures, and are usually directed for conditional probabilities.

2.5 Labeling Example

Consider again the example from Figure 1, consisting of a sequence of four words, and their possible corresponding labels. In the first step of the algorithm, label dependencies are determined, and let us assume that the values for these dependencies are as indicated through the edge weights in Figure 1. Next, vertices in the graph are scored using an iterative ranking algorithm, resulting in a score attached to each label, shown in brackets next to each vertex. Finally, the most probable label for each word is selected. Word w_1 is thus assigned with label $l^1_{w_1}$, since the score of this label (1.39) is the maximum among the scores associated with all its possible labels (1.39, 1.12, 0.86). Similarly, word w_2 is assigned with label $l^2_{w_2}$, w_3 with label $l^1_{w_3}$, and w_4 receives label $l^2_{w_4}$.

2.6 Efficiency Considerations

For a sequence of words $W = \{w_1, w_2, ..., w_n\}$, each word w_i with N_{w_i} admissible labels, the running time of the graph-based sequence data labeling algorithm is proportional with O($C \sum_{i=1}^{n} \sum_{j=i+1}^{i+MaxDist} (N_{w_i} \times N_{w_j})$) (the time spent in building the label graph and iterating the algorithm for a constant number of times C). This is order of magnitudes better than the running time of O($\prod_{i=1}^{n} N_{w_i}$) for algorithms that attempt to select the best sequence of labels by searching through the entire space of possible label combinations, although it can be significantly higher than the running time of O($\sum_{i=1}^{n} N_{w_i}$) for individual data labeling.

2.7 Other Algorithms for Sequence Data Labeling

It is interesting to contrast our algorithm with previously proposed models for sequence data labeling, e.g. Hidden Markov Models, Maximum Entropy Markov Models, or Conditional Random Fields. Although they differ in the model used (generative, discriminative, or dual), and the type of probabilities involved (joint or conditional), these previous algorithms are all parameterized algorithms that typically require parameter training through maximization of likelihood on training examples. In these models, parameters that maximize sequence probabilities are *learned* from a corpus during a *training phase*, and then applied to the annotation of new unseen data. Instead, in the algorithm proposed in this paper, the likelihood of a sequence of labels is determined during *test phase*, through random walks performed on the label graph built for the data to be annotated. While current evaluations of our algorithm are performed on an unsupervised labeling task, future work will consider the evaluation of the algorithm in the presence of an annotated corpus, which will allow for direct comparison with these previously proposed models for sequence data labeling.

3 Experiments in Word Sense Disambiguation

The algorithm for sequence data labeling is illustrated and tested on an all-words word sense disambiguation problem. Word sense disambiguation is a labeling task consisting of assigning the correct meaning to each open-class word in a sequence (usually a sentence). Most of the efforts for solving this problem were concentrated so far toward targeted supervised learning, where each sense tagged occurrence of a particular word is transformed into a feature vector used in an automatic learning process. The applicability of such supervised algorithms is however limited to those few words for which sense tagged data is available, and their accuracy is strongly connected to the amount of labeled data available at hand. Instead, algorithms that attempt to disambiguate all-words in unrestricted text have received significantly less attention, as the development and success of such algorithms has been hindered by both (a) lack of resources (training data), and (b) efficiency aspects resulting from the large size of the problem.

3.1 Graph-based Sequence Data Labeling for Unsupervised Word Sense Disambiguation

To apply the graph-based sequence data labeling algorithm to the disambiguation of an input text, we need information on labels (word senses) and dependencies (word sense dependencies). Word senses can be easily obtained from any sense inventory, e.g. WordNet or LDOCE. Sense dependencies can be derived in various ways, depending on the type of resources available for the language and/or domain at hand. In this paper, we explore the unsupervised derivation of sense dependencies using information drawn from machine readable dictionaries, which is general and can be applied to any language or domain for which a sense inventory is available.

Relying exclusively on a machine readable dictionary, a sense dependency can be defined as a measure of similarity between word senses. There are several metrics that can be used for this purpose, see for instance (Budanitsky and Hirst, 2001) for an overview. However, most of them rely on measures of semantic distance computed on semantic networks, and thus they are limited by the availability of explicitly encoded semantic relations (e.g. *is-a*, *part-of*). To maintain the unsupervised aspect of the algorithm, we chose instead to use a measure of similarity based on sense definitions, which can be computed on any dictionary, and can be evaluated across different parts-of-speech.

Given two word senses and their corresponding definitions, the sense similarity is determined as a function of definition overlap, measured as the number of common tokens between the two definitions, after running them through a simple filter that eliminates all stop-words. To avoid promoting long definitions, we also use a normalization factor, and divide the content overlap of the two definitions with the length of each definition. This sense similarity measure is inspired by the definition of the Lesk algorithm (Lesk, 1986).

Starting with a sense inventory and a function for computing sense dependencies, the application of the sequence data labeling algorithm to the unsupervised disambiguation of a new text proceeds as follows. First, for the given text, a label graph is built by adding a vertex for each possible sense for all open-class words in the text. Next, weighted edges are drawn using the definition-based semantic similarity measure, computed for all pairs of senses for words found within a certain distance ($MaxDist$, as defined in Algorithm 1). Once the graph is constructed, the graph-based ranking algorithm is applied, and a score is determined for all word senses in the graph. Finally, for each open-class word in the text, we select the vertex in the label graph which has the highest score, and label the word with the corresponding word sense.

3.2 An Example

Consider the task of assigning senses to the words in the text *The church bells no longer rung on Sundays*[2]. For the purpose of illustration, we assume at most three senses for each word, which are shown in Figure 2. Word senses and definitions are obtained from the WordNet sense inventory (Miller, 1995). All word senses are added as vertices in the label graph, and weighted edges are drawn as dependencies among word senses, derived using the definition-based similarity measure (no edges are drawn between word senses with a similarity of zero). The resulting label graph is an undirected weighted graph, as shown in Figure 2. After running the ranking algorithm, scores are identified for each word-sense in the graph, indicated between brackets next to each node. Selecting for each word the sense with the largest score results in the following sense assignment: *The church#2 bells#1*

The **church bells** no longer **rung** on **Sundays**.

church
1: one of the groups of Christians who have their own beliefs and forms of worship
2: a place for public (especially Christian) worship
3: a service conducted in a church

bell
1: a hollow device made of metal that makes a ringing sound when struck
2: a push button at an outer door that gives a ringing or buzzing signal when pushed
3: the sound of a bell

ring
1: make a ringing sound
2: ring or echo with sound
3: make (bells) ring, often for the purposes of musical edifi cation

Sunday
1: fi rst day of the week; observed as a day of rest and worship by most Christians

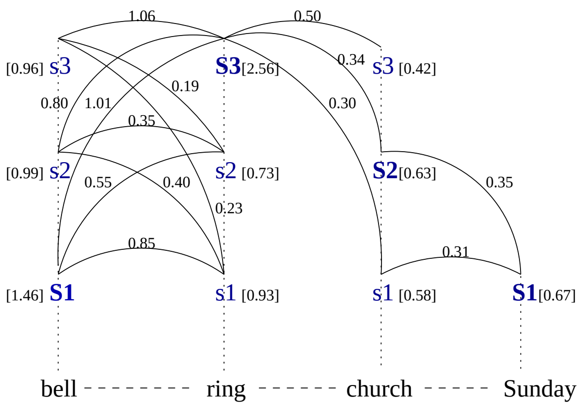

Figure 2: The label graph for assigning senses to words in the sentence *The church bells no longer rung on Sundays.*

[2]Example drawn from the data set provided during the SENSEVAL-2 English all-words task. Manual sense annotations were also made available for this data.

no longer rung#3 on Sundays#1, which is correct according to annotations performed by professional lexicographers.

3.3 Results and Discussion

The algorithm was primarily evaluated on the SENSEVAL-2 English all-words data set, consisting of three documents from Penn Treebank, with 2,456 open-class words (Palmer et al., 2001). Unlike other sense-annotated data sets, e.g. SENSEVAL-3 or SemCor, SENSEVAL-2 is the only testbed for all-words word sense disambiguation that includes a sense map, which allows for additional coarse-grained sense evaluations. Moreover, there is a larger body of previous work that was evaluated on this data set, which can be used as a base of comparison.

The performance of our algorithm is compared with the disambiguation accuracy obtained with a variation of the Lesk algorithm[3] (Lesk, 1986), which selects the meaning of an open-class word by finding the word sense that leads to the highest overlap between the corresponding dictionary definition and the current context. Similar to the definition similarity function used in the graph-based disambiguation algorithm (Section 3.1), the overlap measure used in the Lesk implementation does not take into account stop-words, and it is normalized with the length of each definition to avoid promoting longer definitions.

We are thus comparing the performance of sequence data labeling, which takes into account label dependencies, with individual data labeling, where a label is selected independent of the other labels in the text. Note that both algorithms rely on the same knowledge source, i.e. dictionary definitions, and thus they are directly comparable. Moreover, none of the algorithms take into account the dictionary sense order (e.g. the most frequent sense provided by WordNet), and therefore they are both fully unsupervised.

Table 1 shows precision and recall figures[4] for a context size ($MaxDist$) equal to the length of each sentence, using: (a) sequence data labeling with iterative graph-based algorithms; (b) individual data labeling with a version of the Lesk algorithm; (c) random baseline. Evaluations are run for both fine-grained and coarse-grained sense distinctions, to determine the algorithm performance under different classification granularities.

The accuracy of the graph-based sequence data labeling algorithm exceeds by a large margin the individual data labeling algorithm, resulting in 10.7% error rate reduction for fine-grained sense distinctions, which is statistically significant ($p < 0.0001$, paired t-test). Performance improvements are equally distributed across all parts-of-speech, with comparable improvements obtained for nouns, verbs, and adjectives. A similar error rate reduction of 11.0% is obtained for coarse-grained sense distinctions, which suggests that the performance of the graph-based sequence data labeling algorithm does not depend on classification granularity, and similar improvements over individual data labeling can be obtained regardless of the average number of labels per word.

We also measured the variation of performance with context size, and evaluated the disambiguation accuracy for both algorithms for a window size ranging from two words to an entire sentence. The window size parameter limits the number of surrounding words considered when seeking label dependencies (sequence data labeling), or the words counted in the measure of definition–context overlap (individual data labeling). Figure 3 plots the disambiguation accuracy of the two algorithms as a function of context size. As seen in the figure, both algorithms benefit from larger contexts, with a steady increase in performance observed for increasingly larger window sizes. Although the initial growth observed for the sequence data labeling algorithm is somewhat sharper, the gap between the two curves stabilizes for window sizes larger than five words, which suggests that the improvement in performance achieved with sequence data labeling over individual data labeling does not depend on the size of available context.

The algorithm was also evaluated on two other data sets, SENSEVAL-3 English all-words data (Snyder and Palmer, 2004) and a subset of SemCor (Miller et al., 1993), although only fine-grained sense evaluations could be conducted on these test sets. The disambiguation precision on the SENSEVAL-3 data was measured at 52.2% using sequence data labeling, compared to 48.1% obtained with individual

[3]Given a sequence of words, the original Lesk algorithm attempts to identify the combination of word senses that maximizes the redundancy (overlap) across all corresponding definitions. The algorithm was later improved through a method for simulated annealing (Cowie et al., 1992), which solved the combinatorial explosion of word senses, while still finding an optimal solution. However, recent comparative evaluations of different variants of the Lesk algorithm have shown that the performance of the original algorithm is significantly exceeded by an algorithm variation that relies on the overlap between word senses and current context (Vasilescu et al., 2004). We are thus using this latter Lesk variant in our implementation.

[4]Recall is particularly low for each individual part-of-speech because it is calculated with respect to the entire data set. The overall precision and recall figures coincide, reflecting the 100% coverage of the algorithm.

Part-of speech	Fine-grained sense distinctions						Coarse-grained sense distinctions					
	Random baseline		Individual (Lesk)		Sequence (graph-based)		Random baseline		Individual (Lesk)		Sequence (graph-based)	
	P	R	P	R	P	R	P	R	P	R	P	R
Noun	41.4%	19.4%	50.3%	23.6%	57.5%	27.0%	42.7%	20.0%	51.4%	24.1%	58.8%	27.5%
Verb	20.7%	3.9%	30.5%	5.7%	36.5%	6.9%	22.8%	4.3%	31.9%	6.0%	37.9%	7.1%
Adjective	41.3%	9.3%	49.1%	11.0%	56.7%	12.7%	42.6%	42.6%	49.8%	11.2%	57.6%	12.9%
Adverb	44.6%	5.2%	64.6%	7.6%	70.9%	8.3%	40.7%	4.8%	65.3%	7.7%	71.9%	8.5%
ALL	37.9%	37.9%	48.7%	48.7%	**54.2%**	**54.2%**	38.7%	38.7%	49.8%	49.8%	**55.3%**	**55.3%**

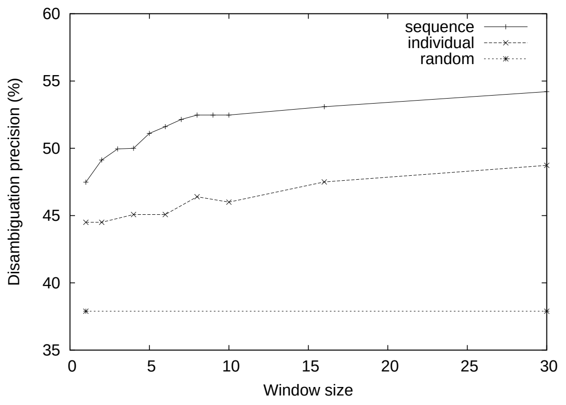

Figure 3: Disambiguation results using sequence data labeling, individual labeling, and random baseline, for various context sizes.

data labeling, and 34.3% achieved through random sense assignment. The average disambiguation figure obtained on all the words in a random subset of 10 SemCor documents, covering different domains, was 56.5% for sequence data labeling, 47.4% for individual labeling, and 35.3% for the random baseline.

Comparison with Related Work

For a given sequence of ambiguous words, the original definition of the Lesk algorithm (Lesk, 1986), and more recent improvements based on simulated annealing (Cowie et al., 1992), seek to identify the combination of senses that maximizes the overlap among their dictionary definitions. Tests performed with this algorithm on the SENSEVAL-2 data set resulted in a disambiguation accuracy of 39.5%. This precision is exceeded by the Lesk algorithm variation used in the experiments reported in this paper, which measures the overlap between sense definitions and the current context, for a precision of 48.7% on the same data set (see Table 1). In the SENSEVAL-2 evaluations, the best performing fully unsupervised algorithm[5] was developed by (Litkowski, 2001), who combines analysis of multiword units and contextual clues based on collocations and content words from dictionary definitions and examples, for an overall precision and recall of 45.1%. More recently, (McCarthy et al., 2004) reports one of the best results on the SENSEVAL-2 data set, using an algorithm that automatically derives the most frequent sense for a word using distributional similarities learned from a large raw corpus, for a disambiguation precision of 53.0% and a recall of 49.0%.

Another related line of work consists of the disambiguation algorithms based on lexical chains (Morris and Hirst, 1991), and the more recent improvements reported in (Galley and McKeown, 2003) – where threads of meaning are identified throughout a text. Lexical chains however only take into account connections between concepts identified in a static way, without considering the importance of the concepts that participate in a relation, which is recursively determined in our algorithm. Moreover, the construction of lexical chains requires structured dictionaries such as WordNet, with explicitly defined semantic relations between word senses, whereas our algorithm can also work with simple unstructured dictionaries that provide only word sense definitions. (Galley and McKeown, 2003) evaluated their algorithm on the nouns from a subset of SEMCOR, reporting 62.09% disambiguation precision. The performance of our algorithm on the same subset of SEMCOR nouns was measured at 64.2%[6]. Finally, another disambiguation method relying on graph algorithms that exploit the

[5]Algorithms that integrate the most frequent sense in WordNet are not considered here, since this represents a supervised knowledge source (WordNet sense frequencies are derived from a sense-annotated corpus).

[6]Note that the results are not directly comparable, since (Galley and McKeown, 2003) used the WordNet sense order to break the ties, whereas we assume that such sense order frequency is not available, and thus we break the ties through random choice.

structure of semantic networks was proposed in (Mihalcea et al., 2004), with a disambiguation accuracy of 50.9% measured on all the words in the SENSEVAL-2 data set.

Although it relies exclusively on dictionary definitions, the graph-based sequence data labeling algorithm proposed in this paper, with its overall performance of 54.2%, exceeds significantly the accuracy of all these previously proposed unsupervised word sense disambiguation methods, proving the benefits of taking into account label dependencies when annotating sequence data. An additional interesting benefit of the algorithm is that it provides a ranking over word senses, and thus the selection of two or more most probable senses for each word is also possible.

4 Conclusions

We proposed a graphical algorithm for sequence data labeling that relies on random walks on graphs encoding label dependencies. Through the label graphs it builds for a given sequence of words, the algorithm exploits relations between word labels, and implements a concept of *recommendation*. A label recommends other related labels, and the strength of the recommendation is recursively computed based on the importance of the labels making the recommendation. In this way, the algorithm simultaneously annotates all the words in an input sequence, by identifying the most probable (most *recommended*) set of labels.

The algorithm was illustrated and tested on an unsupervised word sense disambiguation problem, targeting the annotation of all words in unrestricted texts. Through experiments performed on standard sense-annotated data sets, the graph-based sequence data labeling algorithm was shown to significantly outperform the accuracy achieved through individual data labeling, resulting in a statistically significant error rate reduction of 10.7%. The disambiguation method was also shown to exceed the performance of previously proposed unsupervised word sense disambiguation algorithms. Moreover, comparative results obtained under various experimental settings have shown that the algorithm is robust to changes in classification granularity and context size.

Domain-Specific Sense Distributions and Predominant Sense Acquisition

Abstract

Distributions of the senses of words are often highly skewed. This fact is exploited by word sense disambiguation (WSD) systems which back off to the predominant sense of a word when contextual clues are not strong enough. The domain of a document has a strong influence on the sense distribution of words, but it is not feasible to produce large manually annotated corpora for every domain of interest. In this paper we describe the construction of three sense annotated corpora in different domains for a sample of English words. We apply an existing method for acquiring predominant sense information automatically from raw text, and for our sample demonstrate that (1) acquiring such information automatically from a mixed-domain corpus is more accurate than deriving it from SemCor, and (2) acquiring it automatically from text in the same domain as the target domain performs best by a large margin. We also show that for an all words WSD task this automatic method is best focussed on words that are salient to the domain, and on words with a different acquired predominant sense in that domain compared to that acquired from a balanced corpus.

1 Introduction

From analysis of manually sense tagged corpora, Kilgarriff (2004) has demonstrated that distributions of the senses of words are often highly skewed. Most researchers working on word sense disambiguation (WSD) use manually sense tagged data such as SemCor (Miller et al., 1993) to train statistical classifiers, but also use the information in SemCor on the overall sense distribution for each word as a back-off model. In WSD, the heuristic of just choosing the most frequent sense of a word is very powerful, especially for words with highly skewed sense distributions (Yarowsky and Florian, 2002). Indeed, only 5 out of the 26 systems in the recent SENSEVAL-3 English all words task (Snyder and Palmer, 2004) outperformed the heuristic of choosing the most frequent sense as derived from SemCor (which would give 61.5% precision and recall[1]). Furthermore, systems that did outperform the first sense heuristic did so only by a small margin (the top score being 65% precision and recall).

Over a decade ago, Gale et al. (1992) observed the tendency for one sense of a word to prevail in a given discourse. To take advantage of this, a method for automatically determining the "one sense" given a discourse or document is required. Magnini et al. (2002) have shown that information about the domain of a document is very useful for WSD. This is because many concepts are specific to particular domains, and for many words their most likely meaning in context is strongly correlated to the domain of the document they appear in. Thus, since word sense distributions are skewed and depend on the domain at hand we would like to know *for each domain of application* the most likely sense of a word.

However, there are no extant *domain-specific* sense tagged corpora to derive such sense distribution information from. Producing them would be extremely costly, since a substantial corpus would have to be annotated by hand for every domain of interest. In response to this problem, McCarthy et al. (2004) proposed a method for *automatically* inducing the

[1]This figure is the mean of two different estimates (Snyder and Palmer, 2004), the difference being due to multiword handling.

predominant sense of a word from raw text. They carried out a limited test of their method on text in two domains using subject field codes (Magnini and Cavaglià, 2000) to assess whether the acquired predominant sense information was broadly consistent with the domain of the text it was acquired from. But they did not evaluate their method on hand-tagged domain-specific corpora since there was no such data publicly available.

In this paper, we evaluate the method on domain specific text by creating a sense-annotated gold standard[2] for a sample of words. We used a lexical sample because the cost of hand tagging several corpora for an all-words task would be prohibitive. We show that the sense distributions of words in this lexical sample differ depending on domain. We also show that sense distributions are more skewed in domain-specific text. Using McCarthy et al.'s method, we automatically acquire predominant sense information for the lexical sample from the (raw) corpora, and evaluate the accuracy of this and predominant sense information derived from SemCor. We show that in our domains and for these words, first sense information automatically acquired from a general corpus is more accurate than first senses derived from SemCor. We also show that deriving first sense information from text in the same domain as the target data performs best, particularly when focusing on words which are salient to that domain.

