These two ways of decomposition are widely used in various tagging problems in natural language processing. The issue with such decompositions is that you have only the information about the preceding (or following) tags when performing local classification.

From the viewpoint of local classification, we want to give the classifier as much information as possible because the information about neighboring tags is useful in general.

As an example, consider the situation where we are going to annotate a three-word sentence with part-of-speech tags. Figure 1 shows the four possible ways of decomposition. They correspond to the following equations:

$$(a)\ P(t_1...t_3|o) = P(t_1|o)P(t_2|t_1o)P(t_3|t_2o) \tag{5}$$

$$(b)\ P(t_1...t_3|o) = P(t_3|o)P(t_2|t_3o)P(t_1|t_2o) \tag{6}$$

$$(c)\ P(t_1...t_3|o) = P(t_1|o)P(t_3|o)P(t_2|t_3t_1o) \tag{7}$$

$$(d)\ P(t_1...t_3|o) = P(t_2|o)P(t_1|t_2o)P(t_3|t_2o) \tag{8}$$

(a) and (b) are the standard left-to-right and right-to-left decompositions. Notice that in decomposition (c), the local classifier can use the information about the tags on both sides when deciding t_2. If, for example, the second word is difficult to tag (e.g. an unknown word), we might as well take the decomposition structure (c) because the local classifier can use rich information when deciding the tag of the most difficult word. In general if we have an n-word sentence and adopt a first-order markov assumption, we have 2^{n-1} possible ways of decomposition because each of the $n-1$ edges in the corresponding graph has two directions (left-to-right or right-to-left).

Our bidirectional inference method is to consider all possible decomposition structures and choose the "best" structure and tag sequence. We will show in the next section that this is actually possible in polynomial time by dynamic programming.

As for the training, let us look at the equations of four different decompositions above. You can notice that there are only four types of local conditional probabilities: $P(t_i|t_{i-1}o)$, $P(t_i|t_{i+1}o)$, $P(t_i|t_{i-1}t_{i+1}o)$, and $P(t_i|o)$.

This means that if we have these four types of local classifiers, we can consider any decomposition structures in the decoding stage. These local classifiers can be obtained by training with corresponding neighboring tag information. Training the first two types of classifiers is exactly the same as the training of popular left-to-right and right-to-left sequential classification models respectively.

If we take a second-order markov assumption, we need to train 16 types of local classifiers because each of the four neighboring tags of a classification target has two possibilities of availability. In general, if we take a k-th order markov assumption, we need to train 2^{2k} types of local classifies.

2.1 Polynomial Time Inference

This section describes an algorithm to find the decomposition structure and tag sequence that give the highest probability. The algorithm for the first-order case is an adaptation of the algorithm for decoding the best sequence on a bidirectional dependency network introduced by (Toutanova et al., 2003), which originates from the Viterbi decoding algorithm for second-order markov models.

Figure 2 shows a polynomial time decoding algorithm for our bidirectional inference. It enumerates all possible decomposition structures and tag sequences by recursive function calls, and finds the highest probability sequence. Polynomial time is achieved by caching. Note that for each local classification, the function chooses the appropriate local classifier by taking into account the directions of the adjacent edges of the classification target.

```
function bestScore()
{
  return bestScoreSub(n+2, $\langle end, end, end \rangle$, $\langle L, L \rangle$);
}

function bestScoreSub(i+1, $\langle t_{i-1}, t_i, t_{i+1} \rangle$, $\langle d_{i-1}, d_i \rangle$)
{
  // memorization
  if (cached(i+1, $\langle t_{i-1}, t_i, t_{i+1} \rangle$, $\langle d_{i-1}, d_i \rangle$))
    return cache(i+1, $\langle t_{i-1}, t_i, t_{i+1} \rangle$, $\langle d_{i-1}, d_i \rangle$);
  // left boundary case
  if (i = -1)
    if ($\langle t_{i-1}, t_i, t_{i+1} \rangle$ = $\langle start, start, start \rangle$)    return 1;
    else                                                                                  return 0;
  // recursive case
  $P$ = localClassification(i, $\langle t_{i-1}, t_i, t_{i+1} \rangle$, $\langle d_{i-1}, d_i \rangle$);
  return $\max_{d_{i-2}} \max_{t_{i-2}} P \times$
          bestScoreSub(i, $\langle t_{i-2}, t_{i-1}, t_i \rangle$, $\langle d_{i-2}, d_{i-1} \rangle$);
}

function localClassification(i, $\langle t_{i-1}, t_i, t_{i+1} \rangle$, $\langle d_{i-1}, d_i \rangle$)
{
  if ($d_{i-1} = L$ & $d_i = L$)    return $P(t_i|t_{i+1}, o)$;
  if ($d_{i-1} = L$ & $d_i = R$)    return $P(t_i|o)$;
  if ($d_{i-1} = R$ & $d_i = L$)    return $P(t_i|t_{i-1}t_{i+1}, o)$;
  if ($d_{i-1} = R$ & $d_i = R$)    return $P(t_i|t_{i-1}, o)$;
}
```

Figure 2: Pseudo-code for bidirectional inference for the first-order conditional markov models. d_i is the direction of the edge between t_i and t_{i+1}.

The second-order case is similar but slightly more complex. Figure 3 shows the algorithm. The recursive function needs to consider the directions of the four adjacent edges of the classification target, and maintain the directions of the two neighboring edges to enumerate all possible edge directions. In addition, the algorithm rules out cycles in the structure.

2.2 Decoding with the Easiest-First Strategy

We presented a polynomial time decoding algorithm in the previous section. However, polynomial time is not low enough in practice. Indeed, even the Viterbi decoding of second-order markov models for POS tagging is not practical unless some pruning method is involved. The computational cost of the bidirectional decoding algorithm presented in the previous section is, of course, larger than that because it enumerates all possible directions of the edges on top of the enumeration of possible tag sequences.

In this section we present a greedy version of the decoding method for bidirectional inference, which

```
function bestScore()
{
  return bestScoreSub(n+3, $\langle end, end, end, end, end\rangle$, $\langle L, L, L, L\rangle$, $\langle L, L\rangle$);
}

function bestScoreSub(i+2, $\langle t_{i-2}, t_{i-1}, t_i, t_{i+1} t_{i+2}\rangle$, $\langle d'_{i-1}, d_{i-1}, d_i, d'_{i+1}\rangle$, $\langle d_{i-2}, d'_i\rangle$)
{
  // to avoid cycles
  if ($d_{i-1}$ = $d_i$ & $d_i$ != $d'_i$)   return 0;
  // memorization
  if (cached(i+2, $\langle t_{i-2}, t_{i-1}, t_i, t_{i+1} t_{i+2}\rangle$, $\langle d'_{i-1}, d_{i-1}, d_i, d'_{i+1}\rangle$, $\langle d_{i-2}, d'_i\rangle$)
    return cache(i+2, $\langle t_{i-2}, t_{i-1}, t_i, t_{i+1} t_{i+2}\rangle$, $\langle d'_{i-1}, d_{i-1}, d_i, d'_{i+1}\rangle$, $\langle d_{i-2}, d'_i\rangle$);
  // left boundary case
  if (i = -2)
    if ($\langle t_{i-2}, t_{i-1}, t_i, t_{i+1}, t_{i+2}\rangle$ = $\langle start, start, start, start, start\rangle$)   return 1;
    else                                                                      return 0;
  // recursive case
  $P$ = localClassification(i, $\langle t_{i-2}, t_{i-1}, t_i, t_{i+1}, t_{i+2}\rangle$, $\langle d'_{i-1}, d_{i-1}, d_i, d'_{i+1}\rangle$);
  return $\max_{d'_{i-2}} \max_{d_{i-3}} \max_{t_{i-3}} P\times$ bestScoreSub(i+1, $\langle t_{i-3}, t_{i-2}, t_{i-1}, t_i t_{i+1}\rangle$, $\langle d'_{i-2}, d_{i-2}, d_{i-1}, d'_i\rangle$, $\langle d_{i-3}, d'_{i-1}\rangle$);
}
```

Figure 3: Pseudo-code for bidirectional inference for the second-order conditional markov models. d_i is the direction of the edge between t_i and t_{i+1}. d'_i is the direction of the edge between t_{i-1} and t_{i+1}. We omit the localClassification function because it is the obvious extension of that for the first-order case.

is extremely simple and significantly more efficient than full bidirectional decoding.

Instead of enumerating all possible decomposition structures, the algorithm determines the structure by adopting the easiest-first strategy. The whole decoding algorithm is given below.

1. Find the “easiest” word to tag.
2. Tag the word.
3. Go back to 1. until all the words are tagged.

We assume in this paper that the “easiest” word to tag is the word for which the classifier outputs the highest probability. In finding the easiest word, we use the appropriate local classifier according to the availability of the neighboring tags. Therefore, in the first iteration, we always use the local classifiers trained with no contextual tag information (i.e. $(P(t_i|o))$. Then, for example, if t_3 has been tagged in the first iteration in a three-word sentence, we use $P(t_2|t_3 o)$ to compute the probability for tagging t_2 in the second iteration (as in Figure 1 (b)).

A naive implementation of this algorithm requires $O(n^2)$ invocations of local classifiers, where n is the number of the words in the sentence, because we need to update the probabilities over the words at each iteration. However, a k-th order Markov assumption obviously allows us to skip most of the probability updates, resulting in $O(kn)$ invocations of local classifiers. This enables us to build a very efficient tagger.

3 Maximum Entropy Classifier

For local classifiers, we used a maximum entropy model which is a common choice for incorporating various types of features for classification problems in natural language processing (Berger et al., 1996).

Regularization is important in maximum entropy modeling to avoid overfitting to the training data. For this purpose, we use the maximum entropy modeling with inequality constraints (Kazama and Tsujii, 2003). The model gives equally good performance as the maximum entropy modeling with Gaussian priors (Chen and Rosenfeld, 1999), and the size of the resulting model is much smaller than that of Gaussian priors because most of the parameters become zero. This characteristic enables us to easily handle the model data and carry out quick decoding, which is convenient when we repetitively perform experiments. This modeling has one parameter to tune, which is called the *width factor*. We tuned this parameter using the development data in each type of experiments.

Current word	w_i	& t_i

4 Experiments

To evaluate the bidirectional inference methods presented in the previous sections, we ran experiments on POS tagging and text chunking with standard English data sets.

Although achieving the best accuracy is not the primary purpose of this paper, we explored useful feature sets and parameter setting by using development data in order to make the experiments realistic.

4.1 Part-of-speech tagging experiments

We split the Penn Treebank corpus (Marcus et al., 1994) into training, development and test sets as in (Collins, 2002). Sections 0-18 are used as the training set. Sections 19-21 are the development set, and sections 22-24 are used as the test set. All the experiments were carried out on the development set, except for the final accuracy report using the best setting.

For features, we basically adopted the feature set provided by (Toutanova et al., 2003) except for complex features such as crude company-name detection features because they are specific to the Penn Treebank and we could not find the exact implementation details. Table 1 lists the feature templates used in our experiments.

We tested the proposed bidirectional methods, conventional unidirectional methods and the bidirectional dependency network proposed by Toutanova (Toutanova et al., 2003) for comparison. [1]. All the models are second-order. Table 2 shows the accuracy and tagging speed on the development data [2]. Bidirectional inference methods clearly outperformed unidirectional methods. Note that the easiest-first decoding method achieves equally good performance as full bidirectional inference. Table 2 also shows that the easiest-last strategy, where we select and tag the most difficult word at each iteration, is clearly a bad strategy.

An example of easiest-first decoding is given below:

[1]For dependency network and full bidirectional decoding, we conducted pruning because the computational cost was too large to perform exhaustive search. We pruned a tag candidate if the zero-th order probability of the candidate $P(t_i|o)$ was lower than one hundredth of the zero-th order probability of the most likely tag at the token.

[2]Tagging speed was measured on a server with an AMD Opteron 2.4GHz CPU.

The/DT/4 company/NN/7 had/VBD/11 sought/VBN/14 increases/NNS/13 totaling/VBG/12 $/$/2 80.3/CD/5 million/CD/8 ,/,/1 or/CC/6 22/CD/9 %/NN/10 ./././3

Each token represents Word/PoS/DecodingOrder. Typically, punctuations and articles are tagged first. Verbs are usually tagged in later stages because their tags are likely to be ambiguous.

We applied our bidirectional inference methods to the test data. The results are shown in Table 3. The table also summarizes the accuracies achieved by several other research efforts. The best accuracy is 97.24% achieved by bidirectional dependency networks (Toutanova et al., 2003) with a richer set of features that are carefully designed for the corpus. A perceptron algorithm gives 97.11% (Collins, 2002). Gimenez and Marquez achieve 97.05% with support vector machines (SVMs). This result indicates that bidirectional inference with maximum entropy modeling can achieve comparable performance to other state-of-the-art POS tagging methods.

4.2 Chunking Experiments

The task of chunking is to find non-recursive phrases in a sentence. For example, a chunker segments the sentence "He reckons the current account deficit will narrow to only 1.8 billion in September" into the following,

[NP He] [VP reckons] [NP the current account deficit] [VP will narrow] [PP to] [NP only 1.8 billion] [PP in] [NP September] .

We can regard chunking as a tagging task by converting chunks into tags on tokens. There are several ways of representing text chunks (Sang and Veenstra, 1999). We tested the Start/End representation in addition to the popular IOB2 representation since local classifiers can have fine-grained information on the neighboring tags in the Start/End representation.

For training and testing, we used the data set provided for the CoNLL-2000 shared task. The training set consists of section 15-18 of the WSJ corpus, and the test set is section 20. In addition, we made the development set from section 21 [3].

We basically adopted the feature set provided in

	t_{i+1}, t_{i+2}	& t_i

Table 4: Feature templates used in chunking experiments.

(Collins, 2002) and used POS-trigrams as well. Table 4 lists the features used in chunking experiments.

Table 5 shows the results on the development set. Again, bidirectional methods exhibit better performance than unidirectional methods. The difference is bigger with the Start/End representation. Dependency networks did not work well for this chunking task, especially with the Start/End representation.

We applied the best model on the development set in each chunk representation type to the test data. Table 6 summarizes the performance on the test set. Our bidirectional methods achieved F-scores of 93.63 and 93.70, which are better than the best F-score (93.48) of the CoNLL-2000 shared task (Sang and Buchholz, 2000) and comparable to those achieved by other state-of-the-art methods.

5 Discussion

There are some reports that one can improve the performance of unidirectional models by combining outputs of multiple taggers. Shen et al. (2003) reported a 4.9% error reduction of supertagging by

[3] We used the Perl script provided on http://ilk.kub.nl/~ sabine/chunklink/

pairwise voting between left-to-right and right-to-left taggers. Kudo et al. (2001) attained performance improvement in chunking by conducting weighted voting of multiple SVMs trained with distinct chunk representations. The biggest difference between our approach and such voting methods is that the local classifier in our bidirectional inference methods can have rich information for decision. Also, voting methods generally need many tagging processes to be run on a sentence, which makes it difficult to build a fast tagger.

Our algorithm can be seen as an ensemble classifier by which we choose the highest probability one among the different taggers with all possible decomposition structures. Although choosing the highest probability one is seemingly natural and one of the simplest ways for combining the outputs of different taggers, one could use a different method (e.g. summing the probabilities over the outputs which share the same label sequence). Investigating the methods for combination should be an interesting direction of future work.

As for the computational cost for training, our methods require us to train 2^{2n} types of classifiers when we adopt an nth order markov assumption. In many cases a second-order model is sufficient because further increase of n has little impact on performance. Thus the training typically takes four or 16 times as much time as it would take for training a single unidirectional tagger, which looks somewhat expensive. However, because each type of classifier can be trained independently, the training can be performed completely in parallel and run with the same amount of memory as that for training a single classifier. This advantage contrasts with the case for CRFs which requires substantial amount of memory and computational cost if one tries to incorporate higher-order features about tag sequences.

Tagging speed is another important factor in building a practical tagger for large-scale text mining. Our inference algorithm with the easiest-first strategy needs no Viterbi decoding unlike MEMMs and CRFs, and makes it possible to perform very fast tagging with high precision.

6 Conclusion

We have presented a bidirectional inference algorithm for sequence labeling problems such as POS tagging, named entity recognition and text chunking. The algorithm can enumerate all possible decomposition structures and find the highest probability sequence together with the corresponding decomposition structure in polynomial time. We have also presented an efficient bidirectional inference algorithm based on the easiest-first strategy, which gives comparable performance to full bidirectional inference with significantly lower computational cost.

Experimental results of POS tagging and text chunking show that the proposed bidirectional inference methods consistently outperform unidirectional inference methods and our bidirectional MEMMs give comparable performance to that achieved by state-of-the-art learning algorithms including kernel support vector machines.

A natural extension of this work is to replace the maximum entropy modeling, which was used as the local classifiers, with other machine learning algorithms. Support vector machines with appropriate kernels is a good candidate because they have good generalization performance as a single classifier. Although SVMs do not output probabilities, the easiest-first method would be easily applied by considering the margins output by SVMs as the confidence of local classification.

Abstract

Finite-state approaches have been highly successful at describing the morphological processes of many languages. Such approaches have largely focused on modeling the phone- or character-level processes that generate candidate lexical *types*, rather than *tokens* in *context*. For the full analysis of words in context, *disambiguation* is also required (Hakkani-Tür et al., 2000; Hajič et al., 2001). In this paper, we apply a novel source-channel model to the problem of morphological disambiguation (segmentation into morphemes, lemmatization, and POS tagging) for concatenative, templatic, and inflectional languages. The channel model exploits an existing morphological dictionary, constraining each word's analysis to be linguistically valid. The source model is a factored, conditionally-estimated random field (Lafferty et al., 2001) that learns to disambiguate the full sentence by modeling local contexts. Compared with baseline state-of-the-art methods, our method achieves statistically significant error rate reductions on Korean, Arabic, and Czech, for various training set sizes and accuracy measures.

1 Introduction

One of the great successes in computational linguistics has been the construction of morphological analyzers for diverse languages. Such tools take in words and enumerate the possible morphological analyses—typically a sequence of morphemes, perhaps part-of-speech tagged. They are often encoded as finite-state transducers (Kaplan and Kay, 1981; Koskenniemi, 1983; Beesley and Karttunen, 2003).

What such tools do not provide is a means to *disambiguate* a word in *context*. For languages with complex morphological systems (inflective, agglutinative, and polysynthetic languages, for example), a word form may have many analyses. To pick the right one, we must consider the word's context. This problem has been tackled using statistical sequence models for Turkish (Hakkani-Tür et al., 2000) and Czech (Hajič et al., 2001); their approaches (and ours) are not unlike POS tagging, albeit with complex tags.

[*]This work was supported by a Fannie and John Hertz Foundation Fellowship, a NSF Fellowship, and a NDSEG Fellowship (sponsored by ARO and DOD). The views expressed are not necessarily endorsed by sponsors. We thank Eric Goldlust and Markus Dreyer for Dyna language support and Jason Eisner, David Yarowsky, and three anonymous reviewers for comments that improved the paper. We also thank Jan Hajič and Pavel Krbec for sharing their Czech tagger.

In this paper, we describe context-based models for morphological disambiguation that take full account of existing morphological dictionaries by estimating *conditionally* against only dictionary-accepted analyses of a sentence (§2). These models are an instance of conditional random fields (CRFs; Lafferty et al., 2001) and include overlapping features. Our applications include diverse disambiguation frameworks and we make use of linguistically-inspired features, such as local lemma dependencies and inflectional agreement. We apply our model to Korean and Arabic, demonstrating state-of-the-art results in both cases (§3). We then describe how our model can be expanded to complex, structured morphological tagging, including an efficient estimation method, demonstrating performance on Czech (§4).

2 Modeling Framework

Our framework is a source-channel model (Jelinek, 1976). The *source* (modeled probabilistically by p_s) generates a sequence of unambiguous tagged morphemes $\mathbf{y} = \langle y_1, y_2, ...\rangle \in \mathcal{Y}^+$ ($\mathcal{Y}$ is the set of unambiguous tagged morphemes in the language).[1] The precise contents of the tag will vary by language and corpus but will minimally include POS. $\mathbf{y}$ passes through a *channel* (modeled by p_c), which outputs $\mathbf{x} = \langle x_1, x_2, ...\rangle \in (\mathcal{X} \cup \{\textsc{oov}\})^+$, a sequence of surface-level words in the language and out-of-vocabulary words (OOV; $\mathcal{X}$ is the language's vocabulary). Note that $|\mathbf{x}|$ may be smaller than $|\mathbf{y}|$, since some morphemes may combine to make a word. We will denote by $\mathbf{y}_i$ the contiguous subsequence of $\mathbf{y}$ that generates x_i; $\vec{y}$ will refer to a dictionary-recognized *type* in $\mathcal{Y}^+$.

At test time, we *decode* the observed $\mathbf{x}$ into the most probable sequence of tag/morpheme pairs:

$$\hat{\mathbf{y}} = \operatorname*{argmax}_{\mathbf{y}} p(\mathbf{y} \mid \mathbf{x}) = \operatorname*{argmax}_{\mathbf{y}} p_s(\mathbf{y}) \cdot p_c(\mathbf{x} \mid \mathbf{y}) \quad (1)$$

Training involves constructing p_s and p_c. We assume that there exists a training corpus of text (each word x_i annotated with its correct analysis $\mathbf{y}_i^*$) and a morphological dictionary. We next describe the channel model and the source model.

[1]The sequence also includes segmentation markings between words, not shown to preserve clarity.

Figure 1: Lattices for example sentences in Korean (a), Arabic (b), and Czech (c). Arabic lemmas are not shown, and some Arabic and Czech arcs are unlabeled, for readability. The Arabic morphemes are shown in Buckwalter's encoding. The arcs in the correct path through each lattice are solid (incorrect arcs are dashed). Note the adjective-noun agreement in the correct path through the Czech lattice (c). The Czech lattice has no lemma-ambiguity; this is typical in Czech (see §4).

2.1 Morphological dictionaries and the channel

A great deal of research has gone into developing morphological analysis tools that enumerate valid analyses $\vec{y} \in \mathcal{Y}^+$ for a particular word $x \in \mathcal{X}$. Typically these tools are unweighted and therefore do not enable token disambiguation.[2]

They are available for many languages. We will refer to this source of categorial lexical information as a morphological dictionary d that maps $\mathcal{X} \to 2^{\mathcal{Y}^+}$. The set $d(x)$ is the set of analyses for word x; the set $d(\mathbf{x})$ is the set of whole-sentence analyses for sentence $\mathbf{x} = \langle x_1, x_2, ...\rangle$.

$d(\mathbf{x})$ can be represented as an acyclic lattice with a "sausage" shape familiar from work in speech recognition (Mangu et al., 1999). Note that for languages with bound morphemes, $d(x)$ will consist of a set of sequences of tokens, so a given "link" in the sausage lattice may contain paths of different lengths. Fig. 1 shows sausage lattices for sentences in three languages.

In this paper, the dictionary defines the support set of the channel model. That is, $p_c(\mathbf{x} \mid \mathbf{y}) > 0$ if and only if $\mathbf{y} \in d(\mathbf{x})$. This is a clean way to incorporate domain knowledge into the probabilistic model; this kind of constraint has been applied in previous work at decoding time (Hakkani-Tür et al., 2000; Hajič et al., 2001). In such a model, each word is independent of its neighbors (because the dictionary ignores context).

Estimation. A *unigram* channel model defines

$$p_c(\mathbf{x} \mid \mathbf{y}) \overset{\text{def}}{=} \prod_{i=1}^{|\mathbf{x}|} p(x_i \mid \mathbf{y}_i) \qquad (2)$$

The simplest estimate of this model is to make $p(\cdot, \cdot)$ *uniform* over $(x, \vec{y})$ such that $\vec{y} \in d(x)$. Doing so and marginalizing to get $p(x \mid \vec{y})$ makes the channel model encode categorial information only, leaving all learning to the source model.[3]

Another way to estimate this model is, of course, from data. This is troublesome, because—modulo optionality—x is expected to be *known* given $\vec{y}$, resulting in a huge model with mostly 1-valued probabilities. Our solution is to take a *projection* π of $\vec{y}$ and let $p(\cdot \mid \vec{y}) \approx p(\cdot \mid \pi(\vec{y}))$. In this paper, π maps the analysis to its morphological tag (or tag sequence). We will refer to this as the "tag channel."

OOV. Morphological dictionaries typically do not have complete coverage of a language. We can augment them in two ways using the training data. If a known word x (one for which $d(x)$ is non-empty) appears in the training dataset with an analysis not in $d(x)$, we add the entry to the dictionary. Unknown words (those not recognized by the dictionary) are replaced by an OOV symbol. $d(\text{OOV})$ is taken to be the set of all analyses for any OOV word seen in training. Rather than attempt to recover the morpheme sequence for an OOV word, in this paper we try only for the tag sequence, replacing all of an OOV's morphemes with the OOV symbol. Since OOV symbols account for less than 2% of words in our corpora, we leave

[2] *Probabilistic* modeling of what we call the morphological channel was first carried out by Levinger et al. (1995), who used unlabeled data to estimate $p(\vec{y} \mid x)$ for Hebrew, with the support defined by a dictionary.

[3] Note that this makes the channel term in Eq. 1 a constant. Then decoding means maximizing $p_s(\mathbf{y})$ over $\mathbf{y} \in d(\mathbf{x})$, equivalently maximizing $p(\mathbf{y} \mid d(\mathbf{x}))$.

more sophisticated channel models to future work.

2.2 The source model

The source model p_s defines a probability distribution over $\mathcal{Y}^+$, sequences of (tag, morpheme) pairs. Our source models can be viewed as weighted multi-tape finite-state automata, where the weights are associated with local, often overlapping features of the path through the automaton.

Estimation. We estimate the source *conditionally* from annotated data. That is, we maximize

$$\sum_{(\mathbf{x},\mathbf{y})\in\mathcal{X}^+\times\mathcal{Y}^+} \tilde{p}(\mathbf{x},\mathbf{y}) \log p_s\left(\mathbf{y} \mid d(\mathbf{x}), \vec{\theta}\right) \quad (3)$$

where $\tilde{p}(\cdot,\cdot)$ is the empirical distribution defined by the training data and $\vec{\theta}$ are the model parameters. In terms of Fig. 1, our learner maximizes the weight of the correct (solid) path through each lattice, at the expense of the other incorrect (dashed) paths. Note that

$$\log p_s\left(\mathbf{y} \mid d(\mathbf{x}), \vec{\theta}\right) = \log \frac{p_s\left(\mathbf{y} \mid \vec{\theta}\right)}{\sum_{\mathbf{y}'\in d(\mathbf{x})} p_s\left(\mathbf{y}' \mid \vec{\theta}\right)} \quad (4)$$

The sum in the denominator is computed using a dynamic programming algorithm (akin to the forward algorithm); it involves computing the sum of all paths through the "sausage" lattice of possible analyses for $\mathbf{x}$. By doing this, we allow knowledge of the support of the *channel* model to enter into our estimation of the *source* model. It is important to note that the *estimation* of the model (the objective function used in training, Eq. 3) is distinct from the source-channel *structure* of the model (Eq. 1).

The lattice-conditional estimation approach was first used by Kudo et al. (2004) for Japanese segmentation and hierarchical POS-tagging and by Smith and Smith (2004) for Korean morphological disambiguation. The resulting model is an instance of a *conditional random field* (CRF; Lafferty et al., 2001). When training a CRF for POS tagging, IOB chunking (Sha and Pereira, 2003), or word segmentation (Peng et al., 2004), one typically structures the conditional probabilities (in the objective function) using domain knowledge: in POS tagging, the set of allowed tags for a word is used; in IOB chunking, the bigram "O I" is disallowed; and in segmentation, a lexicon is used to enumerate the possible word boundaries.[4]

[4]This refinement is in the same vein as the move from *maximum likelihood* estimation to *conditional* estimation. MLE would make the sum in the denominator of Eq. 4 $\mathcal{Y}^+$, which for log-linear models is often intractable to compute (and for sequence models may not converge). Conditional estimation limits the sum to the subset of $\mathcal{Y}^+$ that is consistent with $\mathbf{x}$, and our variant further stipulates consistency with the dictionary entries for $\mathbf{x}$.

Our approach is the same, with two modifications. First, we model the relationship between labels y_i and words x_i in a separately-estimated channel model (§2.1). Second, our labels are complex. Each word x_i is tagged with a *sequence* of one or more tagged morphemes; the tags may include multiple fields. This leads to models with more parameters. It also makes the dictionary especially important for limiting the size of the sum in the denominator, since a complex label set $\mathcal{Y}$ could in principle lead to a huge hypothesis space for a given sentence $\mathbf{x}$. Importantly, it makes training conditions more closely match testing conditions, ruling out hypotheses a dictionary-aware decoder would never consider.

Optimization. The objective function (Eq. 3) is concave and known to have a unique global maximum. Because log-linear models and CRFs have been widely described elsewhere (e.g., Lafferty, 2001), we note only that we apply a standard first-order numerical optimization method (L-BFGS; Liu and Nocedal, 1989). The structure, features, and regularization of our models will be described in §3 and §4.

Prior work (morphological source models). Hakkani-Tür et al. (2000) described a system for Turkish that was essentially a source model; Hajič et al. (2001) described an HMM-based system for Czech that could be viewed as a combined source and channel. Both used dictionaries and estimated their (generative) models using maximum likelihood (with smoothing).[5] Given enough data, a ML-estimated model will learn to recognize a good path $\mathbf{y}$, but it may not learn to discriminate a good $\mathbf{y}$ from wrong alternatives *per se*. The generative framework is limiting as well, disallowing the straightforward inclusion of arbitrary overlapping features. We present a competitive Czech model in §4.

3 Concatenative Models

The beauty of log-linear models is that estimation is straightforward given *any* features, even ones that are not orthogonal (i.e., "overlap"). This permits focusing on feature (or feature template) selection without worries about the mathematics of training.

We consider two languages modeled by concatenative processes with surface changes at morpheme boundaries: Korean and Arabic.

Our model includes features for tag n-grams, morpheme n-grams, and pairs of the two (possibly of different lengths and offsets). Fig. 2 illustrates TM3, our base model. TM3 includes feature templates for some tuples of three or fewer elements, plus begin and end templates.

[5]Hajič et al. also included a rule-based system for pruning hypotheses, which gave slight performance gains.

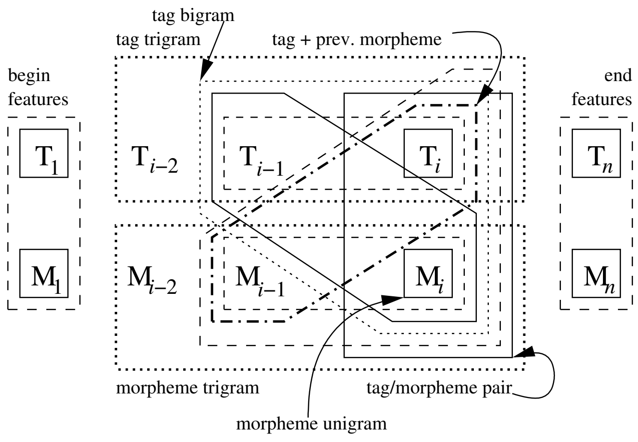

Figure 2: The base two-level trigram source model, TM3. Each polygon corresponds to a feature template. This is a two level, second-order Markov model (weighted finite-state machine) parameterized with overlapping features. Note that only some features are labeled in the diagram.

A variant, TM3H, includes all of the same templates, plus a similar set of templates that look only at *head* morphemes. For instance, a feature fires for each trigram of heads, even though there are (bound) morphemes between them. This increases the domain of locality for semantic content-bearing morphemes. This model requires slight changes to the dynamic programming algorithms for inference and training (the previous two heads must be remembered at each state).

Every instantiation of the templates seen in *any* lattice $d(\mathbf{x})$ built from training data is included in the model, not just those seen in correct analyses $\mathbf{y}^*$.[6]

3.1 Experimental design

In all of our experiments, we vary the training set size and the amount of smoothing, which is enforced by a diagonal Gaussian prior (L_2 regularizer) with variance σ^2. The $\sigma^2 = \infty$ case is equivalent to not smoothing. We compare performance to the expected performance of a randomized baseline that picks for each word token x an analysis from $d(x)$; this gives a measure of the amount of ambiguity and is denoted "channel only." Performance of unigram, bigram, and trigram HMMs estimated using maximum likelihood (barely smoothed, using add-10^{-14}) is also reported. (The unigram HMM simply picks the most likely $\vec{y}$ for each x, based on training data and is so marked.)

In the experiments in this section, we report three performance measures. *Tagging* accuracy is the fraction of words whose tag sequence was correctly identified in entirety; *morpheme* accuracy is defined analogously. *Lemma* accuracy is the fraction of words whose lemma was correctly identified.

3.2 Korean experiments

We applied TM3 and TM3H to Korean. The dataset is the Korean Treebank (Han et al., 2002), with up to 90% used for training and 10% (5K words) for test. The morphological dictionary is `klex` (Han, 2004). There are 27 POS tags in the tag set; the corpus contains 10K word types and 3,272 morpheme types. There are 1.7 morphemes per word token on average ($\sigma = 0.75$). A Korean word generally consists of a head morpheme with a series of enclitic suffixes. In training the head-augmented model TM3H, we assume the first morpheme of every word is the head and lemma.