The paper is structured as follows. In section 2 we summarise McCarthy et al.'s predominant sense method. We then (section 3) describe the new gold standard corpora, and evaluate predominant sense accuracy (section 4). We discuss the results with a proposal for applying the method to an all-words task, and an analysis of our results in terms of this proposal before concluding with future directions.

2 Finding Predominant Senses

We use the method described in McCarthy et al. (2004) for finding predominant senses from raw text. The method uses a thesaurus obtained from the text by parsing, extracting grammatical relations and then listing each word (w) with its top k nearest neighbours, where k is a constant. Like McCarthy et al. (2004) we use $k = 50$ and obtain our thesaurus using the distributional similarity metric described by Lin (1998). We use WordNet (WN) as our sense inventory. The senses of a word w are each assigned a ranking score which sums over the distributional similarity scores of the neighbours and weights each neighbour's score by a WN Similarity score (Patwardhan and Pedersen, 2003) between the sense of w and the sense of the neighbour that maximises the WN Similarity score. This weight is normalised by the sum of such WN similarity scores between all senses of w and and the senses of the neighbour that maximises this score. We use the WN Similarity **jcn** score (Jiang and Conrath, 1997) since this gave reasonable results for McCarthy et al. and it is efficient at run time given precompilation of frequency information. The **jcn** measure needs word frequency information, which we obtained from the British National Corpus (BNC) (Leech, 1992). The distributional thesaurus was constructed using subject, direct object adjective modifier and noun modifier relations.

3 Creating the Three Gold Standards

In our experiments, we compare for a sample of nouns the sense rankings created from a balanced corpus (the BNC) with rankings created from domain-specific corpora (FINANCE and SPORTS) extracted from the Reuters corpus (Rose et al., 2002). In more detail, the three corpora are:

BNC: The 'written' documents, amounting to 3209 documents (around 89.7M words), and covering a wide range of topic domains.

FINANCE: 117734 FINANCE documents (around 32.5M words) topic codes: ECAT and MCAT

SPORTS: 35317 SPORTS documents (around 9.1M words) topic code: GSPO

We computed thesauruses for each of these corpora using the procedure outlined in section 2.

3.1 Word Selection

In our experiments we used FINANCE and SPORTS domains. To ensure that a significant number of the chosen words are relevant for these domains, we did not choose the words for our experiments completely randomly. The first selection criterion we applied used the Subject Field Code (SFC) re-

[2]This resource will be made publicly available for research purposes in the near future.

source (Magnini and Cavaglià, 2000), which assigns domain labels to synsets in WN version 1.6. We selected all the polysemous nouns in WN 1.6 that have at least one synset labelled SPORT and one synset labelled FINANCE. This reduced the set of words to 38. However, some of these words were fairly obscure, did not occur frequently enough in one of the domain corpora or were simply too polysemous. We narrowed down the set of words using the criteria: (1) frequency in the BNC $\geq$ 1000, (2) at most 12 senses, and (3) at least 75 examples in each corpus. Finally a couple of words were removed because the domain-specific sense was particularly obscure[3]. The resulting set consists of 17 words[4]: *club, manager, record, right, bill, check, competition, conversion, crew, delivery, division, fishing, reserve, return, score, receiver, running*

We refer to this set of words as **F&S cds**. The first four words occur in the BNC with high frequency ($\geq$ 10000 occurrences), the last two with low frequency ($\leq$ 2000) and the rest are mid-frequency.

Three further sets of words were selected on the basis of domain salience. We chose eight words that are particularly salient in the Sport corpus (referred to as **S sal**), eight in the Finance corpus (**F sal**), and seven that had equal (not necessarily high) salience in both, (**eq sal**). We computed salience as a ratio of normalised document frequencies, using the formula

$$S(w, d) = \frac{N_{wd}/N_d}{N_w/N}$$

where N_{wd} is the number of documents in domain d containing the noun (lemma) w, N_d is the number of documents in domain d, N_w is the total number of documents containing the noun w and N is the total number of documents.

To obtain the sets **S sal**, **F sal** and **eq sal** we generated the 50 most salient words for both domains and 50 words that were equally salient for both domains. These lists of 50 words were subjected to the same constraints as set **F&S cds**, that is occurring in the BNC $\geq$ 1000, having at most 12 senses, and having at least 75 examples in each corpus. From the remaining words we randomly sampled 8 words from the **Sport** salience list and **Finance** list and 7 from the salience list for words with equal salience in both domains. The resulting sets of words are:

S sal: *fan, star, transfer, striker, goal, title, tie, coach*

F sal: *package, chip, bond, market, strike, bank, share, target*

eq sal: *will, phase, half, top, performance, level, country*

The average degree of polysemy for this set of 40 nouns in WN (version 1.7.1) is 6.6.

3.2 The Annotation Task

For the annotation task we recruited linguistics students from two universities. All ten annotators are native speakers of English.

We set up annotation as an Open Mind Word Expert task[5]. Open Mind is a web based system for annotating sentences. The user can choose a word from a pull down menu. When a word is selected, the user is presented with a list of sense definitions. The sense definitions were taken from WN1.7.1 and presented in random order. Below the sense definitions, sentences with the target word (highlighted) are given. Left of the sentence on the screen, there are as many tick-boxes as there are senses for the word plus boxes for 'unclear' and 'unlisted-sense'. The annotator is expected to first read the sense definitions carefully and then, after reading the sentence, decide which sense is best for the instance of the word in a particular sentence. Only the sentence in which the word appears is presented (not more surrounding sentences). In case the sentence does not give enough evidence to decide, the annotator is expected to check the 'unclear' box. When the correct sense is not listed, the annotator should check the 'unlisted-sense' box.

The sentences to be annotated were randomly sampled from the corpora. The corpora were first part of speech tagged and lemmatised using RASP (Briscoe and Carroll, 2002). Up to 125 sentences were randomly selected for each word from each corpus. Sentences with clear problems (e.g. containing a begin or end of document marker, or mostly not text) were removed. The first 100 remaining sentences were selected for the task. For a few

[3]For example the Finance sense of 'eagle' (a former gold coin in US worth 10 dollars) is very unlikely to be found.

[4]One more word, 'pitch', was in the original selection. However, we did not obtain enough usable annotated sentences (section 3.2) for this particular word and therefore it was discarded.

[5]http://www.teach-computers.org/word-expert/english/

words there were not exactly 100 sentences per corpus available. The Reuters corpus contains quite a few duplicate documents. No attempts were made to remove duplicates.

3.3 Characterisation of the Annotated Data

Most of the sentences were annotated by at least three people. Some sentences were only done by two annotators. The complete set of data comprises 33225 tagging acts.

The inter-annotator agreement on the complete set of data was 65%[6]. For the BNC data it was 60%, for the Sports data 65% and for the Finance data 69%. This is lower than reported for other sets of annotated data (for example it was 75% for the nouns in the SENSEVAL-2 English all-words task), but quite close to the reported 62.8% agreement between the first two taggings for single noun tagging for the SENSEVAL-3 English lexical sample task (Mihalcea et al., 2004). The fairest comparison is probably between the latter and the inter-annotator agreement for the BNC data. Reasons why our agreement is relatively low include the fact that almost all of the sentences are annotated by three people, and also the high degree of polysemy of this set of words.

Problematic cases

The unlisted category was used as a miscellaneous category. In some cases a sense was truly missing from the inventory (e.g. the word ‘tie’ has a ‘game’ sense in British English which is not included in WN 1.7.1). In other cases we had not recognised that the word was really part of a multiword (e.g. a number of sentences for the word ‘chip’ contained the multiword ‘blue chip’). Finally there were a number of cases where the word had been assigned the wrong part of speech tag (e.g. the verb ‘will’ had often been mistagged as a noun). We identified and removed all these systematic problem cases from the unlisted senses. After removing the problematic unlisted cases, we had between 0.9% (FINANCE) and 4.5% (SPORTS) unlisted instances left. We also had between 1.8% (SPORTS) and 4.8% (BNC) unclear instances. The percentage of unlisted instances reflects the fit of WN to the data whilst that of unclear cases reflects the generality of the corpus.

[6]To compute inter-annotator agreement we used Amruta Purandare and Ted Pedersen’s OMtoSVAL2 Package version 0.01.

The sense distributions

WSD accuracy is strongly related to the entropy of the sense distribution of the target word (Yarowsky and Florian, 2002). The more skewed the sense distribution is towards a small percentage of the senses, the lower the entropy. Accuracy is related to this because there is more data (both training and test) shared between fewer of the senses. When the first sense is very predominant (exceeding 80%) it is hard for any WSD system to beat the heuristic of always selecting that sense (Yarowsky and Florian, 2002).

The sense distribution for a given word may vary depending on the domain of the text being processed. In some cases, this may result in a different predominant sense; other characteristics of the sense distribution may also differ such as entropy of the sense distribution and the dominance of the predominant sense. In Table 1 we show the entropy per word in our sample and relative frequency (relfr) of its first sense (fs), for each of our three gold standard annotated corpora. We compute the entropy of a word’s sense distribution as a fraction of the possible entropy (Yarowsky and Florian, 2002)

$$H_r(P) = \frac{H(P)}{log_2(\#senses)}$$

where $H(P) = -\sum_{i \in senses} p(i) log_2 p(i)$. This measure reduces the impact of the number of senses of a word and focuses on the uncertainty within the distribution. For each corpus, we also show the average entropy and average relative frequency of the first sense over all words.

From Table 1 we can see that for the vast majority of words the entropy is highest in the BNC. However there are exceptions: *return*, *fan* and *title* for FINANCE and *return*, *half*, *level*, *running strike* and *share* for SPORTS. Surprisingly, **eq sal** words, which are not particularly salient in either domain, also typically have lower entropy in the domain specific corpora compared to the BNC. Presumably this is simply because of this small set of words, which seem particularly skewed to the financial domain. Note that whilst the distributions in the domain-specific corpora are more skewed towards a predominant sense, only 7 of the 40 words in the FINANCE corpus and 5 of the 40 words in the SPORTS corpus have only one sense attested. Thus, even in domain-specific corpora ambiguity is

Training	Testing		
	BNC	FINANCE	SPORTS
BNC	**40.7**	43.3	33.2
FINANCE	39.1	**49.9**	24.0
SPORTS	25.7	19.7	**43.7**
Random BL	19.8	19.6	19.4
SemCor FS	32.0 (32.9)	33.9 (35.0)	16.3 (16.8)

Table 2: WSD using predominant senses, training and testing on all domain combinations.

Test - Train	**F&S cds**	**F sal**	**S sal**	**eq sal**
BNC-APPR	33.3	51.5	39.7	48.0
BNC-SC	28.3	44.0	24.6	36.2
FINANCE-APPR	37.0	70.2	38.5	70.1
FINANCE-SC	30.3	51.1	22.9	33.5
SPORTS-APPR	42.6	18.1	65.7	46.9
SPORTS-SC	9.4	38.1	13.2	12.2

Table 3: WSD using predominant senses, with training data from the same domain or from SemCor.

still present, even though it is less than for general text. We show the sense number of the first sense (fs) alongside the relative frequency of that sense. We use 'ucl' for unclear and 'unl' for unlisted senses where these are predominant in our annotated data. Although the predominant sense of a word is not always the domain-specific sense in a domain-specific corpus, the domain-specific senses typically occur more than they do in non-relevant corpora. For example, sense 11 of *return* (a tennis stroke) was not the first sense in SPORTS, however it did have a relative frequency of 19% in that corpus and was absent from BNC and FINANCE.

4 Predominant Sense Evaluation

We have run the predominant sense finding algorithm on the raw text of each of the three corpora in turn (the first step being to compute a distributional similarity thesaurus for each, as outlined in section 2). We evaluate the accuracy of performing WSD purely with the predominant sense heuristic using all 9 combinations of training and test corpora. The results are presented in Table 2. The random baseline is $\sum_{i \in tokens} \frac{1}{\#senses(i)}$. We also give the accuracy using a first sense heuristic from SemCor ('SemCor FS'); the precision is given alongside in brackets because a predominant sense is not supplied by SemCor for every word. [7] The automatic method proposes a predominant sense in every case.

The best results are obtained when training on a domain relevant corpus. In all cases, when training on appropriate training data the automatic method for finding predominant senses beats both the random baseline and the baseline provided by SemCor.

Table 3 compares WSD accuracy using the automatically acquired first sense on the 4 categories of words **F&S cds**, **F sal**, **S sal** and **eq sal** separately. Results using the training data from the appropriate domain (e.g. SPORTS training data for SPORTS test data) are indicated with 'APPR' and contrasted with the results using SemCor data, indicated with 'SC'. [8] We see that for words which are pertinent to the domain of the test text, it pays to use domain specific training data. In some other cases, e.g. **F sal** tested on SPORTS, it is better to use SemCor data. For the **eq sal** words, accuracy is highest when FINANCE data is used for training, reflecting their bias to financial senses as noted in section 3.3.

5 Discussion

We are not aware of any other domain-specific manually sense tagged corpora. We have created sense tagged corpora from two specific domains for a sample of words, and a similar resource from a balanced corpus which covers a wide range of domains. We have used these resources to do a quantitative evaluation which demonstrates that automatic acquisition of predominant senses outperforms the SemCor baseline for this sample of words.

The domain-specific manually sense tagged resource is an interesting source of information in itself. It shows for example that (at least for this particular lexical sample), the predominant sense is much more dominant in a specific domain than it is in the general case, even for words which are not particularly salient in that domain. Similar observations can be made about the average number of encountered senses and the skew of the sense distributions. It also shows that although the predominant sense is more dominant and domain-specific

[7]There is one such word in our sample, *striker*.

[8]For SemCor, precision figures for the **S sal** words are up to 4% higher than the accuracy figures given, however they are still lower than accuracy using the domain specific corpora; we leave them out due to lack of space.

senses are used more within a specific domain, there is still a need for taking local context into account when disambiguating words. The predominant sense heuristic is hard to beat for some words within a domain, but others remain highly ambiguous even within a specific domain. The *return* example in section 3.3 illustrates this.

Our results are for a lexical sample because we did not have the resources to produce manually tagged domain-specific corpora for an all words task. Although sense distribution data derived from SemCor can be more accurate than such information derived automatically (McCarthy et al., 2004), in a given domain there will be words for which the SemCor frequency distributions are inappropriate or unavailable. The work presented here demonstrates that the automatic method for finding predominant senses outperforms SemCor on a sample of words, particularly on ones that are salient to a domain. As well as domain-salient words, there will be words which are not particularly salient but still have different distributions than in SemCor. We therefore propose that automatic methods for determining the first sense should be used when either there is no manually tagged data, or the manually tagged data seems to be inappropriate for the word and domain under consideration. While it is trivial to find the words which are absent or infrequent in training data, such as SemCor, it is less obvious how to find words where the training data is not appropriate. One way of finding these words would be to look for differences in the automatic sense rankings of words in domain specific corpora compared to those of the same words in balanced corpora, such as the BNC. We assume that the sense rankings from a balanced text will more or less correlate with a balanced resource such as SemCor. Of course there will be differences in the corpus data, but these will be less radical than those between SemCor and a domain specific corpus. Then the automatic ranking method should be applied in cases where there is a clear deviation in the ranking induced from the domain specific corpus compared to that from the balanced corpus. Otherwise, SemCor is probably more reliable if data for the given word is available.

There are several possibilities for the definition of "clear deviation" above. One could look at differences in the ranking over all words, using a measure such as pairwise agreement of rankings or a ranking correlation coefficient, such as Spearman's. One could also use the rankings to estimate probability distributions and compare the distributions with measures such as alpha-skew divergence (Lee, 1999). A simple definition would be where the rankings assign different predominant senses to a word. Taking this simple definition of deviation, we demonstrate how this might be done for our corpora.

Training	Testing	
	FINANCE	SPORTS
Finance	35.5	-
Sports	-	40.9
SemCor	14.2 (15.3)	10.0

Table 4: WSD accuracy for words with a different first sense to the BNC.

We compared the automatic rankings from the BNC with those from each domain specific corpus (SPORTS and FINANCE) for all polysemous nouns in SemCor. Although the majority are assigned the same first sense in the BNC as in the domain specific corpora, a significant proportion (31% SPORTS and 34% FINANCE) are not. For all words WSD in either of these domains, it would be these words for which automatic ranking should be used. Table 4 shows the WSD accuracy using this approach for the words in our lexical sample with a different automatically computed first sense in the BNC compared to the target domain (SPORTS or FINANCE). We trained on the appropriate domain for each test corpus, and compared this with using SemCor first sense data. The results show clearly that using this approach to decide whether to use automatic sense rankings performs much better than always using SemCor rankings.

6 Conclusions

The method for automatically finding the predominant sense beat SemCor consistently in our experiments. So for some words, it pays to obtain automatic information on frequency distributions from appropriate corpora. Our sense annotated corpora exhibit higher entropy for word sense distributions for domain-specific text, even for words which are not specific to that domain. They also show that different senses predominate in different domains and that dominance of the first sense varies to a great extent, depending on the word. Previous work in all words WSD has indicated that techniques using hand-tagged resources outperform unsupervised methods. However, we demonstrate that it is possible to apply a fully automatic method to a subset of pertinent words to improve WSD accuracy. The automatic method seems to lead to better performance for words that are salient to a domain. There are also other words which though not particularly domain-salient, have a different sense distribution to that anticipated for a balanced corpus. We propose that in order to tackle an all words task, automatic methods should be applied to words which have a substantial difference in sense ranking compared to that obtained from a balanced corpus. We demonstrate that for a set of words which meet this condition, the performance of the automatic method is far better than when using data from SemCor. We will do further work to ascertain the best method for quantifying "substantial change".

We also intend to exploit the automatic ranking to obtain information on sense frequency distributions (rather than just predominant senses) given the genre as well as the domain of the text. We plan to combine this with local context, using collocates of neighbours in the thesaurus, for contextual WSD.

Abstract

This paper proposes a hybrid Chinese named entity recognition model based on multiple features. It differentiates from most of the previous approaches mainly as follows. Firstly, the proposed Hybrid Model integrates coarse particle feature (POS Model) with fine particle feature (Word Model), so that it can overcome the disadvantages of each other. Secondly, in order to reduce the searching space and improve the efficiency, we introduce heuristic human knowledge into statistical model, which could increase the performance of NER significantly. Thirdly, we use three sub-models to respectively describe three kinds of transliterated person name, that is, Japanese, Russian and Euramerican person name, which can improve the performance of PN recognition. From the experimental results on People's Daily testing data, we can conclude that our Hybrid Model is better than the models which only use one kind of features. And the experiments on MET-2 testing data also confirm the above conclusion, which show that our algorithm has consistence on different testing data.

1 Introduction

Named Entity Recognition (NER) is one of the key techniques in the fields of Information Extraction, Question Answering, Parsing, Metadata Tagging in Semantic Web, etc. In MET-2 held in conjunction with the Seventh Message Understanding Conference (MUC-7), the task of NER is defined as recognizing seven sub-categories entities: person (PN), location (LN), organization (ON), time, date, currency and percentage. As for Chinese NEs, we further divide PN into five sub-classes, that is, Chinese PN (CPN), Japanese PN (JPN), Russian PN (RPN), Euramerican PN (EPN) and abbreviated PN (APN) like "吴先生/Mr. Wu". Similarly, LN is split into common LN (LN) like "中关村/Zhongguancun" and abbreviated LN (ALN) such as "京/Beijing", "沪/Shanghai". The recognition of time (TM) and numbers (NM) is comparatively simpler and can be implemented via finite state automata. Therefore, our research focuses on the recognition of CPN, JPN, RPN, EPN, APN, LN, ALN and ON.

Compared to English NER, Chinese NER is more difficult. We think that the main differences between Chinese NER and English NER lie in: (1) Unlike English, Chinese lacks the capitalization information which can play very important roles in identifying named entities. (2) There is no space between words in Chinese, so we have to segment the text before NER. Consequently, the errors in word segmentation will affect the result of NER.

In this paper, we proposes a hybrid Chinese NER model based on multiple features which emphasizes on (1) combining fine particle features (Word Model) with coarse particle features (POS Model); (2) integrating human knowledge into statistical model; (3) and using diverse sub-models for different kinds of entities. Especially, we divide transliterated person name into three sub-classes according to their characters set, that is, JPN, RPN and EPN. In order to deduce the complexity of the model and the searching space, we divide the rec-

Proceedings of Human Language Technology Conference and Conference on Empirical Methods in Natural Language Processing (HLT/EMNLP), pages 427–434, Vancouver, October 2005. ©2005 Association for Computational Linguistics

ognition process into two steps: (1) word segmentation and POS tagging; (2) named entity recognition based on the first step.

Trained on the NEs labeled corpus of five-month People's Daily corpus and tested on one-month People's Daily corpus, the Hybrid Model achieves the following performance. The precision and the recall of PN (including CPN, JPN, RPN, EPN, AP N), LN (including ALN) and ON are respectively (94.06%, 95.21%), (93.98%, 93.48%), and (84.69%, 86.86%). From the experimental results on People's Daily testing data, we can conclude that our Hybrid Model is better than other models which only use one kind of features. And the experiments on MET-2 testing data also confirm the above conclusion, which show that our algorithm has consistence on different testing data.

2 Related Work

On the impelling of international evaluations like MUC, CoNLL, IEER and ACE, the researches on English NER have achieved impressive results. For example, the best English NER system[Chinchor. 1998] in MUC7 achieved 95% precision and 92% recall. However, Chinese NER is far from mature. For example, the performance (precision, recall) of the best Chinese NER system in MET-2 is (66%, 92%), (89%, 91%), (89%, 88%) for PN, LN and ON respectively.

Recently, approaches for NER are a shift away from handcrafted rules[Grishman, et al. 1995] [Krupka, et al. 1998][Black et al. 1998] towards machine learning algorithms, i.e. unsupervised model like DL-CoTrain, CoBoost[Collins, 1999, 2002], supervised learning like Error-driven [Aberdeen, et al. 1995], Decision Tree [Sekine, et al. 1998], HMM[Bikel, et al. 1997] and Maximum Entropy[Borthwick, et al. 1999][Mikheev, et al.1998].

Similarly, the models for Chinese NER can also be divided into two categories: Individual Model and Integrated Model.

Individual Model[Chen, et al. 1998][Sun, et al. 1994][Zheng, et al. 2000] consists of several sub-models, each of them deals with a kind of entities. For example, the recognition of PN may be statistical-based model, while LN and ON may be rule-based model like [Chen, et al. 1998]. Integrated Model[Sun, et al. 2002] [Zhang, et al. 2003][Yu, et al. 1998][Chua, et al. 2002] deals with all kinds of entities in a unified statistical framework. Most of these integrated models can be viewed as a HMM model. The differences among them are the definition of state and the features used in entity model and context model.

In fact, a NER model recognizes named entities through mining the intrinsic features in the entities and the contextual features around the entities. Most of existing approaches employ either coarse particle features, like POS and ROLE[Zhang, et al. 2003], or fine particle features like word. The data sparseness problem is serious if only using fine particle features, and coarse particle features will lose much important information though without serious data sparseness problem. *Our idea is that coarse particle features should be integrated into fine particle features to overcome the disadvantages of them.* However, most systems do not combine them and especially ignore the impact of POS.

Inspired by the algorithms of identifying BaseNP and Chunk[Xun, et al. 2000], we propose a hybrid NER model which emphasizes on combining coarse particle features (POS Model) with fine particle features (Word Model). Though the Hybrid Model can overcome the disadvantages of the Word Model and the POS Model, there are still some problems in such a framework. Data sparseness still exists and very large searching space in decoding will influence efficiency. *Our idea is that heuristic human knowledge can not only improve the time efficiency, but also solve the data sparseness problem to some extent by restricting the generation of entity candidates.* So we intend to incorporate human knowledge into the statistical model to improve efficiency and effectivity of the Hybrid Model.

Similarly, for capturing intrinsic features in different types of entities, we design several sub-models for each kind of entities. For example, we divide transliterated person name into three sub-classes according to their characters sets, that is, JPN, RPN and EPN.

3 Chinese NER with Multiple Features

Chinese NEs have very distinct word features in their composition and contextual information. For example, about 365 highest frequently used surnames cover 99% Chinese surnames[Sun, et al. 1994]. Similarly the characters used for transliterated names are also limited. LNs and ONs often end with the specific words like "省/province" and "公司/company". However, data sparseness is very serious when using word features. So we try to introduce coarse particle feature to overcome the data sparseness problem. POS features are simplest and easy to obtain. Therefore, our hybrid model combines word feature with POS feature to recognize Chinese NEs.

Given a word/pos sequence as equation (1):

$$W/T = w_1/t_1 \cdots w_i/t_i \cdots w_n/t_n \qquad (1)$$

where n is the number of words and t_i is the POS of word w_i. The task of Chinese NE identification is to find the optimal sequence WC^*/TC^* by splitting, combining and classifying the sequence of (1).

$$WC^*/TC^* = wc_1/tc_2 \cdots wc_i/tc_i \cdots wc_m/tc_m \qquad (2)$$

where $wc_i = \lfloor w_j \cdots w_{j+l} \rfloor$, $tc_i = \lfloor t_j \cdots t_{j+l} \rfloor$, $m \le n$.

Note that the definition of words in $\{w_i\}$ set is that each kind of NEs (including PN, APN, LN, ALN, ON, TM, NM) is defined as a word and all the other words in the vocabulary are also defined as individual words. Consequently, $\{w_i\}$ set has $|V|+7$ words, where $|V|$ is the size of vocabulary. The size of $\{t_i\}$ set is 48 which include PKU POS tagging set1 and each kind of NEs.

Obviously, we could obtain the optimal sequence WC^*/TC^* through the following three models: the Word Model, the POS Model and the Hybrid Model.

The Word Model employs word features for NER, which is introduced by [Sun, et al. 2002]. The POS Model employs POS features for NER. This paper proposes a Hybrid Model which combines word features with POS features.

We will describe these models in detail in following section.

3.1 The Hybrid Model

For the convenience of description, we take apart equation (1) into two components: word sequence as equation (3) and POS sequence as (4).

$$W = w_1\, w_2 \cdots w_i \cdots w_n \qquad (3)$$

$$T = t_1\, t_2 \cdots t_i \cdots t_n \qquad (4)$$

The Word Model estimates the probability of generating a NE from the viewpoint of word sequence, which can be expressed in equation (5).

$$WC^* = argmax_{wc} P(WC)P(W \mid WC) \qquad (5)$$

The POS Model estimates the probability of generating a NE from the viewpoint of POS sequence, which can be expressed in equation (6).

$$TC^* = argmax_{TC} P(TC)P(T \mid TC) \qquad (6)$$

Our proposed Hybrid Model combines the Word Model with the POS Model, which can be expressed in the equation (7).

$$\begin{aligned}
&(WC^*, TC^*) \\
&= argmax_{(WC,TC)} P(WC, TC \mid W, T) \\
&= argmax_{(WC,TC)} P(WC, TC, W, T)P(W, T) \\
&= argmax_{(WC,TC)} P(WC, TC, W, T) \\
&\approx argmax_{(WC,TC)} P(W \mid WC)P(WC)[P(T \mid TC)P(TC)]^{\xi}
\end{aligned} \qquad (7)$$

where factor $\zeta > 0$ is to balance the Word Model and the POS Model.

Therefore, the Hybrid Model consists of four sub-models: word context model *P(WC)*, POS context model *P(TC)*, word entity model *P(W|WC)* and POS entity model *P(T|TC)*.

3.2 Context Model

The word context model and the POS context model estimate the probability of generating a word or a POS given previous context. *P(WC)* and *P(TC)* can be estimated according to (8) and (9) respectively.

$$P(WC) = \prod_{i=1}^{m} P(wc_i \mid wc_{i\ 2}\ wc_{i\ 1}) \qquad (8)$$

$$P(TC) = \prod_{i=1}^{m} P(tc_i \mid tc_{i\ 2}\ tc_{i\ 1}) \qquad (9)$$

3.3 Word Entity Model

Different types of NEs have different structures and intrinsic characteristics. Therefore, a single model can't capture all types of entities. Typical, character-based model is more appropriate for PNs, whereas, word-based model is more competent for LNs and ONs. Especially, we divided transliterated PN into three categories such as JPN, RPN and EPN.

For the sake of estimating the probability of generating a NE, we define 19 sub-classes shown as Table 1 according to their position in NEs.

Tag	Description
Sur	Surname of CPN
Dgb	First character of Given Name of CPN
Dge	Last character of Give Name of CPN
Bfn	First character of EPN
Mfn	Middle character of EPN
Efn	Last character of EPN
RBfn	First character of RPN
RMfn	Middle character of RPN
REfn	Last character of RPN
JBfn	surname of JPN
JMfn	Middle character of JPN
JEfn	Last character of JPN
Bol	First word of LN
Mol	Middle word of LN
Eol	Last word of LN
Aloc	Single character LN
Boo	First word of ON
Moo	Middle word of ON
Eoo	Last word of ON

Table 1 Sub-classes in Entity Model

3.3.1 Word Entity Model for PN

For the class of PN (including CPN, APN, JPN, RPN and EPN), the word entity model is a character-based trigram model which can be expressed in equation (10).

$$\begin{aligned} & P\left(w_{wc_{i1}} \cdots w_{wc_{ik}} \mid wc_i\right) \\ & = P\left(w_{wc_{i1}} \cdots w_{wc_{ik}} \mid BNe \overbrace{MNe \cdots MNe}^{k-2} ENe \right) \\ & \cong P\left(w_{wc_{i1}} \mid BNe\right) \times \prod_{l=2}^{k-1} P\left(w_{wc_{il}} \mid MNe, w_{wc_{i(l-1)}}\right) \\ & \times P\left(w_{wc_{ik}} \mid ENe, w_{wc_{i(k-1)}}\right) \end{aligned} \qquad (10)$$

where, BNe, MNe and ENe denotes the first, middle and last characters respectively.

The word entity models for PN are estimated with Chinese, Japanese, Russian and Euramerican names lists which contain 15.6 million, 0.15 million, 0.44 million, 0.4 million entities respectively.

3.3.2 Word Entity Model for LN and ON

For the class of LN and ON, the word entity model is a word-based trigram model. The model can be expressed by (11).

$$\begin{aligned} & P\left(w_{wc_i\ start} \cdots w_{wc_i\ end} \mid wc_i\right) \\ & = P\left(wc_{wc_{i1}} \cdots wc_{wc_{il}} \cdots wc_{wc_{ik}} \mid BNe \overbrace{MNe \cdots MNe}^{k\ 2} ENe \right) \\ & = P\left(wc_{wc_{i1}} \mid BNe\right) P\left(w_{wc_{i1}\ start} .. w_{wc_{i1}\ end} \mid wc_{wc_{i1}}\right) \\ & \times \prod_{l=2}^{k\ 1} P\left(wc_{il} \mid MNe, wc_{i(l\ 1)}\right) P\left(w_{wc_{il}\ start} \cdots w_{wc_{il}\ end} \mid wc_{wc_{il}}\right) \\ & \times P\left(wc_{wc_{ik}} \mid ENe, wc_{wc_{i(k\ 1)}}\right) P\left(w_{wc_{ik}\ start} \cdots w_{wc_{ik}\ end} \mid wc_{ik}\right) \end{aligned} \qquad (11)$$

The word entity models and the POS entity model for LN and ON are estimated with LN and ON names lists which respectively contain 0.44 mil-lion and 3.2 million entities.

3.3.3 Word Entity Model for ALN

For the class of ALN, we use word-based bi-gram model. The entity model for ALN can be expressed by equation (12).

$$P\left(w_i \mid ALoc\right) = \frac{C\left(w_i, ALoc\right)}{C(ALoc)} \qquad (12)$$

where w_i is the ALN which includes single and multiple characters ALN.

3.4 POS Entity Model

But for the class of PN, it's very difficult to obtain the corpus to train POS Entity Model. For the sake of simplification, we use word entity model shown in equation (10) to replace the POS entity model.

For the class of LN and ON, POS entity model can be expressed by equation (13).

$$\begin{aligned} & P\left(t_{tc_i\ start} \cdots t_{tc_i\ end} \mid tc_i\right) \\ & = P\left(tc_{tc_{i1}} \cdots tc_{tc_{il}} \cdots tc_{tc_{ik}} \mid BNe \overbrace{MNe \cdots MNe}^{k\ 2} ENe \right) \\ & = P\left(tc_{tc_{i1}} \mid BNe\right) P\left(t_{tc_{i1}\ start} .. t_{wc_{i1}\ end} \mid tc_{tc_{i1}}\right) \\ & \times \prod_{l=2}^{k\ 1} P\left(tc_{il} \mid MNe, tc_{i(l\ 1)}\right) P\left(t_{tc_{il}\ start} \cdots t_{tc_{il}\ end} \mid tc_{tc_{il}}\right) \\ & \times P\left(tc_{tc_{ik}} \mid ENe, tc_{tc_{i(k\ 1)}}\right) P\left(t_{tc_{ik}\ start} \cdots t_{tc_{ik}\ end} \mid tc_{ik}\right) \end{aligned} \qquad (13)$$

While for the class of ALN, POS entity model is shown as equation (14).

$$P\left(t_i \mid ALoc\right) = \frac{C\left(ti, ALoc\right)}{C(ALoc)} \qquad (14)$$

4 Heuristic Human Knowledge

In this section, we will introduce heuristic human knowledge that is used for Chinese NER and the method of how to incorporate them into statistical model which are shown as follows.

1. CPN surname list (including 476 items) and JPN surnames list (including 9189 items): Only those characters in the surname list can trigger person name recognition.

2. RPN and EPN characters lists: Only those consecutive characters in the transliterated character list form a candidate transliterated name.

3. Entity Length Restriction: Person name cannot span any punctuation and the length of CN cannot exceed 8 characters while the length of TN is unrestrained.

4. Location keyword list (including 607 items): If the word belongs to the list, 2~6 words before the salient word are accepted as candidate LNs.

5. General word list (such as verbs and prepositions): Words in the list usually is followed by a location name, such as "在/at", "去/go". If the current word is in the list, 2~6 words following it are accepted as candidate LNs.

6. ALN name list (including 407 items): If the current word belongs to the list, we accept it as a candidate ALN.

7. Organization keyword list (including 3129 items): If the current word is in organization keyword list, 2~6 words before keywords are accepted as the candidate ONs.

8. An organization name template list: We mainly use organization name templates to recognize the missed nested ONs in the statistical model. Some of these templates are as follows:

ON-->LN D OrgKeyWord*
ON-->PN D OrgKeyWord*
ON-->ON OrgKeyWord

D and *OrgKeyWord* denote words in the middle of ONs and ONs keywords. *D** means repeating zero or more times.

5 Back-off Model to Smooth

Data sparseness problem still exists. As some parameters were never observed in training corpus, the model will back off to a less powerful model. The escape probability[Black, et al. 1998] was adopted to smooth the statistical model shown as (15).

$$\hat{p}(W_N|W_1\cdots W_{N\ 1}) = \lambda_N p(W_N|W_1\cdots W_{N\ 1}) + \lambda_{N\ 1}p(W_N|W_2\cdots W_{N\ 1}) + \cdots + \lambda_1 p(W_N) + \lambda_0 p_0 \quad (15)$$

where $\lambda_N = 1\quad e_N$, $\lambda_i = (1\quad e_i)\sum_{k=i+1}^{N} e_k, 0 < i < N$, and e_i is the escape probability which can be estimated by equation (16).

$$e_N = \frac{q(W_1W_2\cdots W_{N\ 1})}{f(W_1W_2\cdots W_{N\ 1})} \quad (16)$$

$q(w_1w_2...w_{N-1})$ in (16) denotes the number of different symbol w_N that have directly followed the word sequence $w_1w_2...w_{N-1}$.

6 Experiments

In this chapter, we will conduct experiments to answer the following questions.

Will the Hybrid Model be more effective than the Word Model and the POS Model? To answer this question, we will compare the performances of models with different parameter ζ and find the best value of ζ in equation (7).

Will the conclusion from different testing sets be consistent? To answer this question, we evaluate models on the MET-2 test data and compare the performances of the Word Model, the POS Model and the Hybrid Model.

Will the performance be improved significantly after combining human knowledge? To answer this question, we compare two models with and without human knowledge.

In our evaluation, only NEs with correct boundaries and correct categories are considered as the correct recognition. We conduct evaluations in terms of precision, recall and F-Measure. Note that PNs in experiments includes all kinds of PNs and LNs include ALNs.

6.1 Will the Hybrid Model be More Effective Than the Word Model and POS Model?

The parameter ζ in equation (7) denotes the balancing factor of the Word Model and the POS Model. The larger ζ, the larger contribution of the POS Model. The smaller ζ, the larger contribution of the Word Model. So the task of this experiment is to find the best value of ζ. In this experiment, the training corpus is from five-month's People's Daily tagged with NER tags and the testing set is from one-month's People's Daily.

With the change of ζ, the performances of recognizing PNs are shown in Fig.1.

Note that the left, middle and right point in abscissa respectively denote the performance of the

Word Model, the Hybrid Model and the POS Model.

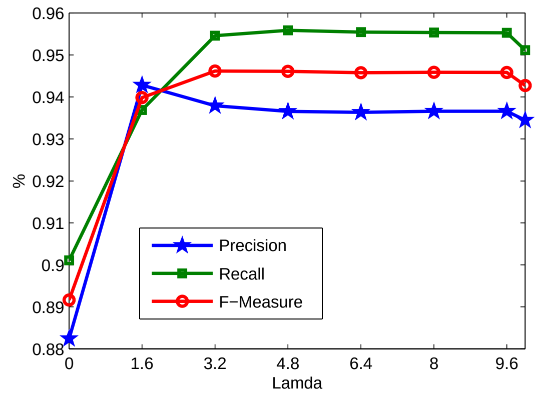

Fig.1 Performance of Recognizing LNs Impacted by ζ

From Fig.1, we can find that the performances of recognizing PNs are improved with the increasing of ζ in the beginning stage but decline in the ending. This experiment shows that the Word Model and the POS Model can overcome their disadvantages, and it is a feasible approach to integrate the Word Model and the POS Model in order to improve the performance PNs recognition.

With the change of ζ, the performances of recognizing LNs are shown in Fig.2.

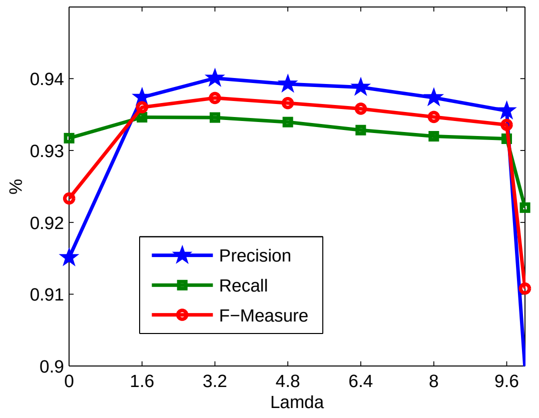

Fig.2 Performance of Recognizing LNs Impacted by ζ

As the Fig.2 shows, the precision and recall of LNs are improved with the increasing of ζ and decreased in the later stage. This phenomenon also proves that the Hybrid Model is better for recognizing LN than either the Word Model or the POS Model.

Similarly, with the change of ζ, the performances of recognizing ONs are shown in Fig.3.

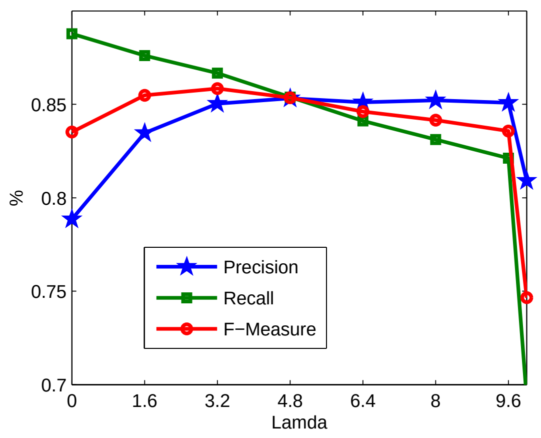

Fig.3 Performance of Recognizing LNs Impacted by ζ

Comparing Fig.3 with Fig.1 and Fig.2, we find that the POS Model has different impact on recognizing ONs from that on recognizing PNs and LNs. Especially, the POS Model has obvious side-effect on the recall. We speculate that the reasons may be that the probability of generating POS sequence by POS entity model is lower than that by POS context model.

According to Fig.1~Fig.3, we choose the best value ζ = 2.8. And the performances of different models are shown in Table 2 in detail.

		P(%)	R(%)	F(%)
Hybrid Model (ζ= 2.8)	**PN**	94.06	95.21	94.63
	LN	93.98	93.48	93.73
	ON	84.69	86.86	85.76
Word Model				
	PN	88.24	90.11	89.16
	LN	91.50	93.17	92.32
	ON	78.85	88.77	83.52
POS Model				
	PN	93.44	95.11	94.27
	LN	89.97	92.20	91.07
	ON	80.90	69.29	74.65

Table 2 Performance of the Hybrid Model, the Word Model and the POS Model

From Table 2, we find that the F-Measures of the Hybrid Model for PN, LN, ON are improved by 5.4%, 1.4%, 2.2% respectively in comparison with the Word Model, and these F-Measures are improved by 0.4%, 2.7%, 11.1% respectively in comparison with the POS Model.

Conclusion 1: The experimental results validate our idea that the Hybrid Model can improve the performance of both the Word Model and the POS Model. However, the improvements for PN, LN and ON are different. That is, the POS Model has obvious side-effect on the recall of ON recognition at all times, while the recalls for PN and ON recognition are improved in the beginning but decreased in the ending with the increasing of ζ.