Results are shown in Tab. 1. TM3H achieved very slight gains over TM3, and the tag channel model was helpful only with the smaller training set. The oracle (last line of Tab. 1) demonstrates that the coverage of the dictionary remains an obstacle, particularly for recovering morphemes. Another limitation is the small amount of training data, which may be masking differences among estimation conditions. We report the performance of TM3H with "factored" estimation. This will be discussed in detail in §4; it means that a model containing *only* the head features was trained on its own, then combined with the independently trained TM3 model at test time. Factored training was slightly faster and did not affect performance at all; accuracy scores were identical with unfactored training.

Prior work (Korean). Similar results were presented by Smith and Smith (2004), using a similar estimation strategy with a model that included far more feature templates. TM3 has about a third as many parameters and TM3H about half; performance is roughly the same (numbers omitted for space). Korean disambiguation results were also reported by Cha et al. (1998), who applied a deterministic morpheme pattern dictionary to segment words, then used a bigram HMM tagger. They also applied transformation-based learning to fix common errors. Due to differences in tag set and data, we cannot compare to that model; a bigram baseline is included.

3.3 Arabic experiments

We applied TM3 and TM3H to Arabic. The dataset is the Arabic Treebank (Maamouri et al., 2003), with up to 90% used for training and 10% (13K words) for test. The morphological dictionary is Buckwalter's analyzer (version 2), made available by the LDC (Buckwalter, 2004).[7] This analyzer has total coverage of the corpus; there are no

[6]If we used only features observed to occur in $\mathbf{y}^*$, we would not be able to learn negative weights for *unlikely* bits of structure seen in the lattice $d(\mathbf{x})$ but not in $\mathbf{y}^*$.

[7]Arabic morphological processing was also addressed by Kiraz (2000), who gives a detailed review of symbolic work in that area, and by Darwish (2002).

Table 1: Korean (left, 5K test-set) and Arabic (right, 13K test-set) disambiguation. A word is marked correct only if its entire tag (or morpheme) sequence (or lemma) was correctly identified. Morpheme and lemma accuracy do not include OOV words. The oracle is an upper bound on accuracy given the morphological dictionary. *These models do not explicitly predict lemmas; the lemma is chosen arbitrarily from those that match the hypothesized tag/morpheme sequence for each word. **Bold** scores indicate a significant improvement over the trigram HMM (binomial sign test, $p < 0.05$).

OOV words. There are 139 distinct POS tags; these contain some inflectional information which we treat atomically. For speed, TM3H was trained in two separate pieces: TM3 and the lemma features added by TM3H.

Arabic has a templatic morphology in which consonantal roots are transformed into surface words by the insertion of vowels and ancillary consonants. Our system does not model this process except through the use of Buckwalter's dictionary to define the set of analyses for each word (cf., Daya et al., 2004, who modeled interdigitation in Hebrew). We treat the analysis of an Arabic word as a sequence $\vec{y}$ of pairs of morphemes and POS tags, plus a lemma. The lemma, given in the dictionary, provides further disambiguation beyond the head morpheme. The lemma is a standalone dictionary headword and not merely the consonantal root, as in some other work. The "heads" modeled by TM3H correspond to these lemmas. There are 20K word types, and 34K morpheme types. There are 1.7 morphemes per word token on average ($\sigma = 0.77$).

Results are shown in Tab. 1. Across tasks and training set sizes, our models reduce error rates by more than 36% compared to the trigram HMM source with tag channel. The TM3H model and the tag channel offer slight gains over the base TM3 model (especially on lemmatization), though the tag channel offers no help in POS tagging.

Prior work (Arabic). Both Diab et al. (2004) and Habash and Rambow (2005) use support-vector machines with local features; the former for tokenization, POS tagging, and base phrase chunking; the latter for full morphological disambiguation. Diab et al. report results for a coarsened 24-tag set, while we use the full 139 tags from the Arabic Treebank, so the systems are not directly comparable. Habash and Rambow present even better results on the same POS tag set. Our full disambiguation results appear to be competitive with theirs. Khoja (2001) and Freeman (2001) describe Arabic POS taggers and many of the issues involved in developing them, but because tagged corpora did not yet exist, there are no comparable quantitative results.

4 Czech: Model and Experiments

Inflective languages like Czech present a new set of challenges. Our treatment of Czech is not concatenative; following prior work, the analysis for each word x is a single tag/lemma pair y. Inflectional affixes in the surface form are represented as features in the tag. While lemmatization of Czech is not hard (there is little ambiguity), tagging is quite difficult, because morphological tags are highly complex. Our tag set is the Prague Dependency Treebank (PDT; Hajič, 1998) set, which consists of fifteen-field tags that indicate POS as well as inflectional information (case, number, gender, etc.). There are over

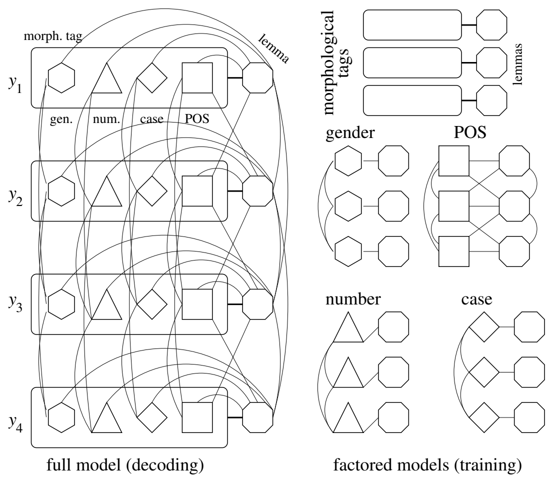

Figure 3: The Czech model, shown as an undirected graphical model. The structure of the full model is on the left; factored components for estimation are shown on the right. Each of these five models contains a subset of the TM3 features. The full model is only used to decode. The factored models make training faster and are used for pruning.

1,400 distinct tag types in the PDT.

Czech has been treated probabilistically before, perhaps most successfully by Hajič et al. (2001).[8] In contrast, we estimate conditionally (rather than by maximum likelihood for a generative HMM) and separate the training of the source and the channel. We also introduce a novel *factored* treatment of the morphological tags.

4.1 Factored tags and estimation

Because Czech morphological tags are not monolithic, the choice among them can be treated as several more or less orthogonal decisions. The case feature of one word, for example, is expected to be conditionally independent of the next word's gender, given the next word's case. Constraints in the language are expected to cause features like case, number, and gender to agree locally (on words that have such features) and somewhat independently of each other. Coarser POS tagging may be treated as another, roughly independent stream.

Log-linear models and the use of a morphological dictionary make this kind of tag factoring possible. Our approach is to separately train five log-linear models. Each model is itself an instance of some of the templates from TM3, modeling a projection of the full analysis. The model and its factored components are illustrated in Fig. 3.

POS model. The full tag is replaced by the POS tag (the first two fields); there are 60 POS tags. The TM3 feature templates are included twice: once for the full tag and once for a coarser tag (the first PDT field, for which there are 12 possible values).[9]

Gender, number, and case models. The full tag is replaced by the gender (or case or number) field. This model includes bigrams and trigrams as well as field-morpheme unigram features. These models are intended to learn to predict local agreement.

Tag-lemma model. This model contains unigram features of full PDT tags, both alone and with lemmas. It is intended to learn to penalize morphological tags that are rare, or that are rare with a particular lemma. In our formulation, this is *not* a channel model, because it ignores the surface word forms.

Each model is estimated independently of the others. The lattice $d(\mathbf{x})$ against which the conditional probabilities are estimated contains the relevant *projection* of the full morphological tags (with lemmas). To decode, we run a Viterbi-like algorithm that uses the union of all models' features to pick the best analysis (full morphological tags and lemmas) allowed by the dictionary.

There are two important advantages of factored training. First, each model is faster to train alone than a model with all features merged; in fact, training the fully merged model takes far too long to be practical. Second, factored models can be held out at test time to measure their effect on the system, without retraining.

Prior work (factored training). Separately training different models that predict the same variables (e.g., $\mathbf{x}$ and $\mathbf{y}$) then combining them for consensus-based inference (either through a mixture or a product of probabilities) is an old idea (Genest and Zidek, 1986). Recent work in learning weights for the component "expert" models has turned to *cooperative* techniques (Hinton, 1999). Decoding that finds $\mathbf{y}$ (given $\mathbf{x}$) to maximize some weighted average of log-probabilities is known as a *logarithmic opinion pool* (LOP). LOPs were applied to CRFs (for named entity recognition and tagging) by Smith et al. (2005), with an eye toward regularization. Their experts (each a CRF) contained overlapping feature sets, and the combined model achieved much the same effect as training a single model with smoothing. Note that our models, unlike theirs, *partition* the feature space; there is only one CRF, but some parameters are ignored when estimating other parameters. We have not estimated log-domain mixing coefficients—we weight all models' contributions equally. Sutton and McCallum (2005) have applied factored estimation to CRFs, motivated (like us) by speed; they also describe how factored estimation

[8]Czech morphological processing was studied by Petkevič (2001), Hlaváčová (2001) (who focuses on handling OOV words), and Mráková and Sedlacek (2003) (who use partial parsing to reduce the set of possible analyses), *inter alia*.

[9]Lemma-trigram and fine POS-unigram/lemma-bigram features were eliminated to limit model size.

Table 2: Czech disambiguation: test-set (109K words) accuracy. A word is marked correct only if its entire morphological tag (or morpheme or POS tag) was correctly identified. Note that the full tag is a complex, 15-field morphological label, while "POS" is a projection down to a tagset of size 60. Lemma accuracy does not include OOV words. *The POS-only model selects only POS, not full tags; these measures are expected performance if the full tag is selected randomly from those in the dictionary that match the selected POS. †Required more aggressive pruning. **Bold** scores were significantly better than the HMM of Hajič et al. (binomial sign test, $p < 0.05$). Our models were slightly but significantly worse on full tagging, but showed significant improvements on recovering POS tags and lemmas.

maximizes a lower bound on the unfactored objective. Smith and Smith (2004) applied factored estimation to a bilingual weighted grammar, driven by data limitations.

4.2 Experiments

Our corpus is the PDT (Hajič, 1998), with up to 60% used for training and 10% (109K words) used for test.[10] The morphological dictionary is the one packaged with the PDT; it covers about 98% of the tokens in the corpus. The remaining 2% have (unsurprisingly) a diverse set of 300–400 distinct tags, depending on the training set size.[11]

Results are shown in Tab. 2. We compare to the HMM of (Hajič et al., 2001) *without* its OOV component.[12] We report morphological tagging accuracy on words; we also report lemma accuracy (on non-OOV words), POS accuracy on all words, and POS accuracy on OOV words. The channel model (not shown) tended to have a small, harmful effect on performance.

Without any explicit OOV treatment, our POS-only component model significantly reduces lemma and POS errors compared to Hajič et al.'s model. On recovering *full* morphological tags, our *full* model is close in performance to Hajič et al., but still significantly worse. It is likely that for many tasks, these performance gains are more helpful than the loss on full tagging is harmful.

Why doesn't our full model perform as well as Hajič et al.'s model? An error analysis reveals that our full model (768K, $\sigma^2 = 1$), compared to the HMM (768K) had 91% as many number errors but 0.1% more gender and 31% more case errors. Taking out those three models ("POS & tag-lemma" in Fig. 2) is helpful on all measures except full tagging accuracy, due in part to substantially increased errors on gender (87% increase), case (54%), and number (35%). The net effect of these components, then, is helpful, but not quite helpful enough to match a well-smoothed HMM on complex tagging. We compared the models on the training set and found the same pattern, demonstrating that this is not merely a matter of over-fitting.

5 Future Work

Two clear ways to improve our models present themselves. The first is better OOV handling, perhaps through an improved channel model. Possibilities include learning weights to go inside the FST-encoded dictionaries and

[10]We used less than the full corpus to keep training time down; note that the training sets are nonetheless substantially larger than in the Korean and Arabic experiments.

[11]During training, these project down to manageable numbers of hypotheses in the factored models. At test-time, however, Viterbi search is quite difficult when OOV symbols occur consecutively. To handle this, we prune OOV arcs from the lattices using the factored POS and inflectional models. For each OOV, every model prunes a projection of the analysis (e.g., the POS model prunes POS tags) until 90% of the posterior mass or 3 arcs remain (whichever is more conservative). Viterbi decoding is run on a lattice containing OOV arcs consistent with the pruned projected lattices.

[12]Results *with* the OOV component are also reported in Tab. 2, but we cannot guarantee their experimental validity, since the OOV component is pre-trained and may have been trained on data in our test set.

directly modeling spelling changes. The second is to turn our factored model into a LOP. Training the mixture coefficients should be straightforward (if time-consuming) with a development dataset.

A drawback of our system (especially for Czech) is that some components (most notably, the Czech POS model) take a great deal of time to train (up to two weeks on 2GHz Pentium systems). Speed improvements are expected to come from eliminating some of the overlapping feature templates, generalized speedups for log-linear training, and perhaps further factoring.

6 Conclusion

We have explored morphological disambiguation of diverse languages using log-linear sequence models. Our approach reduces error rates significantly on POS tagging (Arabic and Czech), morpheme sequence recovery (Korean and Arabic), and lemmatization (all three languages), compared to baseline state-of-the-art methods For complex analysis tasks (e.g., Czech tagging), we have demonstrated that factoring a large model into smaller components can simplify training and achieve excellent results. We conclude that a *conditionally*-estimated source model informed by an existing morphological dictionary (serving as an unweighted channel) is an effective approach to morphological disambiguation.

Mining Key Phrase Translations from Web Corpora

Abstract

Key phrases are usually among the most information-bearing linguistic structures. Translating them correctly will improve many natural language processing applications. We propose a new framework to mine key phrase translations from web corpora. We submit a source phrase to a search engine as a query, then expand queries by adding the translations of topic-relevant hint words from the returned snippets. We retrieve mixed-language web pages based on the expanded queries. Finally, we extract the key phrase translation from the second-round returned web page snippets with phonetic, semantic and frequency-distance features. We achieve 46% phrase translation accuracy when using top 10 returned snippets, and 80% accuracy with 165 snippets. Both results are significantly better than several existing methods.

1 Introduction

Key phrases such as named entities (person, location and organization names), book and movie titles, science, medical or military terms and others [1], are usually among the most information-bearing linguistic structures. Translating them correctly will improve the performance of cross-lingual information retrieval, question answering and machine translation systems. However, these key phrases are often domain-specific, and people constantly create new key phrases which are not covered by existing bilingual dictionaries or parallel corpora, therefore standard data-driven or knowledge-based machine translation systems cannot translate them correctly.

As an increasing amount of web information becomes available, exploiting such a huge information resource is becoming more attractive. (Resnik 1999) searched the web for parallel corpora while (Lu et al. 2002) extracted translation pairs from anchor texts pointing to the same webpage. However, parallel webpages or anchor texts are quite limited, and these approaches greatly suffer from the lack of data.

However, there are many web pages containing useful bilingual information where key phrases and their translations both occur. See the example in Figure 1. This example demonstrates web page snippets[2] containing both a Chinese key phrase "浮士德" and its translation**,** "Faust".

We thus can transform the translation problem into a data mining problem by retrieving these mixed-language web pages and extracting their translations. We propose a new framework to mine key phrase translations from web corpora. Given a source key phrase (here a Chinese phrase), we first retrieve web page snippets containing this phrase using the Google search engine. We then expand queries by adding the translations of topic-relevant hint words from the returned snippets. We submit the source key phrase and expanded queries again to Google to retrieve mixed-language web page snippets. Finally, we extract the key phrase translation from the second-round returned snippets with phonetic, semantic and frequency-distance features.

[1] Some name and terminology is a single word, which could be regarded as a one-word phrase.

[2] A snippet is a sentence or paragraph containing the key phrase, returned with the web page URLs.

Figure 2. Returned mixed-language web page snippets using cross-lingual query expansion

We achieve 46% phrase translation accuracy when using 10 returned snippets, and 80% accuracy with 165 snippets. Both results are significantly better than several existing methods.

The reminder of this paper is organized as follows: cross-lingual query expansion is discussed in section 2; key phrase translation extraction is addressed in section 3. In section 4 we present experimental results, which is followed by relevant works and conclusions.

2 Retrieving Web Page Snippets through Cross-lingual Query Expansion

For a Chinese key phrase *f*, we want to find its translation *e* from the web, more specifically, from the mixed-language web pages or web page snippets containing both *f* and *e*. As we do not know *e*, we are unable to directly retrieve such mixed-language web page using (*f*,*e*) as the query.

However, we observed that when the author of a web page lists both *f* and *e* in a page, it is very likely that *f*′ and *e*′ are listed in the same page, where *f’* is a Chinese hint word topically relevant to *f*, and *e’* is *f*’s translation. Therefore if we know a Chinese hint word *f’*, and we know its reliable translation, *e’*, we can send (*f*, *e’*) as a query to retrieve mixed language web pages containing (*f*, *e*).

For example, to find web pages which contain translations of “浮士德”(Faust), we expand the query to “浮士德+goethe” since “歌德” (Goethe) is the author of “浮士德” (Faust). Figure 2 illustrates retrieved web page snippets with expanded queries. We find that newly returned snippets contain more correct translations with higher ranks.

To propose a “good” English hint *e*′ for *f*, first we need to find a Chinese hint word *f*′ that is relevant to *f*. Because *f* is often an OOV word, it is unlikely that such information can be obtained from existing Chinese monolingual corpora. Instead, we query Google for web pages containing *f*. From the returned snippets we select Chinese words *f'* based on the following criteria:

1. *f'* should be relevant to *f* based on the co-occurrence frequency. On average, 300 Chinese words are returned for each query *f*. We only consider those words that occur at least twice to be relevant.
2. *f'* can be reliably translated given the current bilingual resources (e.g. the LDC Chinese-English lexicon[3] with 81,945 translation entries).
3. The meaning of *f'* should not be too ambiguous. Words with many translations are not used.
4. *f'* should be translated into noun or noun phrases. Given the fact that most OOV words are noun or noun phrases, we ignore those source words which are translated into other part-of-speech words. The British National Corpus[4] is used to generate the English noun lists.

For each *f*, the top Chinese words *f'* with the highest frequency are selected. Their corresponding translations are then used as the cross-lingual hint words for *f*. For example, for OOV word *f* = 浮士德 (Faust), the top candidate *f'*s are "歌德(Goethe)", "简介(introduction)", "文学(literature)" and "悲剧(tragedy)". We expand the original query "浮士德" to "浮士德+ goethe", "浮士德 + introduction", "浮士德 + literature", "浮士德 + tragic", and then query Google again for web page snippets containing the correct translation "Faust".

3 Extracting Key Phrase Translation

When the Chinese key phrase and its English hint words are sent to Google as the query, returned web page snippets contain the source query and possibly its translation. We preprocess the snippets to remove irrelevant information. The preprocessing steps are:

1. Filter out HTML tags;
2. Convert HTML special characters (e.g., "&lt") to corresponding ASCII code (">");
3. Segment Chinese words based on a maximum string matching algorithm, which is used to calculate the translation probability between a Chinese key phrase and an English translation candidate.
4. Replace punctuation marks with phrase separator '|';
5. Replace non-query Chinese words with placeholder mark '+', as they indicate the distance between an English phrase and the Chinese key phrase.

For example, the snippet

> 《<b>廊桥遗梦</b>》(the bridges of madison county)[review]. 发布者：anjing | 发布时间：2004-01-25 星期日 02:13 | 最新更新时间

is converted into

> | <b> 廊 桥 遗 梦 </b> | the_bridges_of_Madison_county | review | ++ + | anjing | ++ ++ | 2004-01-25 +++ 02 13 | + + ++ ++,

where "<b>" and "</b>" mark the start and end positions of the Chinese key phrase. The candidate English phrases, "the bridges of madison county", "review" and "anjing", will be aligned to the source key phrase according to a combined feature set using a transliteration model which captures the pronunciation similarity, a translation model which captures the semantic similarity and a frequency-distance model reflecting their relevancy. These models are described below.

3.1 Transliteration Model

The transliteration model captures the phonetic similarity between a Chinese phrase and an English translation candidate via string alignment. Many key phrases are person and location names, which are phonetically translated and whose written forms resemble their pronunciations. Therefore it is possible to discover these translation pairs through their surface strings. Surface string transliteration does not need a pronunciation lexicon to map words into phoneme sequences; thus it is especially appealing for OOV word translation. For non-Latin languages like Chinese, a romanization

[3]http://www.ldc.upenn.edu/Catalog/CatalogEntry.jsp?catalogId=LDC2002L27
[4] http://www.natcorp.ox.ac.uk/

script called "pinyin" maps each Chinese character into Latin letter strings. This normalization makes the string alignment possible.

We adopt the transliteration model proposed in (Huang, et al. 2003). This model calculates the probabilistic Levinstein distance between a romanized source string and a target string. Unlike the traditional Levinstein distance calculation, the character alignment cost is not binary (0/1); rather it is the logarithm of character alignment probability, which ensures that characters with similar pronunciations (e.g. `p` and `b`) have higher alignment probabilities and lower cost. These probabilities are automatically learned from bilingual name lists using EM.

Assume the Chinese phrase f has J Chinese characters, $f_1, f_2, ... f_J$, and the English candidate phrase e has L English words, $e_1, e_2, ..., e_L$. The transliteration cost between a Chinese query f and an English translation candidate e is calculated as:

$$C_{trl}(e, f) \approx \sum_j \log p(e_{a_j} \mid y_j) = \sum_j \sum_i \log p(e_{a_{(i,j)}} \mid y_{i,j}).$$

where y_j is the pinyin of Chinese character f_j, $y_{j,i}$ is the i th letter in y_j, and e_{a_j} and $e_{a_{(j,i)}}$ are their aligned English letters, respectively. $p(e_{(i,j)} \mid y_{i,j})$ is the letter transliteration probability. The transliteration costs between a Chinese phrase and an English phrase is approximated by the sum of their letter transliteration cost along the optimal alignment path, which is identified based on dynamic programming.

3.2 Translation Model

The translation model measures the semantic equivalence between a Chinese phrase and an English candidate. One widely used model is the IBM model (Brown et al. 1993). The phrase translation probability is computed using the IBM model-1 as:

$$P_{trans}(f \mid e) = \frac{1}{L^J} \prod_{j=1}^{J} \sum_{l=1}^{L} p(f_j \mid e_l)$$

where $p(f_j \mid e_l)$ is the lexical translation probabilities, which can be calculated according to the IBM models. This alignment model is asymmetric, as one source word can only be aligned to one target word, while one target word can be aligned to multiple source words. We estimate both $P_{trans}(f \mid e)$ and $P_{trans}(e \mid f)$, and define the NE translation cost as:

$$C_{trans}(e, f) = \log P_{trans}(e \mid f) + \log P_{trans}(f \mid e).$$

3.3 Frequency-Distance Model

The more often a bilingual phrase pair co-occurs, or the closer a bilingual phrase pair is within a snippet, the more likely they are translations of each other. The frequency-distance model measures this correlation.

Suppose S is the set of returned snippets for query f, and a single returned snippet is $s_i \in S$. The source phrase occurs in s_i as $f_{i,j}$ ($j \geq 1$ since f may occur several times in a snippet). The frequency-distance weight of an English candidate e is

$$w(e) = \sum_{s_i} \sum_{f_{i,j}} \frac{1}{d(f_{i,j}, e)}$$

where $d(f, e)$ is the distance between phrase $f_{i,j}$ and e, i.e., how many words are there between the two phrases (the separator `|` is not counted).

3.4 Feature Combination

Define the confidence measure for the transliteration model as:

$$\phi_{trl}(e \mid f) = \frac{\exp[C_{trl}(e, f)] w(e)^m}{\sum_{e'} \exp[C_{trl}(e', f)] w(e')^m},$$

where *e* and *e'* are English candidate phrases, and *m* is the weight of the distance model. We empirically choose m=2 in our experiments. This measure indicates how good the English phrase *e* is compared with other candidates based on transliteration model. Similarly the translation model confidence measure is defined as:

$$\phi_{trans}(e \mid f) = \frac{\exp[C_{trans}(e, f)] w(e)^m}{\sum_{e'} \exp[C_{trans}(e', f)] w(e')^m}.$$

The overall feature cost is the linear combination of transliteration cost and translation cost, which are weighted by their confidence scores respectively:

$$C(e,f)=\lambda\phi_{trl}(e\mid f)\exp[C_{trl}(e,f)]+ (1-\lambda)\phi_{trans}(e\mid f)\exp[C_{trans}(e,f)]$$

where the linear combination weight λ is chosen empirically. While ϕ_{trl} and ϕ_{trans} represent the relative rank of the current candidate among all compared candidates, C_{trl} and C_{trans} indicate its absolute likelihood, which is useful to reject the top 1 incorrect candidate if the true translation does not occur in any returned snippets.

4 Experiments

We evaluated our approach by translating a set of key phrases from different domains. We selected 310 Chinese key phrases from 12 domains as the test set, which were almost equally distributed within these domains. We also manually translated them as the reference translations. Table 1 shows some typical phrases and their translations, where one may find that correct key phrase translations need both phonetic transliterations and semantic translations. We evaluated *inclusion rate*, defined as the percentage of correct key phrase translations which can be retrieved in the returned snippets; *alignment accuracy*, defined as the percentage of key phrase translations which can be correctly aligned given that these translations are included in the snippets; and *overall translation accuracy*, defined as the percentage of key phrases which can be translated correctly. We compared our approach with the LiveTrans[5] (Cheng et.al. 2004) system, an unknown word translator using web corpora, and we observed better translation performance using our approach.

4.1 Query Translation Inclusion Rate

In the first round query search, for each Chinese key phrase *f*, on average 13 unique snippets were returned to identify relevant Chinese hint words *f'*, and the top 5 *f*'s were selected to generate hint words *e*'s. In the second round *f* and *e*'s were sent to Google again to retrieve mixed language snippets, which were used to extract *e*, the correct translation of *f*.

Figure 3 shows the inclusion rate vs. the number of snippets used for three mixed-language web page searching strategies:

Table 1. Test set key phrases

- Search any web pages containing *f* (Zhang and Vines 2004);
- Only search *English* web pages[6] containing *f* (Cheng et al. 2004);
- Search any web pages containing *f* and hint words *e'*, as proposed in this paper.

The first search strategy resulted in a relatively low inclusion rate; the second achieved a much higher inclusion rate. However, because such English pages were limited, and on average only 45 unique snippets could be found for each *f*, which resulted in a maximum inclusion rate of 85.8%. In the case of the cross-lingual query expansion, the search space was much larger but more focused and we achieved a high inclusion rate of 89.7% using 32 mixed-language snippets and 95.2% using 165 snippets, both from the second round retrieval.

[6] These web pages are labeled by Google as "English" web pages, though they may contain non-English characters.

Features	No Hints (Inc = 44.19%) (avg. snippets = 10)	With Hints (Inc = 95.16%) (avg. snippets=130)
Trl	51.45	17.97
Trans	51.45	40.68
Fq-dis	53.62	73.22
Trl+Trans	63.04	51.36
Trl+Trans+ Fq-dis	65.94	86.73

Table 2. Alignment accuracies using different features

These search strategies are further discussed in the section 5.

4.2 Translation Alignment Accuracy

We evaluated our key phrase extraction model by testing queries whose correct translations were included in the returned snippets. We used different feature combinations on differently sized snippets to compare their alignment accuracies. Table 2 shows the result. Here "Trl" means using the transliteration model, "Trans" means using the translation model, and "Fq-dis" means using Frequency-Distance model. The frequency-distance model seemed to be the strongest single model in both cases (with and without hint words), while incorporating phonetic and semantic features provided additional strength to the overall performance. Combining all three features together yielded the best accuracy. Note that when more candidate translations were available through query expansion, the alignment accuracy improved by 30% relative due to the frequency-distance model. However, using transliteration and/or translation models alone decreased performance because of more incorrect translation candidates from returned snippets. After incorporating the frequency-distance model, correct translations have the maximum frequency-distance weights and are more likely to be selected as the top hypothesis. Therefore the combined model obtained the highest translation accuracy.

4.3 Overall Translation Quality

The overall translation qualities are listed in Table 3, where we showed the translation accuracies of the top 5 hypotheses using different number of snippets. A hypothesized translation was considered to be correct when it matched one of the reference translations. Using more snippets always increased the overall translation accuracy, and with all the 165 snippets (on average per query), our approach achieved 80% top-1 translation accuracy, and 90% top-5 accuracy.

Snippets Used	Accuracy of the Top-N Hyp. (%)				
	Top1	**Top2**	**Top3**	**Top4**	**Top5**
10	46.1	55.2	59.0	61.3	62.3
20	57.4	64.2	69.7	72.6	72.9
50	63.2	74.5	77.7	79.7	80.6
100	75.2	84.5	85.8	87.4	87.4
165	**80.0**	**86.5**	**89.0**	**90.0**	**90.0**
BabelFish[7] MT	31.3	N/A	N/A	N/A	N/A
CMU-SMT	21.9	N/A	N/A	N/A	N/A
LiveTrans (Fast)	20.6	30.0	36.8	41.9	45.2
LiveTrans (Smart)	30.0	41.9	48.7	51.0	52.9

Table 3. Overall translation accuracy

We compared the translations from a research statistical machine translation system (CMU-SMT, Vogel et al. 2003) and a web-based MT engine (BabelFish). Due to the lack of topic-relevant contexts and many OOV words occurring in the source key phrases, their results were not satisfactory. We also compare our system with LiveTrans, which only searched within English web pages, thus with limited search space and more noises (incorrect English candidates). Therefore it was more difficult to select the correct translation. Table 4 lists some example key phrase translations mined from web corpora, as well as translations from the BabelFish.

5 Relevant Work

Both (Cheng et al. 2004) and (Zhang and Vines 2004) exploited web corpora for translating OOV terms and queries. Compared with their work, our proposed method differs in both webpage search

*: Incorrect translations

Table 4. Key phrase translation from web mining and a MT engine

space and translation extraction features. Figure 4 illustrates three different search strategies. Suppose we want to translate the Chinese query “浮士德”. (Cheng et al. 2004) only searched 188 English web pages which contained the source query, and 53% of them (100 pages) had the correct translations. (Zhang and Vines 2004) searched the whole 55,100 web pages, 10% of them (5490 pages) had the correct translation. Our approach used query expansion to search any web pages containing “浮士德” and English hint words, which was a larger search space than (Cheng et al. 2004) and more focused compared with (Zhang and Vines 2004), as illustrated with the shaded region in Figure 4. For translation extraction features, we took advantage of machine transliteration and machine translation models, and combined them with frequency and distance information.

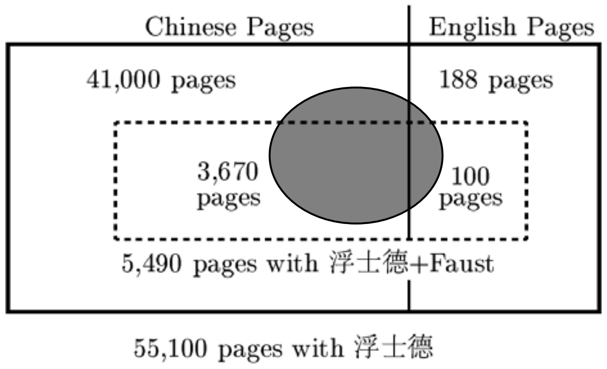

Figure 4. Web search space strategy comparison

6 Discussion and Future Work

In this paper we demonstrated the feasibility of the proposed approach by searching for the English translation for a given Chinese key phrase, where we use punctuations and Chinese words as the boundary of candidate English translations. In the future we plan to try more flexible translation candidate selection methods, and apply them to other language pairs. We also would like to test our approach on more standard test sets, and compare the performance with other systems.

Our approach works on short snippets for query expansion and translation extraction, and the computation time is short. Therefore the search engine’s response time is the major factor of computational efficiency.

7 Conclusion

We proposed a novel approach to mine key phrase translations from web corpora. We used cross-lingual query expansion to retrieve more relevant web pages snippets, and extracted target translations combining transliteration, translation and frequency-distance models. We achieved significantly better results compared to the existing methods.

Abstract

Traditional approaches to Information Extraction (IE) from speech input simply consist in applying text based methods to the output of an Automatic Speech Recognition (ASR) system. If it gives satisfaction with low Word Error Rate (WER) transcripts, we believe that a tighter integration of the IE and ASR modules can increase the IE performance in more difficult conditions. More specifically this paper focuses on the robust extraction of Named Entities from speech input where a temporal mismatch between training and test corpora occurs. We describe a Named Entity Recognition (NER) system, developed within the French Rich Broadcast News Transcription program ESTER, which is specifically optimized to process ASR transcripts and can be integrated into the search process of the ASR modules. Finally we show how some *metadata* information can be collected in order to adapt NER and ASR models to new conditions and how they can be used in a task of Named Entity indexation of spoken archives.