6.2 Will the Conclusion from Different Testing Sets be Consistent?

We also conduct experiments on the MET-2 testing corpus to validate our conclusion from Exp.1, that is, the Hybrid Model could achieve better performance than either the Word Model or the POS Model alone. The experimental results (F-Measure) on MET-2 are shown in Table 3.

Model	**Word Model**	**Hybrid Model**	**POS Model**
PN	75.21%	**80.77**%	76.61%
LN	89.78%	**90.95**%	89.81%
ON	76.30%	**80.21**%	76.83%

Table 3 F-Measure on MET-2 test corpus

Comparing Table 3 with Table 2, we find that the performances of models on MET-2 are not as good as that on People Daily's testing data. The main reason lies in that the NE definitions in People Daily's corpus are different from that in MET-2. However, Table 3 can still validate our conclude 1, that is, the Hybrid Model is better than both the Word Model and the POS Model. For example, the F-Measures of the Hybrid Model for PN, LN and ON are improved by 5.6%, 1.2% and 3.9% respectively in comparison with the Word Model, and these F-Measures are improved by 4.2%, 3.1% and 3.4% respectively in comparison with the POS Model.

Conclusion 2: Though the performances of the Hybrid Model on MET-2 are not as good as that on People's Daily corpus, the experimental results also support conclusion 1, i.e. the Hybrid Model which combining the Word Model with the POS Model can achieve better performance than either the Word Model or the POS Model.

6.3 Will the Performance be Improved Significantly after Incorporating Human Knowledge?

One of our ideas in this paper is that human knowledge can not only reduce the search space, but also improve the performance through avoiding generating the noise NEs. This experiment will be conducted to validate this idea. Table 4 shows the performances of models with and without human knowledge.

		P(%)	R(%)	F(%)
Model I	**PN**	91.81	70.65	79.85
	LN	79.47	88.83	83.89
	ON	64.95	80.63	71.95
Model II				
	PN	94.06	95.21	94.63
	LN	93.98	93.48	93.73
	ON	84.69	86.86	85.76

Table 4 Performances Impacted by Human Knowledge

From Table 4, we find that F-Measure of model with human knowledge (Model II) is improved by 14.8%，9.8%，13.8% for PN, LN and ON respectively compared with that of the model without human knowledge (Model I).

Conclusion 3: From this experiment, we learn that human knowledge can not only reduce the search space, but also significantly improve the performance of pure statistical model.

7 Conclusion

In this paper, we propose a hybrid Chinese NER model which combines multiple features. The main contributions are as follows: ① The proposed Hybrid Model emphasizes on integrating coarse particle feature (POS Model) with fine particle feature (Word Model), so that it can overcome the disadvantages of each other; ② In order to reduce the search space and improve the efficiency of model, we incorporate heuristic human knowledge into statistical model, which could increase the performance of NER significantly; ③ For capturing intrinsic features in different types of entities, we design several sub-models for different entities. Especially, we divide transliterated person name into three sub-classes according to their characters set, that is, CPN JPN, RPN and EPN.

There is a lack of effective recognition strategy for abbreviated ONs such as 昆明机床(Kunming Machine Tool Co.,Ltd), 凤凰光学(Phoenix Photonics Ltd) in this paper. And most of misrecognized ONs in current system belong to them. So in the future work, we will be focusing more on recognizing abbreviated ONs.

Cluster-specific Named Entity Transliteration

Fei Huang

School of Computer Science
Carnegie Mellon University, Pittsburgh, PA 15213
fhuang@cs.cmu.edu

Abstract

Existing named entity (NE) transliteration approaches often exploit a general model to transliterate NEs, regardless of their origins. As a result, both a Chinese name and a French name (assuming it is already translated into Chinese) will be translated into English using the same model, which often leads to unsatisfactory performance. In this paper we propose a cluster-specific NE transliteration framework. We group name origins into a smaller number of clusters, then train transliteration and language models for each cluster under a statistical machine translation framework. Given a source NE, we first select appropriate models by classifying it into the most likely cluster, then we transliterate this NE with the corresponding models. We also propose a phrase-based name transliteration model, which effectively combines context information for transliteration. Our experiments showed substantial improvement on the transliteration accuracy over a state-of-the-art baseline system, significantly reducing the transliteration character error rate from 50.29% to 12.84%.

1 Introduction

Named Entity (NE) translation and transliteration are very important to many multilingual natural language processing tasks, such as machine translation, crosslingual information retrieval and question answering. Although some frequently occurring NEs can be reliably translated using information from existing bilingual dictionaries and parallel or monolingual corpora (Al-Onaizan and Knight, 2002; Huang and Vogel, 2002; Lee and Chang, 2003), less frequently occurring NEs, especially new names, still rely on machine transliteration to generate their translations.

NE machine transliteration generates a phonetically similar equivalent in the target language for a source NE, and transliteration patterns highly depend on the name's origin, e.g., the country or the language family this name is from. For example, when transliterating names[1] from Chinese into English, as shown in the following example, the same Chinese character "金" is transliterated into different English letters according to the origin of each person.

金人庆 --- **Jin** Renqing (China)
金大中 --- **Kim** Dae-jung (Korea)
马丁 路德 金 --- Martin Luther **King** (USA)
金丸信 --- **Kane**maru Shin (Japan)
何塞 华金 布伦纳 --- Jose Joa**quin** Brunner (Chile)

Several approaches have been proposed for name transliteration. (Knight and Graehl, 1997) proposed a generative transliteration model to transliterate foreign names in Japanese back to English using finite state transducers. (Stalls and Knight, 1998) expanded that model to Arabic-English transliteration. (Meng et al. 2001) developed an English-Chinese NE transliteration technique using pronunciation lexicon and phonetic mapping rules. (Virga and Khudanpur, 2003) applied statistical machine translation models to "translate" English names into Chinese characters for Mandarin spoken document retrieval. All these approaches exploit a general model for NE transliteration, where source names from different origins or language families are transliterated into the target language with the same rules or probability distributions, which fails to capture their different

[1] Assuming foreign names are already transliterated into Chinese.

transliteration patterns. Alternatively, (Qu and Grefenstette, 2004) applied language identification of name origins to select language-specific transliterations when back-transliterating Japanese names from English to Japanese. However, they only classified names into three origins: Chinese, Japanese and English, and they used the Unihan database to obtain the mapping between kenji characters and romanji representations.

Ideally, to explicitly model these transliteration differences we should construct a transliteration model and a language model for each origin. However, some origins lack enough name translation pairs for reliable model training. In this paper we propose a cluster-specific NE transliteration framework. Considering that several origins from the same language family may share similar transliteration patterns, we group these origins into one cluster, and build cluster-specific transliteration and language models.

Starting from a list of bilingual NE translation pairs with labeled origins, we group closely related origins into clusters according to their language and transliteration model perplexities. We train cluster-specific language and transliteration models with merged name translation pairs. Given a source name, we first select appropriate models by classifying it into the most likely cluster, then we transliterate the source name with the corresponding models under the statistical machine translation framework. This cluster-specific transliteration framework greatly improves the transliteration performance over a general transliteration model. Further more, we propose a phrase-based transliteration model, which effectively combines context information for name transliteration and achieves significant improvements over the traditional character-based transliteration model.

The rest of the paper is organized as following: in section 2 we introduce the NE clustering and classification schemes, and we discuss the phrase-based NE transliteration in section 3. Experiment settings and results are given in section 4, which is followed by our conclusion.

2 Name Clustering and Classification

Provided with a list of bilingual name translation pairs whose origins are already labeled, we want to find the origin clusters where closely related origins (countries sharing similar languages or cultural heritages) are grouped together.

We define the similarity measure between two clusters as their LM and TM perplexities. Let $S_i = \{(F_i, E_i)\}$ denote a set of name translation pairs from origin i, from which model θ_i is trained: $\theta_i = (P_{c(i)}, P_{e(i)}, P_{t(i)})$. Here $P_{c(i)}$ and $P_{e(i)}$ are N-gram character language models (LM) for source and target languages, and $P_{t(i)}$ is a character translation model trained based on IBM translation model 1 (Brown et.al. 1993). The distance between origin i and origin j can be symmetrically defined as:

$$d(i,j) = -\frac{1}{|S_i|}\log P(S_i \mid \theta_j) - \frac{1}{|S_j|}\log P(S_j \mid \theta_i),$$

where, assuming name pairs are generated independently,

$$P(S_i \mid \theta_j) \propto \sum_{t=1}^{|S_i|} \log[P_{c(j)}(F_i^t)P_{t(j)}(E_i^t \mid F_i^t) + P_{e(j)}(E_i^t)P_{t(j)}(F_i^t \mid E_i^t)]$$

We calculate the pair-wise distances among these origins, and cluster them with group-average agglomerative clustering. The distance between clusters C_i and C_j is defined as the average distance between all origin pairs in each cluster. This clustering algorithm initially sets each origin as a single cluster, then recursively merges the closest cluster pair into one cluster until an optimal number of clusters is formed.

Among all possible cluster configurations, we select the optimal cluster number based on the model perplexity. Given a held-out data set L, a list of name translation pairs from different origins, the probability of generating L from a cluster configuration Θ_ω is the product of generating each name pair from its most likely origin cluster:

$$P(L \mid \Theta_\omega) = \prod_{t=1}^{|L|} \max_{j \in \Theta_\omega} P(F^t, E^t \mid \theta_j)P(\theta_j)$$
$$= \prod_{t=1}^{|L|} \max_{j \in \Theta_\omega} P_{c(j)}(F^t)P_{e(j)}(E^t)P(\theta_j)$$

We calculate the language model perplexity:

$$pp(L, \Theta_\omega) = 2^{-\frac{1}{|L|}\log P(L \mid \Theta_\omega)} = P(L \mid \Theta_\omega)^{-1/|L|},$$

and select the model configuration with the smallest perplexity. We clustered 56K Chinese-English name translation pairs from 112 origins, and evaluate the perplexities of different models (number of

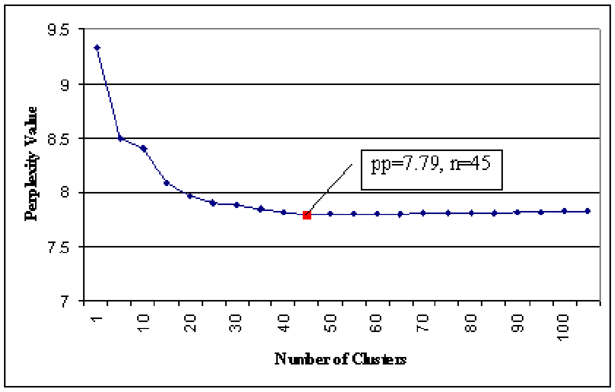

Figure 1. Perplexity value of LMs with different number of clusters

clusters) with regard to a held-out 3K name pairs. As shown in Figure 1, the perplexity curve reaches its minimum when $n = 45$. This indicates that the optimal cluster number is 45.

Table 1 lists some typical origin clusters. One may notice that countries speaking languages from the same family are often grouped together. These countries are either geographically adjacent or historically affiliated. For example, in the English cluster, the Netherlands (Dutch) seems an abnormality. In the clustering process it was first grouped with the South Africa, which was colonized by the Dutch and the English in the seventeenth century. This cluster was further grouped into the English-speaking cluster. Finally, some origins cannot be merged with any other clusters because they have very unique names and translation patterns, such as China and Japan, thus they are kept as single origin clusters.

For name transliteration task, given a source name *F* we want to classify it into the most likely cluster, so that the appropriate cluster-specific model can be selected for transliteration. Not knowing *F*'s translation *E*, we cannot apply the translation model and the target language model for name origin classification. Instead we train a Bayesian classifier based on N-gram source character language models, and assign the name to the cluster with the highest LM probability. Assuming a source name is composed of a sequence of source characters: $F = \{f_1, f_2, ..., f_l\}$. We want to find the cluster j^* such that

Arabic	Afghanistan, Algeria, Egypt, Iran, Iraq, Jordan, Kuwait, Pakistan, Palestine, Saudi Arabia, Sudan, Syria, Tunisia, Yemen, …
Spanish-Portuguese	Angola, Argentina, Bolivia, Brazil, Chile, Colombia, Cuba, Ecuador, Mexico, Peru, Portugal, Spain, Venezuela, …
English	Australia, Canada, Netherlands, New Zealand, South Africa, UK, USA, …
Russian	Belarus, Kazakhstan, Russia, Ukraine
East European	Bosnia and Herzegovina, Croatia, Yugoslavia
French (African)	Benin, Burkina Faso, Cameroon, Central African Republic, Congo, Gabon, Ivory Coast
German	Austria, Germany, Switzerland
French	Belgium, France, Haiti
Korean	North Korea, South Korea
Danish-Swedish	Denmark, Norway, Sweden
Single Clusters	China Japan Indonesia Israel ……

Table 1 Typical name clusters (n=45)

$$\begin{aligned} j^* &= \arg\max_j P(\theta_j \mid F) \\ &= \arg\max_j P(\theta_j) P(F \mid \theta_j) \qquad (1) \\ &= \arg\max_j P(\theta_j) P_{c(j)}(F) \end{aligned}$$

where $P(\theta_j)$ is the prior probability of cluster *j*, estimated based on its distribution in all the training data, and $P_{c(j)}(F)$ is the probability of generating this source name based on cluster j's character language model.

3 Phrase-Based Name Transliteration

Statistical NE transliteration is similar to the statistical machine translation in that an NE translation pair can be considered as a parallel sentence pair, where "words" are characters in source and target languages. Due to the nature of name transliteration, decoding is mostly monotone.

NE transliteration process can be formalized as:

$$E^* = \text{argmax}_E\, P(E \mid F) = \text{argmax}_E\, P(F \mid E)P(E)$$

where E^* is the most likely transliteration for the source NE F, $P(F|E)$ is the transliteration model and $P(E)$ is the character-based target language model. We train a transliteration model and a language model for each cluster, using the name translation pairs from that cluster.

3.1 Transliteration Model

A transliteration model provides a conditional probability distribution of target candidates for a given source transliteration unit: a single character or a character sequence, i.e., "phrase". Given enough name translation pairs as training data, we can select appropriate source transliteration units, identify their target candidates from a character alignment path within each name pair, and estimate their transliteration probabilities based on their co-occurrence frequency.

A naive choice of source transliteration unit is a single character. However, single characters lack contextual information, and their combinations may generate too many unlikely candidates. Motivated by the success of phrase-based machine translation approaches (Wu 1997, Och 1999, Marcu and Wong 2002 and Vogel et. al., 2003), we select transliteration units which are long enough to capture contextual information while flexible enough to compose new names with other units. We discover such source transliteration phrases based on a character collocation likelihood ratio test (Manning and Schutze 1999). This test accepts or rejects a null hypothesis that the occurrence of one character f_1 is independent of the other, f_2, by calculating the likelihood ratio between the independent (H_0) and dependent (H_1) hypotheses:

$$\begin{aligned}\log\lambda &= \log\frac{L(H_0)}{L(H_1)}\\ &= \log L(c_{12}, c_1, p) + \log L(c_2 - c_{12}, N - c_1, p)\\ &\quad - \log L(c_{12}, c_1, p_1) - \log L(c_2 - c_{12}, N - c_1, p_2)\end{aligned}$$

L is the likelihood of getting the observed character counts under each hypothesis. Assuming the character occurrence frequency follows a binomial distribution, $L(k,n,x) = \binom{n}{k} x^k (1-x)^{n-k}$,

c_1, c_2, c_{12} are the frequencies of f_1, f_2 and $f_1 \wedge f_2$, and N is the total number of characters. p, p_1 and p_2 are defined as:

$$p = \frac{c_2}{N}, \quad p_1 = \frac{c_{12}}{c_2}, \quad p_2 = \frac{c_2 - c_{12}}{N - c_1}.$$

We calculate the likelihood ratio for any adjacent source character pairs, and select those pairs whose ratios are higher than a predefined threshold. Adjacent character bigrams with one character overlap can be recursively concatenated to form longer source transliteration phrases. All these phrases and single characters are combined to construct a cluster-specific phrase segmentation vocabulary list, T. For each name pair in that cluster, we

1. Segment the Chinese character sequence into a source transliteration phrase sequence based on maximum string matching using T;
2. Convert Chinese characters into their romanization form, *pinyin*, then align the pinyin with English letters via phonetic string matching, as described in (Huang et. al., 2003);
3. Identify the initial phrase alignment path based on the character alignment path;
4. Apply a beam search around the initial phrase alignment path, searching for the optimal alignment which minimizes the overall phrase alignment cost, defined as:

$$A^* = \arg\min_A \sum_{a_i \in A} D(f_i, e_{a_i}).$$

Here f_i is the ith source phrase in F, e_{a_i} is its target candidate under alignment A. Their alignment cost D is defined as the linear interpolation of the phonetic transliteration cost $\log P_{trl}$ and semantic translation cost $\log P_{trans}$:

$$D(f,e) = \lambda \log P_{trl}(e \mid f) + (1-\lambda)\log P_{trans}(e \mid f),$$

where P_{trl} is the product of the letter transliteration probabilities over aligned pinyin-English letter pairs, P_{trans} is the phrase translation probability calculated from word translation probabilities, where a "word" refers to a Chinese character or a English letter. More details about these costs are described in (Huang et. al., 2003). λ is a cluster-specific interpolation weight, reflecting the relative contributions of the transliteration cost and the translation cost. For example, most Latin language names are often phonetically translated into Chinese, thus the transliteration cost is usually the dominant feature. However, Japanese names are often semantically translated when they contain characters borrowed from Chinese, therefore the translation cost is more important for the Japanese model (λ=0 in this case). We empirically select the interpolation weight for each cluster, based on their transliteration performance on held-out name pairs, and the combined model with optimal interpolation weights achieves the best overall performance.

We estimate the phrase transliteration probability according to their normalized alignment frequencies. We also include frequent sub-name translations (first, middle and last names) in the transliteration dictionary. Table 2 shows some typical transliteration units (characters or phrases) from three clusters. They are mostly names or sub-names capturing cluster-specific transliteration patterns. It also illustrates that in different clusters the same character has different transliteration candidates with different probabilities, which justifies the cluster-specific transliteration modeling.

Arabic	穆罕默德 mohamed 阿卜杜勒 abdul 艾哈迈德 ahmed
	尤: yo (0.27) y(0.19) you(0.14)…
English	约翰 john 威廉 william 彼得 peter
	尤: u(0.25) you(0.38) joo(0.16)…

	尤： yu(0.49) y(0.08) iu(0.07)…

Table 2. Transliteration units examples from three name clusters.

3.2 Language model and decoding

For each cluster we train a target character language model from target NEs. We use the N-gram models with standard smoothing techniques.

During monotone decoding, a source NE is segmented into a sequence of transliteration units, and each source unit is associated with a set of target candidate translations with corresponding probabilities. A transliteration lattice is constructed to generate all transliteration hypotheses, among which the one with the minimum transliteration and language model costs is selected as the final hypothesis.

4 Experiment Results

We selected 62K Chinese-English person name translation pairs for experiments. These origin-labeled NE translation pairs are from the name entity translation lists provided by the LDC[2] (including the who'swho (china) and who'swho (international) lists), and devided into three parts: system training (90%), development (5%) and testing (5%). In the development and test data, names from each cluster followed the same distribution as in the training data.

4.1 NE Classification Evaluation

We evaluated the source name classification accuracy, because classification errors will lead to incorrect model selection, and result in bad transliteration performance in the next step. We trained 45 cluster-specific N-gram source character language models, and classified each source name into the most likely cluster according to formula 1. We evaluated the classification accuracy on a held-out test set with 3K NE pairs. We also experimented with different *N* values. Table 3 shows the classification accuracy, where the 3-gram model achieves the highest classification accuracy. A detailed analysis indicates that some classification errors are due to the inherent uncertainty of some names, e. g, "骆家辉 (Gary Locke)", a Chinese American, was classified as a Chinese name based on its source characters while his origin was labeled as USA.

N=2	N=3	N=4	N=5	N=6	N=7
83.62	**84.88**	84.00	84.04	83.94	83.94

Table 3. Source name origin classification accuracies

[2] http://www.ldc.upenn.edu

4.2 NE Transliteration Evaluation

We first evaluated transliteration results for each cluster, then evaluated the overall results on the whole test set, where a name was transliterated using the cluster-specific model in which it was classified. The evaluation metrics are:

- Top1 accuracy (**Top1**), the percentage that the top1 hypothesis is correct, i.e., the same as the reference translation;
- Top 5 accuracy (**Top5**), the percentage that the reference translation appears in the generated top 5 hypotheses;
- Character error rate (**CER**), the percentage of incorrect characters (inserted, deleted and substituted English letters) when the top 1 hypothesis is aligned to the reference translation.

Our baseline system was a character-based general transliteration model, where 56K NE pairs from all clusters were merged to train a general transliteration model and a language model (**CharGen**). We compare it with a character-based cluster-specific model (**CharCls**) and a phrase-based cluster-specific model (**PhraCls**). The CERs of several typical clusters are shown in Table 4.