1 Introduction

Named Entity Recognition (NER) is a crucial step in many Information Extraction (IE) tasks. It has been a specific task in several evaluation programs such as the Message Understanding Conferences (MUC), the Conferences on Natural Language Learning (CoNLL), the DARPA HUB-5 program or more recently the French ESTER Rich Transcription program on Broadcast News data. Most of these conferences have studied the impact of using transcripts generated by an Automatic Speech Recognition (ASR) system rather than written texts. It appears from these studies that unlike other IE tasks, NER performance is greatly affected by the Word Error Rate (WER) of the transcripts processed. To tackle this problem, different ideas have been proposed: modeling explicitly the ASR errors (Palmer and Ostendorf, 2001) or using the ASR system alternate hypotheses found in word lattices (Saraclar and Sproat, 2004). However performance in NER decreases dramatically when processing high WER transcripts like the ones that are obtained with unmatched conditions between the ASR training model and the data to process. This paper investigates this phenomenon in the framework of the NER task of the French Rich Transcription program of Broadcast News ESTER (Gravier et al., 2004). Several issues are addressed:

- how to jointly optimize the ASR and the NER models ?
- what is the impact in term of ASR and NER performance of a temporal mismatch between the corpora used to train and test the models and how can it be recovered by means of metadata information ?
- Can metadata information be used for indexing large spoken archives ?

After a quick overview of related works in IE from speech input, we present the ESTER evaluation program ; then we introduce a NER system tightly integrated to the ASR process and show how it can successfully index high WER spoken databases thanks to metadata.

2 Information extraction from large spoken archives

The NIST Topic Detection and Tracking (Fiscus and Doddington, 2002) and TREC document retrieval evaluation programs has studied the impact of recognition errors in the overall performance of Information Extraction systems for tasks like story segmentation or topic detection and retrieval. This impact has been shown to be very limited compared to clean text corpora. The main explanation for this phenomenon is the *redundancy effect*: themes, topics are very likely to be represented in texts by many occurrences of salient words characterizing them. Therefore, even if some of these words are missing, numerical Information Extraction methods can use the remaining salient words and discard the noise generated by ASR errors.

However, this phenomenon is not true for tasks related to the extraction of fine grained entities, like Named Entities. Indeed, several studies have shown that F-measure and WER are strongly correlated : 0.7 points of F-measure lost for each additional 1% of WER according to (Miller et al., 2000) on the experiments of 1998 NIST Hub-4 evaluations (Przybocki et al., 1999).

Despite the continuous improvement of ASR techniques, high WER transcriptions are inevitable in difficult conditions like those found in large spoken archives like in the MALACH project (Ramabhadran et al., 2003). Moreover, Named Entities extraction performance is greatly affected by a mismatch between training and testing data. This is due mainly because proper names, which represent most of the Named Entity items, are a very dynamic category of words, strongly related to the period of time representing the documents to process. Therefore this mismatch is inevitable when dealing with archives spreading over a long period of time and containing multiple domain information.

One way of tackling this problem is to gather *metadata* information related to the documents to process. This information can be newspaper corpora related to the same period of time, abstract describing the document content, or simply lists of terms or entities likely to occur. Although such collected data can be used to update the ASR and NER models, the potential gain is rather small unless the metadata corpus gathered fits perfectly the document to process and is of a reasonable size. But another way of exploiting this metadata information is to use it as set of index terms that are going to be explicitly looked for in the processed documents. We present in section 7 an implementation of this idea that uses word lattices as input.

3 The ESTER Named Entity evaluation program

This work has been done within the framework of the French Rich Transcription program of Broadcast News ESTER. ESTER is organized by *l'Association Francophone de la Communication Parlée* (AFCP), *la Délégation Générale pour l'Armement* (DGA) and the *Evaluation language Resources Distribution Agency* (ELDA). The ESTER corpus is made of 100 hours of Broadcast News data (from 6 French speaking radio channels), manually transcribed, and labeled with a tagset of about 30 Named Entity categories folded in 8 main types:

- persons (**pers**): human beings, fiction characters, animals;
- locations (**loc**): geographical, traffic lines, electronic and real addresses, dial numbers;
- organizations (**org**): political, business, non profit;
- geo-socio-political groups (**gsp**): clans, families, nations, administrative regions;
- amounts (**amount**): durations, money, lengths, temperature, age, weight and speed;
- time (**time**): relative and absolute time expressions, hours;
- products (**prod**): art, printings, awards and vehicles;

- facilities (**fac**): buildings, monuments.

This data is divided in 3 sets: a training set (84%), a development set(8%) and a test set (8%). There is a 6 month gap difference between the training corpus and the test corpus while the development corpus matches the training data from a temporal point of view: the training corpus contains Broadcast News spreading from 2002 to December 2003; the development corpus contains news from 2003; the test corpus has been recorded in October 2004. There are also 2 new radio channels in the test corpus which were not in the training data.

For these reasons the development data is called the *matched corpus* as the recording conditions match those of the training corpus and the test data is called the *unmatched corpus*. As a consequence, we can study the effect of unmatched conditions on ASR as well as IE performance and propose solutions for dealing with this problem.

One of the main characteristics of the ESTER corpus is the size of the NE tagset and the high ambiguity rate among the NE categories (eg. administrative regions and geographical locations): 83% of the *matched corpus* entities occur in the training corpus and 40% of them are ambiguous whereas only 61% of the *unmatched corpus* entities occur in the training corpus and 32% of them are ambiguous.

The most commonly used measures for evaluating NE extraction performance are Slot Error Rate (SER) and F-measure. SER is very similar to WER because it takes into account fine grained errors like insertions, deletions and substitutions (entity type and extent). The scoring process is based on the same alignment between reference and hypothesis data than the one obtained for measuring WER and SER is known for being more accurate and penalizing than F-measure. Both measures weights can be adjusted to favor recall or precision and therefore adapted to a specific task.

$$SER = 100 * \frac{\sum_{e \in \mathcal{E}} \alpha_e |e|}{|\textit{Ref slots}|} \qquad F_\beta = \frac{(1+\beta^2)RP}{R+\beta^2 P}$$

$$R = \frac{|\textit{Correct slots}|}{|\textit{Ref slots}|} \qquad P = \frac{|\textit{Correct slots}|}{|\textit{Hyp slots}|}$$

with $e \in \mathcal{E}$ being an error type (insertion, deletion, type, extent, type+extent, multiple) and α_e its weight (resp. $1, 1, .5, .5, .8, 1.5$) ; P is the precision and R the recall; F_1 is used in this paper.

4 Extracting NE from written text vs. ASR output

As previously mentioned in section 2, WER and SER performance are strongly correlated. Besides the intrinsic difficulties of ASR (robustness to noise, speaker variation, lack of coverage of the Language Models used, …), there is a source of errors which is particularly important in IE from speech input: the Out-Of-Vocabulary (OOV) word phenomenon. Indeed, ASR models are built on huge textual corpus and only contain the most frequent words to limit computation and memory usage. If this is the right approach to WER reduction, it is certainly not valuable to information extraction where unlikely events are considered as important. For instance, many document retrieval models use inverse document frequency (rareness) as a word weighting parameter. So, unlikely proper names are not in reach of the ASR transcription system and hence cannot be spotted by a Named Entity extraction module.

In addition to Out-of-Vocabulary words, two other phenomenons have also a strong impact on NER performance: the insertion of erroneous proper names that automatically trigger the insertion of an entity and spontaneous speech phenomenons. These speech dysfluencies (hesitations, filled pauses, false starts...) reduce the quality of the transcript because they are usually not covered by language models (built from textual data) or artificially introduced. One should remove these from the transcript to improve the quality of the labeling.

In order to deal with ASR errors two approaches have been proposed:

- modeling explicitly the ASR errors, thanks to a development corpus and a set of confidence measures, in order to detect the possible errors of the 1-best word string hypothesis (with the type of errors) before extracting the NEs (Palmer and Ostendorf, 2001);

- exploiting a search space bigger than the 1-best hypothesis alone, either by taking into account an n-best list (Zhai et al., 2004) or the whole word lattice (Saraclar and Sproat, 2004).

The method proposed in this paper is close to this second approach where the whole word lattice output by the ASR system is used in order to increase NER performance from noisy input.

We will present also in the next section a new strategy for adapting NER models to ASR transcripts, based on one of the main characteristics of such transcripts: a closed vocabulary is used by the ASR system. To our knowledge this has never been fully exploited by NER systems. Indeed while the key point of NER systems on written text is their generalization capabilities when processing unknown words, this feature is not relevant for ASR transcripts as the system cannot generate words out of the lexicon (there are no unknown words). Therefore we propose here to fully exploit this constraint (close vocabulary): since the OOV words cannot appear in the ASR transcripts, the NER models can by over-trained on the words belonging to the ASR lexicon. This is going to be developed in the next section.

5 Robust Named Entity extraction

We have developed in this study two NER systems: one is based on the freely available NLP tool *Lingpipe*[1], adapted and trained on the French ESTER corpus and dedicated to process text input. This system is going to be called NER_{text} in the experiment section. The second NER system has been developed for this study and is specifically built for being tightly integrated with the ASR processes. The two main features of this system, called NER_{asr} in the following, are its ability to process word lattices and the fact that the NER models are trained for a specific ASR lexicon. These two systems are going to be presented in the next sections.

5.1 Text-based NER system: NER_{text}

Among all the different methods that have been proposed for NER, one can find rule based models (Cunningham et al., 2002), Maximum Entropy models (Brothwick et al., 1998), Conditionnal Random Fields or probabilistic HMM-based models (Bikel et al., 1999).

Lingpipe implements an HMM-based model. It maximizes the probability of a tag sequence T_i over a word sequence W_i. A context of two preceding words and one preceding tag is used to approximate this probability. Generalization is done through a simple process: words occurring with low frequency are replaced by feature based categories (capitalized, contains digits, ...). In this approach, there must be one tag per word. Words starting and ending entities are labeled with special tags. Because some features are lacking in ASR transcripts (e.g. capitalization, digits, sentence boundaries, ...) some word lists for each kind of features are added as presented in (Appelt and Martin, 1999).

[1]Lingpipe: `http://alias-i.com/lingpipe/`

5.2 ASR-based NER system: NER_{asr}

Errors occurring in ASR output lead NER systems to overgenerate NE detections. This is due to both erroneous words insertions in the ASR transcripts as well as some abusive generalization made by the NER systems. If these generalization capabilities are very important for processing unknown words in written texts, they can be an handicap in a closed-vocabulary situation like the one observed when processing ASR output. In order to reduce and control the insertion rate of our NER system, we implemented a two level approach: the first level is made of NE grammars coded as Finite State Machine (FSM) transducers and the second level is a statistical HMM-based tagger.

5.2.1 NE transducers

To each NE category is attached a set of regular grammars, extracted from the ESTER training corpus and generalized thanks to the annotation guidelines and web-gathered word lists. Theses grammars are represented by Finite State Machines (FSMs) (thanks to the AT&T GRM/FSM toolkit (Allauzen et al., 2003)). These FSMs are transducers that accept word sequences on the input symbols and output NE labels on the output symbols. They are all grouped together in a single transducer, called T_{gram}, with a filler model that accepts any string of words. Because these FSMs are lexicalized with the words of the ASR lexicon, one can control the generalization capabilities of the grammars thanks to the occurrence contexts of these words in the training corpus. During the NER process, the first step is to compose the FSM representing the NE transducer and the output of the ASR module (either a 1-best word string or a word lattice, both encoded as an FSM called G).

5.2.2 NE tagger

The result of the composition of the NE transducer with the ASR output is an FSM ($G \circ T_{gram}$) containing all the possible parsing made by the NE grammars. In order to find the best analysis a statistical model is used to decide between entity types and entities boundaries. This model is a 2nd order n-gram model (trigram) represented by a weighted FSM (called T_{tagger}) with the same framework as the grammars. The most likely NE label sequence is obtained by finding the best path in the FSM: $G \circ T_{gram} \circ T_{tagger}$. This corresponds to maximize the following probability:

$$P_W = \prod_{i=1}^{n} P(W_i, T_i | W_{i-1}, T_{i-1}, W_{i-2}, T_{i-2})$$

This model is similar to the one implemented in *Lingpipe* but it uses different smoothing methods. Similarly, first and last words of entities are represented by special tags (this helps getting more accurate boundaries) and low frequency words (appearing less than a fixed number of times in the training corpus) are generalized using their Part-Of-Speech tags. The key points of this approach are that it has a better control of the generalization capabilities than a feature based NER system, thanks to the NE grammars; it integrates the closed vocabulary constraint of the ASR systems; and it is not limited to the 1-best word hypothesis but can use the full ASR search space (through word lattices) in order to detect entities. Processing word lattices allows us to output, at the end of the extraction process, an n-best list of NE hypotheses. To each hypothesis are attached two scores:

- the likelihood score given by the ASR model to the best word string supporting this NE hypothesis in the word lattice;
- the probability $P(W_n, T_n, \ldots, W_0, T_0)$ given by the NE tagger to the sequence of NE labels $T_0, \ldots, T_n$ and the sequence of words $W_0, \ldots, W_n$.

From this n-best list we can estimate the *Oracle* performance of the NER system. This measure is the recall measure upper bound than can be obtained by extracting all the possible entities from a word lattice, thanks to the NE transducers, and simulating a perfect strategy that always take the right decision in choosing among all the possible entities.

Decision strategies on such an n-best of NE hypothesis can also involve other levels of information on the document to process like the date or the theme, for example. In the evaluation presented in the next section we compare this Oracle performance measure to the results of the simplest decision strategy which consists in choosing the NE hypothesis with the highest likelihood.

5.3 Evaluation

The evaluation presented in Tables 1 and 2 is performed using the Slot Error Rate and the F-measure on the *matched* and *unmatched* corpora presented in section 3.

corpus	*matched*		*unmatched*	
tagger	SER	F-m	SER	F-m
NER$_{text}$	21	84	27	79
NER$_{asr}$	23	84	37	74
WER	0		0	

Figure 1: F-measure and Slot Error Rate measures on the ESTER reference corpora (*matched* and *unmatched*) for both NER systems

corpus	*matched*		*unmatched*		
tagger	SER	F-m	SER	F-m	Oracle
NER$_{text}$	42	72	55	63	61.9
NER$_{asr}$	41	73	54	63	76.9
WER	21.2		26.4		

Figure 2: F-measure, Slot Error Rate and Oracle recall measures on the ASR output of the *matched* and *unmatched* corpora for both NER systems

Figure 1 presents SER and F-measure on the two test sets (*matched* and *unmatched*) for the text oriented (*NER$_{text}$*) and the speech oriented (*NER$_{asr}$*) NER systems, on clean text (manual transcripts). Figure 2 shows the results obtained on the ASR transcripts.

As expected on manually transcribed data, *NER$_{text}$* obtains better results than *NER$_{asr}$* (which has poorer generalization capabilities). On the ASR outputs the results obtained by both systems are comparable however *NER$_{asr}$* has the advantage of processing word lattices, leading to an interesting Oracle performance. We are studying now more elaborate decision strategies in order to take fully advantage of this feature.

The decrease in F-measure observed between the reference and the ASR transcripts is similar to the one obtained in other studies (Miller et al., 2000). One observation that can be made on these results is the impact of the time mismatch between the training and the test corpora. A 6 month difference in the *unmatched* corpus leads to a very big drop in both SER and F-measure. This can be explained by the fact that NEs are very time-dependent. We are going now to present some methods developed to tackle this problem.

6 Updating Language and NE models with metadata information

The only mismatch between the training and the *unmatched* corpus of our experiments is a 6 months temporal mismatch, therefore we collected a corpus of newsletters made on a daily basis by the French newspaper *Le Monde* corresponding to these 6 months. These newsletters contain an abstract of the news of each day. We make the following two hypotheses:

- firstly these newsletters are related to the same time period as the *unmatched* corpus, therefore integrating them into the ASR models (lexicon+Language Model) should help reducing the OOV word effect;
- secondly because they represent an abstract of the news of each day, the Named Entities occurring in a particular newsletter should contain all the major events of the corresponding day and therefore constitutes a useful list of terms that can be used for indexing a Broadcast News document related to the same period of time.

6.1 NE distribution analysis

This newsletter corpus contains 1M words and after being tagged by the *NER$_{text}$* system, 140k entities were extracted. To check the relevance of this corpus for adapting the models to the *unmatched* test corpus, we studied the distribution of the words and the entities for each day, from January to December 2004. The *unmatched* test corpus is made of Broadcast News ranging from October 10th to October 16th 2004. The following observations were made: 72% of the NEs and 60% of the words contained in them occur only one day in this corpus; the intersection of the NEs occurring in both the newsletter of a particular day and the entities belonging to the *unmatched* test corpus shows a peak, illustrated by figure 3, for the days of the test corpus; at this peak, 25% of the NEs are used the same day in the two corpora.

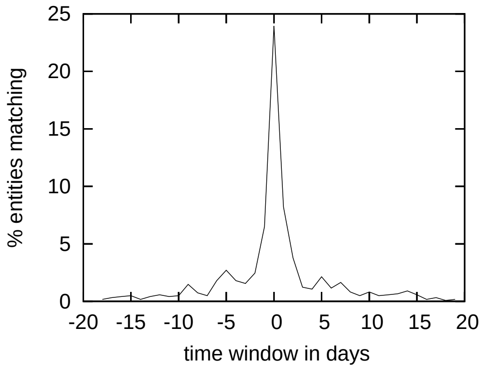

Figure 3: Percentage of entities of the unmatched corpus occuring at least n days earlier or later in the newsletter corpus (at a window of 0 days, entities appear on the same day in both corpus).

The first observation matches those presented in (Whittaker, 2001) and validates our approach which consists in carefully adapting the ASR and NER models with data corresponding to the exact period of time as the one of the documents to process: by taking into account a larger period of time for the adaptation corpus, the necessity of restraining the models to the most frequent entities would lead to discard low frequency terms that can be crucial for characterizing the news of a given day.

If the second observation clearly highlights the correlation between the NE distribution in both corpora, it also points out that only 25% of the entities of the *unmatched* corpus occur in the newsletters corresponding to the same days. Therefore the potential improvement in the overall NER performance is clearly limited. This will be confirmed in the next section, however one can think that if these entities are shared, for a given day, by both corpora, it is because they represent the key topics of this day and therefore they can be considered as very relevant indexing terms for applications like document retrieval. This last point is developed in section 7.

6.2 Model adaptation

Several studies (Whittaker, 2001; Federico and Bertoldi, 2001; Chen et al., 2004) propose adaptation methods of a general language model to the possibly small corpora extracted from these kinds of metadata information (an overview of these methods can be found in (Bellegarda, 2004)). Depending on the adaptation method and the kind of metadata information used, some gains in performance have been reported. But it appears that the choice of the metadata and the size of the adaptation corpus collected are critical in this adaptation process: if the adaptation corpus is not exactly related to the topics of the document to process, no real gains are obtained (e.g. (Chen et al., 2004) reports that the best gains were obtained with a story-based adaptation method).

From all these previous works, our system implements the following adaptation process:

- the text corpus corresponding to the newsletters is added to the ASR language model by means of a linear interpolation;
- proper names occuring twice or more in the newsletter corpus are added to the ASR lexicon;
- for the same days as those of the *unmatched* corpus, this cutoff is suppressed and all the proper names are added;
- the Named Entity wordlists and grammars are also enriched with these proper names and entities extracted from the collected corpus.

1K new proper names were added to the 65K word ASR lexicon. The general OOV reduction obtained was 0.14% leading to an absolute WER reduction of 0.3%. Similarly the SER decreased of about 0.3% thanks to this adaptation and the Oracle recall measure in the word lattices was improved by an absolute 3%. These improvements are not significant enough to justify the use of this kind of metadata information for improving the general performance of both ASR and NER processes. However, if we focus now on the entities occurring in the newsletters corresponding to the exact days of the *unmatched* corpus, the improvement is much more significant, as presented in the next section.

7 Named Entity Indexation

As previously mentioned, 25% of the *unmatched* corpus entities occur in the newsletters corresponding to the same day as those of the *unmatched* test. In order to measure the improvement obtained with our adaptation technique on these particular entities, we did the following experiment:

- a set of 352 entities was selected from the newsletters related to same period of time as the test, these entities represent the indexing terms that are going to be looked for in the word lattices of the *unmatched* corpus;
- the NER_{asr} system was then applied to these word lattices with two conditions: the word lattices and the NER models before adaptation and those obtained after adaptation with the newsletter corpus;
- precision, recall, F-measure and Oracle error rate were estimated for both conditions.

Condition	Prec.	Recall	F-m	Oracle
no adaptation	87.0	75.7	80.9	83.6
with adaptation	87.5	83.9	85.7	92

Figure 4: Extraction results on the selected NEs on the *unmatched* corpus with and without adaptation of the ASR and NER models on the newsletter corpus

As we can see in table 4, the adaptation process increases very significantly the recall measure of the NE extraction. This is particularly relevant in some IE tasks like the document retrieval task.

8 Conclusion

We have presented in this paper a robust Named Entity Recognition system dedicated to process ASR transcripts. The FSM-based approach allows us to control the generalization capabilities of the system while the statistical tagger provides good labeling decisions. The main feature of this system is its ability to extract n-best lists of NE hypothesis from word lattices leaving the decision strategy choosing to either emphasize the recall or the precision of the extraction, according to the task targeted. A comparison between this approach and a standard approach based on the NLP tools *Lingpipe* validates our hypotheses. This integration of the ASR and the NER processes is particularly important in difficult conditions like those that can be found in large spoken archives where the training corpus does not match all the documents to process. A study of the use of metadata information in order to adapt the ASR and NER models to a specific situation showed that if the overall improvement is small, some salient information related to the metadata added can be better extracted by means of this adaptation.

Abstract

We have studied how context specific web corpus can be automatically created and mined for discovering semantic similarity relationships between terms (words or phrases) from a given collection of documents (*target collection*). These relationships between terms can be used to adjust the standard vectors space representation so as to improve the accuracy of similarity computation between text documents in the target collection. Our experiments with a standard test collection (Reuters) have revealed the reduction of similarity errors by up to 50%, twice as much as the improvement by using other known techniques.

1 Introduction

Many modern information management tasks such as document retrieval, clustering, filtering and summarization rely on algorithms that compute similarity between text documents. For example, clustering algorithms, by definition, place documents similar to each other into the same cluster. Topic detection algorithms attempt to detect documents or passages similar to those already presented to the users. "Query by example" retrieval is based on similarity between a document selected as example and the other ones in the collection. Even a classical retrieval task can be formulated as rank ordering according to the similarity between the document (typically very short) representing user's query and all the documents in the collection.

For similarity computation, text documents are represented by *terms* (words or phrases) that they have, and encoded by vectors according to a predominantly used vector space model (Salton & McGill, 1983). Each coordinate corresponds to a *term* (word or phrase) possibly present within a document. Within that model, a high similarity between a pair of documents can be only indicated by sharing same terms. This approach has apparent limitations due to the notorious vocabulary problem (Furnas et al., 1997): people very often use different words to describe semantically similar objects. For example, within a classical vector space model, the similarity algorithm would treat words *car* and *automobile* as entirely different, ignoring semantic similarity relationship between them.

It has been known for a long time that semantic similarity relationships between terms can be discovered by their co-occurrence in the same documents or in the vicinity of each other within documents (von Rijsbergen, 1977). Until the 1990s, the studies exploring co-occurrence information for building a thesaurus and using it in automated query expansion (adding similar words to the user query) resulted in mixed results (Minker et al., 1972; Peat & Willett, 1991). The earlier difficulties may have resulted from the following reasons:

1) The test collections were small, sometimes only few dozens of documents. Thus, there was only a small amount of data available for statistical co-occurrence analysis (mining), not enough to establish reliable associations.

2) The evaluation experiments were based on retrieval tasks, short, manually composed queries. The queries were at times ambiguous and, as a result, wrong terms were frequently added to the query. E.g. initial query "jaguar" may be expanded with the words "auto", "power", "engine" since they co-occur with "jaguar" in auto related documents. But, if the user was actually referring to an animal then the retrieval accuracy would degrade after the expansion.

3) The expansion models were overly simplistic, e.g. by merely adding more keywords to Boolean queries (e.g. "jaguar OR auto OR power OR car").

Although more recent works removed some of the limitations and produced more encouraging results (Grefenstette, 1994; Church et al., 1991; Hearst et al., 1992; Schutze and Pedersen, 1997; Voorhees, 1994) there are still a number of questions that remain open:

1) What is the range for the magnitude of the improvement. Can the effect be of practical importance?

2) What are the best mining algorithms and formulas? How crucial is the right choice of them?

3) What is the best way to select a corpus for mining? Specifically, is it enough to mine only within the same collection that is involved in retrieval, clustering or other processing (*target collection*), or constructing and mining a larger

external corpus (like a subset of World Wide Web) would be of much greater help?
4) Even if the techniques studied earlier are effective (or not) for query expansion within the document retrieval paradigm, are they also effective for a more general task of document similarity computation? Similarity computation stays behind almost all information retrieval tasks including text document retrieval, summarization, clustering, categorization, query by example etc. Since documents are typically longer than user composed queries, their vector space representations are much richer and thus expanding them may be more reliable due to implicit disambiguation.

Answering these questions constitutes the novelty of our work. We have developed a Context Specific Similarity Expansion (CSSE) technique based on word co-occurrence analysis within pages automatically harvested from the WWW (Web corpus) and performed extensive testing with a well known Reuters collection (Lewis, 1997). To test the similarity computation accuracy, we designed a simple combinatorial metric which reflects how accurately (as compared to human judgments) the algorithm, given a document in the collection, orders all the other documents in the collection by the perceived (computed) similarity. We believe that using this metric is more objective and reliable than trying to include all the traditional metrics specific to each application (e.g. recall/precision for document retrieval, type I/II errors for categorization, clustering accuracy etc.) since the latter may depend on the other algorithmic and implementation details in the system. For example, most clustering algorithms rely on the notion of similarity between text documents, but each algorithm (k-means, minimum variance, single link, etc.) follows its own strategy to maximize similarity within a cluster.

We have found out that our CSSE technique have reduced similarity errors by up to 50%, twice as much as the improvement due to using other known techniques such as Latent Semantic Indexing (LSI) and Pseudo Relevance Feedback (PRF) within the same experimental framework. In addition to this dramatic improvement, we have established the importance of the following for the success of the expansion: 1) using external corpus (a constructed subset of WWW) in addition to the target collection 2) taking the context of the target collection into consideration 3) using the appropriate mining formulas. We suggest that these three crucial components within our technique make it significantly distinct from those explored early and also explain more encouraging results.

The paper is structured as follows. Section 2 discusses previous research results that are closely related to our investigation. Section 3 presents algorithms implemented in our experiments. Section 4 describes our experiments including error reduction, sensitivity analysis, and comparison with other techniques. Finally, Section 5 concludes the paper by explaining our key contributions and outlining our future research.

2 Related Work

Most of the prior works performed only mining within the target collection itself and revealed results ranging from small improvements to negative effects (degrading performance). Throughout our paper, we refer to them as *self-mining* to distinguish from mining *external* corpus, which we believe is more promising for similarity computation between documents due to the following intuitive consideration. Within self-mining paradigm, terms *t1* and *t2* have to frequently co-occur in the collection in order to be detected as associated (synonymic). In that case, expanding document *D* representation with a term *t2* when the document already has term *t1* is not statistically likely to enrich its representation since t2 is likely to be in document *D* anyway. We believe mining external larger and contextually related corpus has the potential to discover more interesting associations with much higher reliability than just from the target collection. That is why, this paper focuses on constructing and mining the external corpus.

There are very few studies that used external corpus and standard evaluation collections. Grefenstette (1994) automatically built a thesaurus and applied it for query expansion, producing better results than using the original queries. Gauch et al. (1998) used one standard collection for mining (TREC4) and another (TREC5) for testing and achieved 7.6% improvement. They also achieved 28.5% improvement on the narrow-domain Cystic Fibrosis collection. Kwok (1998) also reported similar results with TREC non Web collections. Ballesteros and Croft (1998) used unlinked corpora to reduce the ambiguity associated with phrasal and term translation in Cross-Language Retrieval.

There are even fewer studies involving semantic mining on the Web and its methodological evaluation. Géry and Haddad Géry (1999) used about 60,000 documents from one specific domain for mining similarity among French terms and tested the results using 4 ad hoc queries. Sugiura and Etzioni (2000) developed a tool called Q-Pilot that mined the web pages retrieved by commercial search engines and expanded the user query by adding similar terms. They reported preliminary yet encouraging results but tested only the overall system, which includes the other, not directly related to mining features, such as clustering, pseudo-relevance feedback, and selecting the appropriate external search engine. Furthermore, they only used the correctness of the engine selection as the evaluation metric. There are some other well known techniques that do not perform mining for a thesaurus explicitly but still capture and utilize semantic similarity between the terms in an implicit way, namely Latent Semantic Indexing (LSI) and Pseudo Relevance Feedback (PRF). Latent Semantic Indexing (Analysis) (Deerwester et al., 1998) a technique based on Singular Value Decomposition, was studied in a number of works. It reduces the number of dimensions in the document space thus reducing the noise (linguistic variations) and bringing semantically similar terms together, thus it

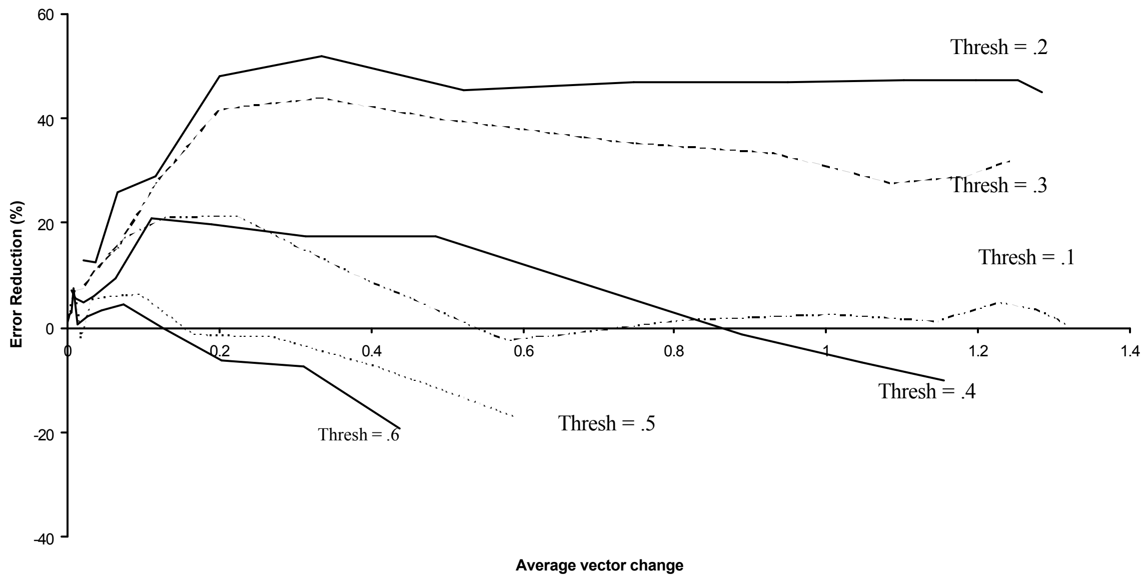

Figure 1. The average error reduction (%) as a function of average document vector change *Ca* for various threshold parameters *Thresh*.

takes into consideration the correlation between the terms. The reported improvements so far however have not exceeded 10-15% in standard collections) and sensitive to the choice of the semantic axis (reduced dimensions). The general idea behind the Pseudo Relevance Feedback (PRF) (Croft & Harper, 1979) or its more recent variation called Local Context Analysis (Xu & Croft, 2000) is to assume that the top rank retrieved documents are relevant and use certain terms from them for the query expansion. A simple approach has been found to increase performance over 23% on the TREC3 and TREC4 collections and became internal part of modern IR systems. Although this idea has been only applied so far to users' queries, we extended it in this study to similarity computation between documents in order to compare with our approach. Although we believe this extension is novel, it is not the focus of this study. It is also worth mentioning that both LSI and PRF fall into "self-mining" category since they do not require external corpus.

A manually built and maintained ontology (a thesaurus), such as WorldNet, may serve as a source of similarity between terms and has been shown to be useful for retrieval tasks (Voorhees, 1994). However, one major drawback of manual approach is high cost of creating and maintaining. Besides, the similarity between terms is context specific. For example, for a campus computer support center the words *student*, *faculty*, *user* are almost synonyms, but for designers of educational software (e.g. Blackboard), the words *student* and *faculty* would represent entirely different roles.

Although the terms "mining", "web mining" and "knowledge discovery" have been used by other researchers in various contexts (Cooley, 1997), we believe it is legitimate to use them to describe our work for two major reasons: 1) We use algorithms and formulas coming from the data mining field, specifically signal to noise ratio association metric (Church, 1989; Church, 1991) 2) Our approach interacts with commercial search engines and harvests web pages contextually close to the target collection, and there is mining of resources (the search engine database) and discovery of content (web pages) involved. We admit that the term "mining" may be also used for a more sophisticated or different kind of processing than our approach here.

3 Algorithms And Implementations

The target collection (Reuters in our experiment) is indexed and its most representative terms are used to construct a corpus from an external source (e. g. World Wide Web). The term-to-term similarity matrix is created by co-occurrence analysis within the corpus and subsequently used to expand document vectors in order to improve the accuracy (correctness) of similarity computation between the documents in the target collection. Although in this work we do not study the effects on the individual applications of the similarity computation, it is crucial for such tasks as retrieval, clustering, categorization or topic detection.

3.1 Building a Web Corpus

We designed and implemented a heuristic algorithm that takes advantage of the capabilities provided by commercial web search engines. In our study, we used AltaVista (www.altavista.com), but most other search engines would also qualify for the task. Ideally, we would like to obtain web pages that

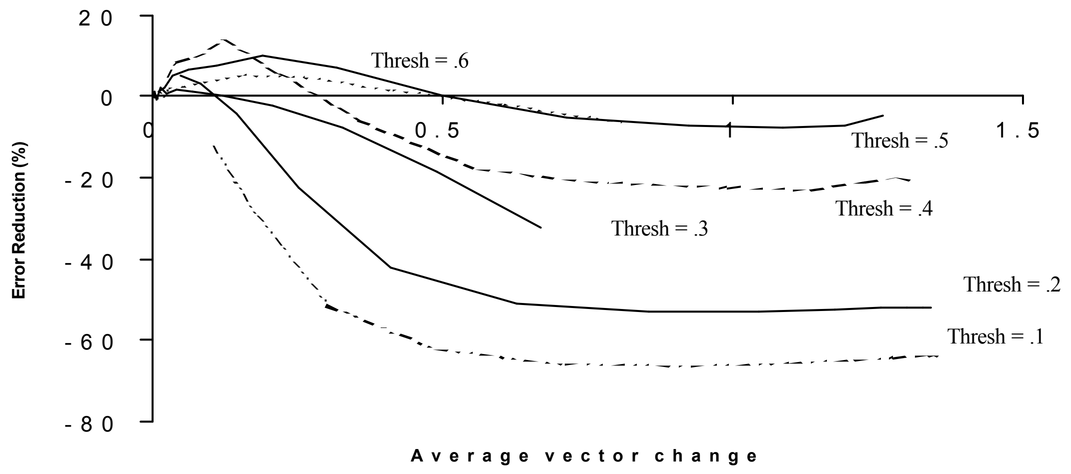

Figure 2. The average error reduction (%) as a function of average document vector change *Ca* for various threshold parameters *Tresh* without "context hint" terms.

contain the terms from the target collection in the similar context. While constructing Web corpus, our spider automatically sends a set of queries to AltaVista and obtains the resulting URLs. The spider creates one query for each term t_i out of 1000 most frequent terms in the target collection (stop words excluded) according to the following formula:

$$q_i = \text{"+"} + t_i + \text{" "} + context\_hint$$

, where + means string concatenation, quotes are used to represent text strings literally and *context_hint* is composed of the top most frequent terms in the target collection (stop words excluded) separated by empty space. Although this way of defining context may seem a bit simplistic, it still worked surprisingly well for our purpose.

According to AltaVista, a word or phrase preceded by '+' sign has to be present in the search results. The presence of the other words and phrases (context hint string in our case) is only desirable but not required. The total number of the context hint terms (108 in this study) is limited by the maximum length of the query string that the search engine can accept.

We chose to use only top 1000 terms for constructing corpus to keep the downloading time manageable. We believe using a larger corpus would demonstrate even larger improvement. Approximately 10% of those terms were phrases. We only used the top 200 hits from each query and only first 20Kbytes of HTML source from each page to convert it into plain text. After removing duplicate URLs and empty pages, we had 19,198 pages in the Web corpus to mine.

Downloading took approximately 6 hours and was performed in parallel, spawning up to 20 java processes at a time, but it still remained the largest scalability bottleneck.

3.2 Semantic Similarity Discovery

CSSE performs co-occurrence analysis at the document level and computes the following values: *df(t1, t2)* is the joint document frequency, i.e., the number of web pages where both terms *t1* and *t2* occur. df(t) is the document frequency of the term t, i.e., the number of web pages in which the term t occurs. Then, CSSE applies a well known signal to noise ratio formula coming from data mining (Church, 1991) to establish similarity between terms *t1* and *t2*:

$$sim(t1, t2) = \log \frac{N \cdot df(t1,t2)}{df(t1) \cdot df(t2)} / \log N, \qquad (1)$$

where *N* is the total number of documents in the mining collection (corpus),

log N is the normalizing factor, so the *sim* value would not exceed *1* and be comparable across collections of different size.

Based on the suggestions from the other studies using formula (1), before running our tests, we decided to discard as spurious all the co-occurrences that happened only within one or two pages and all the similarities that are less than the specified threshold *(Thresh).*

3.3 Vector Expansion

Since we were modifying document vectors (more general case), but not queries as in the majority of prior studies, we refer to the process as *vector expansion*. As we wrote in literature review, there are many possible heuristic ways to perform vector expansion. After preliminary tests, we settled on the simple linear modification with post re-normalization as presented below. The context of the target collection is represented by the similarity matrix *sim(t1, t2)* mined as described in the preceding section. Our vector expansion algorithm adds all the related terms to the vector representation of the document *D* with the weights proportional to the degree of the relationships and the global inverse document frequency (IDF) weighting of the added terms:

$w(t, D)' = w(t, D) +$

$$a \sum_{t' \in d} w(t', D)\, sim(t', t) \log \frac{N}{df(t)}, \text{ where}$$

w(t, D) is the initial, not expanded, weight of the term *t* in the document *D* (assigned according to TF-IDF weighting scheme in our case); *w'(t, D)* is the modified weight of the term *t* in the document *D; t'* iterates through all *(*possibly repeating) terms in the document *D ;* a is the adjustment factor (a parameter controlled in the expansion process).

4 Experiments

4.1 Similarity Error Reduction

Since in this study we were primarily concerned with improving similarity computation but not retrieval per se, we chose a widely used for text categorization Reuters collection (Lewis, 1997) over TREC or similar collections with relevance judgments. We used a modified version of Lewis' (1992) suggestion to derive our evaluation metric, which is similar to the metric derived from Kruskal-Goodman statistics used in Haveliwala et al. (2002) for a study with Yahoo web directory (www.yahoo.com). Intuitively, the metric reflects the probability of algorithm guessing the correct order (called *ground truth*), imposed by a manually created hierarchy (simplified to a partition in Reuters case). Ideally, for each document *D,* the similarity computation algorithm should indicate documents sharing one or more Reuters categories with document D to be more similar to the document *D* than the documents not sharing any categories with *D*. We formalized this intuitive requirement into a metric by the following way. Let's define a test set *Sa* to be the set of all the document triples *(D, D1, D2)* such that $D^{1}D1$, $D^{1}D2$, $D1^{1}D2$, and furthermore *D* shares at least one common category with *D1* but no common categories with *D2*. We defined *total error count* (*Ec*) as the number of triples in the test set *Sa* such that *sim(D, D1) < sim(D, D2)* since it should be the other way around. Our accuracy metric reported below is the total error count normalized by the size of the test set *Sa*: *similarity error = Ec / #Sa,* computed for each Reuters topics and averaged across all of them. The metric ranges from 0 (ideal case) to .5 (random ordering). It also needed an adjustment to provide the necessary continuity as justified in the following. Since the documents are represented by very sparse vectors, very often (about 5% of all triples) documents *D, D1, D2* do not have any terms in common and as a result similarity computation results in a tie: *sim(D,D1) = sim (D, D2)*. A tie can not be considered an error because in that case one can suggest a trivial improvement to the similarity algorithm by simply breaking the ties at random in any direction with an equal chance, and thus reducing errors in 50% of all ties. This is why the metric counts half of all the ties as errors, which completely removes this discontinuity.

We used all the Reuters *78* topics from the "commodity code" group since they are the most "semantic", not trying the others (Economic Indicator Codes, Currency Codes, Corporate Codes). We discarded the topics that had only 1 document and used only the documents that had at least one of the topics. This reduced our test collection to *1841* documents, still statistically powerful and computationally demanding since millions of triples had to be considered (even after some straightforward algorithmic optimizations). After indexing and stemming (Porter, 1980) the total number of unique stems used for the vector representation was *11461*.

Weighting Scheme	boolean vectors	TF only	IDF only	TF-IDF
Similarity Error	0.1750	0.1609	0.1278	0.1041

Table 2. Comparison of different weighting schemes with the original (not expanded) documents.

Table 2 lists the similarity error averaged by topics for the different weighting schemes we tried first in our experiment. Since TF-IDF weighting was by far the best in this evaluation set up, we limited our expansion experiments to TF-IDF scheme only. For similarity measure between document vectors, we used the most common negative Euclidian distance after normalizing the vectors to unit length. It can be shown, that cosine metric (dot product), the other popular metric, results in the same order and, thus same similarity error as well. Without normalization or stemming the errors were almost twice as much larger.

Although we varied the adjustment parameter *a* in our experiment, for better interpretation, we plotted our primary metric (average error reduction) as a function of *Ca*, the average Euclidian distance between the original and the modified document vectors when both vectors are normalized to unit length. *Ca* serves as a convenient parameter controlling the degree of change in the document vectors, better than *a*, because same values of *a* may result in different changes depending on the term-to-term similarity matrix *sim(t1, t2)*. In theory, *Ca* varies from *0* (no change) to $\sqrt{2}$, the case of maximum possible change (no common terms between initial and expanded representation). By varying adjustment factor *a* from 0 to 10 and higher we observed almost the entire theoretical range of *Ca*: starting from negligible change and going all the way to $\sqrt{2}$, where the added terms entirely dominated the original ones. The average number of terms in the document representation was in 60-70 range before expansion and in 200-300 range after the expansion. This of course increased computational burden. Nevertheless, even after the expansion, the vector representations still remained sparse and we were able to design and implement some straightforward algorithmic improvements taking advantage of this sparsity to keep processing time manageable. The expansion for entire Reuters collection was taking less than one minute on a workstation with Pentium III 697 MHz processor, 256 MB of RAM, with all the sparse representations of the documents and similarity matrix stored in primary memory. This renders the expansion suitable for online processing.

To evaluate the performance of each technique, we used the error reduction (%) relatively to the baseline shown in Table 1 (TF-IDF column) averaged across all the topics, which corresponds to the lowest

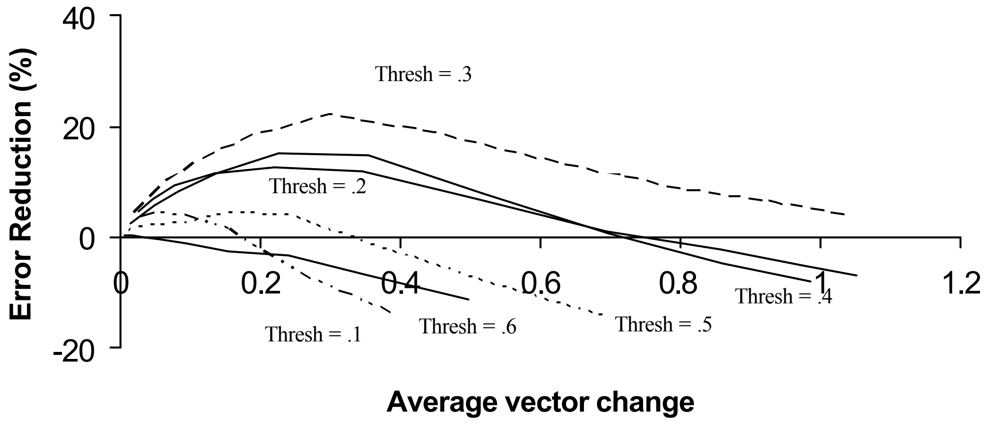

Figure 3. The average error reduction (%) as a function of average document vector change *Ca* for various threshold parameters *Tresh* without using external mining collection.

original non-expanded similarity error. Figure 1 shows the error reduction as a function of *Ca* for various values of *Thresh*. We stopped increasing *Ca* once the improvement dropped below -10% to save testing time. Several facts can be observed from the results:

1) The error reduction for *Thresh* in the mid range of *Ca [.2-.4]* is very stable, achieves *50%* , which is very large compared with the other known techniques we used for comparison as discussed below. The effect is also comparable with the difference between various weighting functions (Table 2), which we believe renders the improvement practically significant.

2) For small thresholds (*Thresh* < *.1*), the effect is not that stable, possibly since many non-reliable associations are involved in the expansion.

3) Larger thresholds (*Thresh* > *.4*) are also not very reliable since they result in a small number of associations created, and thus require large values of adjustment parameter *a* in order to produce substantial average changes in the document vectors (*Ca*), which results in too drastic change in some document vectors.

4) The error reduction curve is unimodal: it starts from 0 for small *Ca*, since document vectors almost do not change, and grows to achieve maximum for *Ca* somewhere in relatively wide *.1 - .5* range. Then, it decreases, because document vectors may be drifting too far from the original ones, falling below *0* for some large values of *Ca*.

5) For thresholds (*Thresh*) *.2* and *.3*, the effect stays positive even for large values of *Ca*, which is an interesting phenomenon because document vectors are getting almost entirely replaced by their expanded representations.

Some sensitivity of the results with respect to the parameters *Thresh, Ca* is a limitation as occurs similarly to virtually all modern IR improvement techniques. Indeed, Latent Semantic Indexing (LSI) needs to have number of semantic axis to be correctly set, otherwise the performance may degrade. Pseudo Relevance Feedback (PRF) depends on several parameters such as number of documents to use for feedback, adjustment factor, etc. All previously studied expansion techniques depend on the adjustment factor as well. The specific choice of the parameters for real life applications is typically performed manually based on trial and error or by following a machine learning approach: splitting data into training and testing sets. Based on the above results, the similarity threshold (*Thresh*) in *.2-.4* and *Ca* in *.1-.5* range seem to be a safe combination, not degrading and likely to significantly (*20-50%*) improve performance. The performance curve being unimodal with respect to both *Ca* and *Thresh* also makes it easier to tune by looking for maxima. Although we have involved only one test collection in this study, this collection (Reuters) varies greatly in the content and the size of the documents, so we hope our results will generalize to other collections.

We also verified that the effect typically diminishes when the size of the mining collection (corpus) is reduced by random sub-sampling. Those results were also similar to those obtained 4 months earlier, although only 80% of the pages in the mining corpus remained.

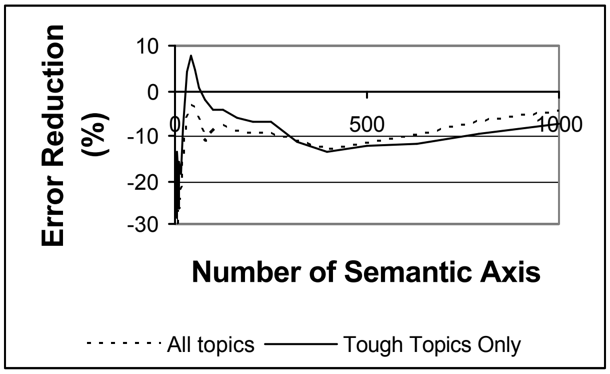

Figure 4. Comparing to LSI.

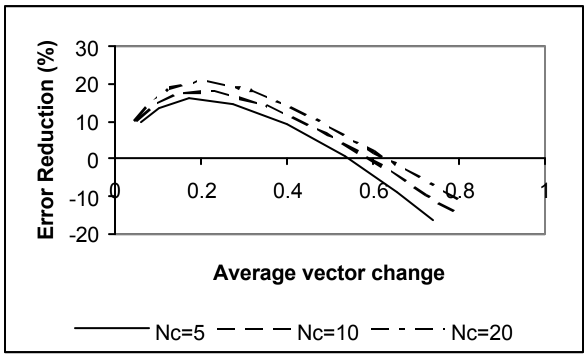

Figure 5. The error reduction as the function of the average vector change due to Pseudo Relevance Feedback for several cut-off numbers Nc.

4.2 Sensitivity Analysis

To test the importance of the context, we removed the "context hint" terms from the queries used by our agent, and created another (less context specific) corpus for mining. We obtained *175,336* unique URLs, much more than with using "context hint" terms since the overlap between different query results was much smaller. We randomly selected *25,000 URLs* of them and downloaded the referred pages. Then, to make the comparison more objective, we randomly selected *19,198* pages (same number as with using context hint) of the non-empty downloaded pages. We mined the similarity relationships from the selected documents in the same way as described above. The resulting improvement (shown in the Figure 2) was indeed much smaller (*13%* and less) than with using "context hint" terms. It also degrades much quicker for larger *Ca* and more sensitive to the choice of *Thresh*. This may explain why mixed results were reported in the literate when the similarity thesaurus was constructed in a very general setting, but not specifically for the target collection in mind. It is also interesting to note a similar behavior of error reduction as the function of *Ca* and *Thresh*: it is unimodal with maximum in approximately same range of arguments. This may also serve as indirect evidence of stability of the effect (even if smaller in that case) with respect to the parameters involved.

To verify the importance of using external corpus vs. self-mining, we mined the similarity relationships from the same collection (Reuters) that we used for the tests (target collection) using the same mining algorithms. Figure 3 shows that the effect of such "self-mining" is relatively modest (up to 20%), confirming that using the external corpus (the Web in our approach) was crucial. Again, the behavior of the error reduction (even smaller in that case) with respect to *Ca* and *Thresh* is similar to the context specific web corpus mining.

4.3 Comparison with Other Techniques

Figure 4 shows the similarity error reduction as a function of the number of semantic axis when LSI is applied. The effect with the entire collection (second column) is always negative. So, the Reuters collection in our experiment set up was found to be not a good application of LSI technique, possibly because many of the topics have already small errors even before applying LSI. To verify our implementation and the applicability of LSI to the similarity computation, we applied it only to the "tougher" 26 topics, those in the upper half if ordered by the original similarity error. As Figure 4 reveals, LSI is effective in that case for numbers of semantic axis comparable with number of topics in the target collection. Our findings are well in line with reported in prior research.

We adapted the classic Pseudo Relevance Feedback algorithm (Qiu, 1993), which has been so far applied only to document retrieval tasks, to similarity computation in a straightforward way and also tried several variations of if (not described here due to lack of space). Figure 5 shows the effect as a function of adjustment factor *a* for various cut-off parameters *Nc* (the number of top ranked documents used for feedback). The effect achieves the maximum of around *21%*, consistent with the results reported in prior research. The improvement is close in magnitude to the one due to "self-mining" described above. We do not claim that our approach is better than PRF since it is not entirely meaningful to make this comparison due to the number of parameters and implementation details involved in both. Also, more important, the techniques rely on different source of data: PRF is a "self-mining" approach while CSSE builds and mines external corpus. Thus, CSSE can be used in addition to PRF.

5 Conclusions

In this paper, we proposed and empirically studied an approach to improve similarity computation between text documents by creating a context specific Web corpus and performing similarity mining within it. The results demonstrated that the similarity errors can be reduced by additional 50% after all the standard procedures such as stemming, term weighting, and vector normalization. We also established the crucial importance of the following three factors, which we believe make our technique distinct from those already explored early and explain more encouraging results that we obtained: *1) Using external corpus. 2) Taking the context of the target collection into consideration. 3) Using the appropriate mining formula.* Another important distinction and possible explanation of a more dramatic effect is our focus on similarity computation between text documents, rather than on document retrieval tasks, which have been more extensively studied in the past. Similarity computation is a more general procedure, which in turns defines the quality of virtually all other specific tasks such as document retrieval, summarization, clustering, categorization, topic detection, query by example, etc. Our future plans are to overcome some of the limitations in this study, specifically using more than a single (although standard and very diverse) collection and study other experimental setups, such as document retrieval, text categorization, or topic detection and tracking.

Hidden–Variable Models for Discriminative Reranking

Abstract

We describe a new method for the representation of NLP structures within reranking approaches. We make use of a conditional log–linear model, with hidden variables representing the assignment of lexical items to word clusters or word senses. The model learns to automatically make these assignments based on a discriminative training criterion. Training and decoding with the model requires summing over an exponential number of hidden–variable assignments: the required summations can be computed efficiently and exactly using dynamic programming. As a case study, we apply the model to parse reranking. The model gives an F–measure improvement of $\approx 1.25\%$ beyond the base parser, and an $\approx 0.25\%$ improvement beyond the Collins (2000) reranker. Although our experiments are focused on parsing, the techniques described generalize naturally to NLP structures other than parse trees.

1 Introduction

A number of recent approaches in statistical NLP have focused on *reranking* algorithms. In reranking methods, a baseline model is used to generate a set of candidate output structures for each input in training or test data. A second model, which typically makes use of more complex features than the baseline model, is then used to rerank the candidates proposed by the baseline. Reranking approaches have given improvements in accuracy on a number of NLP problems including parsing (Collins, 2000; Charniak and Johnson, 2005), machine translation (Och and Ney, 2002; Shen et al., 2004), information extraction (Collins, 2002), and natural language generation (Walker et al., 2001).

The success of reranking approaches depends critically on the choice of *representation* used by the reranking model. Typically, each candidate structure (e.g., each parse tree in the case of parsing) is mapped to a feature–vector representation. Previous work has generally relied on two approaches to representation: explicitly hand–crafted features (e.g., in Charniak and Johnson (2005)) or features defined through kernels (e.g., see Collins and Duffy (2002)).

This paper describes a new method for the representation of NLP structures within reranking approaches. We build on the intuition that lexical items in natural language often fall into word clusters (for example, *president* and *chairman* might belong to the same cluster) or fall into distinct word senses (e.g., *bank* might have two distinct senses). Our method involves a hidden–variable model, where the hidden variables correspond to an assignment of words to either clusters or word–senses. Lexical items are automatically assigned their hidden values using unsupervised learning within a discriminative reranking approach.

We make use of a conditional log–linear model for our task. Formally, hidden variables within the log–linear model consist of *global* assignments, where a global assignment entails an assignment of every word in the sentence to some hidden cluster or sense value. The number of such global assignments grows exponentially fast with the length of the sentence being processed. Training and decoding with the model requires summing over the exponential number of possible global assignments, a major technical challenge in our model. We show that the required summations can be computed efficiently and exactly using dynamic–programming methods (i.e., the belief propagation algorithm for Markov random fields (Yedidia et al., 2003)) under certain restrictions on features in the model.

Previous work on reranking has made heavy use of lexical statistics, but has treated lexical items as atoms. The motivation for our method comes from the observation that statistics based on lexical items are critical, but that these statistics suffer considerably from problems of data sparsity and word–

sense polysemy. Our model has the ability to alleviate data sparsity issues by learning to assign words to word clusters, and can mitigate problems with word–sense polysemy by learning to assign lexical items to underlying word senses based upon contextual information. A critical difference between our method and previous work on unsupervised approaches to word–clustering or word–sense discovery is that our model is trained using a discriminative criterion, where the assignment of words to clusters or senses is driven by the reranking task in question.

As a case study, in this paper we focus on syntactic parse reranking. We describe three model types that can be captured by our approach. The first method emulates a clustering operation, where the aim is to place similar words (e.g., *president* and *chairman*) into the same cluster. The second method emulates a *refinement* operation, where the aim is to recover distinct senses underlying a single word (for example, distinct senses underlying the noun *bank*). The third definition makes use of an existing ontology (i.e., WordNet (Miller et al., 1993)). In this case the set of possible hidden values for each word corresponds to possible WordNet senses for the word.

In experimental results on the Penn Wall Street Journal treebank parsing domain, the hidden–variable model gives an F–measure improvement of $\approx 1.25\%$ beyond a baseline model (the parser described in Collins (1999)), and gives an $\approx 0.25\%$ improvement beyond the reranking approach described in Collins (2000). Although the experiments in this paper are focused on parsing, the techniques we describe generalize naturally to other NLP structures such as strings or labeled sequences. We discuss this point further in Section 6.1.

2 Related Work

Various machine–learning methods have been used within reranking tasks, including conditional log–linear models (Ratnaparkhi et al., 1994; Johnson et al., 1999), boosting methods (Collins, 2000), variants of the perceptron algorithm (Collins, 2002; Shen et al., 2004), and generalizations of support–vector machines (Shen and Joshi, 2003). There have been several previous approaches to parsing using log–linear models and hidden variables. Riezler et al. (2002) describe a discriminative LFG parsing model that is trained on standard (syntax only) treebank annotations by treating each tree as a full LFG analysis with an observed c-structure and hidden f-structure. Clark and Curran (2004) present an alternative CCG parsing approach that divides each CCG parse into a dependency structure (observed) and a derivation (hidden). More recently, Matsuzaki et al. (2005) introduce a probabilistic CFG augmented with hidden information at each nonterminal, which gives their model the ability to tailor itself to the task at hand. The form of our model is closely related to that of Quattoni et al. (2005), who describe a hidden–variable model for object recognition in computer vision.

The approaches of Riezler et al., Clark and Curran, and Matsuzaki et al. are similar to our own work in that the hidden variables are exponential in number and must be handled with dynamic–programming techniques. However, they differ from our approach in the definition of the hidden variables (the Matsuzaki et al. model is the most similar). In addition, these three approaches don't use reranking, so their features must be restricted to local scope in order to allow dynamic–programming approaches to training. Finally, these approaches use Viterbi or other approximations during decoding, something our model can avoid (see section 6.2).

In some instantiations, our model effectively clusters words into categories. Our approach differs from standard word clustering in that the clustering criteria is directly linked to the reranking objective, whereas previous word–clustering approaches (e.g. Brown et al. (1992) or Pereira et al. (1993)) have typically leveraged distributional similarity. In other instantiations, our model establishes word–sense distinctions. Bikel (2000) has done previous work on incorporating the WordNet hierarchy into a generative parsing model; however, this approach requires data with word–sense annotations whereas our model deals with word–sense ambiguity through unsupervised discriminative training.

3 The Hidden–Variable Model

In this section we describe a hidden–variable model based on conditional log–linear models. Each sentence s_i for $i = 1 \ldots n$ in our training data has a set of n_i candidate parse trees $t_{i,1}, \ldots, t_{i,n_i}$, which are the output of an N–best baseline parser. Each candidate parse has an associated F–measure score, indicating its similarity to the gold–standard parse. Without loss of generality, we define $t_{i,1}$ to be the parse with the highest F–measure for sentence s_i.

Given a candidate parse tree $t_{i,j}$, the hidden–variable model assigns a domain of hidden values to each word in the tree. For example, the hidden–value domain for the word *bank* could be $\{bank_1, bank_2, bank_3\}$ or $\{\mathsf{NN}_1, \mathsf{NN}_2, \mathsf{NN}_3\}$. Detailed descriptions of the domains we used are given in Section 4.1. Formally, if $t_{i,j}$ spans m words then the hidden–value domains for each word are the sets $H_1(t_{i,j}), \ldots, H_m(t_{i,j})$. A global hidden–value assignment, which attaches a hidden value to every word in $t_{i,j}$, is written $\mathbf{h} = (h_1, \ldots, h_m) \in \mathbf{H}(t_{i,j})$, where $\mathbf{H}(t_{i,j}) = H_1(t_{i,j}) \times \ldots \times H_m(t_{i,j})$ is the set of all possible global assignments for $t_{i,j}$.

We define a feature–based representation Φ such that $\Phi(t_{i,j}, \mathbf{h}) \in \mathbb{R}^d$ is a vector of feature occurrence counts that describes candidate parse $t_{i,j}$ with global assignment $\mathbf{h} \in \mathbf{H}(t_{i,j})$. We write Φ_k for $k = 1 \ldots d$ to denote the k^{th} component of the vector Φ. Each component of the feature vector is the count of some substructure within $(t_{i,j}, \mathbf{h})$. For example, Φ_{12} and Φ_{101} could be defined as follows:

$$\begin{aligned} \Phi_{12}(t_{i,j}, \mathbf{h}) &= \text{Number of times the word } \textit{the} \text{ occurs with hidden value } \textit{the}_3 \text{ and part of speech tag } \mathsf{DT} \text{ in } (t_{i,j}, \mathbf{h}). \\ \Phi_{101}(t_{i,j}, \mathbf{h}) &= \text{Number of times } \textit{CEO}_1 \text{ appears as the subject of } \textit{owns}_2 \text{ in } (t_{i,j}, \mathbf{h}) \end{aligned} \quad (1)$$

We use a parameter vector $\Theta \in \mathbb{R}^d$ to define a log–linear distribution over candidate trees together with global hidden–value assignments:

$$p(t_{i,j}, \mathbf{h} \mid s_i, \Theta) = \frac{e^{\Phi(t_{i,j},\mathbf{h})\cdot\Theta}}{\sum_{j',\mathbf{h}' \in \mathbf{H}(t_{i,j'})} e^{\Phi(t_{i,j'},\mathbf{h}')\cdot\Theta}}$$

By marginalizing out the global assignments, we obtain a distribution over the candidate parses alone:

$$p(t_{i,j} \mid s_i, \Theta) = \sum_{\mathbf{h} \in \mathbf{H}(t_{i,j})} p(t_{i,j}, \mathbf{h} \mid s_i, \Theta) \quad (2)$$

Later in this paper we will describe how to train the parameters of the model by minimizing the following loss function—which is the negative log–likelihood of the training data—with respect to Θ:

$$\begin{aligned} L(\Theta) &= -\sum_i \log p(t_{i,1} \mid s_i, \Theta) \\ &= -\sum_i \log \textstyle\sum_{\mathbf{h} \in \mathbf{H}(t_{i,1})} p(t_{i,1}, \mathbf{h} \mid s_i, \Theta) \end{aligned} \quad (3)$$

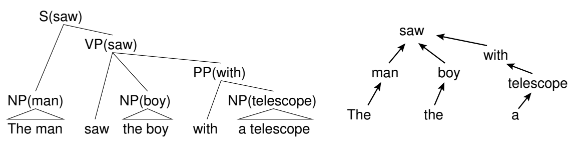

Figure 1: A sample parse tree and its dependency tree.

3.1 Local Feature Vectors

Note that the number of possible global assignments (i.e., $|\mathbf{H}(t_{i,j})|$) grows exponentially fast with respect to the number of words spanned by $t_{i,j}$. This poses a problem when training the model, or when calculating the probability of a parse tree through Eq. 2. This section describes how to address this difficulty by restricting features to sufficiently local scope. In Section 3.2 we show that this restriction allows efficient training and decoding of the model.

The restriction to local feature–vectors makes use of the dependency structure underlying the parse tree $t_{i,j}$. Formally, for tree $t_{i,j}$, we define the corresponding dependency tree $\mathbf{D}(t_{i,j})$ to be a set of edges between words in $t_{i,j}$, where $(u, v) \in \mathbf{D}(t_{i,j})$ if and only if there is a head–modifier dependency between words u and v. See Figure 1 for an example dependency tree. We restrict the definition of Φ in the following way[1]. If w, u and v are word indices, we introduce single–variable local feature vectors $\phi(t_{i,j}, w, h_w) \in \mathbb{R}^d$ and pairwise local feature vectors $\phi(t_{i,j}, u, v, h_u, h_v) \in \mathbb{R}^d$. The global feature vector $\Phi(t_{i,j}, \mathbf{h})$ is then decomposed into a sum over the local feature vectors:

$$\begin{aligned} \Phi(t_{i,j}, \mathbf{h}) = &\sum_{1 \le w \le m} \phi(t_{i,j}, w, h_w) + \\ &\sum_{(u,v) \in \mathbf{D}(t_{i,j})} \phi(t_{i,j}, u, v, h_u, h_v) \end{aligned} \quad (4)$$

Notice that the second sum, over pairwise local feature vectors, respects the dependency structure $\mathbf{D}(t_{i,j})$. Section 3.2 describes how this decomposition of Φ leads to an efficient and exact dynamic–programming approach that, during training, allows us to calculate the gradient $\frac{\partial L}{\partial \Theta}$ and, during testing, allows us to find the most probable candidate parse.

In our implementation, each dimension of the local feature vectors is an indicator function signaling the presence of a feature, so that a sum over local feature vectors in a tree gives the occurrence count

[1]Note that the restriction on local feature vectors only concerns the inclusion of hidden values; features may still observe arbitrary structure within the underlying parse tree $t_{i,j}$.

of features in that tree. For instance, define

$$\phi_{12}(t_{i,j}, w, h_w) = \left[\!\left[\begin{array}{l} h_w = \textit{the}_3 \text{ and tree } t_{i,j} \text{ assigns word} \\ w \text{ to part–of–speech DT} \end{array} \right]\!\right]$$

$$\phi_{101}(t_{i,j}, u, v, h_u, h_v) = \left[\!\left[\begin{array}{l} (h_u, h_v) = (\textit{CEO}_1, \textit{owns}_2) \\ \text{and tree } t_{i,j} \text{ places } (u, v) \text{ in} \\ \text{a subject–verb relationship} \end{array} \right]\!\right]$$

where the notation $[\![\mathcal{P}]\!]$ signifies a $0/1$ indicator of predicate $\mathcal{P}$. When summed over the tree, these definitions of ϕ_{12} and ϕ_{101} yield global features Φ_{12} and Φ_{101} as given in the previous example (see Eq. 1).