Because more than half of the training name pairs are from Latin language clusters, the general transliteration and language models adopted the Latin name transliteration patterns. As a result, it obtained reasonable performance (20-30% CERs) on Latin language names, such as Spanish, English and French names, but strikingly high (over 70%) CERs on oriental language names such as Chinese and Japanese names, even though the Chinese cluster has the most training data.

When applying the character-based cluster-specific models, transliteration CERs consistently decreased for all clusters (ranging from 6.13% relative reduction for the English cluster to 97% for the Chinese cluster). As expected, the oriental language names obtained the most significant error reduction because the cluster-specific models were able to represent their unique transliteration patterns. When we applied the phrased-based transliteration models, CERs were further reduced by 23% ~ 51% for most clusters, because the context information were encapsulated in the transliteration phrases. An exception was the Chinese cluster, where names were often translated according to the pinyin of single characters, thus phrase-based transliteration slightly decreased the performance.

The transliteration performance of different clusters varied a lot. The Chinese cluster achieved 96.09% top 1 accuracy and 1.69% CER with the character-based model, and other clusters had CERs ranging from 7% to 30%. This was partly because of the lack of training data (e.g, for the Japanese cluster), and partly because of unique transliteration patterns of different languages. We try to measure this difference using the average number of translations per source phrase (**AvgTrans**), as shown in Table 4. This feature reflected the transliteration pattern regularity, and seemed linearly correlated with the CERs. For example, compared with the English cluster, Russian names have more regular translation patterns, and its CER is only 1/3 of the English cluster, even with only half size of training data.

In Table 5 we compared translation examples from the baseline system (**CharGen**), the phrase-based cluster-specific system (**PhraCls**) and a online machine translation system, the **BabelFish**[3]. The **CharGen** system transliterated every name in the Latin romanization way, regardless of each name's original language. The **BabelFish** system inappropriately translated source characters based on their semantic meanings, and the results were difficult to understand. The **PhraCls** model captured cluster-specific contextual information, and achieved the best results.

We evaluated three models' performances on all the test data, and showed the result in Table 6. The **CharGen** model performed rather poorly transliterating oriental names, and the overall CER was around 50%. This result was comparable to other state-of-the-art statistical name transliteration systems (Virga and Khudanpur, 2003). The **CharCls** model significantly improved the top1 and top 5 transliteration accuracies from 3.78% to 51.08%, and from 5.84% to 56.50%, respectively. Consistently, the CER was also reduced from 50.29% to 14.00%. Phrase-based transliteration further increased the top 1 accuracy by 9.3%, top 5 accuracy by 10.7%, and reduced the CER by 8%, relatively. All these improvements were statistically significant.

Table 6 Transliteration result comparison

5 Conclusion

We have proposed a cluster-specific NE transliteration framework. This framework effectively modeled the transliteration differences of source names from different origins, and has demonstrated substantial improvement over the baseline general model. Additionally, phrase-based transliteration further improved the transliteration performance by a significant margin.

Abstract

There has been little prior work on Named Entity Recognition for ”informal” documents like email. We present two methods for improving performance of person name recognizers for email: email-specific structural features and a recall-enhancing method which exploits name repetition across multiple documents.

1 Introduction

Named entity recognition (NER), the identification of entity names in free text, is a well-studied problem. In most previous work, NER has been applied to news articles (e.g., (Bikel et al., 1999; McCallum and Li, 2003)), scientific articles (e.g., (Craven and Kumlien, 1999; Bunescu and Mooney, 2004)), or web pages (e.g., (Freitag, 1998)). These genres of text share two important properties: documents are written for a fairly broad audience, and writers take care in preparing documents. Important genres that do *not* share these properties include instant messaging logs, newsgroup postings and email messages. We refer to these genres as “informal” text.

Informal text is harder to process automatically. Informal documents do not obey strict grammatical conventions. They contain grammatical and spelling errors. Further, since the audience is more restricted, informal documents often use group- and task-specific abbreviations and are not self-contained. Because of these differences, existing NER methods may require modifications to perform well on informal text.

In this paper, we investigate NER for informal text with an experimental study of the problem of recognizing personal names in email—a task that is both useful and non-trivial. An application of interest is corpus anonymization. Automatic or semi-automatic email anonymization should allow using large amounts of informal text for research purposes, for example, of medical files. Person-name extraction and other NER tasks are helpful for automatic processing of informal text for a large variety of applications (Culotta et al., 2004; Cohen et al., 2005).

We first present four corpora of email text, annotated with personal names, each roughly comparable in size to the MUC-6 corpus[1]. We experimentally evaluate the performance of conditional random fields (CRF) (Lafferty et al., 2001), a state-of-the art machine-learning based NER methods on these corpora. We then turn to examine the special attributes of email text (vs. newswire) and suggest venues for improving extraction performance. One important observation is that email messages often include some structured, easy-to-recognize names, such as names within a header, names appearing in automatically-generated phrases, as well as names in signature files or sign-offs. We therefore suggest a set of specialized *structural* features for email; these features are shown to significantly improve performance on our corpora.

We also present and evaluate a novel method for exploiting *repetition* of names in a test corpus. Techniques for exploiting name repetition within documents have been recently applied to newswire text

[1]Two of these are publicly available. The others can not be distributed due to privacy considerations.

(e.g., (Humphreys et al., 1998)), scientific abstracts (e.g., (Bunescu and Mooney, 2004)) and seminar announcements (Sutton and Mccallum, 2004); however, these techniques rely on either NP analysis or capitalization information to pre-identify candidate coreferent name mentions, features which are not reliable in email. Furthermore, we argue that name repetition in email should be inferred by examining *multiple documents* in a corpus, which is not common practice. We therefore present an alternative efficient scheme for increasing recall in email, using the whole corpus. This technique is shown to always improve recall substantially, and to almost always improve F1 performance.

2 Corpora

Two email corpora used in our experiments were extracted from the CSpace email corpus (Kraut et al., 2004), which contains email messages collected from a management course conducted at Carnegie Mellon University in 1997. In this course, MBA students, organized in teams of four to six members, ran simulated companies in different market scenarios. We believe this corpus to be quite similar to the work-oriented mail of employees of a small or medium-sized company. This text corpus contains three header fields: "From", "Subject", and "Time". *Mgmt-Game* is a subcorpora consisting of all emails written over a five-day period. In the experiments, the first day worth of email was used as a training set, the fourth for tuning and the fifth day as a test set. *Mgmt-Teams* forms another split of this data, where the training set contains messages between different teams than in the test set; hence in *Mgmt-Teams*, the person names appearing in the test set are generally different than those that appear in the training set.

The next two collections of email were extracted from the Enron corpus (Klimt and Yang, 2004). The first subset, *Enron-Meetings*, consists of messages in folders named "meetings" or "calendar"[2]. Most but not all of these messages are meeting-related. The second subset, *Enron-Random*, was formed by repeatedly sampling a user name (uniformly at random among 158 users), and then sampling an email from that user (uniformly at random).

Annotators were instructed to include nicknames and misspelled names, but exclude person names that are part of an email address and names that are part of a larger entity name like an organization or location (e.g., "David Tepper School of Business").

The sizes of the corpora are given in Table 1. We limited training size to be relatively small, reflecting a real-world scenario.

Corpus	# Documents			#Words	#Names
	Train	Tune	Test	x1000	
Mgmt-Teams	120	82	83	105	2,792
Mgmt-Game	120	216	264	140	2,993
Enron-Meetings	244	242	247	204	2,868
Enron-Random	89	82	83	286	5,059

Table 1: Summary of the corpora used in the experiments. The number of words and names refer to the whole annotated corpora.

3 Existing NER Methods

In our first set of experiments we apply CRF, a machine-learning based probabilistic approach to labeling sequences of examples, and evaluate it on the problem of extracting personal names from email. Learning reduces NER to the task of *tagging* (i.e., classifying) each word in a document. We use a set of five tags, corresponding to (1) a one-token entity, (2) the first token of a multi-token entity, (3) the last token of a multi-token entity, (4) any other token of a multi-token entity and (5) a token that is not part of an entity.

The sets of features used are presented in Table 2. All features are instantiated for the focus word, as well as for a window of 3 tokens to the left and to the right of the focus word. The *basic features* include the lower-case value of a token t, and its *capitalization pattern*, constructed by replacing all capital letters with the letter "X", all lower-case letters with "x", all digits with "9" and compressing runs of the same letter with a single letter. The *dictionary features* define various categories of words including common words, first names, last names [3] and "roster names" [4] (international names list, where first and

[2] with two exceptions: (a) six very large files were removed, and (b) one very large "calendar" folder was excluded.

[3] We used US Census' lists of the most common first and last names in the US, available from http://www.census.gov/genealogy/www/freqnames.html

[4] A dictionary of 16,623 student names across the country, obtained as part of the RosterFinder project (Sweeney, 2003)

Basic Features
t, lexical value, lowercase (binary form, e.g. $f(t$=”hello”)=1)
capitalization pattern of t (binary form, e.g. $f(t.cap$=x+)=1)
Dictionary Features
inCommon: t in common words dictionary
inFirst: t in first names dictionary
inLast: t in last names dictionary
inRoster: t in roster names dictionary
First: inFirst ∩ ¬isLast ∩ ¬inCommon
Last: ¬inFirst ∩ inLast ∩ ¬inCommon
Name: (First ∪ Last ∪ inRoster) ∩ ¬ inCommon
Title: t in a personal prefixes/suffixes dictionary
Org: t in organization suffixes dictionary
Loc: t in location suffixes dictionary
Email Features
t appears in the header
t appears in the “from” field
t is a probable “signoff” (≈ after two line breaks and near end of message)
t is part of an email address (regular expression)
does the word starts a new sentence (≈ capitalized after a period, question or exclamation mark)
t is a probable initial (X or X.)
t followed by the bigram ”and I”
t capitalized and followed by a pronoun within 15 tokens

Table 2: Feature sets

last names are mixed.) In addition, we constructed some composite dictionary features, as specified in Table 2: for example, a word that is in the first-name dictionary and is not in the common-words or last-name dictionaries is designated a ”sure first name”.

The common-words dictionary used consists of base forms, conjugations and plural forms of common English words, and a relatively small ad-hoc dictionary representing words especially common in email (e.g., ”email”, ”inbox”). We also use small manually created word dictionaries of prefixes and suffixes indicative of persons (e.g., ”mr”, ”jr”), locations (e.g., ”ave”) and organizations (e.g., ”inc”).

Email structure features: We perform a simplified document analysis of the email message and use this to construct some additional features. One is an indicator as to whether a token t is equal to some token in the ”from” field. Another indicates whether a token t in the email body is equal to some token appearing in the whole header. An indicator feature based on a regular expression is used to mark tokens that are part of a probable ”sign-off” (i.e., a name at the end of a message). Finally, since the annotation rules do not consider email addresses to be names, we added an indicator feature for tokens that are inside an email address.

Figure 1: Predictive contexts for personal-name words for MUC-6 (left) and Mgmt-Game (right) corpora. A features is denoted by its direction comparing to the focus word (l/r), offset and lexical value.

We experimented with features derived from POS tags and NP-chunking of the email, but found the POS assignment too noisy to be useful. We did include some features based on approximate linguistic rules. One rule looks for capitalized words that are not common words and are followed by a pronoun within a distance of up to 15 tokens. (As an example, consider “Contact Puck tomorrow. *He* should be around.”). Another rule looks for words followed by the bigram “and I”. As is common for hand-coded NER rules, both these rules have high precision and low recall.

3.1 Email vs Newswire

In order to explore some of the differences between email and newswire NER problems, we stripped all header fields from the Mgmt-Game messages, and trained a model (using basic features only) from the resulting corpus of email bodies. Figure 1 shows the features most indicative of a token being part of a name in the models trained for the Mgmt-Game and MUC-6 corpora. To make the list easier to interpret, it includes only the features corresponding to tokens surrounding the focus word.

As one might expect, the important features from the MUC-6 dataset are mainly formal name titles such as ”mr”, ”mrs”, and ”jr”, as well as job titles and other pronominal modifiers such as ”president” and ”judge”. However, for the Mgmt-Game corpus, most of the important features are related to email-specific structure. For example, the features ”left.1.by” and “left.2.by” are often associated with a quoted excerpt from another email message, which in the Mgmt-Game corpus is often marked by mailers with text like ”Excerpts from mail: 7-

Sep-97 Re: paper deadline by Richard Wang". Similarly, features like "left.1.thanks" and "right.1.ps" indicate a "signoff" section of an email, as does "right.2.home" (which often indicates proximity to a home phone number appearing in a signature).

3.2 Experimental Results

We now turn to evaluate the usefulness of the feature sets described above. Table 3 gives entity-level F1 performance [5] for CRF trained models for all datasets, using the basic features alone (B); the basic and email-tailored features (B+E); the basic and dictionary features (B+D); and, all of the feature sets combined (B+D+E). All feature sets were tuned using the Mgmt-Game validation subset. The given results relate to previously unseen test sets.

Dataset	B	B+E	B+D	B+D+E
Mgmt-Teams	68.1	75.7	82.0	87.9
Mgmt-Game	79.2	84.2	90.7	91.9
Enron-Meetings	59.0	71.5	78.6	76.9
Enron-Random	68.1	70.2	72.9	76.2

Table 3: F1 entity-leavel performance for the sets of features, across all datasets, with CRF training.

The results show that the email-specific features are very informative. In addition, they show that the dictionary features are especially useful. This can be explained by the relatively weak contextual evidence in email. While dictionaries are useful in named entities extraction in general, they are in fact more essential when extracting names from email text, where many name mentions are part of headers, names lists etc. Finally, the results for the combined feature set are superior in most cases to any subset of the features.

Overall the level of performance using all features is encouraging, considering the limited training set size. Performance on Mgmt-Teams is somewhat lower than for Mgmt-Game mainly because (by design) there is less similarity between training and test sets with this split. Enron emails seem to be harder than Mgmt-Game emails, perhaps because they include fewer structured instances of names. Enron-Meetings emails also contain a number of constructs that were not encountered in the Mgmt-Game corpus, notably lists (e.g., of people attending a meeting), and also include many location and organization names, which are rare in Mgmt-Game. A larger set of dictionaries might improve performance for the Enron corpora.

[5] No credit awarded for partially correct entity boundaries.

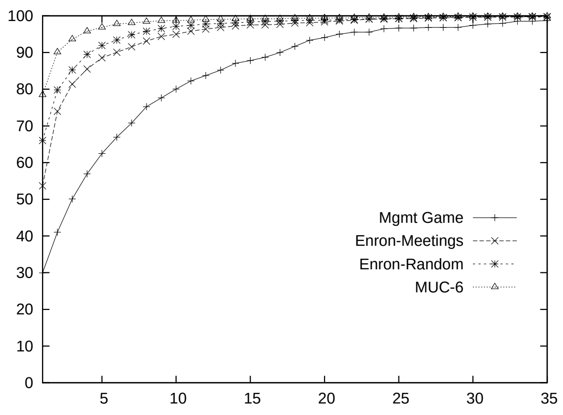

Figure 2: Cumulative percentage of person-name tokens w that appear in at most K distinct documents as a function of K.

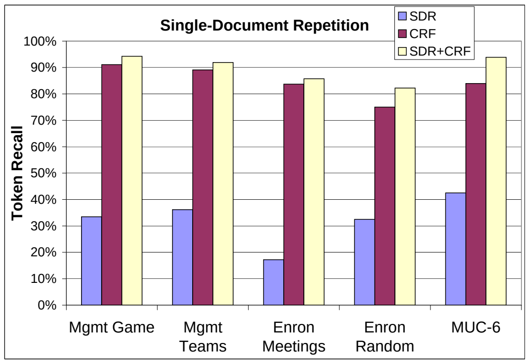
4 Repetition of named entities in email

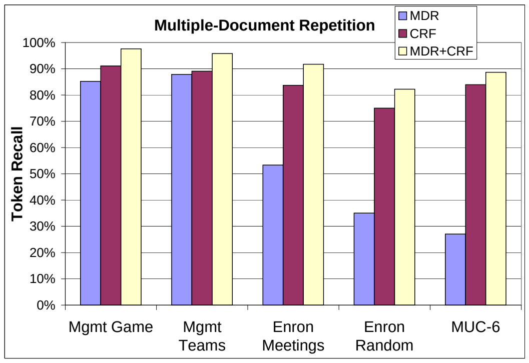
In the experiments described above, the extractors have high precision, but relatively low recall. This typical behavior suggests that some sort of recall-enhancing procedure might improve overall performance.

One family of recall-enhancing techniques are based on looking for multiple occurrences of names in a document, so that names which occur in ambiguous contexts will be more likely to be recognized. It is an intuitive assumption that the ways in which names repeat themselves in a corpus will be different in email and newswire text. In news stories, one would expect repetitions within a *single document* to be common, as a means for an author to establish a shared context with the reader. In an email corpus, one would expect names to repeat more frequently across the corpus, in *multiple documents*—at least when the email corpus is associated with a group that works together closely. In this section we support this conjecture with quantitative analysis.

In a first experiment, we plotted the percentage of person-name tokens w that appear in at most K distinct documents as a function of K. Figure 2 shows this function for the Mgmt-Game, MUC-6, Enron-Meetings, and Enron-Random datasets. There is a large separation between MUC-6 and Mgmt-Game, the most workgroup-oriented email corpus. In MUC-6, for instance, almost 80% of the



(a) SDR



(b) MDR

Figure 3: Upper bounds on recall and recall improvements associated with methods that look for terms that re-occur within a single document (SDR) or across multiple documents (MDR).

names appear in only a single document, while in Mgmt-Game, only 30% of the names appear in only a single document. At the other extreme, in MUC-6, only 1.3% of the names appear in 10 or more documents, while in Mgmt-Game, almost 20% do. The Enron-Random and Enron-Meetings datasets show distributions of names that are intermediate between Mgmt-Game and MUC-6.

As a second experiment, we implemented two very simple extraction rules. The *single document repetition* (SDR) rule marks every token that occurs more than once inside a single document as a name. Adding tokens marked by the SDR rule to the tokens marked by the learned extractor generates a new extractor, which we will denote SDR+CRF. Thus, the recall of SDR+CRF serves as an upper bound on the token recall[6] of any recall-enhancing method that improves the extractor by exploiting repetition within a single document. Analogously, the *multiple document repetition* (MDR) rule marks every token that occurs in more than one document as a name. Again, the token recall of MDR+CRF rule is an upper bound on the token recall of any recall-enhancing method that exploits token repetition across multiple documents.

The left bars in Figure 3 show the recall obtained by the SDR (top) and the MDR rule (bottom). The MDR rule has highest recall for the two Mgmt corpora, and lowest recall for the MUC-6 corpus. Conversely, for the SDR rule, the highest recall level obtained is for MUC-6. The middle bars show the token recall obtained by the CRF extractor, using all features. The right bars show the token recall of the SDR+CRF and MDR+CRF extractors. Comparing them to the other bars, we see that the maximal potential recall gain from a SDR-like method is on MUC-6. For MDR-like methods, there are large potential gains on the Mgmt corpora as well as on Enron-Meetings and Enron-Random to a lesser degree. This probably reflects the fact that the Enron corpora are from a larger and more weakly interacting set of users, compared to the Mgmt datasets.

These results demonstrate the importance of exploiting repetition of names across multiple documents for entity extraction from email.

5 Improving Recall With Inferred Dictionaries

Sequential learners of the sort used here classify tokens from each document independently; moreover, the classification of a word w is independent of the classification of other occurrences of w elsewhere in the document. That is, the fact that a word w has appeared somewhere in a context that clearly indicates that it is a name does not increase the probability that it will be classified as a name in other, more ambiguous contexts.

Recently, sequential learning methods have been extended to directly utilize information about name co-occurrence in learning the sequential classifier. This approach provides an elegant solution to modeling repetition within a single document. However, it requires identifying candidate related entities in advance, applying some heuristic. Thus, Bunescu &

[6]Token level recall is recall on the task of classifying tokens as inside or outside an entity name.

Mooney (2004) link between similar NPs (requiring their head to be identical), and Sutton and Mccallum (2004) connect pairs of identical capitalized words. Given that in email corpora capitalization patterns are not followed to a large extent, there is no adequate heuristic that would link candidate entities prior to extraction. Further, it is not clear if a collective classification approach can scale to modeling multiple-document repetition.

We suggest an alternative approach of recall-enhancing name matching, which is appropriate for email. Our approach has points of similarity to the methods described by Stevenson and Gaizauskas (2000), who suggest matching text against name dictionaries, filtering out names that are also common words or appear as non-names in high proportion in the training data. The approach described here is more systematic and general. In a nutshell, we suggest applying the *noisy* dictionary of predicted names over the test corpus, and use the approximate (predicted) name to non-name proportions over the test set itself to filter out ambiguous names. Therefore, our approach does not require large amount of annotated training data. It also does not require word distribution to be similar between train and test data. We will now describe our approach in detail.

5.1 Matching names from dictionary

First, we construct a dictionary comprised of all spans predicted as names by the learned model. For personal names, we suggest expanding this dictionary further, using a transformation scheme. Such a scheme would construct a family of possible variations of a name n: as an example, Figure 4 shows name variations created for the name span "Benjamin Brown Smith". Once a dictionary is formed, a single pass is made through the corpus, and every longest match to some name-variation is marked as a name[7]. It may be that a partial name span n_1 identified by the extractor is subsumed by the full name span n_2 identified by the dictionary-matching scheme. In this case, entity-level precision is increased, having corrected the entity's boundaries.

[7]Initials-only variants of a name, e.g., ”bs” in Figure 4 are marked as a name only if the “inSignoff” feature holds—i.e., if they appear near the end of a message in an apparent signature.

benjamin brown smith	benjamin-brown-s.	b. brown s.	bbs

benjamin-brown s.	benjamin s.	b. s.	

Figure 4: Names variants created from the name “Benjamin Brown Smith”

5.2 Dictionary-filtering schemes

The noisy dictionary-matching scheme is susceptible to false positives. That is, some words predicted by the extractor to be names are in fact non-names. Presumably, these non-names could be removed by simply eliminating low-confidence predictions of the extractor; however, ambiguous words –that are not exclusively personal names in the corpus– may need to be identified and removed as well. We note that ambiguity better be evaluated in the context of the corpus. For example, "Andrew" is a common first name, and may be confidently (and correctly) recognized as one by the extractor. However, in the Mgmt-Game corpus, "Andrew" is also the name of an email server, and most of the occurrences of this name in this corpus are *not* personal names. The high frequency of the word "Andrew" in the corpus, coupled with the fact that it is only sometimes a name, means that adding this word to the dictionary leads to a substantial drop in precision.

We therefore suggest a measure for filtering the dictionary. This measure combines two metrics. The first metric, *predicted frequency* (PF), estimates the degree to which a word appears to be used consistently as a name throughout the corpus:

$$PF(w) \equiv \frac{cpf(w)}{ctf(w)}$$

where $cpf(w)$ denotes the number of times that a word w is predicted as part of a name by the extractor, and $ctf(w)$ is the number of occurrences of the word w in the entire test corpus (we emphasize that estimating this statistic based on test data is valid, as it is fully automatic ”blind” procedure).

Predicted frequency does not assess the likely cost of adding a word to a dictionary: as noted above, ambiguous or false dictionary terms that occur frequently will degrade accuracy. A number of statistics could be used here; for instance, practitioners sometimes filter a large dictionary by simply discarding all words that occur more than k times in a test corpus. We elected to use the *inverse document frequency* (IDF) of w to measure word frequency:

$$IDF(w) \equiv \frac{\log(\frac{N+0.5}{df(w)})}{\log(N+1)}$$

Here $df(w)$ is the number of documents that contain a word w, and N is the total number of documents in the corpus. Inverse document frequency is often used in the field of information retrieval (Allan et al., 1998), and the formula above has the virtue of being scaled between 0 and 1 (like our PF metric) and of including some smoothing. In addition to bounding the cost of a dictionary entry, the IDF formula is in itself a sensible filter, since personal names will not appear as frequently as common English words.

The joint filter combines these two multiplicatively, with equal weights:

$$PF.IDF(w) : PF(w) \times IDF(w)$$

PF.IDF takes into consideration both the probability of a word being a name, and how common it is in the entire corpus. Words that get low PF.IDF scores are therefore either words that are highly ambiguous in the corpus (as derived from the extractors' predictions) or are common words, which were inaccurately predicted as names by the extractor.

In the MDR method of Figure 3, we imposed an artificial requirement that words must appear in more than one document. In the method described here, there is no such requirement: indeed, words that appear in a small number of documents are given higher weights, due to the IDF factor. Thus this approach exploits both single-document and multiple-document repetitions.

In a set of experiments that are not described here, the PF.IDF measure was found to be robust to parameter settings, and also preferable to its separate components in improving recall at minimal cost in precision. As described, the PF.IDF values per word range between 0 and 1. One can vary the threshold, under which a word is to be removed from the dictionary, to control the precision-recall trade-off. We tuned the PF.IDF threshold using the validation subsets, optimizing entity-level F1 (a threshold of 0.16 was found optimal).

In summary, our recall-enhancing strategy is as follows:

1. Learn an extractor E from the training corpus C_{train}.
2. Apply the extractor E to a test corpus C_{test} to assign a preliminary labeling.
3. Build a dictionary S_{θ_*} including the names n such that (a) n is extracted somewhere in the preliminary labeling of the test corpus, or is derived from an extracted name applying the name transformation scheme and (b) $PF.IDF(n) > \theta_*$.
4. Apply the dictionary-matching scheme of Section 5.1, using the dictionary S_{θ_*} to augment the preliminary labeling, and output the result.

5.3 Experiments with inferred dictionaries

Table 4 shows results using the method described above. We consider all of the email corpora and the CRF learner, trained with the full feature set. The results are given in terms of relative change, compared to the baseline results generated by the extractors ($score_{result}/score_{baseline} - 1$) and final value.

As expected, recall is always improved. Entity-level F1 is increased as well, as recall is increased more than precision is decreased. The largest improvements are for the Mgmt corpora —the two e-mail datasets shown to have the largest potential improvement from MDR-like methods in Figure 3. Recall improvements are more modest for the Enron datasets, as was anticipated by the MDR analysis. Another reason for the gap is that extractor baseline performance is lower for the Enron datasets, so that the Enron dictionaries are noisier.

As detailed in Section 2, the Mgmt-Teams dataset was constructed so that the names in the training and test set have only minimal overlap. The performance improvement on this dataset shows that repetition of mostly-novel names can be detected using our method. This technique is highly effective when names are novel, or dense, and is optimal when extractor baseline precision is relatively high.

Dataset	Precision	Recall	F1
Mgmt-Teams	-0.9% / 92.9	+8.5% / 89.8	+3.9% / 91.3
Mgmt-Game	-0.8% / 94.5	+8.4% / 96.2	+3.8% / 95.4
Enron-Meetings	-2.5% / 81.1	+4.7% / 74.9	+1.2% / 77.9
Enron-Random	-3.8% / 79.2	+4.9% / 74.3	+0.7% / 76.7

Table 4: Entity-level relative improvement and final result, applying name-matching on models trained with CRF and the full feature set (F1 baseline given in Table 3).

6 Conclusion

This work applies recently-developed sequential learning methods to the task of extraction of named entities from email. This problem is of interest as an example of NER from informal text—text that has been prepared quickly for a narrow audience.

We showed that informal text has different characteristics from formal text such as newswire. Analysis of the highly-weighted features selected by the learners showed that names in informal text have different (and less informative) types of contextual evidence. However, email also has some structural regularities which make it easier to extract personal names. We presented a detailed description of a set of features that address these regularities and significantly improve extraction performance on email.

In the second part of this paper, we analyzed the way in which names repeat in different types of corpora. We showed that repetitions within a single document are more common in newswire text, and that repetitions that span multiple documents are more common in email corpora. Additional analysis confirms that the potential gains in recall from exploiting multiple-document repetition is much higher than the potential gains from exploiting single-document repetition.

Based on this insight, we introduced a simple and effective method for exploiting multiple-document repetition to improve an extractor. One drawback of the recall-enhancing approach is that it requires the entire test set to be available: however, our test sets are of only moderate size (83 to 264 documents), and it is likely that a similar-size sample of unlabeled data would be available in many practical applications. The approach substantially improves recall and often improves F1 performance; furthermore, it can be easily used with any NER method.

Taken together, extraction performance is substantially improved by this approach. The improvements seem to be strongest for email corpora collected from closely interacting groups. On the Mgmt-Teams dataset, which was designed to reduce the value of memorizing specific names appearing in the training set, F1 performance is improved from 68.1% for the out-of-the-box system (or 82.0% for the dictionary-augmented system) to 91.3%. For the less difficult Mgmt-Game dataset, F1 performance is improved from 79.2% for an out-of-the-box CRF-based NER system (or 90.7% for a CRF-based system that uses several large dictionaries) to 95.4%. As future work, experiments should be expanded to include additional entity types and other types of informal text, such as blogs and forum postings.

Matching Inconsistently Spelled Names in Automatic Speech Recognizer Output for Information Retrieval

Hema Raghavan and James Allan
Department of Computer Science
University of Massachusetts Amherst
Amherst, MA 01003, USA
{hema,allan}@cs.umass.edu

Abstract

Many proper names are spelled inconsistently in speech recognizer output, posing a problem for applications where locating mentions of named entities is critical. We model the distortion in the spelling of a name due to the speech recognizer as the effect of a noisy channel. The models follow the framework of the IBM translation models. The model is trained using a parallel text of closed caption and automatic speech recognition output. We also test a string edit distance based method. The effectiveness of these models is evaluated on a name query retrieval task. Our methods result in a 60% improvement in F1. We also demonstrate why the problem has not been critical in TREC and TDT tasks.

1 Introduction

Proper names are key to our understanding of topics in news. For example, to determine that a news story is on the 2004 elections in the United States, the words *President Bush*, *John Kerry* and *USA* are necessary features of the story. In other words, names of people, places and organizations are key entities of a news story. For many tasks, like in topic detection and tracking (TDT), the entities form an important feature for distinguishing topics from one another. For example, it is the people that distinguish stories on the 2004 election from stories on the 2000 U.S election. Names, especially rare and foreign ones are a problem for automatic speech recognition (ASR) systems as they are often out of vocabulary (OOV) i.e., they do not exist in the lexicon of the ASR system. An OOV word is replaced with the most similar word in the lexicon of the speech recognizer. Sometimes, even if a name is in the lexicon of the speech recognizer, it may have multiple spelling variants. The following is a sample ASR snippet from the TDT3 [1] corpus that demonstrates how the same entity may have different spellings even within the same snippet of ASR text.

...newspaper quotes **qaddafi** *is saying they'll turn them over but only if they're allowed ..leader moammar* **gadhafi** *says he doesn't want an international confrontation over the suspects in the..*

In this work, we aim to find methods by which to cluster or group names in ASR text. We evaluate a variety of techniques that range from a simple string-edit distance model to generative models using both intrinsic and extrinsic evaluations. We get statistically significant improvements in results for ad-hoc retrieval when the query is just the name of a person. We also explain why the problem of misspelled proper names in ASR has not been an issue in the TREC spoken document retrieval (SDR) track or in topic detection and tracking (TDT). We demonstrate how the problem would be of significance when the query is short, containing mainly names with little or no context.

[1] http:///www.ldc.upenn.edu/projects/tdt3/

2 Related Work

That names can be spelled differently is a problem that has been addressed by the database community in great detail. They found that the problem was rising in significance with the increasing interest in reconciling different databases. Differences in names due to spelling errors, spelling variants and transliteration errors have been dealt with by different kinds of approximate string matching techniques like Soundex, Phonix, and String Edit distance (James C. French, 1997; Zobel and Dart, 1996). The nature of the problem is identical when the domain consists of databases of documents but in order to apply techniques that were developed for names by the database community one would have to first detect names in the corpus, and then normalize them to some canonical form. This is the approach taken by Raghavan and Allan (Raghavan and Allan, 2004) who showed that normalizing names using Soundex codes resulted in a 10% improvement on the TDT3 Story Link Detection Task. They tested their method on newswire stories only. Their difficulty in applying Soundex to the ASR documents was that detecting names in ASR is too error prone for their methods to be useful (Miller et al., 2000).

Spoken document retrieval was a track at the TREC-6,7 and 8 (Voorhees and Harman, 1997; Voorhees and Harman, 1998; Voorhees and Harman, 1999) conferences. At the TREC-8 SDR track the conclusion was that ASR is not really an issue for ad hoc retrieval. However, the queries in those tracks were not centered on any entity. The TREC-8 proceedings also acknowledge that mean average precision dropped as named entity word error rate (NE-WER) increased. A typical speech recognizer has a lexicon of about 60K and for this size of a lexicon, about 10% of the person names are out of vocabulary (OOV).

The problem of alternate spellings of names has also been explored by the cross lingual information retrieval community (Virga and Khudanpur, 2003; AbdulJaleel and Larkey, 2003). The problem with names in machine translated text is quite similar to the problem with names in ASR text, except that the errors caused by a speech recognizer are often phonetic confusions, which is not necessarily the case for machine translation errors. Spelling errors of names in machine translated text are typically consistent. A given word in the source language always translates to the same word in the target language for a given machine translation system. As seen earlier, ASR systems do not exhibit such consistency.

Another problem that resembles the one we are addressing in this paper is that of spelling correction. Spelling correction has been tackled in several different ways (Durham et al., 1983), in some cases with the use of contextual cues (Golding and Roth, 1999) and in some cases it has been modeled as a "noisy channel problem" (Kernighan et al., 1990). The latter approach is similar to ours because we also approach the problem of spelling variations due to speech recognizer errors as analogous to the errors caused by a noisy channel. However, spelling correction methods must rectify human errors (typographic errors and common confusions) whereas speech recognizer errors are different.

Additionally, the argument that *Jon Smith* and *John Smythe* may genuinely be different people and should not be considered to be the same entity is more of a cross-document co-reference problem. The problem we are attempting to solve in this paper is one of grouping names that "sound like" each other together, without considering the problem of cross document co-reference. For example, the name *Lewinsky* has 199 occurrences in the TDT3 corpus, and also appears as *Lewinski* (1324 times), and *Lewenskey* (171 times). Most of these occurrences refer to *Monica Lewinsky*. The aim is to group all these variants together, without taking into consideration which ones refer to the same person. We then measure the effectiveness of our methods on various retrieval tasks.

Perhaps the most similar work from the point of view of the task is work in word spotting in audio output (Amir et al., 2001). The queries are single words and the task is to locate their mention in audio. The starting point in that work is however, a phonetic transcript of the audio signal and the emphasis is not on locating names. Our starting point is automatic speech recognizer output, and we aim to locate names in particular.

3 Our Approaches

In this section we explain the techniques by which we group names together. One method uses string edit distance to group names that are variants of each other. The other techniques are some of the possible generative models suitable to this task.

An **equivalence class** is defined as a group of names such that any two names in that class are variants of each other and such that there exist no two names from different equivalence classes that are variants of each other. An equivalence class is represented as a set of names enclosed in curly braces as {*name-1 name-2 ...*}

Four of our models are trained on a parallel text of ASR and manual transcripts (or closed caption depending on availability) in order to learn a probabilistic model of ASR errors. The parallel text consists of pairs of sentences: sentences from the ASR output and the corresponding manual transcripts. This is a common technique in machine translation for which the IBM translation models are popular methods (Brown et al., 1993).

As a convention, we use uppercase letters to denote ASR output and lowercase for manual transcriptions. Given an input of parallel text of ASR and manual transcriptions, the model learns a probabilistic dictionary. The dictionary contains pairs of closed caption and ASR words and the probability that the closed caption word is generated from a given word in ASR. Thus, the model might learn a high probability for *P(CAT|kate)*.

3.1 Overview of Methods

We generate equivalence classes of names by clustering a list of names. The algorithm draws links between pairs of words and then clusters the words into equivalence classes such that if a and b are linked and b and c are linked then *a, b* and c are in the same equivalence class. Links between words are generated in five different ways described below.

In the first of our methods we align manual transcripts and ASR sentences using the IBM translation model (Brown et al., 1993) to obtain a probabilistic dictionary. We give details of the translation model in section 3.2. Names are grouped such that if *P(CAT|kate)* is high (above some threshold) then there is a link between *CAT* and *kate*. This is called the *Simple Aligned* method. Some sample pairs of words obtained by this technique are shown in figure 1.

We can also ask a human to create a list of equivalence classes of names. We describe our method of obtaining such a list in section 4. This method is called the *Supervised* method.

Figure 1: Example of pairs of words obtained by Simple Aligned

Given a list of equivalence classes, pairs of names that go together can easily be generated such that for each pair, both words are obtained from the same equivalence class. In this way equivalence classes of names obtained from the Simple Aligned and Supervised methods can be used to create a list of pairs of names that form parallel text to train a character level machine translation model. We would expect this model to learn a high probability for similar sounding alphabets, e.g., a high probability for $P(C|k)$. Depending on where the training set of pairs of names for this method comes from, we get two possible systems. These are called the *Generative Unsupervised* method and *Generative Supervised* method respectively. Note that the Generative Unsupervised method is not completely unsupervised; we still need the parallel text of ASR and manual transcripts, but we don't need a human to do the added grouping of names into equivalence classes. A character level translation model helps us generalize better to unseen words.

We also grouped together names that differ by a string edit distance of one, giving a fifth system. In particular, we use the Levenshtein distance (Levenshtein, 1966), that is the number of insertions, deletions and substitutions needed to convert one string to the other. Many methods employed by the database community build on string edit distance. The method works well but has some disadvantages. Consider a user who types in a query containing a name such that the spelling, as typed by the user, never occurs in the corpus. To employ string edit distance, one would have to compare the query name against all the words in the vocabulary of the corpus to find the most similar strings. With a generative model, only the query needs to be expanded using the translation model, thereby speeding up the search process. The string edit distance model on the other hand, is completely unsupervised and needs no training in the form of parallel text. Both methods have their advantages and disadvantages, and the use of one method over the other is situation dependent.

3.2 Details

To learn alignments, translation probabilities, etc in the first method we used work that has been done in statistical machine translation (Brown et al., 1993), where the translation process is considered to be equivalent to a corruption of the source language text to the target language text due to a *noisy channel*. We can similarly consider that an ASR system corrupts the spelling of a name as a result of a noisy channel. To obtain the closed caption word c, of an ASR word a, we want to find the string for which the probability $P(c|a)$ is highest. This is modeled as

$$P(c|a) = \frac{P(c)P(a|c)}{P(a)} \tag{1}$$

For a given name a, since $P(a)$ is constant, the problem reduces to one of maximizing $P(c)P(a|c)$. $P(c)$ is called the language model. We need to model $P(a|c)$ as opposed to directly modeling $P(c|a)$ so that our model assigns more probability to well formed English names.

Given a pair of sentences (c, a), an alignment $\mathcal{A}(c, a)$ is defined as the mapping from the words in c to the words in a. If there are l closed caption words and m ASR words, there are 2^{lm} alignments in $\mathcal{A}(c, a)$. $l \in \mathcal{A}(c, a)$ can be denoted as a series $l_1^m = l_1, l_2 ... l_m$ where $l_j = i$ means that a word in position j of the ASR string is aligned with a word in position i of the closed caption string. Then $P(a|c)$ is computed as follows:

$$\begin{aligned} P(a|c) &= \sum_l P(a, l|c) \\ P(a, l|c) &= P(m|c) \prod_j^m P(l_j | l_1^{j-1}, a_1^{j-1}, m, e) \\ &\quad \times P(a_j | l_1^j, a_1^{j-1}, m, c) \end{aligned} \tag{2}$$

where a_j is a word in position j of the string a, and a_1^j is the series $a_1 ... a_j$. The model is generative in the following way: we first choose for each word in the closed caption string the number of ASR words that will be connected to it, then we pick the identity of those ASR words and finally we pick the actual positions that these words will occupy. There are five different IBM translation models (Brown et al., 1993). Models 3 and 4 build on the above equations, and also incorporate the notion of fertility. Fertility takes into account that a given word in closed caption may be omitted by an ASR system, or one word may result in two or more, like *Iraq* → *I ROCK* (This is a true example). The models are trained using Expectation Maximization. Further details are in the original paper (Brown et al., 1993).

The IBM models have shown good performance in machine translation, and especially so within certain families of languages, for example in translating between French and English or between Sinhalese and Tamil (Brown et al., 1993; Weerasinghe, 2004). Pairs of closed caption and ASR sentences or words (as the case may be) are akin to a pair of closely related languages.

For the Generative Unsupervised and Generative Supervised methods, we use the same models, but in this case the training set consists of pairs of words obtained from the ASR and closed caption text as opposed to sentences. In other words, the place of words in the previous case is taken by characters. Modeling fertility, etc, again fits very well in this case. For example the terminal character e is often dropped in ASR, and a single o in closed caption may result in a double o in ASR or vice versa.

4 Experimental Set Up

4.1 Corpora

For experiments in this paper we used the TREC-6 and TREC-7 SDR track data (Voorhees and Harman, 1998). We also used the TDT2 and TDT3 corpora. For TREC-6 we had the ASR output provided by NIST (WER 34%). The TREC-7 corpus consists of the output of the Dragon systems speech recognizer (WER 29.5%). For the TDT sources we had the ASR output of the BBN Byblos Speech recognizer provided by the LDC. NIST provides human generated transcripts for the TREC corpora and LDC provides closed caption quality transcripts with a WER of 14.5% for the TDT corpora. There are 3943, 23282, 1819 and 2866 ASR documents in the TDT2 TDT3, TREC-6 and TREC-7 corpora respectively.

4.2 Intrinsic Evaluation

The Paice evaluation (Paice, 1996) for stemming algorithms (algorithms that reduce a word to its morphological root), attempts to compare the equivalence classes generated by our methods with human judgments.