3.2 Training the Model

We now describe how the loss function in Eq. 3 can be optimized using gradient descent. The gradient of the loss function is given by:

$$\frac{\partial L}{\partial \Theta} = -\sum_i F(t_{i,1}, \Theta) + \sum_{i,j} p(t_{i,j} \,|\, s_i, \Theta) F(t_{i,j}, \Theta)$$

where $F(t_{i,j}, \Theta) = \sum_{\mathbf{h} \in \mathbf{H}(t_{i,j})} \frac{p(t_{i,j}, \mathbf{h} \,|\, s_i, \Theta)}{p(t_{i,j} \,|\, s_i, \Theta)} \Phi(t_{i,j}, \mathbf{h})$ is the expected value of the feature vector produced by parse tree $t_{i,j}$. As we remarked earlier, $|\mathbf{H}(t_{i,j})|$ is exponential in size so direct calculation of either $p(t_{i,j} \,|\, s_i, \Theta)$ or $F(t_{i,j}, \Theta)$ is impractical. However, using the feature–vector decomposition in Eq. 4, we can rewrite the key functions of Θ as follows:

$$p(t_{i,j} \,|\, s_i, \Theta) = \frac{Z_{i,j}}{\sum_{j'} Z_{i,j'}}$$

$$F(t_{i,j}, \Theta) = \sum_{\substack{1 \le w \le m \\ h_w \in H_w(t_{i,j})}} p(t_{i,j}, w, h_w) \phi(t_{i,j}, w, h_w) + \sum_{\substack{(u,v) \in \mathbf{D}(t_{i,j}) \\ h_u \in H_u(t_{i,j}) \\ h_v \in H_v(t_{i,j})}} p(t_{i,j}, u, v, h_u, h_v) \phi(t_{i,j}, u, v, h_u, h_v)$$

where $p(t_{i,j}, w, h_w)$ and $p(t_{i,j}, u, v, h_u, h_v)$ are marginalized probabilities and $Z_{i,j}$ is the associated normalization constant:

$$Z_{i,j} = \sum_{\mathbf{h} \in \mathbf{H}(t_{i,j})} e^{\Phi(t_{i,j}, \mathbf{h}) \cdot \Theta}$$

$$p(t_{i,j}, w, x) = \sum_{\mathbf{h} \,|\, h_w = x} p(t_{i,j}, \mathbf{h} \,|\, s_i, \Theta)$$

$$p(t_{i,j}, u, v, x, y) = \sum_{\mathbf{h} \,|\, h_u = x, h_v = y} p(t_{i,j}, \mathbf{h} \,|\, s_i, \Theta)$$

The three quantities above can be computed with belief propagation (Yedidia et al., 2003), a dynamic–programming technique that is efficient[2] and exact when the graph $\mathbf{D}(t_{i,j})$ is a tree, which is the case in our parse reranking model. Having calculated the gradient in this way, we minimize the loss using stochastic gradient descent[3] (LeCun et al., 1998).

4 Features for Parse Reranking

The previous section described hidden–variable models for discriminative reranking. We now describe features for the parse reranking problem. We focus on the definition of hidden–value domains and local feature vectors in the reranking model.

4.1 Hidden–Value Domains and Local Features

Each word in a parse tree is given a domain of possible hidden values by the hidden–variable model. Models with widely varying behavior can be created by changing the way these domains are defined. In particular, in this section we will see how different definitions of the domains give rise to the three main model types: clustering, refinement, and mapping into a pre–built ontology such as WordNet.

As illustration, consider a simple approach that splits each word into a domain of three word–sense hidden values (e.g., the word *bank* would yield the domain $\{\textit{bank}_1, \textit{bank}_2, \textit{bank}_3\}$). In this approach, each word receives a domain of hidden values that is not shared with any other word. The model is then able to distinguish several different usages for each word, emulating a refinement operation. An alternative approach is to split each word's part–of–speech tag into several sub–tags (e.g., *bank* would yield $\{\text{NN}_1, \text{NN}_2, \text{NN}_3\}$). This approach assigns the same domain to many words; for instance, singular nouns such as *bond*, *market*, and *bank* all receive the same domain. The behavior of the model then emulates a clustering operation.

Figure 2 shows the single–variable and pairwise features used in our experiments. The features are shown with hidden variables corresponding to word–specific hidden values, such as $\textit{shares}_1$ or $\textit{bought}_3$. In our experiments, we made use of features such as those in Figure 2 in combination with the following four definitions of the hidden–value

[2]The running time of belief propagation varies linearly with the number of nodes in $\mathbf{D}(t_{i,j})$ and quadratically with the cardinality of the largest hidden–value domain.

[3]We also performed some experiments using the conjugate gradient descent algorithm (Johnson et al., 1999). However, we did not find a significant difference between the performance of either method. Since stochastic gradient descent was faster and required less memory, our final experiments used the stochastic gradient method.

$(shares_1, bought_3,\ \text{Dependency: VBD, NP, VP, Right, +Adj, -CC})$
$(shares_1, bought_3,\ \text{Rule: VP} \rightarrow \text{VBD}_{\text{head}}, \text{NP}_{\text{mod}}, \text{PP, NP})$
$(shares_1, bought_3,\ \text{Gpar Rule: S} \rightarrow \text{VP} \rightarrow \text{VBD}_{\text{head}}, \text{NP}_{\text{mod}}, \text{PP, NP})$

Figure 2: The features used in our model. We show the single–variable features produced for hidden value *shares*$_1$ and the pairwise features produced for hidden values $(\textit{shares}_1, \textit{bought}_3)$, in the context of the given parse fragment. Highest NT = highest nonterminal, Up Path = sequence of ancestor nonterminals, Down Path = sequence of headed nonterminals, Head Rule = rules headed by the word, Mod Rule = rule in which word acts as modifier, Head/Mod Gpar Rule = Head/Mod Rule plus grandparent nonterminal.

domains (in each case we give the model type that results from the definition—clustering, refinement, or pre–built ontology—in parentheses):

Lexical (Refinement) Each word is split into three sub–values. See Figure 2 for an example of features generated for this choice of domain.

Part–of–Speech (Clustering) The part–of–speech tag of each word is split into five sub–values. In Figure 2, the word *shares* would be assigned the domain $\{\text{NNS}_1, \ldots, \text{NNS}_5\}$, and the word *bought* would have the domain $\{\text{VBD}_1, \ldots, \text{VBD}_5\}$.

Highest Nonterminal (Clustering) The highest nonterminal to which each word propagates as a headword is split into five sub–values. In Figure 2 the word *bought* yields domain $\{\text{S}_1, \ldots, \text{S}_5\}$, while *in* yields $\{\text{PP}_1, \ldots, \text{PP}_5\}$.

Supersense (Pre–Built Ontology) We borrow the idea of using WordNet lexicographer filenames as broad "supersenses" from Ciaramita and Johnson (2003). For each word, we split each of its supersenses into three sub–supersenses. If no supersenses are available, we fall back to splitting the part–of–speech into five sub–values. For example, *shares* has the supersenses noun.possession, noun.act and noun.artifact, which yield the domain $\{\text{noun.possession}_1, \text{noun.act}_1, \text{noun.artifact}_1, \ldots \text{noun.possession}_3, \text{noun.act}_3, \text{noun.artifact}_3\}$. On the other hand, *in* does not have any WordNet supersenses, so it is assigned the domain $\{\text{IN}_1, \ldots, \text{IN}_5\}$.

4.2 The Final Feature Sets

We created eight feature sets by combining the four hidden–value domains above with two alternative definitions of dependency structures: standard head–modifier dependencies and "sibling dependencies." When using sibling dependencies, connections are established between the headwords of adjacent siblings. For instance, the head–modifier dependencies produced by the tree fragment in Figure 2 are $(\textit{bought}, \textit{shares})$, $(\textit{bought}, \textit{in})$, and $(\textit{bought}, \textit{yesterday})$, while the corresponding sibling dependencies are $(\textit{bought}, \textit{shares})$, $(\textit{shares}, \textit{in})$, and $(\textit{in}, \textit{yesterday})$.

4.3 Mixed Models

The different hidden–variable models display varying strengths and weaknesses. We created mixtures of different models using a weighted average:

$$\log p(t_{i,j}|s_i) = \sum_{m=1}^{M} \lambda_m \log p_m(t_{i,j}|s_i, \Theta_m) - Z(s_i)$$

where $Z(s_i)$ is a normalization constant that can be ignored, as it does not affect the ranking of parses. The λ_m weights are determined through optimization of parsing scores on a development set.

5 Experimental Results

We trained and tested the model on data from the Penn Treebank (Marcus et al., 1994). Candidate parses were produced by an N–best version of the Collins (1999) parser. Our training data consists of Treebank Sections 2–21, divided into a training corpus of 35,540 sentences and a development corpus of 3,676 sentences. In later experiments, we made use of a secondary development corpus of 1,914 sentences from Section 0. Sections 22–24, containing 5,455 sentences, were held out as the test set.

For each of the eight feature sets described in Section 4.2, we used the stochastic gradient descent

	Section 22		Section 23		Section 24		Total	
	LR	**LP**	**LR**	**LP**	**LR**	**LP**	**LR**	**LP**
C99	89.12	89.20	88.14	88.56	87.17	87.97	88.19	88.60
MIX	90.43	90.61	89.25	89.69	88.46	89.29	89.41	89.87
C2K	90.27	90.62	89.43	89.97	88.56	89.58	89.46	90.07
MIX+	90.57	90.79	89.80	90.27	88.78	89.73	89.78	90.29

Table 1: The results on Sections 22–24. **LR** = Labeled Recall, **LP** = Labeled Precision.

method to optimize the parameters of the model. We created various mixtures of the eight models using the weighted–average technique described in Section 4.3, testing the accuracy of each mixture on the secondary development set. Our final model was a mixture of three of the eight possible models: supersense hidden values with sibling trees, lexical hidden values with sibling trees, and highest nonterminal hidden values with normal head–modifier trees.

Our final tests evaluated four models. The two baseline models are the Collins (1999) base parser, C99, and the Collins (2000) reranker, C2K. The first new model is the MIX model, which is a combination of the C99 base model with the three models described above. The second new model, MIX+, is created by augmenting MIX with features from the method in C2K. Table 1 shows the results. The MIX model obtains an F–measure improvement of $\approx 1.25\%$ over the C99 baseline, an improvement that is comparable to the C2K reranker. The MIX+ model yields an improvement of $\approx 0.25\%$ beyond C2K.

We tested the significance of 8 comparisons corresponding to the results in Table 1 using the sign test[4]: we tested MIX vs. C99 on Sections 22, 23, and 24 individually, as well as on Sections 22–24 taken as a whole; we also tested MIX+ vs. C2K on these 4 test sets. Of the 8 comparisons, all showed significant improvements at the level $p \leq 0.01$ with the exception of one test, MIX+ vs. C2K on Section 24.

6 Discussion

6.1 Applying the Model to Other NLP Tasks

In this section, we discuss how hidden–variable models might be applied to other NLP problems, and in particular to structures other than parse trees. To summarize the model, the major components of the approach are as follows:

• We assume some set of candidate structures $t_{i,j}$, which are to be reranked by the model. Each structure $t_{i,j}$ has $n_{i,j}$ words $w_1, \ldots, w_{n_{i,j}}$, and each word w_k has a set $H_k(t_{i,j})$ of possible hidden values.

• We assume a graph $\mathbf{D}(t_{i,j})$ for each $t_{i,j}$ that defines possible interactions between hidden variables in the model. We assume some definition of local feature vectors, which consider either single hidden variables, or pairs of hidden variables that are connected by an edge in $\mathbf{D}(t_{i,j})$.

The approach can be instantiated in several ways when applying the model to other NLP tasks. We have already seen that by changing the definition of the hidden–value domains $H_k(t_{i,j})$, we can derive models with widely varying behavior. In addition, there is no requirement that the hidden variables only be associated with words in the structure; the hidden variables could be associated with other units. For example, in speech recognition hidden variables could be associated with phonemes rather than words, and in Chinese word segmentation, hidden variables could be associated with individual characters rather than words.

NLP tasks other than parsing involve structures $t_{i,j}$ that are not necessarily parse trees. For example, in speech recognition candidates are simply strings (utterances); in tagging tasks candidates are labeled sequences (e.g., sentences labeled with part–of–speech tag sequences); in machine translation candidate structures may be source–language/target–language pairs, along with alignment structures specifying the correspondence between words in the two languages. Sentences and labeled sequences are in a sense simplifications of the parsing case, where a natural choice for the underlying graph $\mathbf{D}(t_{i,j})$ would be an N^{th} order Markov structure, where each word depends on the previous N words. Machine translation alignments are a more interesting type of structure, where the choice of $\mathbf{D}(t_{i,j})$ might actually depend on the alignment between the two sentences.

As a final note, there is some flexibility in the choice of $\mathbf{D}(t_{i,j})$. In the case that $\mathbf{D}(t_{i,j})$ is a tree belief propagation is exact. In the more general case where $\mathbf{D}(t_{i,j})$ contains cycles, there are alternative algorithms that are either exact (Cowell et al., 1999) or approximate (Yedidia et al., 2003).

[4]The input to the sign test is a set of sentences with judgements for each sentence indicating whether model 1 gives a better parse than model 2, model 2 gives a better parse than model 1, or models 1 and 2 give equal quality parses. When using the sign test, for each sentence in question we calculate the F–measure at the sentence level for the two models being compared, deriving the required judgement from these scores.

6.2 Packed Representations and Locality

One natural extension of our reranker is to adapt it to candidate parses represented as a packed parse forest, so that it can operate on the base parser's full output instead of a limited N-best list. However, as we described in Section 3.1, our features are locally scoped with respect to hidden–variable interactions but unrestricted regarding information derived from the underlying candidate parses, which poses a problem for the use of packed representations. For instance, the Up/Down Path features (see Figure 2) enumerate the vertical sequences of nonterminals that extend above and below a given headword. We could restrict the features to local scope on the candidate parses, allowing dynamic–programming to be used to train the model with a packed representation. However, even with these restrictions, finding $\arg\max_t \sum_{\mathbf{h}} p(t, \mathbf{h} \mid s, \Theta)$ is NP–hard, and the Viterbi approximation $\arg\max_{t,\mathbf{h}} p(t, \mathbf{h} \mid s, \Theta)$ — or other approximations — would have to be used (see Matsuzaki et al. (2005)).

6.3 Empirical Analysis of the Hidden Values

Our model makes no assumptions about the interpretation of the hidden values assigned to words: during training, the model simply learns a distribution over global hidden–value assignments that is useful in improving the log–likelihood of the training data. Intuitively, however, we expect that the model will learn to make hidden–value assignments that are reasonable from a linguistic standpoint. In this section we describe some empirical observations concerning hidden values assigned by the model.

We established a corpus of parse trees with hidden–value annotations, as follows. First, we find the optimal parameters Θ^* on the training set. For every sentence s_i in the training set, we then use Θ^* to find t_i^*, the most probable candidate parse under the model. Finally, we use Θ^* to decode $\mathbf{h}_i^*$, the most probable global assignment of hidden values, for each parse tree t_i^*. We created a corpus of $(t_i^*, \mathbf{h}_i^*)$ pairs for the feature set defined by part–of–speech hidden–value domains and standard dependency structures. The remainder of this section describes trends for several of the most common part–of–speech categories in the corpus.

As a first example, consider the hidden values for the part–of–speech VB (infinitival verb). In the majority of cases, words tagged VB either modify a modal verb tagged MD (e.g., in *the new rate will/*MD *be/*VB *payable*) or the infinitival marker *to* (e.g., in *in an effort to streamline/*VB *bureaucracy*). The statistics of our corpus reflect this distinction. In 11,546 cases of the VB_1 hidden value, 10,652 cases modified *to*, and 81 cases modified modals tagged MD. In contrast, in 11,042 cases of the VB_2 value, the numbers were 8,354 and 599 for modification of modals and *to* respectively, showing the opposite preference. This polarization of hidden values allows modifiers to the VB (e.g., *payable* in *the new rate will be payable*) to be sensitive to whether the verb is modifying a modal or *to*.

In a related case, the hidden values for the part–of–speech TO (corresponding to the word *to*) also show that the model is learning useful structure. Consider cases where *to* heads a clause which may or may not have a subject (e.g., in *it expects* ⟨*its sales to remain steady*⟩ vs. *a proposal* ⟨*to ease reporting requirements*⟩). We find that for hidden values TO_1 and TO_5 together, 946 out of 976 cases have a subject. In contrast, for the hidden value TO_4, only 29 out of 10,148 cases have a subject. This splitting of the TO part–of–speech allows modifiers to *to*, or words modified by *to*, to be sensitive to the presence or absence of a subject in the clause headed by *to*.

Finally, consider the hidden values for the part–of–speech NNS (plural noun). In this case, the model distinguishes contexts where a plural noun acting as the head of a noun–phrase is or isn't modified by a post–modifier (such as a prepositional phrase or relative clause). For hidden value NNS_3, 12,003 out of the 12,664 instances in our corpus have a post–modifier, but for hidden value NNS_5, only 4,099 of the 39,763 occurrences have a post–modifier. Similar contextual effects were observed for other noun categories such as singular or proper nouns.

7 Conclusions and Future Research

The hidden–variable model is a novel method for representing NLP structures in the reranking framework. We can obtain versatile behavior from the model simply by manipulating the definition of the hidden–value domains, and we have experimented with models that emulate word clustering, word refinement, and mappings from words into an existing ontology. In the case of the parse reranking task, the hidden–variable model achieves reranking performance comparable to the reranking approach described by Collins (2000), and the two rerankers can be combined to yield an additive improvement.

Future work may consider the use of hidden–value domains with mixed contents, such as a domain that contains 3 refinement–oriented lexical values and 3 clustering–oriented part–of–speech values. These mixed values would allow the hidden–variable model to exploit interactions between clustering and refinement at the level of words and dependencies. Another area for future research is to investigate the use of unlabeled data within the approach, for example by making use of clusters derived from large amounts of unlabeled data (e.g., see Miller et al. (2004)). Finally, future work may apply the models to NLP tasks other than parsing.

Disambiguation of Morphological Structure using a PCFG

Helmut Schmid
Institute for Natural Language Processing (IMS)
University of Stuttgart

schmid@ims.uni-stuttgart.de

Abstract

German has a productive morphology and allows the creation of complex words which are often highly ambiguous. This paper reports on the development of a head-lexicalized PCFG for the disambiguation of German morphological analyses. The grammar is trained on unlabeled data using the Inside-Outside algorithm. The parser achieves a precision of more than 68% on difficult test data, which is 23% more than the baseline obtained by randomly choosing one of the simplest analyses. Remarkable is the fact that precision drops to 52% without lexicalization.

1 Introduction

German words may be as complex as the following title of a bill: *Rindfleischetikettierungs-überwachungsaufgabenübertragungsgesetz* (law for the transfer of the task of controlling the labeling of beef). The complexity is due to the productive morphological processes of derivation (e.g. *Etikettierung* (labeling) = *Etikett* (label) + *ier* (derivational suffix) + *ung* (nominalization suffix)) and compounding (e.g. *Rindfleisch* (beef) = *Rind* (cattle) + *Fleisch* (meat)). For many words, there is more than one possible analysis. The German SMOR morphology (Schmid et al., 2004) e.g. generates 24 analyses for the word *Abteilungen*. If differences in the case feature are ignored, there are still six analyses, all of them plural:

- *Abt* (abbot) *Ei* (egg) *Lunge* (lung) *n* (plural inflectional ending)
- *Abt* (abbot) *ei* (abbot → abbey) *Lunge* (lung) *n* (plural inflectional ending)
- *Abt* (abbot) *eil* (hurry) *ung* (nominalization suffix) *en* (plural inflectional ending)
- *Abtei* (abbey) *Lunge* (lung) *n* (plural inflectional ending)
- *Abteilung* (department) *en* (plural inflectional ending)
- *ab* (separable verb prefix) *teil* (divide) *ung* (nominalization suffix) *en* (plural inflectional ending)

Here – and in many other cases, as well – the least complex analysis (defined as the number of derivation and compounding steps), namely the plural of *Abteilung* (department), is the correct one. This heuristic is not always successful, however. The word *Reisende* e.g. is analyzed as the compound of *Reis* (rice) + *Ende* (end), and alternately as the nominalization of the present participle *reisend* (traveling). The latter one is correct although it requires two derivational steps (formation of the participle plus nominalization), while the former requires only one compounding step.

The least complex analysis is not necessarily unique. One reason is, that German word forms are often ambiguous wrt. number, gender and case. The adjective *kleine* (small) e.g. receives 7 analyses by SMOR which differ only in the agreement features.

Another reason is that word forms are ambiguous wrt. the part of speech. The word *gerecht* e.g. is either an adjective (fair) or the past participle of the verb *rechen* (to rake). Similarly, the word *gerade* is either an adjective (straight) or an adverb (just). These ambiguities can be resolved based on the context e.g. with a part-of-speech tagger.

Other types of ambiguities are not disambiguated by the syntactic context because the morphosyntactic features are invariant. Compounds with three elements like *Sonderpreisliste*, for instance, are systematically ambiguous between a left-branching (list of special prices) and a right-branching structure (special price-list), but unambiguous regarding their part of speech and agreement features. Some word forms like *Schmerzfreiheit* (absence of pain) can either be analyzed as derivations (schmerzfrei-heit – "painless-ness") or as compounds (Schmerz-freiheit – "pain freedom"). Again, there is no difference in the morphosyntactic features. A further source of ambiguity are the stems: Consider the word *Mittelzuweisung* (allocation of resources). The compounding stem *mittel* could either originate from the adjective *mittel* (average) or from the noun *Mittel* (means). All these ambiguities are not resolvable by the syntactic context because their syntactic properties are identical. However, most of these words have a preferred reading. *Nah verkehrs zug* (commuter train) e.g. is likely to have a left-branching structure, whereas the correct analysis of *Computer bild schirm* (computer monitor) is right-branching.

Considering these features of German morphology, the following disambiguation strategy for morphological ambiguities is proposed: Frequent words should be manually disambiguated and the correct analysis/analyses should be explicitly stored in the lexicon. Ambiguities involving different morphosyntactic features should be resolved by a tagger or parser. The elimination of the remaining ambiguities, namely ambiguities of rare words which are not reflected by the morphosyntactic features, requires a different method. A general strategy is to generate the set of possible analyses, to rank them according to some criterion and to return the best analysis (or analyses). One very simple ranking criterion is the complexity of the analysis e.g. measured by the number of derivational and compounding steps. We will use this criterion as a baseline to which we compare our method.

Given an FST-based morphological analyzer and a training corpus consisting of manually disambiguated analyses, it is also possible to estimate transition probabilities for the finite state transducer and to disambiguate by choosing the most probable path through the transducer network for a given word. A drawback of this approach is the limitation of the type of analyses that finite state transducers can generate. A finite state transducer maps a regular language, the set of word forms, to another regular language, the set of analyses. Therefore it is not able to produce structured analyses as shown in figure 1 (for arbitrary depths). It also fails to represent non-local dependencies, like the one between *Vertrag* (contract) and *Lösung* (solution) in the second analysis of figure 1.

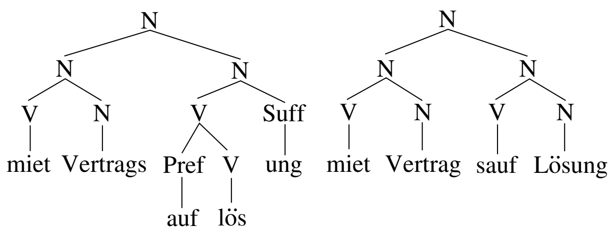

Figure 1: Two morphological analyses of the German word *Mietvertragsauflösung* (leasing contract cancellation); the first one is correct.

Given the limitations of weighted finite-state transducers, we propose to use a more powerful formalism, namely head-lexicalized probabilistic context-free grammars (Carroll and Rooth, 1998; Charniak, 1997) to rank the analyses. Context-free grammars have, of course, no difficulties to generate the analyses shown in figure 1. By assigning probabilities to the grammar rules, we obtain a probabilistic context-free grammar (PCFG) which allows the parser to distinguish between frequent and rare morphological constructions. Nouns e.g. are much more likely to be compounds than verbs. In head-lexicalized PCFGs (HL-PCFGs), the probability of a rule also depends on the lexical head of the constituent. HL-PCFGs are therefore able to learn that nouns headed by *Problem* (problem) are more likely to be compounds (e.g. *Schulprobleme* (school problems)) than nouns headed by *Samstag* (Saturday). Moreover, HL-PCFGs represent lexical dependencies like that between *Vertrag* and *Lösung* in figure 1.

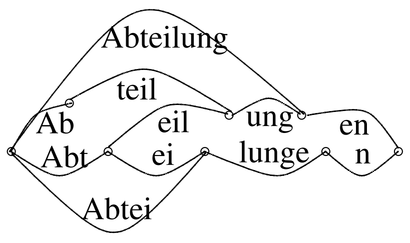

Figure 2: Morpheme lattice

In this paper, we present a HL-PCFG-based disambiguator for German. Using the SMOR morphological analyzer, the input words are first split into morpheme sequences and then analyzed with a HL-PCFG parser. Due to ambiguities, the parser's input is actually a lattice rather than a sequence (see the example in figure 2).

The rest of the paper is organized as follows: In section 2, we briefly review head-lexicalized PCFGs. Section 3 summarizes some important features of SMOR. The development of the grammar will be described in section 4. Section 5 explains the training strategy, and section 6 reports on the annotation of the test data. Section 7 presents the results of an evaluation, section 8 comments on related work, and section 9 summarizes the main points of the paper. Finally, section 10 gives an outlook on future work.

2 Head-Lexicalized PCFGs

A *head-lexicalized parse tree* is a parse tree in which each constituent is labeled with its category and its *lexical head*. The lexical head of a terminal symbol is the symbol itself and the lexical head of a non-terminal symbol is the lexical head of its (unique) head child.

In a head-lexicalized PCFG (HL-PCFG) (Carroll and Rooth, 1998; Charniak, 1997), one symbol on the right-hand side of each rule is marked as the head. A HL-PCFG assumes that (i) the probability of a rule depends on the category **and the lexical head** of the expanded constituent and (ii) that the lexical head of a non-head node depends on its own category, and the category and the lexical head of the parent node. The probability of a head-lexicalized parse tree is therefore:

$$p_{start}(cat(root))\ p_{start}(head(root)|cat(root)) *$$
$$\prod_{n \in N} p_{rule}(rule(n)|cat(n), head(n)) *$$
$$\prod_{n \in A} p_{head}(head(n)|cat(n), pcat(n), phead(n))$$

where

$root$ is the root node of the parse tree
$cat(n)$ is the syntactic category of node n
$head(n)$ is the lexical head of node n
$rule(n)$ is the grammar rule which expands node n
$pcat(n)$ is the syntactic category of the parent of n
$phead(n)$ is the lexical head of the parent of n

HL-PCFGs have a large number of parameters which need to estimated from training data. In order to avoid sparse data problems, the parameters usually have to be smoothed. HL-PCFGs can either be trained on labeled data (supervised training) or on unlabeled data (unsupervised training) using the Inside-Outside algorithm, an instance of the EM algorithm. Training on labeled data usually gives better results, but it requires a treebank which is expensive to create. In our experiments, we used unsupervised training with the LoPar parser which is available at http://www.ims.uni-stuttgart.de/projekte/gramotron/SOFTWARE/LoPar-en.html.

3 SMOR

SMOR (Schmid et al., 2004) is a German FST-based morphological analyzer which covers inflection, compounding, and prefix as well as suffix derivation. It builds on earlier work reported in (Schiller, 1996) and (Schmid et al., 2001).

SMOR uses features to represent derivation constraints. German derivational suffixes select their base in terms of part of speech, the stem type (derivation or compounding stem)[1], the origin (native, classical, foreign), and the structure (simplex, compound, prefix derivation, suffix derivation) of the stem which they combine with. This information is encoded with features. The German derivation suffix *lich* e.g. combines with a simplex derivation stem of a native noun to form an adjective. The feature constraints of *lich* are therefore (1) part of speech = NN (2) stem type = deriv (3) origin = native and (4) structure = simplex.

[1]Suffixes which combine with compounding stems historically evolved from compounding constructions.

4 The Grammar

The grammar used by the morphological disambiguator has a small set of rather general categories for prefixes (P), suffixes (S), uninflected base stems (B), uninflected base suffixes (SB), inflectional endings (F) and other morphemes (W). There is only one rule for compounding and prefix and suffix derivation, respectively, and two rules for the stem and suffix inflection. Additional rules introduce the start symbol TOP and generate special word forms like hyphenated (*Thomas-Mann-Straße*) or truncated words (*Vor-*). Overall, the base grammar has 13 rules. Inflection is always attached low in order to avoid spurious ambiguities. The part of speech is encoded as a feature.

Like SMOR, the grammar encodes derivation constraints with features. Number, gender and case are not encoded. Ambiguities in the agreement features are therefore not reflected in the parses which the grammar generates. This allows us to abstract away from this type of ambiguity which cannot be resolved without contextual information. If some application requires agreement information, it has to be reinserted after disambiguation.

The feature grammar is compiled into a context-free grammar with 1973 rules. In order to reduce the grammar size, the features for origin and complexity were not compiled out. Figure 3 shows a compounding rule (building a noun base stem from a noun compounding stem and a noun base stem), a suffix derivation rule (building an adjective base stem from a noun derivation stem and a derivation suffix), a prefix derivation rule (prefixing a verbal compounding stem) and two inflection rules (for the inflection of a noun and a nominal derivation suffix, respectively) from the resulting grammar. The quote symbol marks the head of a rule.

W.NN.base → W.NN.compound W.NN.base'
W.ADJ.base → W.NN.deriv S.NN.deriv.ADJ.base
W.V.compound → P.V W.V.compound'
W.NN.base → B.NN.base' F.NN
S.ADJ.deriv.NN.base → SB.ADJ.deriv.NN.base' F.NN

Figure 3: Some rules from the context-free grammar

The parser retrieves the categories of the morphemes from a lexicon which also contains information about the standard form of a morpheme. The representation of the morphemes returned by the FST-based word splitter is close to the surface form. Only capitalization is taken over from the standard form. The adjective *ursächlich* (causal), for instance, is split into *Ursäch* and *lich*. The lexicon assigns to *Ursäch* the category *W.NN.deriv* and the standard form *Ursache* (cause).

5 PCFG Training

PCFG training normally requires manually annotated training data. Because a treebank of German morphological analyses was not available, we decided to try unsupervised training using the Inside-Outside algorithm (Lari and Young, 1990). We worked with unlexicalized as well as head-lexicalized PCFGs (Carroll and Rooth, 1998; Charniak, 1997). The lexicalized models used the standard form of the morphemes (see the previous section) as heads.

The word list from a German 300 million word newspaper corpus was used as training data. From the 3.2 million tokens in the word list, SMOR successfully analyzed 2.3 million tokens which were used in the experiment. Training was either type-based (with each word form having the same weight) or token-based (with weights proportional to the frequency). We experimented with uniform and non-uniform initial distributions. In the uniform model, each rule had an initial frequency of 1 from which the probabilities were estimated. In the non-uniform model, the frequency of two classes of rules was increased to 1000. The first class are the rules which expand the start symbol TOP to an adjective or adverb, leading to a preference of these word classes over other word classes, in particular verbs. The second class is formed by rules generating inflectional endings, which induces a preference for simpler analyses.

6 Test Data

The test data was extracted from a corpus of the German newspaper *Die Zeit* which was not part of the training corpus. We prepared two different test corpora. The first test corpus (data1) consisted of 425 words extracted from a randomly selected part of the corpus. We only extracted words with at least one letter which were ambiguous (ignoring ambiguities in number, gender and case) and either nouns, verbs or adjectives and not from the beginning of a sentence. Duplicates were retained. The words were parsed and manually disambiguated. We looked at the context of a word, where this was necessary for disambiguation. Words without a correct analysis were deleted.

In order to obtain more information on the types of ambiguity and their frequency, 200 words were manually classified wrt. the class of the ambiguity. The following results were obtained:

- 39 words (25%) were ambiguous between an adjective and a verb like *gerecht* - "just" (adjective) vs. past participle of *rechen* (to rake).
- 28 words (18%) were ambiguous between a noun and a proper name like *Mann* - "man" vs. *Thomas Mann*
- 19 words were ambiguous between an adjective and an adverb like *gerade* - "straight" vs. "just" (adverb)
- 14 words (9%) showed a complex ambiguity involving derivation and compounding like the word *überlieferung* (tradition) which is either a nominalization of the prefix verb *überliefern* (to bequeath) or a compound of the stems *über* (over) and *Lieferung* (delivery).
- 13 words (8%) were compounds which were ambiguous between a left-branching and a right-branching structure like *Welt rekord höhe* (world record height)
- In 10 words (5%), there was an ambiguity between an adjective and a proper name or noun stem - as in *Höchstleistung* (maximum performance) where *höchst* can be derived from the proper name *Höchst* (a German city) or the superlative *höchst* (highest)
- 6 words (3%) showed a systematic ambiguity between an adjective and a noun caused by adding the suffix *er* to a city name, like *Moskauer* - "Moskau related" vs. "person from Moskau"
- Another 6 words were ambiguous between two different noun stems like *Halle* which is either singular form of *Halle* (hall) or the plural form of *Hall* (reverberation)

Overall 50% of the ambiguities involved a part-of-speech ambiguity.

The second set of test data (data2) was designed to contain only infrequent words which were not ambiguous wrt. part of speech. It was extracted from the same newspaper corpus. Here, we excluded words which were (1) sentence-initial (in order to avoid problems with capitalized words) (2) not analyzed by SMOR (3) ambiguous wrt. part of speech (4) from closed word classes or (5) simplex words. Furthermore, we extracted only words with more than one simplest[2] analysis, in order to make the test data more challenging. The extracted words were sorted by frequency and a block of 1000 word forms was randomly selected from the lower frequency range. All of them had occurred 4 times. We focussed on rare words because frequent words are better disambiguated manually and stored in a table (see the discussion in the introduction).

The 1000 selected word forms were parsed and manually disambiguated. 193 problematic words were deleted from the evaluation set because either (1) no analysis was correct (e.g. *Elsevier*, which was not analyzed as a proper name) or (2) there was a true ambiguity (e.g. *Rottweiler* which is either a dog breed or a person from the city of Rottweil or (3) the lemma was not unique (*Drehtür* (revolving door) could be lemmatized to *Drehtür* or *Drehtüre* with no difference in meaning.) or (4) several analyses were equivalent. The disambiguation was often difficult. Even among the words retained in the test set, there were many that we were not fully sure about. An example is the compound *Natur eis bahn* ("natural ice rink") which we decided to analyze as *Natur-Eisbahn* (nature ice-rink) rather than *Natureis-Bahn* (nature-ice rink).