The Paice evaluation measures the performance of a stemmer based on its understemming and overstemming indices (UI and OI respectively). UI measures the total number of missed links between words and OI measures the total number of false alarm links. A perfect stemmer would have a UI and OI value of zero.

We obtained a list of names to be grouped into equivalence classes in the following way. We did not use a named entity tagger on the corpus because named entity taggers typically have very high word error rates for ASR text (Bikel et al., 1999). Instead we ran the Unix *spell* command on the corpus and used the list of rejected words as the list of names for the annotators to group into equivalence classes. These 296 OOV words are taken to correspond to the names in the corpus. We then obtained the set of ground-truth equivalence classes by a method similar to Paice.

A group of undergraduate students was hired. The list of names was provided to each student in a text editor in alphabetical order. The purpose as explained to them was to group together names that were alternate spellings of similar sounding names together. The student was instructed to go through the list systematically, and for each word to look at the previous 10 words, as well as the following 10 words to see if there were any other variants. If there was a word or a group where the current word was likely to fit in, they were asked to *cut* the word and *paste* it into the appropriate group. In this way, groups were created such that no word could belong to more than one group. The annotators were also asked to mark the words that were indeed names. Of the 296 OOV words, 292 were found to be actual names.

4.3 Extrinsic evaluation

In addition to the Paice evaluation we propose two extrinsic or task based evaluations for our methods. In the first task, given a name as a query, we aim to find all documents that have a mention of that name or any of its variants. In order to obtain queries and relevance judgments for this task we arbitrarily chose 35 groups of names from the ground-truth set of equivalence classes. The TDT3 corpus was chosen to be the test corpus for this task. Hence we eliminated those words that had no occurrence in the TDT3 corpus from the 35 groups of names giving a total of 76 names. Each of the 76 words formed a query. For each name query we consider all documents that contain a mention of any of the names in the equivalence class of the query as relevant to that query. In this way we obtained relevance judgments for the name query task. Some sample queries are shown in figure 2. We use $F1$ (harmonic mean of the precision and recall) as a measure of performance.

Query Equivalence class

2: {*christina christine*}
3: {*toney toni*}
4: {*michelle michel mitchell*}
5: {*columbia colombia colombian*}

Figure 2: Some sample query equivalence classes

Our extrinsic evaluation is spoken document retrieval. The queries on the TREC-6 and TREC-7 corpora are standard TREC spoken document retrieval track queries. For the TDT2 corpus we use one randomly chosen document from each topic as the query. This document is like a long query with plenty of entities and plenty of contextual information. For the TDT3 corpus we use the topic descriptions as provided by the LDC as the queries. The LDC topic descriptions discuss the *events* that describe a topic and the key entities and locations involved in the event. These are representative of shorter queries, rich in entities. LDC has provided relevance judgments for both the TDT2 and TDT3 corpora. Mean average precision was used as the measure of evaluation.

4.4 Implementation Details

We use GIZA++ (Och and Ney, 2003) to train the machine translation system and the ISI ReWrite Decoder (ISI, 2001) to do the actual translations. The decoder takes as input the models learned by

GIZA++ and a sentence from the foreign language. It can output the top n translations of the input sentence. The ReWrite decoder can translate using IBM Model-3 or Model-4. We found Model 3 to have lower perplexity and hence chose it for our experiments. In order to build the language model $P(c)$, we used the CMU Language Modeling toolkit [2]. All retrieval experiments were performed using the LEMUR [3] toolkit, and using the traditional vector space model. In the traditional vector space model queries and documents are represented as vectors of words. Each word in the vector is weighted using a product of term frequency and inverse document frequency. The similarity between a query and a document is measured using the cosine of the angle between the query and document vectors.

The Simple Aligned and Generative Unsupervised methods require a parallel corpus of ASR and closed caption for training. For the name query task we used TDT2, TREC-6 and TREC-7 to train these methods and TDT3 as the test corpus.

The Supervised and Generative Supervised methods require a human to provide pairs of words that are variants of each other. We filtered out those words from the human generated list of equivalence classes that occurred exclusively in the test corpus and in no other corpus. This is equivalent to asking a human to group words in the training corpus. Similarly we trained the Simple Aligned and Generative Unsupervised models using ASR and closed caption text from all other sources except those in the test set.

The models were trained similarly for the SDR experiments. The models were tested on each of the four corpora in turn, and in each case they were trained on everything but the test corpus.

5 Results

5.1 Intrinsic Experiments

Table 1 shows how the different methods perform on the intrinsic evaluation. We also show the UI and OI values for methods that use string edit distances of 2, 3, 4 and 5. Note that the Supervised method is the ground truth for this evaluation, and hence it has a UI and OI value of zero. A string edit distance of 1 has the lowest OI value, meaning there are very few false alarms. Higher string edit distances have lower UI values, with an increase in OI. We will interpret the UI and OI values again after observing performance on the retrieval tasks, so as to interpret the impact of missed links and false alarm links for retrieval.

Method	UI	OI
Simple Aligned	0.236	0.004
Supervised	0	0
Gen Sup	0.393	0.023
Gen Uns	0.351	0.003
Str. Ed. (1)	0.229	0.000
Str. Ed. (2)	0.083	0.003
Str. Ed. (3)	0.039	0.001
Str. Ed. (4)	0.031	0.124
Str. Ed. (5)	0.023	0.336

Table 1: Understemming and Overstemming indices for each of the methods (lower is better)

5.2 Name Query Retrieval experiments

The results of our experiments on the name query task are given in table 2. We report both Macro and Micro averaged (averaged over the equivalence classes of the queries) F1 measures. They do not differ much since the equivalence classes have almost the same number (2-3) of names.

From table 2, all methods improve the baseline F1 score significantly (statistical significance measured using a two tailed t-test with a confidence of 95%). In general, the Simple Aligned, Generative Unsupervised and string edit distance methods are the best performing for this task. The string edit distance improves the baseline by over 60%. The Supervised method is also not as good as the other four of our methods as it does not generalize well to names that occur exclusively in the test set.

String edit distance performs very well on certain equivalence classes of names. For example, on the equivalence class {*Seigal, Segal, Siegal, Siegel*} the precision and recall are 100% each since all of the words in the equivalence class differ from each other by a string edit distance of one. In the case of the equivalence class {*Lewenskey Lewinski Lewinsky*}, the term *Lewenskey* has a string edit distance of 2 (greater than one) from the other two members,

Str. Ed	0.752	0.867	**0.806**	0.751	0.871	**0.807**

Table 2: Results on the Name Query Retrieval task

Lewinsky and *Lewinski*. The equivalence class of {*John Jon Joan*} has very low precision and recall. This is because both *John* and *Jon* differ by a string edit distance of one from so many other names in the corpus, such as *Jong*, resulting in lowered precision.

The Simple Aligned method fails on names it has not seen in the training set. However, for cases like {*Greensborough Greensboro*} the link between these two names is detected using the simple aligned method and by no other. The generative methods can detect variations in spelling due to similar sounding alphabets. For example it can detect the link between *Sydney* and *Sidney*. The generative models were also able to learn that c and k are substitutable for each other. Therefore these models could detect the links between the words in the equivalence class {*Katherine Kathryn Catherine*}.

The Simple Aligned model performs well on the extrinsic evaluations although it has a high OI value. The intrinsic evaluations use judgments by humans. The Simple Aligned method would conflate *Kofi* and *Copy* into one class if that was a genuine ASR error and the alignment was correct, but these two words would not be conflated into the same equivalence class by our annotators and would actually count as a false alarm on the intrinsic evaluations. Therefore, although the OI is high for the Simple Aligned Method, on closer examination we found that some of the false alarms were actually representative of ASR errors.

5.3 Spoken Document Retrieval

We now move on to discuss results on the SDR task. For TDT3 we got statistically significant improvements (an improvement in mean average precision from 0.715 to 0.757) over the baseline using string edit distance. On the remaining corpora we got little or no improvement by our methods. We proceed to explain why this is the case for each of the corpora.

The TREC-7 corpus has only 5 queries with a mention of a name resulting in hardly any gains overall. Similar was the case for TREC-6. Again in the case of the TDT2 corpus, since we used entire documents as stories, there are enough words in the query that a few recognition errors can be tolerated and therefore traditional retrieval is good for the task. There is evidence from previous TREC tracks (Voorhees and Harman, 1999) that shorter queries result in a decrease in retrieval performance and hence we see some improvements for TDT3. Besides, the TDT3 queries were rich in names.

We wanted to check how our methods performed on outputs of different ASR systems. Spoken document retrieval on the TREC-7 data with the output of Dragon systems, which has a word error rate of 29.5%, results in an improvement of 6% using the Simple Aligned method. The NIST-B2 system with a higher WER (46.6%) has an improvement in Mean Average Precision of 6.5%. Similarly with the CUHTK (WER 35.6%) and NIST-B1 (WER 33.8%) and Sheffield (WER 24.6 %) systems we obtained improvements of 1.6%, 0.39% and 0.05% respectively using the Simple Aligned method. Thus, with increasing WER, the named entity word error rate increases significantly, and therefore the benefits of our method are more apparent in such situations.

6 Discussion and Conclusions

We showed (both intrinsically and extrinsically) that string edit distance is an effective technique for locating name variants. We also developed a set of generative models and showed that they are almost as effective at name finding and document retrieval, but are probably more efficient than string edit distance. The generative models need to be trained on parallel text and therefore require human effort for training the models. The advantage of one method over the other is dependent on the size of the corpus and the availability of resources.

The problem has not been of significance in previous TREC tasks or in TDT, because we have always escaped the problem of misspelled names by virtue of the nature of those tasks. In the TREC tasks very few queries are centered on an entity. In all the TDT tasks, one is usually required to compare entire stories with each other. A story is long enough that there are enough words that are in the vocabulary (just like a very long query) or that are correctly recognized, that the ASR errors do not really matter. Therefore, the TDT tasks also do not suffer as a result of these ASR errors.

We can improve and apply our methods to other domains like Switchboard data (Godfrey et al., 1992). Our methods also generalize well across languages since there are no language specific techniques employed.

Part-of-Speech Tagging using Virtual Evidence and Negative Training

Sheila M. Reynolds and **Jeff A. Bilmes**
Department of Electrical Engineering
University of Washington
Seattle, WA 98195-2500
{sheila,bilmes}@ee.washington.edu

Abstract

We present a part-of-speech tagger which introduces two new concepts: virtual evidence in the form of an "observed child" node, and negative training data to learn the conditional probabilities for the observed child. Associated with each word is a flexible feature-set which can include binary flags, neighboring words, etc. The conditional probability of *Tag* given *Word* + *Features* is implemented using a factored language-model with back-off to avoid data sparsity problems. This model remains within the framework of Dynamic Bayesian Networks (DBNs) and is conditionally-structured, but resolves the label bias problem inherent in the conditional Markov model (CMM).

1 Introduction

A common sequence-labeling task in natural language processing involves assigning a part-of-speech (POS) tag to each word in the input text. Previous authors have used numerous HMM-based models (Banko and Moore, 2004; Collins, 2002; Lee et al., 2000; Thede and Harper, 1999) and other types of networks including maximum entropy models (Ratnaparkhi, 1996), conditional Markov models (Klein and Manning, 2002; McCallum et al., 2000), conditional random fields (CRF) (Lafferty et al., 2001), and cyclic dependency networks (Toutanova et al., 2003). All of these models make use of varying amounts of contextual information. In this paper, we present a new model which remains within the well understood framework of Dynamic Bayesian Networks (DBNs), and we show that it produces state-of-the-art results when applied to the POS-tagging task. This new model is conditionally-structured and, through the use of virtual evidence (Pearl, 1988; Bilmes, 2004), resolves the explaining-away problems (often described as label or observation bias) inherent in the CMM.

This paper is organized as follows. In section 2 we discuss the differences between a hidden Markov model (HMM) and the corresponding conditional Markov model (CMM). In section 3 we describe our observed-child model (OCM), introducing the notion of virtual evidence, and providing an information-theoretic foundation for the use of negative training data. In section 4 we discuss our experiments and results, including a comparison of three simple first-order models and state-of-the-art results from our feature-rich second-order OCM.

For clarity, the comparisons and derivations in sections 2 and 3 are done for first-order models using a single binary feature. The same ideas are then generalized to a higher order model with more features (including adjacent words).

2 Generative vs. Conditional Models

In this section we discuss the tradeoffs between the generative hidden Markov model (HMM) and the conditional Markov model (CMM). For pedagogical reasons, the figures and equations are for first order models with a single word-feature.

The HMM shown in Figure 1 includes a single

Proceedings of Human Language Technology Conference and Conference on Empirical Methods in Natural Language Processing (HLT/EMNLP), pages 459–466, Vancouver, October 2005. ©2005 Association for Computational Linguistics

feature (the binary flag *isCap*) in addition to the word itself. Each observation, $o_i = (w_i, f_i)$, is a word-feature pair. Let $\mathbf{o} = \{o_i\}$ be the observation sequence and $\mathbf{s} = \{s_i\}$ be the associated tag (state) sequence. The HMM[1] factorizes the joint probability distribution over these two sequences as:

$$P(\mathbf{s}, \mathbf{o}) = \prod_i P(s_i|s_{i-1})P(w_i|s_i)P(f_i|s_i)$$

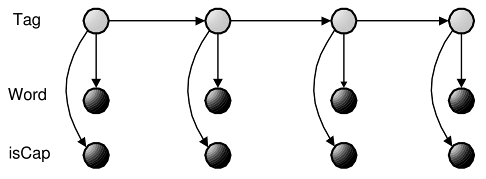

Figure 1: First order HMM.

A similar model often used for sequence labeling tasks is the conditional Markov model (CMM) which reverses the arrows between the words and the tags (Figure 2), and factorizes as:

$$P(\mathbf{s}, \mathbf{o}) = \prod_i P(s_i|s_{i-1}, w_i, f_i)P(w_i)P(f_i)$$

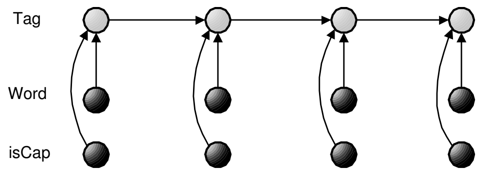

Figure 2: First order CMM.

Because the words and features are observed, this model does not require that we compute the probability of the evidence, $P(\mathbf{o})$, when finding the optimal tag sequence. The tag-sequence $\mathbf{s}$ which maximizes the joint probability $P(\mathbf{s}, \mathbf{o})$ is the same one that maximizes the *conditional* probability $P(\mathbf{s}|\mathbf{o})$. The CMM, therefore, does not require that we model the language, allowing us to focus on modeling the conditional probability of the tags given the words.

The HMM has its advantages as well, principally that it is easier to train than the CMM because it factorizes the joint probability into simpler components. The tables required for $P(s_i|s_{i-1})$ and $P(o_i|s_i)$ are significantly smaller than the one for $P(s_i|s_{i-1}, o_i)$ which may be difficult to estimate due to either data sparsity or normalization issues. One potential disadvantage of the HMM is that when it is trained using a maximum likelihood procedure, it is not necessarily encouraged to optimally classify tags due to its generative nature. One solution is to train the HMM using a discriminative procedure. Another option is to use entirely different models.

A key disadvantage of the CMM is that it makes critical statements about independence that the HMM does not: the converging arrows at each tag put the parent nodes (the previous tag and the current observation) into causal competition and as a result the model states that the previous tag is independent of the current observation. In other words, all states (tags) are independent of future observations (words). The CMM thus incorporates a strong directional bias which does not exist in the HMM.

One way to eliminate this bias is to use a CRF (Lafferty et al., 2001; McCallum, 2003), where factors over neighboring tags may use features from anywhere in the observation sequence. The CRF is discriminative and avoids label/observation bias by using a model that is constrained only in that the conditional distribution factorizes over an undirected Markov chain. However, most popular training procedures for a CRF are time-consuming and complex processes.

3 Using Virtual Evidence

Our goals in this work are to: 1) keep the discriminative nature of the CMM to the extent possible; 2) avoid label and observation bias issues; and 3) stay entirely within the DBN framework where training is relatively simple. We thus propose a new solution to the problem, which retains the discriminative conditional form of "tag given word" from the CMM, but avoids label bias by temporally linking adjacent tags in a new way. Specifically, we employ virtual evidence in the form of a binary observed child node, c_i, between adjacent tags (Figure 3) or a windowed sequence of tags. During decoding, this node will always be observed to be equal to 1 (one). Intuitively, this binary variable acts as an indicator of

[1]In this HMM, Word and isCap are independent given Tag, but this need not be true in general.

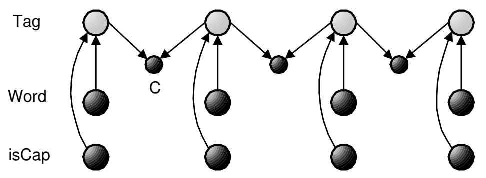

Figure 3: First order observed-child model (OCM) with the tags connected in pairs.

tag-pair consistency. When the tag pairs are consistent (as they are in real text), we should have a high conditional probability that $c_i = 1$; and when the tag pairs are not consistent, the conditional probability that $c_i = 1$ should be low. With this conditional distribution, observing $c_i = 1$ during decoding expresses a preference for consistent tag pairs.

The presence of this observed-child node results in a term in the factorization of the joint probability distribution that couples its parents:

$$P(\mathbf{c}, \mathbf{s}, \mathbf{o}) \propto \prod_i P(c_i | s_{i-1}, s_i) P(s_i | w_i, f_i)$$

where c_i is the observed-child node of tags s_{i-1} and s_i, and we omit the probability of the observations, $P(w_i, f_i)$ which do not affect the final choice of $\mathbf{s}$.

By the rules of d-separation (Pearl, 1988), the existence of c_i defined in this way means that the parents (the adjacent tags) are *not* conditionally independent given the child. This link between adjacent tags through an observed-child node allows for a probabilistic relationship to exist between the adjacent tags. Thus, future words can influence tags, which is not true for the CMM. Whether or not a relationship between tags will actually be learned, however, will critically depend on how the model is trained. In a graphical model, it is the *lack* of an edge that ensures some form of independence; the presence of an edge (or a path made up of two or more edges) does not necessarily ensure the reverse.

3.1 Training

The introduction of virtual evidence into a graphical model requires that careful thought be given to the training process. If we were to naïvely add $c_i = 1$ to all samples of the training data, the model would learn that c_i is constant rather than random, and therefore that it is independent of its parents, s_{i-1} and s_i. In other words, this naïvely-trained model would assume that $P(c_i = 1 | s_{i-1}, s_i) = 1 \; \forall \; (s_{i-1}, s_i)$, and when used to tag the sentences in the test-set (also labeled with $c_i = 1$), it would maximize this simplified joint probability in which the relationship between s_{i-1} and s_i has been lost:

$$P(\mathbf{c}, \mathbf{s}, \mathbf{o}) \propto \prod_i P(s_i | w_i, f_i)$$

In order to induce and thereby have the model *learn* the relationship between the adjacent tags s_{i-1} and s_i, the training has to be modified to include samples that are labeled with $c_i = 0$. The probability table $P(c_i = 1 | s_{i-1}, s_i)$ should favor common (consistent) tag-pairs with high probabilities, while discouraging rare tag-pairs with low probabilities.

Although all observations (in both training and test sets) are labeled with $c_i = 1$, we hypothesize an alternate set of observations labeled with $c_i = 0$. This alternate set will be the source of the negative training data [2]. It is a set of nonsensical sentences with the same distribution over individual tags, i.e. the same $P(s_i)$, but in this set adjacent tags are independent. We denote the total number of training samples by M. This is divided into positive training samples, M_1, and negative training samples, M_0, with $M_1 + M_0 = M$. The ratio of the amount of positive to negative training data should be the same as the ratio of our prior beliefs about tag-pair consistency, namely the ratio of $P(c_i = 1)$ to $P(c_i = 0)$. With no evidence to support that one is more likely than the other, one option is to use the strategy of "assuming the least" and use a maximum entropy prior, setting $M_0 = M_1$. More flexibly, we can define n to be the ratio of the two so that $M_0 = n \cdot M_1$.

Now we derive a method for training the conditional probability table $P(c_i | s_{i-1}, s_i)$ in terms of the pointwise mutual information between the adjacent tags s_{i-1} and s_i. We first rewrite the conditional probability (henceforth abbreviated as p) as:

$$p = P(c_i = 1 | s_{i-1}, s_i) = \frac{P(c_i = 1, s_{i-1}, s_i)}{P(s_{i-1}, s_i)}$$

If the probabilities are maximum likelihood (ML) estimates derived from counts on the training data, we can equivalently write:

$$p = \frac{\mathbf{N}(c_i = 1, s_{i-1}, s_i)}{\mathbf{N}(s_{i-1}, s_i)}$$

[2]This use of implied negative training data is similar to the "neighborhood" concept described in (Smith and Eisner, 2005)

where $\mathbf{N}(\cdot)$ is the count function.