7 Results

The parser was trained using the Inside-Outside algorithm. By default, (a) the initialization of the rule

[2]The complexity of an analysis is measured by the number of derivation and compounding steps.

probabilities was non-uniform as described in section 5, (b) training was based on tokens (i.e. the frequency of the training items was taken into account), and (c) all training iterations were lexicalized. Training was quite fast. One training iteration on 2.3 million word forms took about 10 minutes on a Pentium IV running at 3 GHz.

Figure 4 shows the exact match accuracy of the Viterbi parses depending on the number of training iterations, which ranges from 0 (the initial, untrained model) to 15. For comparison, a baseline result is shown which was obtained by selecting the set of simplest analyses and choosing one of them at random[3]. The baseline accuracy was 45.3%. The parsing accuracy of the default model jumps from a starting value of 41.8% for the untrained model (which is below the baseline) to 58.5% after a single training iteration. The peak performance is reached after 8 iterations with 65.4%. The average accuracy of the models obtained after 6-25 iterations is 65.1%.

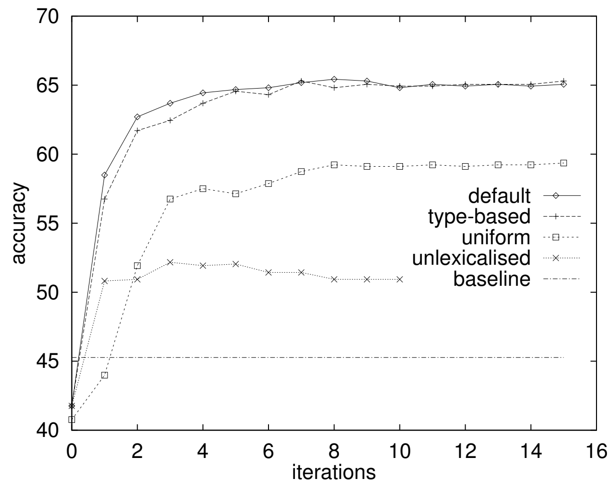

Figure 4: Exact match accuracy on data2

Results obtained with type-based training, where each word receives the same weight ignoring its frequency, were virtually identical to those of the default model. If the parser training was started with a uniform initial model, however, the accuracy dropped by about 6 percentage points. Figure 4 also shows that the performance of an unlexicalized PCFG is about 13% lower.

We also experimented with a combination of unlexicalized and lexicalized training. Lexicalized models have a huge number of parameters. Therefore, there is a large number of locally optimal parameter settings to which the unsupervised training can be attracted. Purely lexicalized training is likely to get stuck in a local optimum which is close to the starting point. Unlexicalized models, on the other hand, have fewer parameters, a smaller number of local optima and a smoother search space. Unlexicalized training is therefore more likely to reach a globally (near-)optimal point and provides a better starting point for the lexicalized training.

Figure 5 shows that initial unlexicalized training indeed improves the accuracy of the parser. With one iteration of unlexicalized training (see "unlex 1" in figure 5), the accuracy increased by about 3%. The maximum of 68.4% was reached after 4 iterations of lexicalized training. The results obtained with 2 iterations of unlexicalized training were very similar. With 3 iterations, the performance dropped almost to the level of the default model. It seems that some of the general preferences learned during unlexicalized training are so strong after three iterations that they cannot be overruled anymore by the lexeme-specific preferences learned in the lexicalized training.

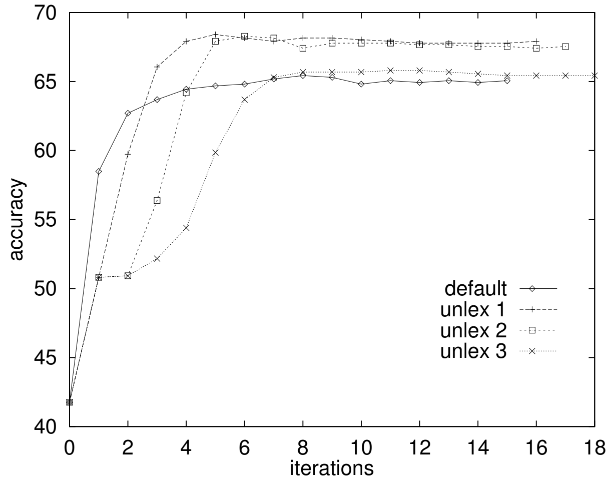

Figure 5: Results on data2 with 0 (default), 1, 2, or 3 iterations of unlexicalized training, followed by lexicalized training

In order to assess the parsing results qualitatively,

[3]In fact, we counted a word with n simplest analyses as $1/n$ correct instead of actually selecting one analysis at random, in order to avoid a dependency of the baseline result on the random number generation.

100 parsing errors of version “unlex 2” were randomly selected and inspected. It turned out that the parser always preferred right-branching structures over left-branching structures in complex compounds with three or more elements, which resulted in 57 errors caused by left-branching structures. Grammars trained without the initial unlexicalized training showed no systematic preference for right-branching structures. In the test data, left-branching structures were two times more frequent than right-branching structures.

29 disambiguation errors resulted from selecting the wrong stem although the structure of the analysis was otherwise correct. In the word *Rechtskonstruktion* (legal construction), for instance, the first element *Rechts* was derived from the adjective *rechts* (right) rather than the noun *Recht* (law). Similarly, the adjective *quelloffen* (open-source) was derived from the verb *quellen* (to swell) rather than the noun *Quelle* (source).

Six errors involved a combination of compounding and suffix derivation (e.g. the word *Flugbegleiterin* (stewardess)). The parser preferred the analysis where the derivation is applied first (*Flug-Begleiterin* (flight attendant[female])), whereas in the gold standard analysis, the compound is formed first (*Flugbegleiter-in* (steward-ess).

In order to better understand the benefits of unlexicalized training, we also examined the differences between the best model obtained with one iteration of unlexicalized (unlex1), and the best model obtained without unlexicalized training (default).

30 cases involved left-branching vs. right-branching compounds. The unlex1 model showed a higher preference for right-branching structures than the default model, but produced also left-branching structures (unlike the model unlex2). In 15 of the 30 cases, unlex1 correctly decided for a right-branching structure; in 13 cases, unlex1 was wrong with proposing a right-branching structure. In two cases, unlex1 correctly predicted a left-branching structure and the default model predicted a right-branching structure.

32 differences were caused by lexical ambiguities. In 24 cases, only one stem was ambiguous. 15 times unlex1 was right (e.g. *Moskaureise* - Moskow trip[sg] vs. Moskow rice[pl]) and nine times the default model was right (e.g. *Jodtabletten* - iodine pill vs. iodine tablet). In 8 cases, two morphemes were involved in the ambiguity. In all these cases, unlex1 generated the correct analysis (e.g. *Sportraum* - “sport room” vs. “Spor[name] dream”).

Nine ambiguities involved the length of verb prefixes. Six times, unlex1 correctly decided for a longer prefix (e.g. *gegenüber-stehen* (to face) instead of *gegen-überstehen* (to “counter-survive”).

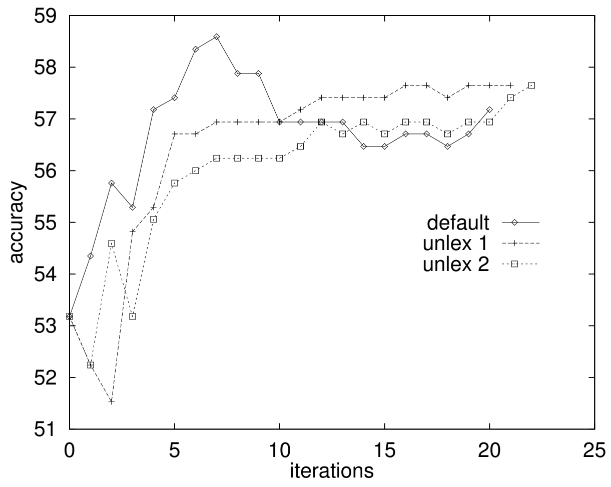

Figure 6: Accuracy on data1 after 0, 1, or 2 iterations of unlexicalized training followed by lexicalized training

In another experiment, we tested the parser on the first test data set (data1) where simplex words, part-of-speech ambiguities, frequent words and repeated occurrences were not removed. The baseline accuracy on this data was 43.75%. Figure 6 shows the results obtained with different numbers of unlexicalized training iterations analogous to figure 5. Strictly lexicalized training produced the best results, here. The maximal accuracy was 58.59% which was obtained after 7 iterations. In contrast to the experiments on data2, the accuracy decreased by more than 1.5% when the training was continued. As said in the introduction, we think that part-of-speech ambiguities are better resolved by a part-of-speech tagger and that frequent words can be disambiguated manually.

8 Related Work

New methods are often first developed for English and later adapted to other languages. This might explain why morphological disambiguation has been so rarely addressed in the past: English morphology is seldom ambiguous except for noun compounds.

We are not aware of any work on the disambiguation of morphological analyses which is directly comparable to ours. Mark Lauer (1995) only considered English noun compounds and applied a different disambiguation strategy based on word association scores.

Koehn and Knight (2003) proposed a splitting method for German compounds and showed that it improves statistical machine translation. Compounds are split into smaller pieces (which have to be words themselves) if the geometric mean of the word frequencies of the pieces is higher than the frequency of the compound. Information from a bilingual corpus is used to improve the splitting accuracy.

Andreas Eisele (unpublished work) implemented a statistical disambiguator for German based on weighted finite-state transducers as described in the introduction. However, his system fails to represent and disambiguate the ambiguities observed in compounds with three or more elements and similar constructions with structural ambiguities.

9 Summary

We presented a disambiguation method for German morphological analyses which is based on a head-lexicalized probabilistic context-free grammar. The words are split into morpheme lattices by a finite state morphology, and then parsed with the probabilistic context-free grammar. The grammar was trained on unlabeled data using the Inside-Outside algorithm and evaluated on 807 manually disambiguated analyses of infrequent words. Different training strategies have been compared. A combination of one iteration of unlexicalized training and four iterations of lexicalized training returned the best results with over 68% exact match accuracy, compared to a baseline of 45% which was obtained by randomly choosing one of the minimally complex analyses. Without lexicalization, the accuracy dropped by 15 percentage points, indicating that lexicalization is essential for morphological disambiguation.

10 Future Work

There are several starting points for improvement. Guidelines should be developed for the manual annotation of data in order to make it less dependent on the annotator's intuitions. More data should be annotated to create a treebank of morphological analyses. Given such a treebank, the parser could be trained on labeled data or on a combination of labeled and unlabeled data, which presumably would further increase the parsing accuracy.

Abstract

We formalize weighted dependency parsing as searching for maximum spanning trees (MSTs) in directed graphs. Using this representation, the parsing algorithm of Eisner (1996) is sufficient for searching over all projective trees in $O(n^3)$ time. More surprisingly, the representation is extended naturally to non-projective parsing using Chu-Liu-Edmonds (Chu and Liu, 1965; Edmonds, 1967) MST algorithm, yielding an $O(n^2)$ parsing algorithm. We evaluate these methods on the Prague Dependency Treebank using online large-margin learning techniques (Crammer et al., 2003; McDonald et al., 2005) and show that MST parsing increases efficiency and accuracy for languages with non-projective dependencies.

1 Introduction

Dependency parsing has seen a surge of interest lately for applications such as relation extraction (Culotta and Sorensen, 2004), machine translation (Ding and Palmer, 2005), synonym generation (Shinyama et al., 2002), and lexical resource augmentation (Snow et al., 2004). The primary reasons for using dependency structures instead of more informative lexicalized phrase structures is that they are more efficient to learn and parse while still encoding much of the predicate-argument information needed in applications.

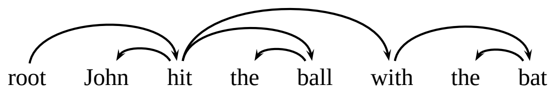

Figure 1: An example dependency tree.

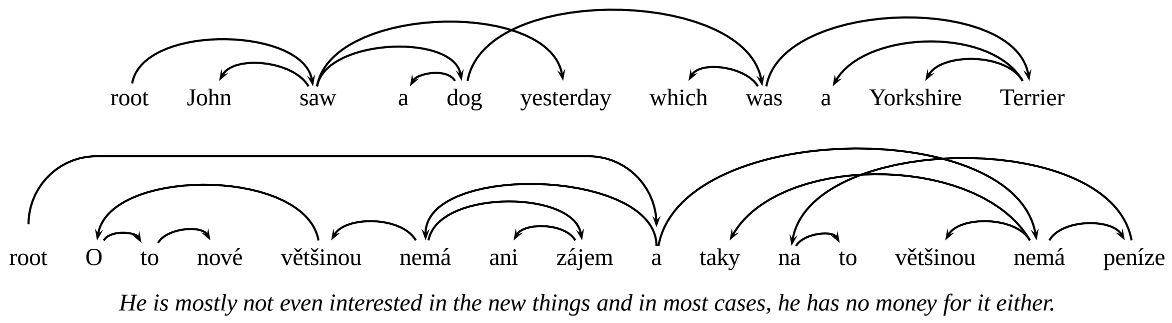
Dependency representations, which link words to their arguments, have a long history (Hudson, 1984). Figure 1 shows a dependency tree for the sentence *John hit the ball with the bat*. We restrict ourselves to *dependency tree* analyses, in which each word depends on exactly one parent, either another word or a dummy root symbol as shown in the figure. The tree in Figure 1 is *projective*, meaning that if we put the words in their linear order, preceded by the root, the edges can be drawn above the words without crossings, or, equivalently, a word and its descendants form a contiguous substring of the sentence.

In English, projective trees are sufficient to analyze most sentence types. In fact, the largest source of English dependency trees is automatically generated from the Penn Treebank (Marcus et al., 1993) and is by convention exclusively projective. However, there are certain examples in which a non-projective tree is preferable. Consider the sentence *John saw a dog yesterday which was a Yorkshire Terrier*. Here the relative clause *which was a Yorkshire Terrier* and the object it modifies (the *dog*) are separated by an adverb. There is no way to draw the dependency tree for this sentence in the plane with no crossing edges, as illustrated in Figure 2. In languages with more flexible word order than English, such as German, Dutch and Czech, non-projective dependencies are more frequent. Rich inflection systems reduce reliance on word order to express



root John saw a dog yesterday which was a Yorkshire Terrier
root O to nové většinou nemá ani zájem a taky na to většinou nemá peníze
He is mostly not even interested in the new things and in most cases, he has no money for it either.

Figure 2: Non-projective dependency trees in English and Czech.

grammatical relations, allowing non-projective dependencies that we need to represent and parse efficiently. A non-projective example from the Czech Prague Dependency Treebank (Hajič et al., 2001) is also shown in Figure 2.

Most previous dependency parsing models have focused on projective trees, including the work of Eisner (1996), Collins et al. (1999), Yamada and Matsumoto (2003), Nivre and Scholz (2004), and McDonald et al. (2005). These systems have shown that accurate projective dependency parsers can be automatically learned from parsed data. However, non-projective analyses have recently attracted some interest, not only for languages with freer word order but also for English. In particular, Wang and Harper (2004) describe a broad coverage non-projective parser for English based on a hand-constructed constraint dependency grammar rich in lexical and syntactic information. Nivre and Nilsson (2005) presented a parsing model that allows for the introduction of non-projective edges into dependency trees through learned edge transformations within their memory-based parser. They test this system on Czech and show improved accuracy relative to a projective parser. Our approach differs from those earlier efforts in searching optimally and efficiently the full space of non-projective trees.

The main idea of our method is that dependency parsing can be formalized as the search for a maximum spanning tree in a directed graph. This formalization generalizes standard projective parsing models based on the Eisner algorithm (Eisner, 1996) to yield efficient $O(n^2)$ exact parsing methods for non-projective languages like Czech. Using this spanning tree representation, we extend the work of McDonald et al. (2005) on online large-margin discriminative training methods to non-projective dependencies.

The present work is related to that of Hirakawa (2001) who, like us, reduces the problem of dependency parsing to spanning tree search. However, his parsing method uses a branch and bound algorithm that is exponential in the worst case, even though it appears to perform reasonably in limited experiments. Furthermore, his work does not adequately address learning or measure parsing accuracy on held-out data.

Section 2 describes an edge-based factorization of dependency trees and uses it to equate dependency parsing to the problem of finding maximum spanning trees in directed graphs. Section 3 outlines the online large-margin learning framework used to train our dependency parsers. Finally, in Section 4 we present parsing results for Czech. The trees in Figure 1 and Figure 2 are untyped, that is, edges are not partitioned into types representing additional syntactic information such as grammatical function. We study untyped dependency trees mainly, but edge types can be added with simple extensions to the methods discussed here.

2 Dependency Parsing and Spanning Trees

2.1 Edge Based Factorization

In what follows, $\boldsymbol{x} = x_1 \cdots x_n$ represents a generic input sentence, and $\boldsymbol{y}$ represents a generic dependency tree for sentence $\boldsymbol{x}$. Seeing $\boldsymbol{y}$ as the set of tree edges, we write $(i, j) \in \boldsymbol{y}$ if there is a dependency in $\boldsymbol{y}$ from word x_i to word x_j.

In this paper we follow a common method of factoring the score of a dependency tree as the sum of the scores of all edges in the tree. In particular, we define the score of an edge to be the dot product between a high dimensional feature representation of the edge and a weight vector,

$$s(i, j) = \mathbf{w} \cdot \mathbf{f}(i, j)$$

Thus the score of a dependency tree $\boldsymbol{y}$ for sentence $\boldsymbol{x}$ is,

$$s(\boldsymbol{x}, \boldsymbol{y}) = \sum_{(i,j)\in\boldsymbol{y}} s(i, j) = \sum_{(i,j)\in\boldsymbol{y}} \mathbf{w} \cdot \mathbf{f}(i, j)$$

Assuming an appropriate feature representation as well as a weight vector **w**, dependency parsing is the task of finding the dependency tree $\boldsymbol{y}$ with highest score for a given sentence $\boldsymbol{x}$.

For the rest of this section we assume that the weight vector **w** is known and thus we know the score $s(i, j)$ of each possible edge. In Section 3 we present a method for learning the weight vector.

2.2 Maximum Spanning Trees

We represent the generic directed graph $G = (V, E)$ by its vertex set $V = \{v_1, \dots, v_n\}$ and set $E \subseteq [1 : n] \times [1 : n]$ of pairs (i, j) of directed edges $v_i \to v_j$. Each such edge has a score $s(i, j)$. Since G is directed, $s(i, j)$ does not necessarily equal $s(j, i)$. A *maximum spanning tree* (MST) of G is a tree $\boldsymbol{y} \subseteq E$ that maximizes the value $\sum_{(i,j)\in\boldsymbol{y}} s(i, j)$ such that every vertex in V appears in $\boldsymbol{y}$. The maximum *projective* spanning tree of G is constructed similarly except that it can only contain projective edges relative to some total order on the vertices of G. The MST problem for directed graphs is also known as the maximum arborescence problem.

For each sentence $\boldsymbol{x}$ we define the directed graph $G_{\boldsymbol{x}} = (V_{\boldsymbol{x}}, E_{\boldsymbol{x}})$ given by

$$\begin{aligned} V_{\boldsymbol{x}} &= \{x_0 = \text{root}, x_1, \dots, x_n\} \\ E_{\boldsymbol{x}} &= \{(i, j) : i \neq j, (i, j) \in [0 : n] \times [1 : n]\} \end{aligned}$$

That is, $G_{\boldsymbol{x}}$ is a graph with the sentence words and the dummy root symbol as vertices and a directed edge between every pair of distinct words and from the root symbol to every word. It is clear that dependency trees for $\boldsymbol{x}$ and spanning trees for $G_{\boldsymbol{x}}$ coincide, since both kinds of trees are required to be rooted at the dummy root and reach all the words in the sentence. Hence, finding a (projective) dependency tree with highest score is equivalent to finding a maximum (projective) spanning tree in $G_{\boldsymbol{x}}$.

```
Chu-Liu-Edmonds($G, s$)
    Graph $G = (V, E)$
    Edge weight function $s : E \to \mathbb{R}$
1.  Let $M = \{(x^*, x) : x \in V, x^* = \arg\max_{x'} s(x', x)\}$
2.  Let $G_M = (V, M)$
3.  If $G_M$ has no cycles, then it is an MST: return $G_M$
4.  Otherwise, find a cycle $C$ in $G_M$
5.  Let $G_C$ = contract$(G, C, s)$
6.  Let $\boldsymbol{y}$ = Chu-Liu-Edmonds$(G_C, s)$
7.  Find a vertex $x \in C$ s. t. $(x', x) \in \boldsymbol{y}, (x'', x) \in C$
8.  return $\boldsymbol{y} \cup C - \{(x'', x)\}$
contract($G = (V, E), C, s$)
1.  Let $G_C$ be the subgraph of $G$ excluding nodes in $C$
2.  Add a node $c$ to $G_C$ representing cycle $C$
3.  For $x \in V - C : \exists_{x' \in C}(x', x) \in E$
      Add edge $(c, x)$ to $G_C$ with
        $s(c, x) = \max_{x' \in C} s(x', x)$
4.  For $x \in V - C : \exists_{x' \in C}(x, x') \in E$
      Add edge $(x, c)$ to $G_C$ with
        $s(x, c) = \max_{x' \in C} [s(x, x') - s(a(x'), x') + s(C)]$
          where $a(v)$ is the predecessor of $v$ in $C$
          and $s(C) = \sum_{v \in C} s(a(v), v)$
5.  return $G_C$
```

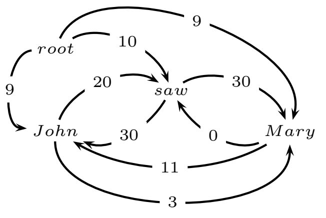
Figure 3: Chu-Liu-Edmonds algorithm for finding maximum spanning trees in directed graphs.

2.2.1 Non-projective Trees

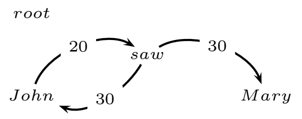
To find the highest scoring non-projective tree we simply search the entire space of spanning trees with no restrictions. Well-known algorithms exist for the less general case of finding spanning trees in undirected graphs (Cormen et al., 1990).

Efficient algorithms for the directed case are less well known, but they exist. We will use here the Chu-Liu-Edmonds algorithm (Chu and Liu, 1965; Edmonds, 1967), sketched in Figure 3 following Leonidas (2003). Informally, the algorithm has each vertex in the graph greedily select the incoming edge with highest weight. If a tree results, it must be the maximum spanning tree. If not, there must be a cycle. The procedure identifies a cycle and contracts it into a single vertex and recalculates edge weights going into and out of the cycle. It can be shown that a maximum spanning tree on the contracted graph is equivalent to a maximum spanning tree in the original graph (Leonidas, 2003). Hence the algorithm can recursively call itself on the new graph. Naively, this algorithm runs in $O(n^3)$ time since each recursive call takes $O(n^2)$ to find the highest incoming edge for each word and to contract the graph. There are at most $O(n)$ recursive calls since we cannot contract the graph more then n times. However, Tarjan (1977) gives an efficient implementation of the algorithm with $O(n^2)$ time complexity for dense graphs, which is what we need here.

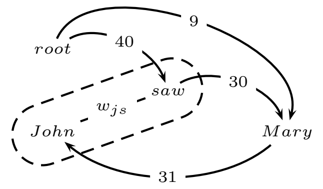
To find the highest scoring non-projective tree for a sentence, $\boldsymbol{x}$, we simply construct the graph $G_{\boldsymbol{x}}$ and run it through the Chu-Liu-Edmonds algorithm. The resulting spanning tree is the best non-projective dependency tree. We illustrate here the application of the Chu-Liu-Edmonds algorithm to dependency parsing on the simple example $\boldsymbol{x} =$ *John saw Mary*, with directed graph representation $G_{\boldsymbol{x}}$,



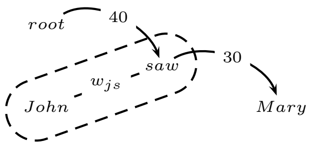
The first step of the algorithm is to find, for each word, the highest scoring incoming edge



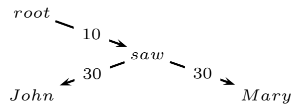
If the result were a tree, it would have to be the maximum spanning tree. However, in this case we have a cycle, so we will contract it into a single node and recalculate edge weights according to Figure 3.



The new vertex w_{js} represents the contraction of vertices *John* and *saw*. The edge from w_{js} to *Mary* is 30 since that is the highest scoring edge from any vertex in w_{js}. The edge from *root* into w_{js} is set to 40 since this represents the score of the best spanning tree originating from *root* and including only the vertices in w_{js}. The same leads to the edge from *Mary* to w_{js}. The fundamental property of the Chu-Liu-Edmonds algorithm is that an MST in this graph can be transformed into an MST in the original graph (Leonidas, 2003). Thus, we recursively call the algorithm on this graph. Note that we need to keep track of the real endpoints of the edges into and out of w_{js} for reconstruction later. Running the algorithm, we must find the best incoming edge to all words



This is a tree and thus the MST of this graph. We now need to go up a level and reconstruct the graph. The edge from w_{js} to *Mary* originally was from the word *saw*, so we include that edge. Furthermore, the edge from *root* to w_{js} represented a tree from *root* to *saw* to *John*, so we include all those edges to get the final (and correct) MST,



A possible concern with searching the entire space of spanning trees is that we have not used any syntactic constraints to guide the search. Many languages that allow non-projectivity are still primarily projective. By searching all possible non-projective trees, we run the risk of finding extremely bad trees. We address this concern in Section 4.

2.2.2 Projective Trees

It is well known that projective dependency parsing using edge based factorization can be handled with the Eisner algorithm (Eisner, 1996). This algorithm has a runtime of $O(n^3)$ and has been employed successfully in both generative and discriminative parsing models (Eisner, 1996; McDonald et al., 2005). Furthermore, it is trivial to show that the Eisner algorithm solves the maximum projective spanning tree problem.

The Eisner algorithm differs significantly from the Chu-Liu-Edmonds algorithm. First of all, it is a bottom-up dynamic programming algorithm as opposed to a greedy recursive one. A bottom-up algorithm is necessary for the projective case since it must maintain the nested structural constraint, which is unnecessary for the non-projective case.

2.3 Dependency Trees as MSTs: Summary

In the preceding discussion, we have shown that natural language dependency parsing can be reduced to finding maximum spanning trees in directed graphs. This reduction results from edge-based factorization and can be applied to projective languages with the Eisner parsing algorithm and non-projective languages with the Chu-Liu-Edmonds maximum spanning tree algorithm. The only remaining problem is how to learn the weight vector **w**.

A major advantage of our approach over other dependency parsing models is its uniformity and simplicity. By viewing dependency structures as spanning trees, we have provided a general framework for parsing trees for both projective and non-projective languages. Furthermore, the resulting parsing algorithms are more efficient than lexicalized phrase structure approaches to dependency parsing, allowing us to search the entire space without any pruning. In particular the non-projective parsing algorithm based on the Chu-Liu-Edmonds MST algorithm provides *true* non-projective parsing. This is in contrast to other non-projective methods, such as that of Nivre and Nilsson (2005), who implement non-projectivity in a *pseudo-projective* parser with edge transformations. This formulation also dispels the notion that non-projective parsing is "harder" than projective parsing. In fact, it is easier since non-projective parsing does not need to enforce the non-crossing constraint of projective trees. As a result, non-projective parsing complexity is just $O(n^2)$, against the $O(n^3)$ complexity of the Eisner dynamic programming algorithm, which by construction enforces the non-crossing constraint.

3 Online Large Margin Learning

In this section, we review the work of McDonald et al. (2005) for online large-margin dependency parsing. As usual for supervised learning, we assume a training set $\mathcal{T} = \{(\boldsymbol{x}_t, \boldsymbol{y}_t)\}_{t=1}^T$, consisting of pairs of a sentence $\boldsymbol{x}_t$ and its correct dependency tree $\boldsymbol{y}_t$. In what follows, $\mathrm{dt}(\boldsymbol{x})$ denotes the set of possible dependency trees for sentence $\boldsymbol{x}$.

The basic idea is to extend the Margin Infused Relaxed Algorithm (MIRA) (Crammer and Singer, 2003; Crammer et al., 2003) to learning with structured outputs, in the present case dependency trees. Figure 4 gives pseudo-code for the MIRA algorithm as presented by McDonald et al. (2005). An online learning algorithm considers a single training instance at each update to **w**. The auxiliary vector **v** accumulates the successive values of **w**, so that the final weight vector is the *average* of the weight vectors after each iteration. This averaging effect has been shown to help overfitting (Collins, 2002).

```
Training data: $\mathcal{T} = \{(\boldsymbol{x}_t, \boldsymbol{y}_t)\}_{t=1}^T$
1. $\mathbf{w}_0 = 0;\ \mathbf{v} = 0;\ i = 0$
2. for $n : 1..N$
3.   for $t : 1..T$
4.     $\min \left\|\mathbf{w}^{(i+1)} - \mathbf{w}^{(i)}\right\|$
       s.t. $s(\boldsymbol{x}_t, \boldsymbol{y}_t) - s(\boldsymbol{x}_t, \boldsymbol{y}') \geq L(\boldsymbol{y}_t, \boldsymbol{y}'), \forall \boldsymbol{y}' \in \mathrm{dt}(\boldsymbol{x}_t)$
5.     $\mathbf{v} = \mathbf{v} + \mathbf{w}^{(i+1)}$
6.     $i = i + 1$
7. $\mathbf{w} = \mathbf{v}/(N * T)$
```

Figure 4: MIRA learning algorithm.

On each update, MIRA attempts to keep the new weight vector as close as possible to the old weight vector, subject to correctly classifying the instance under consideration with a margin given by the loss of the incorrect classifications. For dependency trees, the loss of a tree is defined to be the number of words with incorrect parents relative to the correct tree. This is closely related to the Hamming loss that is often used for sequences (Taskar et al., 2003).

For arbitrary inputs, there are typically exponentially many possible parses and thus exponentially many margin constraints in line 4 of Figure 4.

3.1 Single-best MIRA

One solution for the exponential blow-up in number of trees is to relax the optimization by using only the single margin constraint for the tree with the highest score, $s(\boldsymbol{x}, \boldsymbol{y})$. The resulting online update (to be inserted in Figure 4, line 4) would then be:

$$\begin{aligned}
&\min\ \left\|\mathbf{w}^{(i+1)} - \mathbf{w}^{(i)}\right\| \\
&\text{s.t.}\quad s(\boldsymbol{x}_t, \boldsymbol{y}_t) - s(\boldsymbol{x}_t, \boldsymbol{y}') \geq L(\boldsymbol{y}_t, \boldsymbol{y}') \\
&\text{where } \boldsymbol{y}' = \arg\max_{y'} s(\boldsymbol{x}_t, \boldsymbol{y}')
\end{aligned}$$

McDonald et al. (2005) used a similar update with k constraints for the k highest-scoring trees, and showed that small values of k are sufficient to achieve the best accuracy for these methods. However, here we stay with a single best tree because k-best extensions to the Chu-Liu-Edmonds algorithm are too inefficient (Hou, 1996).

This model is related to the averaged perceptron algorithm of Collins (2002). In that algorithm, the single highest scoring tree (or structure) is used to update the weight vector. However, MIRA aggressively updates **w** to maximize the margin between the correct tree and the highest scoring tree, which has been shown to lead to increased accuracy.

3.2 Factored MIRA

It is also possible to exploit the structure of the output space and factor the exponential number of margin constraints into a polynomial number of local constraints (Taskar et al., 2003; Taskar et al., 2004). For the directed maximum spanning tree problem, we can factor the output by edges to obtain the following constraints:

$$\begin{aligned}&\min \left\|\mathbf{w}^{(i+1)} - \mathbf{w}^{(i)}\right\| \\ &\text{s.t. } s(l,j) - s(k,j) \geq 1 \\ &\forall (l,j) \in \boldsymbol{y}_t, (k,j) \notin \boldsymbol{y}_t\end{aligned}$$

This states that the weight of the correct incoming edge to the word x_j and the weight of all other incoming edges must be separated by a margin of 1. It is easy to show that when all these constraints are satisfied, the correct spanning tree and all incorrect spanning trees are separated by a score at least as large as the number of incorrect incoming edges. This is because the scores for all the correct arcs cancel out, leaving only the scores for the errors causing the difference in overall score. Since each single error results in a score increase of at least 1, the entire score difference must be at least the number of errors. For sequences, this form of factorization has been called local lattice preference (Crammer et al., 2004). Let n be the number of nodes in graph $G_{\boldsymbol{x}}$. Then the number of constraints is $O(n^2)$, since for each node we must maintain $n-1$ constraints.

The factored constraints are in general more restrictive than the original constraints, so they may rule out the optimal solution to the original problem. McDonald et al. (2005) examines briefly factored MIRA for projective English dependency parsing, but for that application, k-best MIRA performs as well or better, and is much faster to train.

4 Experiments

We performed experiments on the Czech Prague Dependency Treebank (PDT) (Hajič, 1998; Hajič et al., 2001). We used the predefined training, development and testing split of this data set. Furthermore, we used the automatically generated POS tags that are provided with the data. Czech POS tags are very complex, consisting of a series of slots that may or may not be filled with some value. These slots represent lexical and grammatical properties such as standard POS, case, gender, and tense. The result is that Czech POS tags are rich in information, but quite sparse when viewed as a whole. To reduce sparseness, our features rely only on the reduced POS tag set from Collins et al. (1999). The number of features extracted from the PDT training set was $13,450,672$, using the feature set outlined by McDonald et al. (2005).

Czech has more flexible word order than English and as a result the PDT contains non-projective dependencies. On average, 23% of the sentences in the training, development and test sets have at least one non-projective dependency. However, less than 2% of total edges are actually non-projective. Therefore, handling non-projective edges correctly has a relatively small effect on overall accuracy. To show the effect more clearly, we created two Czech data sets. The first, Czech-A, consists of the entire PDT. The second, Czech-B, includes only the 23% of sentences with at least one non-projective dependency. This second set will allow us to analyze the effectiveness of the algorithms on non-projective material. We compared the following systems:

1. **COLL1999:** The projective lexicalized phrase-structure parser of Collins et al. (1999).
2. **N&N2005:** The pseudo-projective parser of Nivre and Nilsson (2005).
3. **McD2005:** The projective parser of McDonald et al. (2005) that uses the Eisner algorithm for both training and testing. This system uses k-best MIRA with k=5.
4. **Single-best MIRA:** In this system we use the Chu-Liu-Edmonds algorithm to find the best dependency tree for Single-best MIRA training and testing.
5. **Factored MIRA:** Uses the quadratic set of constraints based on edge factorization as described in Section 3.2. We use the Chu-Liu-Edmonds algorithm to find the best tree for the test data.

4.1 Results

Results are shown in Table 1. There are two main metrics. The first and most widely recognized is *Accuracy*, which measures the number of words that correctly identified their parent in the tree. *Complete* measures the number of sentences in which the resulting tree was completely correct.

Clearly, there is an advantage in using the Chu-Liu-Edmonds algorithm for Czech dependency pars-

	Czech-A		Czech-B	
	Accuracy	**Complete**	**Accuracy**	**Complete**
COLL1999	82.8	-	-	-
N&N2005	80.0	31.8	-	-
McD2005	83.3	31.3	74.8	0.0
Single-best MIRA	84.1	32.2	81.0	**14.9**
Factored MIRA	**84.4**	**32.3**	**81.5**	14.3

Table 1: Dependency parsing results for Czech. Czech-B is the subset of Czech-A containing only sentences with at least one non-projective dependency.

ing. Even though less than 2% of all dependencies are non-projective, we still see an absolute improvement of up to 1.1% in overall accuracy over the projective model. Furthermore, when we focus on the subset of data that only contains sentences with at least one non-projective dependency, the effect is amplified. Another major improvement here is that the Chu-Liu-Edmonds non-projective MST algorithm has a parsing complexity of $O(n^2)$, versus the $O(n^3)$ complexity of the projective Eisner algorithm, which in practice leads to improvements in parsing time. The results also show that in terms of *Accuracy*, factored MIRA performs better than single-best MIRA. However, for the factored model, we do have $O(n^2)$ margin constraints, which results in a significant increase in training time over single-best MIRA. Furthermore, we can also see that the MST parsers perform favorably compared to the more powerful lexicalized phrase-structure parsers, such as those presented by Collins et al. (1999) and Zeman (2004) that use expensive $O(n^5)$ parsing algorithms. We should note that the results in Collins et al. (1999) are different then reported here due to different training and testing data sets.

One concern raised in Section 2.2.1 is that searching the entire space of non-projective trees could cause problems for languages that are primarily projective. However, as we can see, this is not a problem. This is because the model sets its weights with respect to the parsing algorithm and will disfavor features over unlikely non-projective edges.

Since the space of projective trees is a subset of the space of non-projective trees, it is natural to wonder how the Chu-Liu-Edmonds parsing algorithm performs on projective data since it is asymptotically better than the Eisner algorithm. Table 2 shows the results for English projective dependency trees extracted from the Penn Treebank (Marcus et al., 1993) using the rules of Yamada and Matsumoto (2003).

	English	
	Accuracy	**Complete**
McD2005	**90.9**	**37.5**
Single-best MIRA	90.2	33.2
Factored MIRA	90.2	32.3

Table 2: Dependency parsing results for English using spanning tree algorithms.

This shows that for projective data sets, training and testing with the Chu-Liu-Edmonds algorithm is worse than using the Eisner algorithm. This is not surprising since the Eisner algorithm uses the a priori knowledge that all trees are projective.

5 Discussion

We presented a general framework for parsing dependency trees based on an equivalence to maximum spanning trees in directed graphs. This framework provides natural and efficient mechanisms for parsing both projective and non-projective languages through the use of the Eisner and Chu-Liu-Edmonds algorithms. To learn these structures we used online large-margin learning (McDonald et al., 2005) that empirically provides state-of-the-art performance for Czech.

A major advantage of our models is the ability to naturally model non-projective parses. Non-projective parsing is commonly considered more difficult than projective parsing. However, under our framework, we show that the opposite is actually true that non-projective parsing has a lower asymptotic complexity. Using this framework, we presented results showing that the non-projective model outperforms the projective model on the Prague Dependency Treebank, which contains a small number of non-projective edges.

Our method requires a tree score that decomposes according to the edges of the dependency tree. One might hope that the method would generalize to include features of larger substructures. Unfortunately, that would make the search for the best tree intractable (Höffgen, 1993).

Acknowledgments

We thank Lillian Lee for bringing an important missed connection to our attention, and Koby Crammer for his help with learning algorithms. This work has been supported by NSF ITR grants 0205448 and 0428193.

Abstract

Humor is one of the most interesting and puzzling aspects of human behavior. Despite the attention it has received in fields such as philosophy, linguistics, and psychology, there have been only few attempts to create computational models for humor recognition or generation. In this paper, we bring empirical evidence that computational approaches can be successfully applied to the task of humor recognition. Through experiments performed on very large data sets, we show that automatic classification techniques can be effectively used to distinguish between humorous and non-humorous texts, with significant improvements observed over apriori known baselines.

1 Introduction

... pleasure has probably been the main goal all along. But I hesitate to admit it, because computer scientists want to maintain their image as hard-working individuals who deserve high salaries. Sooner or later society will realize that certain kinds of hard work are in fact admirable even though they are more fun than just about anything else. (Knuth, 1993)

Humor is an essential element in personal communication. While it is merely considered a way to induce amusement, humor also has a positive effect on the mental state of those using it and has the ability to improve their activity. Therefore computational humor deserves particular attention, as it has the potential of changing computers into a creative and motivational tool for human activity (Stock et al., 2002; Nijholt et al., 2003).

Previous work in computational humor has focused mainly on the task of humor generation (Stock and Strapparava, 2003; Binsted and Ritchie, 1997), and very few attempts have been made to develop systems for automatic humor recognition (Taylor and Mazlack, 2004). This is not surprising, since, from a computational perspective, humor recognition appears to be significantly more subtle and difficult than humor generation.

In this paper, we explore the applicability of computational approaches to the recognition of verbally expressed humor. In particular, we investigate whether automatic classification techniques are a viable approach to distinguish between humorous and non-humorous text, and we bring empirical evidence in support of this hypothesis through experiments performed on very large data sets.

Since a deep comprehension of humor in all of its aspects is probably too ambitious and beyond the existing computational capabilities, we chose to restrict our investigation to the type of humor found in *one-liners*. A one-liner is a short sentence with comic effects and an interesting linguistic structure: simple syntax, deliberate use of rhetoric devices (e.g. alliteration, rhyme), and frequent use of creative language constructions meant to attract the readers attention. While longer jokes can have a relatively complex narrative structure, a one-liner must produce the humorous effect "in one shot", with very few words. These characteristics make this type of humor particularly suitable for use in an automatic learning setting, as the humor-producing features are guaranteed to be present in the first (and only) sentence.

We attempt to formulate the humor-recognition problem as a traditional classification task, and feed positive (humorous) and negative (non-humorous) examples to an automatic classifier. The humorous data set consists of one-liners collected from the Web using an automatic bootstrapping process. The non-humorous data is selected such that it is structurally and stylistically similar to the one-liners. Specifically, we use three different negative data sets: (1) Reuters news titles; (2) proverbs; and (3) sentences from the British National Corpus (BNC). The classification results are encouraging, with accuracy figures ranging from 79.15% (One-liners/BNC) to 96.95% (One-liners/Reuters). Regardless of the non-humorous data set playing the role of negative examples, the performance of the automatically learned humor-recognizer is always significantly better than apriori known baselines.

The remainder of the paper is organized as follows. We first describe the humorous and non-humorous data sets, and provide details on the Web-based bootstrapping process used to build a very large collection of one-liners. We then show experimental results obtained on these data sets using several heuristics and two different text classifiers. Finally, we conclude with a discussion and directions for future work.

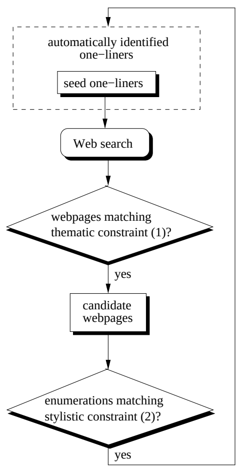
2 Humorous and Non-humorous Data Sets

To test our hypothesis that automatic classification techniques represent a viable approach to humor recognition, we needed in the first place a data set consisting of both humorous (positive) and non-humorous (negative) examples. Such data sets can be used to automatically *learn* computational models for humor recognition, and at the same time *evaluate* the performance of such models.

2.1 Humorous Data

For reasons outlined earlier, we restrict our attention to one-liners, short humorous sentences that have the characteristic of producing a comic effect in very few words (usually 15 or less). The one-liners humor style is illustrated in Table 1, which shows three examples of such one-sentence jokes.

It is well-known that large amounts of training data have the potential of improving the accuracy of the learning process, and at the same time provide insights into how increasingly larger data sets can affect the classification precision. The manual construction of a very large one-liner data set may be however problematic, since most Web sites or mailing lists that make available such jokes do not usually list more than 50–100 one-liners. To tackle this problem, we implemented a Web-based bootstrapping algorithm able to automatically collect a large number of one-liners starting with a short *seed* list, consisting of a few one-liners manually identified.



automatically identified one−liners
seed one−liners
Web search
webpages matching thematic constraint (1)?
yes
candidate webpages
enumerations matching stylistic constraint (2)?
yes

Figure 1: Web-based bootstrapping of one-liners.

The bootstrapping process is illustrated in Figure 1. Starting with the seed set, the algorithm automatically identifies a list of webpages that include at least one of the seed one-liners, via a simple search performed with a Web search engine. Next, the webpages found in this way are HTML parsed, and additional one-liners are automatically identified and added to the seed set. The process is repeated several times, until enough one-liners are collected.

An important aspect of any bootstrapping algorithm is the set of constraints used to steer the process and prevent as much as possible the addition of noisy entries. Our algorithm uses: (1) a *thematic* constraint applied to the theme of each webpage; and (2) a *structural* constraint, exploiting HTML annotations indicating text of similar genre.

The first constraint is implemented using a set of keywords of which at least one has to appear in the URL of a retrieved webpage, thus potentially limiting the content of the webpage to a theme related to that keyword. The set of keywords used in the current implementation consists of six words that explicitly indicate humor-related content: *oneliner*, *one-liner*, *humor*, *humour*, *joke*,

One-liners
Take my advice; I don't use it anyway.
I get enough exercise just pushing my luck.
Beauty is in the eye of the beer holder.
Reuters titles
Trocadero expects tripling of revenues.
Silver fi xes at two-month high, but gold lags.
Oil prices slip as refi ners shop for bargains.
BNC sentences
They were like spirits, and I loved them.
I wonder if there is some contradiction here.
The train arrives three minutes early.
Proverbs
Creativity is more important than knowledge.
Beauty is in the eye of the beholder.
I believe no tales from an enemy's tongue.

Table 1: Sample examples of one-liners, Reuters titles, BNC sentences, and proverbs.

funny. For example, *http://www.berro.com/Jokes* or *http://www.mutedfaith.com/funny/life.htm* are the URLs of two webpages that satisfy this constraint.

The second constraint is designed to exploit the HTML structure of webpages, in an attempt to identify enumerations of texts that include the seed one-liner. This is based on the hypothesis that enumerations typically include texts of similar genre, and thus a list including the seed one-liner is likely to include additional one-line jokes. For instance, if a seed one-liner is found in a webpage preceded by the HTML tag `<li>` (i.e. "list item"), other lines found in the same enumeration preceded by the same tag are also likely to be one-liners.

Two iterations of the bootstrapping process, started with a small seed set of ten one-liners, resulted in a large set of about 24,000 one-liners. After removing the duplicates using a measure of string similarity based on the longest common subsequence metric, we were left with a final set of approximately 16,000 one-liners, which are used in the humor-recognition experiments. Note that since the collection process is automatic, noisy entries are also possible. Manual verification of a randomly selected sample of 200 one-liners indicates an average of 9% potential noise in the data set, which is within reasonable limits, as it does not appear to significantly impact the quality of the learning.

2.2 Non-humorous Data

To construct the set of negative examples required by the humor-recognition models, we tried to identify collections of sentences that were non-humorous, but similar in structure and composition to the one-liners. We do not want the automatic classifiers to learn to distinguish between humorous and non-humorous examples based simply on text length or obvious vocabulary differences. Instead, we seek to enforce the classifiers to identify humor-specific features, by supplying them with negative examples similar in most of their aspects to the positive examples, but different in their comic effect.

We tested three different sets of negative examples, with three examples from each data set illustrated in Table 1. All non-humorous examples are enforced to follow the same length restriction as the one-liners, i.e. one sentence with an average length of 10–15 words.

1. *Reuters* titles, extracted from news articles published in the Reuters newswire over a period of one year (8/20/1996 – 8/19/1997) (Lewis et al., 2004). The titles consist of short sentences with simple syntax, and are often phrased to catch the readers attention (an effect similar to the one rendered by one-liners).
2. *Proverbs* extracted from an online proverb collection. Proverbs are sayings that transmit, usually in one short sentence, important facts or experiences that are considered true by many people. Their property of being condensed, but memorable sayings make them very similar to the one-liners. In fact, some one-liners attempt to reproduce proverbs, with a comic effect, as in e.g. *"Beauty is in the eye of the beer holder"*, derived from *"Beauty is in the eye of the beholder"*.
3. *British National Corpus (BNC)* sentences, extracted from BNC – a balanced corpus covering different styles, genres and domains. The sentences were selected such that they were similar in content with the one-liners: we used an information retrieval system implementing a vectorial model to identify the BNC sentence most similar to each of the 16,000 one-liners[1]. Unlike the Reuters titles or the proverbs, the BNC sentences have typically no added creativity. However, we decided to add this set of negative examples to our experimental setting, in order

[1]The sentence most similar to a one-liner is identifi ed by running the one-liner against an index built for all BNC sentences with a length of 10–15 words. We use a *tf.idf* weighting scheme and a cosine similarity measure, as implemented in the Smart system (*ftp.cs.cornell.edu/pub/smart*)

to observe the level of difficulty of a humor-recognition task when performed with respect to simple text.

To summarize, the humor recognition experiments rely on data sets consisting of humorous (positive) and non-humorous (negative) examples. The positive examples consist of 16,000 one-liners automatically collected using a Web-based bootstrapping process. The negative examples are drawn from: (1) Reuters titles; (2) Proverbs; and (3) BNC sentences.

3 Automatic Humor Recognition

We experiment with automatic classification techniques using: (a) heuristics based on humor-specific stylistic features (alliteration, antonymy, slang); (b) content-based features, within a learning framework formulated as a typical text classification task; and (c) combined stylistic and content-based features, integrated in a stacked machine learning framework.

3.1 Humor-Specific Stylistic Features

Linguistic theories of humor (Attardo, 1994) have suggested many *stylistic features* that characterize humorous texts. We tried to identify a set of features that were both significant and feasible to implement using existing machine readable resources. Specifically, we focus on alliteration, antonymy, and adult slang, which were previously suggested as potentially good indicators of humor (Ruch, 2002; Bucaria, 2004).

Alliteration. Some studies on humor appreciation (Ruch, 2002) show that structural and phonetic properties of jokes are at least as important as their content. In fact one-liners often rely on the reader's awareness of attention-catching sounds, through linguistic phenomena such as alliteration, word repetition and rhyme, which produce a comic effect even if the jokes are not necessarily meant to be read aloud. Note that similar rhetorical devices play an important role in wordplay jokes, and are often used in newspaper headlines and in advertisement. The following one-liners are examples of jokes that include one or more alliteration chains:

Veni, Vidi, Visa: I came, I saw, I did a little shopping.
Infants don't enjoy infancy like adults do adultery.

To extract this feature, we identify and count the number of alliteration/rhyme chains in each example in our data set. The chains are automatically extracted using an index created on top of the CMU pronunciation dictionary[2].

Antonymy. Humor often relies on some type of incongruity, opposition or other forms of apparent contradiction. While an accurate identification of all these properties is probably difficult to accomplish, it is relatively easy to identify the presence of *antonyms* in a sentence. For instance, the comic effect produced by the following one-liners is partly due to the presence of antonyms:

A clean desk is a sign of a cluttered desk drawer.
Always try to be modest and be proud of it!

The lexical resource we use to identify antonyms is WORDNET (Miller, 1995), and in particular the *antonymy* relation among nouns, verbs, adjectives and adverbs. For adjectives we also consider an indirect antonymy via the *similar-to* relation among adjective synsets. Despite the relatively large number of *antonymy* relations defined in WORDNET, its coverage is far from complete, and thus the *antonymy* feature cannot always be identified. A deeper semantic analysis of the text, such as word sense disambiguation or domain disambiguation, could probably help detecting other types of semantic opposition, and we plan to exploit these techniques in future work.

Adult slang. Humor based on adult slang is very popular. Therefore, a possible feature for humor-recognition is the detection of sexual-oriented lexicon in the sentence. The following represent examples of one-liners that include such slang:

The sex was so good that even the neighbors had a cigarette.
Artificial Insemination: procreation without recreation.

To form a lexicon required for the identification of this feature, we extract from WORDNET DOMAINS[3] all the synsets labeled with the domain SEXUALITY. The list is further processed by removing all words with high polysemy (≥ 4). Next, we check for the presence of the words in this lexicon in each sentence in the corpus, and annotate them accordingly. Note that, as in the case of antonymy, WORDNET coverage is not complete, and the *adult slang* feature cannot always be identified.

Finally, in some cases, all three features (alliteration,

[2] Available at *http://www.speech.cs.cmu.edu/cgi-bin/cmudict*

[3] WORDNET DOMAINS assigns each synset in WORDNET with one or more "domain" labels, such as SPORT, MEDICINE, ECONOMY. See *http://wndomains.itc.it*.

antonymy, adult slang) are present in the same sentence, as for instance the following one-liner:

Behind every great$_{al}$ *man*$_{ant}$ *is a great*$_{al}$ *woman*$_{ant}$*, and behind every great*$_{al}$ *woman*$_{ant}$ *is some guy staring at her behind*$_{sl}$*!*

3.2 Content-based Learning

In addition to stylistic features, we also experimented with *content-based features*, through experiments where the humor-recognition task is formulated as a traditional text classification problem. Specifically, we compare results obtained with two frequently used text classifiers, Naïve Bayes and Support Vector Machines, selected based on their performance in previously reported work, and for their diversity of learning methodologies.

Naïve Bayes. The main idea in a Naïve Bayes text classifier is to estimate the probability of a category given a document using joint probabilities of words and documents. Naïve Bayes classifiers assume word independence, but despite this simplification, they perform well on text classification. While there are several versions of Naïve Bayes classifiers (variations of multinomial and multivariate Bernoulli), we use the multinomial model, previously shown to be more effective (McCallum and Nigam, 1998).

Support Vector Machines. Support Vector Machines (SVM) are binary classifiers that seek to find the hyperplane that best separates a set of positive examples from a set of negative examples, with maximum margin. Applications of SVM classifiers to text categorization led to some of the best results reported in the literature (Joachims, 1998).

4 Experimental Results

Several experiments were conducted to gain insights into various aspects related to an automatic humor recognition task: classification accuracy using stylistic and content-based features, learning rates, impact of the type of negative data, impact of the classification methodology.

All evaluations are performed using stratified tenfold cross validations, for accurate estimates. The baseline for all the experiments is 50%, which represents the classification accuracy obtained if a label of "humorous" (or "non-humorous") would be assigned by default to all the examples in the data set. Experiments with uneven class distributions were also performed, and are reported in section 4.4.

4.1 Heuristics using Humor-specific Features

In a first set of experiments, we evaluated the classification accuracy using stylistic humor-specific features: alliteration, antonymy, and adult slang. These are numerical features that act as heuristics, and the only parameter required for their application is a threshold indicating the minimum value admitted for a statement to be classified as humorous (or non-humorous). These thresholds are learned automatically using a decision tree applied on a small subset of humorous/non-humorous examples (1000 examples). The evaluation is performed on the remaining 15,000 examples, with results shown in Table 2[4].

	One-liners	One-liners	One-liners
Heuristic	Reuters	BNC	Proverbs
Alliteration	74.31%	59.34%	53.30%
Antonymy	55.65%	51.40%	50.51%
Adult slang	52.74%	52.39%	50.74%
ALL	76.73%	60.63%	53.71%

Table 2: Humor-recognition accuracy using alliteration, antonymy, and adult slang.

Considering the fact that these features represent *stylistic* indicators, the style of Reuters titles turns out to be the most different with respect to one-liners, while the style of proverbs is the most similar. Note that for all data sets the alliteration feature appears to be the most useful indicator of humor, which is in agreement with previous linguistic findings (Ruch, 2002).

4.2 Text Classification with Content Features

The second set of experiments was concerned with the evaluation of content-based features for humor recognition. Table 3 shows results obtained using the three different sets of negative examples, with the Naïve Bayes and SVM text classifiers. Learning curves are plotted in Figure 2.

	One-liners	One-liners	One-liners
Classifier	Reuters	BNC	Proverbs
Naïve Bayes	96.67%	73.22%	84.81%
SVM	96.09%	77.51%	84.48%

Table 3: Humor-recognition accuracy using Naïve Bayes and SVM text classifiers.

[4]We also experimented with decision trees learned from a larger number of examples, but the results were similar, which confirms our hypothesis that these features are heuristics, rather than learnable properties that improve their accuracy with additional training data.

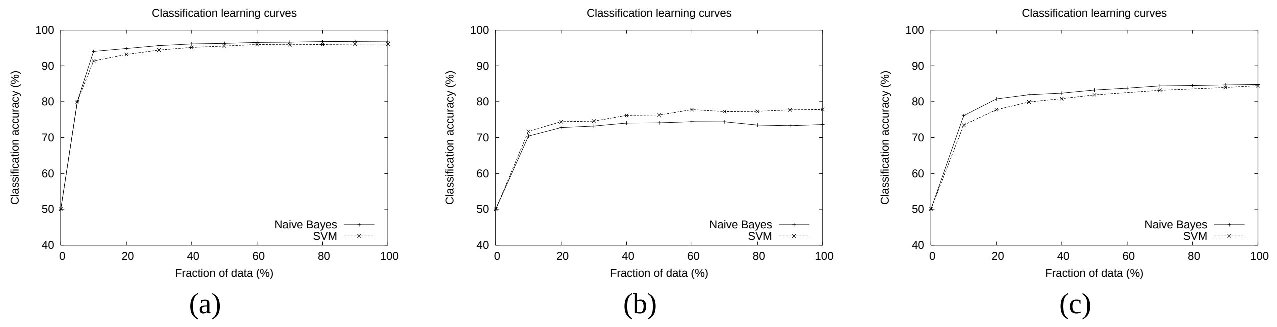


Figure 2: Learning curves for humor-recognition using text classification techniques, with respect to three different sets of negative examples: (a) Reuters; (b) BNC; (c) Proverbs.

Once again, the content of Reuters titles appears to be the most different with respect to one-liners, while the BNC sentences represent the most similar data set. This suggests that joke content tends to be very similar to regular text, although a reasonably accurate distinction can still be made using text classification techniques. Interestingly, proverbs can be distinguished from one-liners using content-based features, which indicates that despite their stylistic similarity (see Table 2), proverbs and one-liners deal with different topics.

4.3 Combining Stylistic and Content Features

Encouraged by the results obtained in the first two experiments, we designed a third experiment that attempts to jointly exploit stylistic and content features for humor recognition. The feature combination is performed using a stacked learner, which takes the output of the text classifier, joins it with the three humor-specific features (alliteration, antonymy, adult slang), and feeds the newly created feature vectors to a machine learning tool. Given the relatively large gap between the performance achieved with content-based features (text classification) and stylistic features (humor-specific heuristics), we decided to implement the second learning stage in the stacked learner using a memory based learning system, so that low-performance features are not eliminated in the favor of the more accurate ones[5]. We use the Timbl memory based learner (Daelemans et al., 2001), and evaluate the classification using a stratified ten-fold cross validation. Table 4 shows the results obtained in this experiment, for the three different data sets.

One-liners Reuters	One-liners BNC	One-liners Proverbs
96.95%	79.15%	84.82%

Table 4: Humor-recognition accuracy for combined learning based on stylistic and content features.

Combining classifiers results in a statistically significant improvement ($p < 0.0005$, paired t-test) with respect to the best individual classifier for the One-liners/Reuters and One-liners/BNC data sets, with relative error rate reductions of 8.9% and 7.3% respectively. No improvement is observed for the One-liners/Proverbs data set, which is not surprising since, as shown in Table 2, proverbs and one-liners cannot be clearly differentiated using stylistic features, and thus the addition of these features to content-based features is not likely to result in an improvement.

4.4 Discussion

The results obtained in the automatic classification experiments reveal the fact that computational approaches represent a viable solution for the task of humor-recognition, and good performance can be achieved using classification techniques based on stylistic and content features.

Despite our initial intuition that one-liners are most similar to other creative texts (e.g. Reuters titles, or the sometimes almost identical proverbs), and thus the learning task would be more difficult in relation to these data sets, comparative experimental results show that in fact it is more difficult to distinguish humor with respect to regular text (e.g. BNC

[5]Using a decision tree learner in a similar stacked learning experiment resulted into a flat tree that takes a classifi cation decision based exclusively on the content feature, ignoring completely the remaining stylistic features.

sentences). Note however that even in this case the combined classifier leads to a classification accuracy that improves significantly over the apriori known baseline.

An examination of the content-based features learned during the classification process reveals interesting aspects of the humorous texts. For instance, one-liners seem to constantly make reference to human-related scenarios, through the frequent use of words such as *man*, *woman*, *person*, *you*, *I*. Similarly, humorous texts seem to often include negative word forms, such as the negative verb forms *doesn't*, *isn't*, *don't*, or negative adjectives like *wrong* or *bad*. A more extensive analysis of content-based humor-specific features is likely to reveal additional humor-specific content features, which could also be used in studies of humor generation.

In addition to the three negative data sets, we also performed an experiment using a corpus of arbitrary sentences randomly drawn from the three negative sets. The humor recognition with respect to this negative mixed data set resulted in 63.76% accuracy for stylistic features, 77.82% for content-based features using Naïve Bayes and 79.23% using SVM. These figures are comparable to those reported in Tables 2 and 3 for One-liners/BNC, which suggests that the experimental results reported in the previous sections do not reflect a bias introduced by the negative data sets, since similar results are obtained when the humor recognition is performed with respect to arbitrary negative examples.

As indicated in section 2.2, the negative examples were selected structurally and stylistically similar to the one-liners, making the humor recognition task more difficult than in a real setting. Nonetheless, we also performed a set of experiments where we made the task even harder, using uneven class distributions. For each of the three types of negative examples, we constructed a data set using 75% non-humorous examples and 25% humorous examples. Although the baseline in this case is higher (75%), the automatic classification techniques for humor-recognition still improve over this baseline. The stylistic features lead to a classification accuracy of 87.49% (One-liners/Reuters), 77.62% (One-liners/BNC), and 76.20% (One-liners/Proverbs), and the content-based features used in a Naïve Bayes classifier result in accuracy figures of 96.19% (One-liners/Reuters), 81.56% (One-liners/BNC), and 87.86% (One-liners/Proverbs).

Finally, in addition to classification accuracy, we were also interested in the variation of classification performance with respect to data size, which is an aspect particularly relevant for directing future research. Depending on the shape of the learning curves, one could decide to concentrate future work either on the acquisition of larger data sets, or toward the identification of more sophisticated features. Figure 2 shows that regardless of the type of negative data, there is significant learning only until about 60% of the data (i.e. about 10,000 positive examples, and the same number of negative examples). The rather steep ascent of the curve, especially in the first part of the learning, suggests that humorous and non-humorous texts represent well distinguishable types of data. An interesting effect can be noticed toward the end of the learning, where for both classifiers the curve becomes completely flat (One-liners/Reuters, One-liners/Proverbs), or it even has a slight drop (One-liners/BNC). This is probably due to the presence of noise in the data set, which starts to become visible for very large data sets[6]. This plateau is also suggesting that more data is not likely to help improve the quality of an automatic humor-recognizer, and more sophisticated features are probably required.

5 Related Work

While humor is relatively well studied in scientific fields such as linguistics (Attardo, 1994) and psychology (Freud, 1905; Ruch, 2002), to date there is only a limited number of research contributions made toward the construction of computational humour prototypes.

One of the first attempts is perhaps the work described in (Binsted and Ritchie, 1997), where a formal model of semantic and syntactic regularities was devised, underlying some of the simplest types of puns (*punning riddles*). The model was then exploited in a system called JAPE that was able to automatically generate amusing puns.

Another humor-generation project was the HAHAcronym project (Stock and Strapparava, 2003), whose goal was to develop a system able to automatically generate humorous versions of existing

[6]We also like to think of this behavior as if the computer is losing its sense of humor after an overwhelming number of jokes, in a way similar to humans when they get bored and stop appreciating humor after hearing too many jokes.

acronyms, or to produce a new amusing acronym constrained to be a valid vocabulary word, starting with concepts provided by the user. The comic effect was achieved mainly by exploiting incongruity theories (e.g. finding a religious variation for a technical acronym).

Another related work, devoted this time to the problem of humor comprehension, is the study reported in (Taylor and Mazlack, 2004), focused on a very restricted type of wordplays, namely the "Knock-Knock" jokes. The goal of the study was to evaluate to what extent wordplay can be automatically identified in "Knock-Knock" jokes, and if such jokes can be reliably recognized from other non-humorous text. The algorithm was based on automatically extracted structural patterns and on heuristics heavily based on the peculiar structure of this particular type of jokes. While the wordplay recognition gave satisfactory results, the identification of jokes containing such wordplays turned out to be significantly more difficult.

6 Conclusion

A conclusion is simply the place where you got tired of thinking. (anonymous one-liner)

The creative genres of natural language have been traditionally considered outside the scope of any computational modeling. In particular humor, because of its puzzling nature, has received little attention from computational linguists. However, given the importance of humor in our everyday life, and the increasing importance of computers in our work and entertainment, we believe that studies related to computational humor will become increasingly important.

In this paper, we showed that automatic classification techniques can be successfully applied to the task of humor-recognition. Experimental results obtained on very large data sets showed that computational approaches can be efficiently used to distinguish between humorous and non-humorous texts, with significant improvements observed over apriori known baselines. To our knowledge, this is the first result of this kind reported in the literature, as we are not aware of any previous work investigating the interaction between humor and techniques for automatic classification.

Finally, through the analysis of learning curves plotting the classification performance with respect to data size, we showed that the accuracy of the automatic humor-recognizer stops improving after a certain number of examples. Given that automatic humor-recognition is a rather understudied problem, we believe that this is an important result, as it provides insights into potentially productive directions for future work. The flattened shape of the curves toward the end of the learning process suggests that rather than focusing on gathering more data, future work should concentrate on identifying more sophisticated humor-specific features, e.g. semantic oppositions, ambiguity, and others. We plan to address these aspects in future work.

Abstract

While there have been many successful applications of machine learning methods to tasks in NLP, learning algorithms are not typically designed to optimize NLP performance metrics. This paper evaluates an ensemble selection framework designed to optimize arbitrary metrics and automate the process of algorithm selection and parameter tuning. We report the results of experiments that instantiate the framework for three NLP tasks, using six learning algorithms, a wide variety of parameterizations, and 15 performance metrics. Based on our results, we make recommendations for subsequent machine-learning-based research for natural language learning.

1 Introduction

Among the most successful natural language learning techniques for a wide variety of linguistic phenomena are supervised inductive learning algorithms for classification. Because of their capabilities for accurate, robust, and efficient linguistic knowledge acquisition, they have been employed in many natural language processing (NLP) tasks.

Unfortunately, supervised classification algorithms are typically designed to optimize accuracy (*e.g.* decision trees) or mean squared error (*e.g.* neural networks). For many NLP tasks, however, these standard performance measures are inappropriate. For example, NLP data can be highly skewed in its distribution of positive and negative examples. In these situations, another metric (perhaps F-measure or a task-specific measure) that focuses on the performance of the minority cases is more appropriate. Indeed, as the NLP field matures more consideration will be given to evaluating the performance of NLP components in context (*e.g.* Is the system easy to use by end users? Does the component respect user preferences? How well does the entire system solve the specific problem?), leading to new and complicated metrics. Optimizing machine learning algorithms to arbitrary performance metrics, however, is not easily done.