Expanding the denominator into two terms:

$$p = \frac{\mathbf{N}(c_i = 1, s_{i-1}, s_i)}{\mathbf{N}(c_i = 1, s_{i-1}, s_i) + \mathbf{N}(c_i = 0, s_{i-1}, s_i)}$$

Without any negative training data (labeled with $c_i = 0$), this ratio would always evaluate to 1, and no probabilistic relationship between s_{i-1} and s_i would be learned.

From the start, we have implicitly postulated a relationship between adjacent tags. We now formally state two hypotheses: H_1 that there *is* a relationship between adjacent tags which can be described by some joint probability distribution $P(s_{i-1}, s_i)$, and the null hypothesis, H_0, that there is no such relationship, i.e. s_{i-1} and s_i are independent:

$$P_{H_1} = P(s_{i-1}, s_i)$$

$$P_{H_0} = P(s_{i-1})P(s_i)$$

Now we can express the counts as follows:

$$\mathbf{N}(c_i = 1, s_{i-1}, s_i) = M_1 \cdot P(s_{i-1}, s_i)$$

$$\mathbf{N}(c_i = 0, s_{i-1}, s_i) = M_0 \cdot P(s_{i-1})P(s_i)$$

where M_1 is the total number of tokens in the (positive) training data, and M_0 is the total number of tokens in the induced negative training data. We substitute M_0 with $n \cdot M_1$ for the reasons mentioned earlier, and simplify to obtain:

$$p = \frac{P(s_{i-1}, s_i)}{P(s_{i-1}, s_i) + nP(s_{i-1})P(s_i)}$$

which can be simplified to obtain:

$$p = \frac{1}{1 + n\left[\frac{P(s_{i-1},s_i)}{P(s_{i-1})P(s_i)}\right]^{-1}}$$

The ratio of probabilities in the denominator is the ratio used in computing the pointwise mutual information between s_{i-1} and s_i. This ratio, which we will call λ, is also the likelihood ratio between the two previously stated hypotheses. Finally, we write the conditional probability as a function of λ:

$$P(c_i = 1|s_{i-1}, s_i) = \frac{1}{1 + n\lambda^{-1}} = \frac{\lambda}{\lambda + n}$$

where $\lambda = \frac{P_{H_1}}{P_{H_0}} = \frac{P(s_{i-1}, s_i)}{P(s_{i-1})P(s_i)} = \frac{P(s_i|s_{i-1})}{P(s_i)}$

The conditional probability, $P(c_i = 1|s_{i-1}, s_i)$ is a mapping $g(\lambda)$ from $\lambda \in [0, \infty)$ to $p \in [0, 1)$.

Beginning with (Church and Hanks, 1989), numerous authors have used the pointwise mutual information between pairs of words to analyze word co-locations and associations. This ratio tells us whether s_{i-1} and s_i co-occur more or less often than would be expected by chance alone.

Consider, for example, the tags DT (determiner) and NN (noun), and the four possible ordered tag-pairs. The probabilities $P(s_i)$ and $P(s_i|s_{i-1})$ derived from the training data (see section 4.1), the likelihood ratio score λ, the conditional probability $p = P(c_i = 1|s_{i-1}, s_i)$, and the occurrence counts $\mathbf{N}$ are shown in Table 1. As expected, the sequence DT-NN (e.g. *the surplus*) occurs very often and gets a high score, while DT-DT (e.g. *this a*) and NN-DT (e.g. *surplus the*) occur infrequently and get low scores. The sequence NN-NN (e.g. *trade surplus*) gets a neutral score ($\lambda \approx 1$) indicating that if the preceding word is a noun, the likelihood that the current word is a noun is nearly equal to the likelihood that any randomly chosen word is a noun.

We present two methods for inducing the negative training counts that are required to train the conditional probability table for $P(c_i|s_{i-1}, s_i)$.

In the first method, we generate "nonsense" sentences by randomly scrambling each sentence in the training-set n times, using a uniform distribution over all possible permutations. This results in n negative training sentences for each positive training sentence and therefore $M_0 = n \cdot M_1$. Effectively, the ratio of priors on c_i is now:

$$\frac{P(c_i = 1)}{P(c_i = 0)} = \frac{M_1}{M_0} = \frac{1}{n}$$

The conditional probability table $P(c_i|s_{i-1}, s_i)$ is

s_{i-1}-s_i	$P(s_i)$	$P(s_i\|s_{i-1})$	λ	p	$\mathbf{N}$
DT-NN	0.129	0.4905	3.80	0.79	37301
NN-NN	0.129	0.1270	0.98	0.49	15571
NN-DT	0.080	0.0071	0.09	0.08	870
DT-DT	0.080	0.0018	0.02	0.02	134

Table 1: Sample likelihood ratio scores (λ), probabilities, p (for $n = 1$), and counts for four tag-pairs.

then trained using all $n+1$ versions of each sentence, thus inducing the desired dependence between s_{i-1} and s_i. The method of scrambling sentences n-times only approximates the theory described above because it is performed on a sentence-by-sentence basis rather than across the entire training set. Also, the resulting negative training data represents only n realizations of a random process, so the total number of samples may not be large enough to approximate the underlying distribution.

In the second method, rather than generate the negative training data in the form of scrambled sentences, we compute the negative-training counts directly, based on the positive unigram counts and the hypotheses presented in section 3.1. For example, the negative bigram counts are a function of the marginal probability of each tag, $P(s_i)$:

$$\mathbf{N}(c_i = 0, s_{i-1}, s_i) = nM_1 \cdot P(s_{i-1})P(s_i)$$

Negative unigram and trigram counts are computed in a similar fashion, and then the conditional probability table is derived as a smoothed back-off model directly from the combined sets of counts.

These two methods are conceptually similar but may exhibit subtle differences: one is randomizing at the sentence level while the other operates over the entire training set and does not have the same sensitivity to small values of n.

4 Experiments and Results

In this section we describe our experiments and the results obtained. Sections 4.1 and 4.2 describe the data sets and features. Section 4.3 presents comparisons between several simple models using just the tags, the words, and a single binary feature for each word. Section 4.4 presents results from a feature-rich second-order observed-child model in which tags are linked in groups of three.

All training of language models is done using the SRILM toolkit (Stolcke, 2002) with the FLM extensions (Bilmes and Kirchhoff, 2003), and the implementation and testing of the various graphical models is carried out with the help of the graphical models toolkit (GMTK) (Bilmes and Zweig, 2002).

4.1 Data Sets

The data used for these experiments is the Wall Street Journal data from Penn Treebank III (Marcus et al., 1994). We extracted tagged sentences from the parse trees and divided the data into training (sections 0-18), development (sections 19-21), and test (sections 22-24) sets as in (Toutanova et al., 2003). Except for the final results for the feature-rich model, all results are on the development set.

4.2 Features

The tagged sentences extracted from the Penn Treebank are pre-processed to generate appropriately-formatted training data for the SRILM toolkit, as well as the vocabulary and observation files to be used during testing.

The pre-processing includes building a dictionary based on the training data. All words containing uppercase letters are converted to lowercase before being written to the dictionary. Words that occur rarely are excluded from the dictionary and are instead mapped to a single out-of-vocabulary word. This is based on the idea from (Ratnaparkhi, 1996) that rare words in the training set are similar to unknown words in the test set, and can be used to learn how to tag the unknown words that will be encountered during testing. In this work, rare words are those that occurr fewer than 5 times. The dictionary also includes special *begin-sentence* and *end-sentence* words, as well as punctuation marks, resulting in a total of 10,824 words. A list of the 45 tags found in the training data is also created, and is similarly augmented with special *begin-sentence* and *end-sentence* tags, for a total of 47 distinct tags.

Each word has associated with it a set of features. During training, these features are used to learn a smoothed back-off model for $P(s_i|w_i, \mathbf{f}_i)$ (where $\mathbf{f}_i$ is a vector of features associated with word w_i).

The following five binary flags, taken from (Toutanova et al., 2003), are derived from the current word w_i and used as features :

- is-capitalized (refers to the first letter only);
- has-digits (word contains one or more digits);
- is-hyphenated (word contains '-');
- is-all-caps (*all* letters are capitalized);
- is-conjunction (true if is-all-caps, has-digits, and is-hyphenated are all true, for example *CFC-12* or *F/A-18*).

Prefixes and suffixes are also known to be informative and so we add a prefix-feature and a suffix-feature to our set. Previous work used all possible prefixes and suffixes ranging in length from 1 to k characters, with $k = 4$ (Ratnaparkhi, 1996), and $k = 10$ (Toutanova et al., 2003). This method results in very long lists of thousands of suffixes and prefixes. In this work, we instead analyzed the rare words in the training data to generate shorter lists of informative prefixes and suffixes, with lengths between 1 and 7 characters. Each prefix/suffix was scored based on the number of times it appeared with a particular tag, and all prefixes/suffixes that scored above 20 (an arbitrarily chosen threshold) were kept. This process resulted in two separate lists: one with 377 prefixes, and the other with 704 suffixes. Each word is then assigned a single prefix feature and a single suffix feature from these lists (which both include an entry for "unknown"). When assigning prefix and suffix features to the rare words (in the training data) or the unknown words (in the test data), we assume that the longest string is the most informative. (This may not necessarily be true: for example, although the suffix *ing* is certainly more informative than *g*, it is less clear whether *ulating* would be more or less informative than *ing*.)

We also include the two adjacent words as features of the current word. Our model provides great flexibility in the choice of features to be included in the current word's feature-set. This feature-set is not limited to binary flags and indeed can include anything that can be extracted from the observation sequence in the pre-processing stage. By using a smoothed back-off model, issues related to data-sparsity and over-fitting are avoided.

4.3 First Order Model Comparisons

In this section we compare results obtained from three first-order models: HMM, CMM, and OCM, using a Naïve Bayes (NB) model as a baseline. The Naïve Bayes model is a zeroth-order model with no connection between adjacent tags, while the first-order models connect adjacent tags in pairs. (Note that the HMM in this case is just a "temporal" NB since given the tag, the features are independent.) In these experiments, the only feature used is the is-capitalized flag (the most informative of the binary flags tested). The results are shown in Table 2.

The conditional probability tables (CPTs) for the CMM and the OCM were generated using the factored language model (FLM) extensions to the SRILM toolkit, wth generalized parallel backoff and Witten-Bell smoothing. (Modified Kneser-Ney smoothing could not be applied because some of the required low-order meta-counts needed by the discount estimator were zero.) The negative training data for the OCM was generated using the scramble method, with values of n as in the table. When no negative training data is used ($n = 0$), the CPT for the observed-child shows a very weak dependence on the specific tag-pair (s_{i-1}, s_i): the probability values in the tag-bigram model range only between 0.89 and 1. This weak dependence results in performance comparable to that of the Naïve Bayes model. That there is any dependence at all is due to the smoothing since $c_i = 0$ is never observed in the training data. With negative training data ($n = 4$), there is a much stronger dependence on the tag-pair, and the values for $P(c_i = 1|s_{i-1}, s_i)$ range between 0.0002 and 1.

model type	token accur.	known-w. accur.	unk.-w. accur.
Naïve Bayes	90.56%	93.83%	43.4%
OCM$_{n=0}$	90.89%	94.07%	45.2%
CMM	93.23%	95.69%	57.9%
OCM$_{n=1}$	93.94%	96.39%	58.6%
HMM	94.30%	96.53%	62.3%
OCM$_{n=4}$	94.42%	96.63%	62.7%

Table 2: Scores for first order models.

We found experimentally that the OCM reached peak performance with $n = 4$ and that for larger n the performance stayed relatively constant: the variation for values of n up to 14 was only 0.05%.

4.4 Feature-Rich Second-Order OCM

In this section we describe the results obtained from a more complex second order OCM with the additional word features described in section 4.2.

This model is illustrated in Figure 4 which, for clarity highlights the details only for one (tag,word) pair. The observed-child node, c_i, now has three parents: the tags s_{i-1}, s_i, and s_{i+1}. Each tag, s_i, in turn has $K + 1$ parents: the current word, w_i, and a set of K features (shown bundled together). The model switches between the two feature bundles as

model description	token accuracy	known-word accuracy	unknown-word accuracy
OCM-I, scramble, $n = 4$	96.39%	96.87%	89.5%
OCM-I, computed counts, $n = 4$	96.41%	96.90%	89.3%
OCM-I, computed counts, $n = 1$	96.41%	96.92%	89.0%
OCM-II, computed counts, $n = 1$	96.64%	97.12%	89.5%
OCM-II, as above, on test-set	96.77%	97.25%	90.0%

Table 3: Tagging accuracy using the feature-rich 2^{nd} order observed-child model.

illustrated, based on the current word. For known words, a small set of features is used, while a much larger set of features is used for unknown words. This switching increases the speed of the model at no cost: the additional features increase the tagging accuracy for unknown words but are redundant for known words.

This model factorizes the joint probability as:

$$P(\mathbf{c}, \mathbf{s}, \mathbf{o}) \propto \prod_i P(c_i | s_{i-1}, s_i, s_{i+1}) P(s_i | w_i, \mathbf{f}_i)$$

where $\mathbf{f}_i$ is the appropriate feature bundle for word w_i, depending on whether w_i is known or unknown.

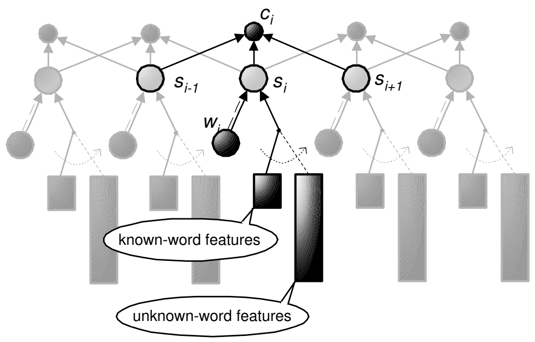

Figure 4: Second order OCM with tags connected in triples and switching sets of word features.

Two sets of experiments were performed using two models, which we will refer to as OCM-I and OCM-II. Both of these are second order models (connecting tags in triples), but with different sets of features. In model OCM-I, the only feature used for known words is the is-capitalized flag used in section 4.3. The unknown words use a total of seven features: suffix, prefix, and all five of the binary flags described in section 4.2. Model OCM-II adds the adjacent words (w_{i-1} and w_{i+1}) to the feature-set for both known and unknown words.

As seen above, the model factorizes the joint probability into two conditional probability terms. Each of these CPTs is implemented as a smoothed, factored-language back-off model.

The observed-child CPT uses generalized backoff, combining at run-time the results of backing off from each of the three parents if the specific tag-triple is not found in the table. The tag CPT uses linear backoff, dropping the adjacent words first. The backoff order for the other features was chosen based on experiments to determine the relative information content of each feature. This resulted in the following backoff order: prefix, has-digit, is-conjunction, is-all-caps, is-hyphenated, suffix, is-capitalized, word (where the least informative feature, prefix, is the first feature to be dropped).

Results from these experiments are shown in Table 3. Except for the last line, which reports results on the test set, all results are on the development set. The first three lines show results obtained from OCM-I (without adjacent word features). The two methods of generating negative training data yield nearly identical results, showing that they are comparable. Comparing rows 2 and 3 in the table we see that the computed-counts method is relatively insensitive to the value of n (for $n \geq 1$).

OCM-II, which uses the adjacent words as features for both known and unknown words further improves overall accuracy, and produces state-of-the-art results. The token-level accuracy result obtained from the OCM-II model on the development set (96.64%) can be directly compared to an accuracy of 96.57% reported in (Toutanova et al., 2003) for a cyclic dependency network using similar word features and the same three tag context.

5 Conclusions

In this paper, we have introduced two new concepts to the problem of part-of-speech tagging: virtual evidence and negative training data. We have moreover shown that this new model can produce state-of-the-art results on this NLP task with appropriately chosen features. The model stays entirely within the mathematically formal language of Bayesian networks, and even though it is conditional in nature, the model does not suffer from label or observation (or directional) bias. Staying within this framework has other advantages as well, including that the training procedures remain within the relatively simple maximum likelihood framework, albeit with appropriate smoothing. We believe that this model holds great promise for other NLP tasks as well as in other applications of machine-learning such as computational biology. In particular the way it factorizes the joint probability into a "horizontal" component which connects various nodes to the virtual-evidence node, and a "vertical" component (used here to link a tag to a set of observations), provides great simplicity, flexibility, and power.

Abstract

This paper presents a bidirectional inference algorithm for sequence labeling problems such as part-of-speech tagging, named entity recognition and text chunking. The algorithm can enumerate all possible decomposition structures and find the highest probability sequence together with the corresponding decomposition structure in polynomial time. We also present an efficient decoding algorithm based on the easiest-first strategy, which gives comparably good performance to full bidirectional inference with significantly lower computational cost. Experimental results of part-of-speech tagging and text chunking show that the proposed bidirectional inference methods consistently outperform unidirectional inference methods and bidirectional MEMMs give comparable performance to that achieved by state-of-the-art learning algorithms including kernel support vector machines.

1 Introduction

The task of labeling sequence data such as part-of-speech (POS) tagging, chunking (shallow parsing) and named entity recognition is one of the most important tasks in natural language processing.

Conditional random fields (CRFs) (Lafferty et al., 2001) have recently attracted much attention because they are free from so-called label bias problems which reportedly degrade the performance of sequential classification approaches like maximum entropy markov models (MEMMs).

Although sequential classification approaches could suffer from label bias problems, they have several advantages over CRFs. One is the efficiency of training. CRFs need to perform dynamic programming over the whole sentence in order to compute feature expectations in each iteration of numerical optimization. Training, for instance, second-order CRFs using a rich set of features can require prohibitive computational resources. Max-margin methods for structured data share problems of computational cost (Altun et al., 2003).

Another advantage is that one can employ a variety of machine learning algorithms as the local classifier. There is huge amount of work about developing classification algorithms that have high generalization performance in the machine learning community. Being able to incorporate such state-of-the-art machine learning algorithms is important. Indeed, sequential classification approaches with kernel support vector machines offer competitive performance in POS tagging and chunking (Gimenez and Marquez, 2003; Kudo and Matsumoto, 2001).

One obvious way to improve the performance of sequential classification approaches is to enrich the information that the local classifiers can use. In standard decomposition techniques, the local classifiers cannot use the information about future tags (e.g. the right-side tags in left-to-right decoding), which would be helpful in predicting the tag of the target word. To make use of the information about future tags, Toutanova et al. proposed a tagging algorithm based on bidirectional dependency networks

(Toutanova et al., 2003) and achieved the best accuracy on POS tagging on the Wall Street Journal corpus. As they pointed out in their paper, however, their method potentially suffers from "collusion" effects which make the model lock onto conditionally consistent but jointly unlikely sequences. In their modeling, the local classifiers can always use the information about future tags, but that could cause a double-counting effect of tag information.

In this paper we propose an alternative way of making use of future tags. Our inference method considers all possible ways of decomposition and chooses the "best" decomposition, so the information about future tags is used only in appropriate situations. We also present a deterministic version of the inference method and show their effectiveness with experiments of English POS tagging and chunking, using standard evaluation sets.

2 Bidirectional Inference

The task of labeling sequence data is to find the sequence of tags $t_1...t_n$ that maximizes the following probability given the observation $o = o_1...o_n$

$$P(t_1...t_n|o). \tag{1}$$

Observations are typically words and their lexical features in the task of POS tagging. Sequential classification approaches decompose the probability as follows,

$$P(t_1...t_n|o) = \prod_{i=1}^{n} p(t_i|t_1...t_{i-1}o). \tag{2}$$

This is the left-to-right decomposition. If we make a first-order markov assumption, the equation becomes

$$P(t_1...t_n|o) = \prod_{i=1}^{n} p(t_i|t_{i-1}o). \tag{3}$$

Then we can employ a probabilistic classifier trained with the preceding tag and observations in order to obtain $p(t_i|t_{i-1}o)$ for local classification. A common choice for the local probabilistic classifier is maximum entropy classifiers (Berger et al., 1996). The best tag sequence can be efficiently computed by using a Viterbi decoding algorithm in polynomial time.

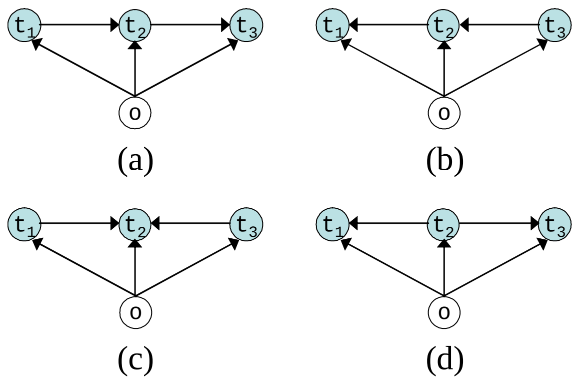

Figure 1: Different structures for decomposition.

The right-to-left decomposition is

$$P(t_1...t_n|o) = \prod_{i=1}^{n} p(t_i|t_{i+1}o). \tag{4}$$