To exacerbate matters, the metric of interest might change depending on how the natural language learning (NLL) component is employed. Some applications might need components with high recall, for example; others, high precision or high F-measure or low root mean squared error. To obtain good results w.r.t. the new metric, however, a different parameterization or different algorithm altogether might be called for, requiring re-training the classifier(s) from scratch.

Caruana *et al.* (2004) have recently proposed **ensemble selection** as a technique for building an ensemble of classifiers that is optimized to an arbitrary performance metric. The approach trains a large number of classifiers using multiple algorithms and parameter settings, with the idea that at least some of the classifiers will perform well on any given performance measure. The best set of classifiers, w.r.t. the target metric, is then greedily selected. (Selecting a set of size 1 is equivalent to parameter and algorithm tuning.) Like other ensemble learning methods (*e.g.* bagging (Breiman, 1996) and boosting (Freund and Schapire, 1996)), ensemble selection has been shown to exhibit reliably better performance than any of the contributing classifiers for a number of learning tasks.

In addition, ensemble selection provides an ancillary benefit: no human expertise is required in selecting an appropriate machine learning algorithm or in choosing suitable parameter settings to get good performance. This is particularly attractive for the NLP community where researchers often rely on the same one or two algorithms and use default parameter settings for simplicity. Ensemble selection is a tool usable by non-experts to find good classifiers optimized to task-specific metrics.

This paper evaluates the utility of the ensemble selection framework for NLL. We use three NLP tasks for the empirical evaluation: noun phrase coreference resolution and two problems from sentiment analysis — identifying private state frames and the hierarchy among them. The evaluation employs six learning algorithms, a wide selection of parameterizations, 8 standard metrics, and 7 task-specific metrics. Because ensemble selection subsumes parameter and algorithm selection, we also measure the impact of parameter and algorithm tuning.

Perhaps not surprisingly, we find first that no one algorithm or parameter configuration performs the best across all tasks or across all metrics. In addition, an algorithm's "tuned" performance (*i.e.* the performance after tuning parameter settings) almost universally matches or exceeds the algorithm's default performance (*i.e.* when using default parameter settings). Out of 154 total cases, the tuned classifier outperforms the default classifier 114 times, matches performance 28 times, and underperforms 12 times. Together, these results indicate the importance of algorithm and parameter selection for comparative empirical NLL studies. In particular, our results show the danger of relying on the same one or two algorithms for all tasks. These results cast doubt on conclusions regarding differences in algorithm performance for NLL experiments that give inadequate attention to parameter selection.

The results of our experiments that use ensemble selection to optimize the ensemble to arbitrary metrics are mixed. We see reliable improvements in performance across almost all of the metrics for only two of the three tasks; for the other data set, ensemble selection tends to hurt performance (although losses are very small). Perhaps more importantly for our purposes, we find that ensemble selection provides small, but consistent gains in performance when considering only the more complex, task-specific metrics — metrics that learning algorithms would find difficult to optimize.

The rest of the paper is organized as follows. Section 2 describes the general learning framework and provides an overview of ensemble selection. We present the particular instantiation of the framework employed in our experiments in Section 3. Section 4 describes the three NLP tasks. Experimental results are given in Section 5. Related work and conclusions follow (sections 6 and 7).

2 Ensemble Selection Framework

2.1 Terminology

We use the term **model** to refer to a classifier produced by some learning algorithm using some particular set of parameters. A model's **configuration** is simply the algorithm and parameter settings used to create the classifier. A **model family** is the set of models made by varying the parameters for one machine learning algorithm. Finally, a **model library** is a collection of models trained for a given task.

2.2 Framework

Abstractly, the framework is the following:

1. Select a variety of learning algorithms.
2. For each algorithm, choose a wide range of settings for the algorithm's parameters.
3. Divide data into training, tuning, and test sets.
4. Build model library.
5. Select target metrics appropriate to problem.
6. Tune parameter settings and/or run ensemble selection algorithm for target metrics.

Building the model library consists of (a) using the training data to train models for all the learning algorithms under all desired combinations of parameter settings, and (b) applying each model to the tuning and test set instances and storing the predictions for use in step (6). Note that models are placed in the library regardless of performance, even though some models have very bad performance. Intuitively, this is because there is no way to know *a priori* which models will perform well on a given metric. Note that producing the base models is fully automatic and requires no expert tuning.

Parameter Tuning: The goal of parameter tuning is to identify the best model for the task according to each target metric. Parameter tuning is handled in the standard way: for each metric, we select the model from the model library with the highest performance on the tuning data and report its performance on the test data.

Ensemble Selection Algorithm: The ensemble selection algorithm (Caruana *et al.*, 2004) ignores model-specific details by *only using the predictions made by the models:* the ensemble makes predictions by averaging the predictions of its constituents. Advantageously, this only requires that predictions made by different models fall in the same range, and that they can be averaged in a meaningful way. Otherwise, models can take any form, including other ensemble methods (*e.g.* bagging or boosting). Conceptually, ensemble selection builds on top of the models in the library and uses their performance as a starting point from which to improve.

The basic ensemble selection algorithm is:

a. Start with an empty ensemble.
b. Add the model that results in the best performance for the current ensemble with respect to the tuning data and the target metric.
c. Repeat (b) for a large, fixed number of iterations.
d. The final ensemble is the ensemble from the best performing iteration on the tuning data for the target metric.

To prevent the algorithm from overfitting the tuning data we use two enhancements given by Caruana *et al.* (2004). First, in step (b) the same model can be selected multiple times (*i.e.* selection with replacement). Second, the ensemble is initialized with the top N models (again, with respect to the target metric on the tuning data). N is picked automatically such that removing or adding a model decreases performance on the tuning data.[1]

The main advantage to this framework is its reusability. After an instantiation of the framework exists, it is straightforward to apply it to multiple NLL tasks and to add additional metrics. Steps (1) and (2) only need to be done once, regardless of the number of tasks and metrics explored. Steps (3)-(5) need only be done once per NLL task. Importantly, the model library is created once for each task (*i.e.* each model configuration is only trained once) regardless of the number (or addition) of performance metrics. Finally, finding a classifier or ensemble optimized to a new metric (step (6)) does not require re-building the model library and is very fast compared to training the classifiers—it only requires averaging the stored predictions. For example, training the model library for our smallest data set took multiple days; ensemble selection built optimized ensembles for each metric in a few minutes.

3 Framework Instantiation

In this section we describe our instantiation of the ensemble selection framework.

Algorithms: We use bagged decision trees (Breiman, 1996), boosted decision stumps (Freund and Schapire, 1996), k-nearest neighbor, a rule learner, and support vector machines (SVM's). We use the following implementations of these algorithms, respectively: `IND` decision tree package (Buntine, 1993); `WEKA` toolkit (Witten and Frank, 2000); `TiMBL` (Daelemans *et al.*, 2000); `RIPPER` (Cohen, 1995); and `SVM`^{light} (Joachims, 1999). Additionally, we use logistic regression (LR) for coreference resolution because an implementation using the `MALLET` (McCallum, 2002) toolkit was readily available for the task. The predictions from all algorithms are scaled to the range $[0, 1]$ with values close to 1 indicating positive predictions and values close to 0 indicating negative predictions.[2]

Parameter Settings: Table 1 lists the parameter settings we vary for each algorithm. Additional domain-specific parameters are also varied for coreference resolution models (see Section 4.1). The model libraries contain models corresponding to the cross product of the various parameter settings for a given algorithm.

Standard Performance Metrics: We evaluate the framework with 8 metrics: accuracy (ACC), average precision (APR), break even point (BEP), F-measure (F1), mean cross entropy (MXE), root mean squared error (RMS), area under the ROC curve (ROC), and SAR. Caruana *et al.* (2004) define SAR as $SAR = \frac{ACC+ROC+(1-RMS)}{3}$. We also evaluate the effects of model selection with task-specific metrics. These are described in Section 4. Our F-measure places equal emphasis on precision

[1]We also experimented with the bagging improvement described by Caruana *et al.* (2004). In our experiments using bagging hurt the performance of ensemble selection.

[2]We follow Caruana *et al.* (2004) in using Platt (2000) scaling to convert the SVM predictions from the range $(-\infty, \infty)$ to the required $[0, 1]$ by fitting them to a sigmoid.

Algorithm	Parameter	Values
Bagged Trees †	tree type	bayes, **c4**, cart, cart0, id3, mml, smml
	# bags	1, 5, 10, **25**
Boosted Stumps	# iterations	2, 4, 8, …, **256**, …1024, 2048
LR ‡	gaussian gamma	0.001, 0.005, 0.01, 0.05, 0.1, 0.5, 1, 5, **10**, 50
K-NN	k	**1**, 3, 5
	search algorithm	**ib1**, igtree
	similarity metric	**overlap**, modified value difference
	feature weighting	**gain ratio**, information gain, chi-squared, shared variance
Rule Learner	class learning order	unordered, **pos first**, neg first, heuristic determined order
	loss ratio	0.5, **1**, 1.5, 2, 3, 4
SVM	margin tradeoff*	10^{-7}, 10^{-6}, …, $\mathbf{10^{-2}}$, $\mathbf{10^{-1}}$, …, 10^{2}
	kernel	**linear**, rbf
	rbf gamma parm	0.001, 0.005, 0.01, 0.05, 0.1, 0.5, 1, 2

Table 1: Summary of model configurations used in experiments. The default settings for each algorithm are in bold. † Bagged trees are not used for identifying PSF's since the IND package does not support features with more than 255 values. Also, for coreference resolution the number of bags is not varied and is always 25. ‡ LR is only used for coreference resolution. * SVM^{light} determines the default margin tradeoff based on data properties. We calculate this value for each data set and use the closest setting among our configurations.

and recall (*i.e.* $\beta = 1$). Note that precision and recall are calculated *with respect to the positive class*.

Ensemble Selection: For the sentiment analysis tasks, ensemble selection iterates 150 times; for the coreference task, the algorithm iterates 200 times. This should be enough iterations, given that the model libraries contain 202, 173, and 338 models. Because computing the MUC-F1 and BCUBED metrics (see Section 4.1) is expensive, ensemble selection only iterates 50 times for these metrics.

4 Tasks

Because of space issues, we necessarily provide only brief descriptions of each NLL task. Readers are referred to the cited papers to obtain detailed descriptions.

4.1 Noun Phrase Coreference Resolution

The goal for a standard noun phrase coreference resolution system is to identify the noun phrases in a document and determine which of them refer to the same entity. Entities can be people, places, things, *etc*. The resulting partitioning of noun phrases creates reference chains with one chain per entity.

We use the same problem formulation as Soon *et al.* (2001) and Ng and Cardie (2002) — a combination of classification and clustering. Briefly, every noun phrase is paired with all preceding noun phrases, creating multiple pairs. For the training data, the pairs are labeled as coreferent or not. A binary classifier is trained to predict the pair labels. During classification, the predicted labels are used to form clusters. Two noun phrases A and B share a cluster if they are either predicted as coreferent by the classifier or if they are transitively predicted as coreferent through one or more other noun phrases. Instance selection (Soon *et al.*, 2001; Ng, 2004) is used to increase the percentage of positive instances in the training set.[3]

We use the learning features described by Ng and Cardie (2002). All learning algorithms are trained with the full set of features. Additionally, the rule learner, SVM, and LR are also trained with a hand-selected subset of the features that Ng and Cardie (2002) find to outperform the full feature set. Essentially this is an additional parameter to set for the learning task.

Special Metrics: Rather than focusing on performance at the pairwise coreference classification level, performance for this task is typically reported using either the MUC metric (Vilain *et al.*, 1995) or the BCUBED metric (Bagga and Baldwin, 1998). Both of these metrics measure the degree that predicted coreference chains agree with an answer key. In particular they measure the chain-level precision and recall (and the corresponding F-measure). We abbreviate these metrics MUC-F1, and B3F1.

Data Set: For our experiments we use the MUC-6 corpus, which contains 60 documents annotated with coreference information. The training, tuning, and test sets consist of documents 1-20, 21-30, and

[3]`Soon-1` instance selection is used for all algorithms; we also use `soon-2` (Ng, 2004) instance selection for the rule learner.

31-60, respectively.

4.2 Identifying Private State Frames

NLP research has recently started looking at how to detect and understand subjectivity in discourse. A key step in this direction is automatically identifying phrases that express subjectivity. In this setting, subjectivity is defined to include implicit and explicit opinions, internal thoughts and emotions, and bias introduced through second-hand reporting. Phrases expressing any of these are called **private state frames**, which we will abbreviate as PSF.

We build directly on experiments done by Wiebe *et al.* (2003). The task is to learn to identify explicit single-word PSF's in context. One learning instance is created for every word in the corpus. Classification labels each instance as a PSF or not. We use the same features as Wiebe *et al.*

Special Metrics: Because the data is highly skewed (2% positive instances), performance measures that focus on how well the minority class is learned are of primary interest. The F-measure defined in Section 3 is a natural choice. We also evaluate performance using geometric accuracy, defined as $GACC = \sqrt{posacc \times negacc}$ where $posacc$ and $negacc$ are the accuracy with respect to the positive and negative instances (Kubat and Matwin, 1997).

Conceivably, an automatic PSF extractor with high precision and mediocre recall could be used to automate the annotation process. For this reason we measure the performance with an unbalanced F-measure that emphasizes precision. Specifically, we try $\beta = 0.5$ (F0.5) and $\beta = 0.2$ (F0.2).

Data Set: We use 400 documents from the MPQA corpus (2002), a collection of news stories manually annotated with PSF information. The 400 documents are randomly split to get 320 training, 40 tuning, and 40 testing documents.

4.3 Determining PSF Hierarchy

The third task is taken from Breck and Cardie (2004). Explicit PSF's each have a **source** that corresponds to the person or entity expressing the subjectivity. In the presence of second-hand reporting, sources are often nested. This has the effect of filtering subjectivity through a chain of sources.

Given sentences annotated with PSF information (*i.e.* which spans are PSF's), the task is to discover the hierarchy among the PSF's that corresponds to the nesting of their respective sources. From each sentence, multiple instances are created by pairing every PSF with every other PSF in the sentence.[4] Let $(PSF_{parent}, PSF_{target})$ denote one of these instances. The classification task is to decide if PSF_{parent} is the parent of PSF_{target} in the hierarchy and to associate a confidence with that prediction. The complete hierarchy can easily be constructed from the predictions by choosing for each PSF its most confidently predicted parent.

Special Metrics: Breck and Cardie (2004) measure task performance with three metrics. The first is the accuracy of the predictions over the instances. The second is a derivative of a measure used to score dependency parses. Essentially, a sentence's score is the fraction of parent links correctly identified. The score for a set of sentences is the average of the individual sentence scores. We refer to this measure as average sentence accuracy (SENTACC). The third measure is the percentage of sentences whose hierarchical structures are perfectly determined (PERFSENT).

Data Set: We use the same data set and features as Breck and Cardie (2004). The annotated sentences from 469 documents in the MPQA Corpus (MPQA Corpus, 2002) are randomly split into training (80%), tuning (10%), and test (10%) sets.

5 Experiments and Results

We evaluate the potential benefits of the ensemble selection framework with two experiments. The first experiment measures the performance improvement yielded by parameter tuning and finds the best performing algorithm. The second experiment measures the performance improvement from ensemble selection.

Performance improvements are measured in terms of performance **gain**. Let a and b be the measured performances for two models A and B on some metric. A's gain over B is simply $a - b$. A performed worse than B if the gain is negative.[5]

[4]Sentences containing fewer than two PSF's are discarded and not used.

[5]MXE and RMS have inverted scales where the best performance is 0. Gain for these metrics equals $(1 - a) - (1 - b)$ so that positive gains are always good. Similarly, where raw MXE and RMS scores are reported we show $1 - score$.

Table 2: Performance gains from parameter tuning. The left column for each algorithm family is the algorithm's performance with default parameter settings. The adjacent 'Parm∆' column gives the performance gain from tuning parameters. For each metric, the best default and tuned performance across all algorithms are *italicized* and **bold-faced**, respectively.

5.1 Experiment 1: Parameter Tuning

Experiment 1 measures, for each of the 3 tasks, the performance of every model on both the tuning and test data for every metric of interest. *Based on tuning set performance,* the best default model, the best model overall, and the best model within each family are selected. The **best default model** is the highest-scoring model that emerges after comparing algorithms without doing any parameter tuning. The **best overall model** corresponds to "tuning" both the algorithm and parameters. The **best model in each family** corresponds to "tuning" the parameters for that algorithm. *Using the test set performances,* the best family models are compared to the corresponding default models to find the gains from parameter tuning.

Table 2 lists the gains achieved by parameter tuning. Each algorithm column compares the algorithm's best model to its default model. On the coreference task, for example, the best KNN model with respect to BEP shows a 20% improvement (or gain) over the default KNN model (for a final BEP score of .5300). The "Avg ∆" column shows the average gain from parameter tuning for each metric.

For each metric, the best default model is italicized while the best overall model is bold-faced. Referring again to the coreference BEP row, the best overall model is a SVM while the best default model is a bagged decision tree. Recall that these distinctions are based on *absolute performance* and not gain. Thus, the best tuned SVM outperforms all other models on this task and metric.[6]

Three conclusions can be drawn from Table 2. *First, no algorithm performs the best on all tasks or on all metrics.* For coreference, the best overall model is either a bagged tree, a rule learner, or a SVM, depending on the target metric. Similarly, for PSF identification the best model depends on the metric, ranging from a KNN to a SVM. Interestingly, bagged decision trees on the PSF hierarchy data outperform the other algorithms on all metrics and seem especially well-suited to the task.

Second, an algorithm's best-tuned model reliably yields non-trivial gains over the corresponding default model. This trend appears to hold regardless of algorithm, metric, and data set. In 114 of the 154

[6]Another interesting example is the best overall model for BEP on the PSF hierarchy task. The baseline (a bagged tree) outperforms the "best" model (a different bagged tree) on the test set even though the best model performed better on the tuning set—otherwise it would not have been selected as the best.

cases parameter tuning improves an algorithm's performance by more than 0.001 (0.1%). In the remaining 40 cases, parameter tuning only hurts 12 times, and never by more than 0.01.

Third, the best default algorithm is not necessarily the best algorithm after tuning parameters. The coreference task, in particular, illustrates the potential problem with using default parameter settings when judging which algorithm is most suited for a problem: 7 out of 10 times the best algorithm changes after parameter tuning.

These results corroborate those found elsewhere (Daelemans and Hoste, 2002; Hoste *et al.*, 2002; Hoste, 2005)—parameter settings greatly influence performance. Further, algorithmic performance differences can change when parameters are changed. Going beyond previous work, our results also underline the need to consider multiple algorithms for NLL. Ultimately, it is important for researchers to thoroughly explore options for **both** algorithm and parameter tuning and to report these in their results.

5.2 Experiment 2: Ensemble Selection

In experiment 2 an ensemble is built to optimize each target metric. The ensemble's performance is compared to that of the best overall model for the metric. Both the ensemble and the best model are selected according to tuning set performance.

Table 3 lists the gains from ensemble selection over the best parameter tuned model. For comparison, the best default and overall performances from Table 2 are reprinted. For example, the ensemble optimized for F1 on the coreference data outperforms the best bagged tree model by about 1% (and the best default model by almost 8%).

Disappointingly, ensemble selection does not consistently improve performance. Indeed, for the PSF hierarchy task ensemble selection reliably hurts performance a small amount. For the other two tasks ensemble selection reliably improves all metrics except GACC (a small loss). In other experiments, however, we optimized F-measure with $\beta = 1.5$ for the PSF identification task. Ensemble selection hurt F1.5 by almost 2%, leading us to question the technique's reliability for our second data set. Interestingly, the aggregate metrics—metrics that measure performance by combining multiple predictions—all benefit from ensemble selection, even for the hierarchy task, *albeit* for small amounts. For our tasks these comprise a subset of the task-specific performance measures: B3F1, MUC-F1, SENTACC, and PERFSENT.

Table 3: Impact from tuning and ensemble selection. *Best default* shows the performance of the best classifier with no parameter tuning (*i.e.* algorithm tuning only). *Best tuned*Δ gives the performance gain from parameter and algorithm tuning. *Ens. Sel.*Δ is the performance gain from ensemble selection over the best tuned model. The best performance for each metric is marked in bold.

While we are not surprised that the positive gains are small,[7] we are surprised at how often ensemble selection hurts performance. As a result, we investigated some of the metrics where ensemble selection hurts performance and found that ensemble selection overfits the tuning data. At this time we are not sure why this overfitting happens for these tasks and not for the ones used by Caruana *et al*. Preliminary investigations suggest that having a smaller model library is a contributing factor (Caruana *et al.* use libraries containing $\sim$ 2000 models). This is consistent with the fact that the task with the largest model library, coreference, benefits the most from ensemble selection. Perhaps the reason that ensemble selection consistently improves performance for

[7]Caruana *et al.* (2004) find the benefit from ensemble selection is only half as large as the benefit from carefully optimizing and selecting the best models in the first place.

the aggregate metrics is that these metrics are harder to overfit.

Based on our results, ensemble selection seems too unreliable for general use in NLL—at least until the model library requirements are better understood. However, ensemble selection is perhaps trustworthy enough to optimize metrics that are difficult to overfit and could not be easily optimized otherwise — in our case, the task-specific aggregate performance measures.

6 Related Work

Hoste *et al.* (2002) and Hoste (2005) study the impact of tuning parameters for k-NN and a rule-learning algorithm on word sense disambiguation and coreference resolution, respectively, and find that parameter settings greatly change results. Similar work by Daelemans and Hoste (2002) shows the fallacy of comparing algorithm performance without first tuning parameters. They find that the best algorithm for a task frequently changes after optimizing parameters. In contrast to our work, these earlier experiments investigate at most two algorithms and only measure performance with one metric per task.

7 Conclusion

We evaluate an ensemble selection framework that enables optimizing classifier performance to arbitrary performance metrics without re-training. An important side benefit of the framework is the fully automatic production of base-level models, removing the need for human expertise in choosing algorithms and parameter settings.

Our experiments show that ensemble selection, compared to simple algorithm and parameter tuning, reliably improves performance for six of the seven task-specific metrics and all four "aggregate" metrics, but only benefits *all* of the metrics for one of our three data sets. We also find that exploring multiple algorithms with a variety of settings is important for getting the best performance. Tuning parameter settings results in 0.05% to 14% average improvements, with most improvements falling between 2% and 10%. To this end, the ensemble selection *framework* can be used as an environment for automatically choosing the best algorithm and parameter settings for a given NLP classification task. More work is needed to understand when ensemble selection can be safely used for NLL.

Abstract

We present a novel almost-unsupervised approach to the task of Word Sense Disambiguation (WSD). We build sense examples automatically, using large quantities of Chinese text, and English-Chinese and Chinese-English bilingual dictionaries, taking advantage of the observation that mappings between words and meanings are often different in typologically distant languages. We train a classifier on the sense examples and test it on a gold standard English WSD dataset. The evaluation gives results that exceed previous state-of-the-art results for comparable systems. We also demonstrate that a little manual effort can improve the quality of sense examples, as measured by WSD accuracy. The performance of the classifier on WSD also improves as the number of training sense examples increases.

1 Introduction

The results of the recent Senseval-3 competition (Mihalcea et al., 2004) have shown that supervised WSD methods can yield up to 72.9% accuracy[1] on words for which manually sense-tagged data are available. However, supervised methods suffer from the so-called knowledge acquisition bottleneck: they need large quantities of high quality annotated data to produce reliable results. Unfortunately, very few sense-tagged corpora are available and manual sense-tagging is extremely costly and labour intensive. One way to tackle this problem is trying to automate the sense-tagging process. For example, Agirre et al. (2001) proposed a method for building topic signatures automatically, where a topic signature is a set of words, each associated with some weight, that tend to co-occur with a certain concept. Their system queries an Internet search engine with monosemous synonyms of words that have multiple senses in WordNet (Miller et al., 1990), and then extracts topic signatures by processing text snippets returned by the search engine. They trained a classifier on the topic signatures and evaluated it on a WSD task, but the results were disappointing.

In recent years, WSD approaches that exploit differences between languages have shown great promise. Several trends are taking place simultaneously under this multilingual paradigm. A classic one is to acquire sense examples using bilingual parallel texts (Gale et al., 1992; Resnik and Yarowsky, 1997; Diab and Resnik, 2002; Ng et al., 2003): given a word-aligned parallel corpus, the different translations in a target language serve as the “sense tags” of an ambiguous word in the source language. For example, Ng et al. (2003) acquired sense examples using English-Chinese parallel corpora, which were manually or automatically aligned at sentence level and then word-aligned using software. A manual selection of target translations was then performed, grouping together senses that share the same translation in Chinese. Finally, the occurrences of the word on the English side of the parallel

[1]This figure refers to the highest accuracy achieved in the Senseval-3 English Lexical Sample task with fine-grained scoring.

Proceedings of Human Language Technology Conference and Conference on Empirical Methods in Natural Language Processing (HLT/EMNLP), pages 547–554, Vancouver, October 2005. ©2005 Association for Computational Linguistics

texts were considered to have been disambiguated and "sense tagged" by the appropriate Chinese translations. A classifier was trained on the extracted sense examples and then evaluated on the nouns in Senseval-2 English Lexical Sample dataset. The results appear good numerically, but since the sense groups are not in the gold standard, comparison with other Senseval-2 results is difficult. As discussed by Ng et al., there are several problems with relying on bilingual parallel corpora for data collection. First, parallel corpora, especially accurately aligned parallel corpora are rare, although attempts have been made to mine them from the Web (Resnik, 1999). Second, it is often not possible to distinguish all senses of a word in the source language, by merely relying on parallel corpora, especially when the corpora are relatively small. This is a common problem for bilingual approaches: useful data for some words cannot be collected because different senses of polysemous words in one language often translate to the same word in the other. Using parallel corpora can aggravate this problem, because even if a word sense in the source language has a unique translation in the target language, the translation may not occur in the parallel corpora at all, due to the limited size of this resource.

To alleviate these problems, researchers seek other bilingual resources such as bilingual dictionaries, together with monolingual resources that can be obtained easily. Dagan and Itai (1994) proposed an approach to WSD using monolingual corpora, a bilingual lexicon and a parser for the source language. One of the problems of this method is that for many languages, accurate parsers do not exist. With a small amount of classified data and a large amount of unclassified data in both the source and the target languages, Li and Li (2004) proposed bilingual bootstrapping. This repeatedly constructs classifiers in the two languages in parallel and boosts the performance of the classifiers by classifying data in each of the languages and by exchanging information regarding the classified data between two languages. With a certain amount of manual work, they reported promising results, but evaluated on relatively small datasets.

In previous work, we proposed to use Chinese monolingual corpora and Chinese-English bilingual dictionaries to acquire sense examples (Wang, 2004)[2]. We evaluated the sense examples using a vector space WSD model on a small dataset containing words with binary senses, with promising results. This approach does not rely on scarce resources such as aligned parallel corpora or accurate parsers.

This paper describes further progress based on our proposal: we automatically build larger-scale sense examples and then train a Naïve Bayes classifier on them. We have evaluated our system on the English Lexical Sample Dataset from Senseval-2 and the results show conclusively that such sense examples can be used successfully in a full-scale fine-grained WSD task. We tried to analyse whether more sense examples acquired this way would improve WSD accuracy and also whether a little human effort on sense mapping could further improve WSD performance.

The reminder of the paper is organised as follows. Section 2 outlines the acquisition algorithm for sense examples. Section 3 describes details of building this resource and demonstrates our application of sense examples to WSD. We also present results and analysis in this section. Finally, we conclude in Section 4 and talk about future work.

2 Acquisition of Sense Examples

Following our previous proposal (Wang, 2004), we automatically acquire English sense examples using large quantities of Chinese text and English-Chinese and Chinese-English dictionaries. The Chinese language was chosen because it is a distant language from English and the more distant two languages are, the more likely that senses are lexicalised differently (Resnik and Yarowsky, 1999). The underlying assumption of this approach is that in general each sense of an ambiguous English word corresponds to a distinct translation in Chinese. As shown in Figure 1, firstly, the system translates senses of an English word into Chinese words, using an English-Chinese dictionary, and then retrieves text snippets from a large amount of Chinese text, with the Chinese translations as queries. Then, the Chinese text snippets are segmented and then translated back to English word by word, using a Chinese-English dic-

{English sense example 2 for sense 2 of w}

Figure 1. Process of automatic acquisition of sense examples. For simplicity, assume w has two senses.

tionary. In this way, for each sense, a set of sense examples is produced. As an example, suppose one wants to retrieve sense examples for the *financial* sense of *interest*. One first looks up the Chinese translations of this sense in an English-Chinese dictionary, and finds that 利息 is the right Chinese translation corresponding to this particular sense. Then, the next stage is to automatically build a collection of Chinese text snippets by either searching in a large Chinese corpus or on the Web, using 利息 as query. Since Chinese is a language written without spaces between words, one needs to use a segmentor to mark word boundaries before translating the snippets word by word back to English. The result is a collection of sense examples for the *financial* sense of *interest*, each containing a bag of words that tend to co-occur with that particular sense. For example, {*interest rate, bank, annual, economy, ...*} might be one of the sense examples extracted for the *financial* sense of *interest*. Note that words in a sense example are unordered.

Since this method acquires training data for WSD systems from raw monolingual Chinese text, it avoids the problem of the shortage of English sense-tagged corpora, and also of the shortage of aligned bilingual corpora. Also, if existing corpora are not big enough, one can always harvest more text from the Web. However, like all methods based on the cross-language translation assumption mentioned above, there are potential problems. For example, it is possible that a Chinese translation of an English sense is also ambiguous, and thus the contents of text snippets retrieved may be regarding a concept other than the one we want. In general, when the assumption does not hold, one could use the *glosses* defined in a dictionary as queries to retrieve text snippets, as comprehensive bilingual dictionaries tend to include translations to all senses of a word, where multiword translations are used when one-to-one translation is not possible. Alternatively, a human annotator could map the senses and translations by hand. As we will describe later in this paper, we chose the latter way in our experiments.

3 Experiments and Results

We firstly describe in detail how we prepared the sense examples and then describe a large scale WSD evaluation on the English Senseval-2 Lexical Sample dataset (Kilgarriff, 2001). The results show that our system trained with the sense examples achieved significantly better accuracy than comparable systems. We also show that when a little manual effort was invested in mapping the English word senses to Chinese monosemous translations, WSD performance improves accordingly. Based on further experiments on a standard binary WSD dataset, we also show that the technique scales up satisfactorily so that more sense examples help achieve better WSD accuracy.

3.1 Building Sense Examples

Following the approach described in Section 2, we built sense examples for the 44 words in the Senseval-2 dataset[3]. These 44 words have 223 senses in total to disambiguate. The first step was translating English senses to Chinese. We used the *Yahoo! Student English-Chinese On-line Dictionary*[4], as well as a more comprehensive electronic dictionary. This is because the *Yahoo!* dictionary is designed for English learners, and its sense granularity is rather coarse-grained. It is good enough for words with fewer or coarse-grained senses. How-

[3]These 44 words cover all nouns and adjectives in the Senseval-2 dataset, but exclude verbs. We discuss this point in section 3.2.

[4]See: http://cn.yahoo.com/dictionary.

ever, the Senseval-2 Lexical Sample task[5] uses WordNet 1.7 as gold standard, which has very fine sense distinctions and translation granularity in the *Yahoo!* dictionary does not conform to this standard. *PowerWord 2002*[6] was chosen as a supplementary dictionary because it integrates several comprehensive English-Chinese dictionaries in a single application. For each sense of an English word entry, both *Yahoo!* and *PowerWord 2002* dictionaries list not only Chinese translations but also English glosses, which provides a bridge between WordNet synsets and Chinese translations in the dictionaries. In detail, to automatically find a Chinese translation for sense s of an English word w, our system looks up w in both dictionaries and determines whether w has the same or greater number of senses as in WordNet. If it does, in one of the bilingual dictionaries, we locate the English gloss g which has the maximum number of overlapping words with the gloss for s in the WordNet synset. The Chinese translation associated with g is then selected. Although this simple method successfully identified Chinese translations for 23 out of the 44 words (52%), translations for the remaining word senses remain unknown because the sense distinctions are different between our bilingual dictionaries and WordNet. In fact, unless an English-Chinese bilingual WordNet becomes available, this problem is inevitable. For our experiments, we solved the problem by manually looking up dictionaries and identifying translations. For each one of the 44 words, *PowerWord 2002* provides more Chinese translations than the number of its synsets in WordNet 1.7. Thus the annotator simply selects the Chinese translations that he considers a best match to the corresponding English senses. This task took an hour for an annotator who speaks both languages fluently.

It is possible that the Chinese translations are also ambiguous, which can make the topic of a collection of text snippets deviate from what is expected. For example, the *oral* sense of *mouth* can be translated as 口 or 口腔 in Chinese. However, the first translation (口) is a single-character word and is highly ambiguous: by combining with other characters, its meaning varies. For example, 出口 means “an exit” or “to export”. On the other hand, the second translation (口腔) is monosemous and should be used. To assess the influence of such “ambiguous translations”, we carried out experiments involving more human labour to verify the translations. The same annotator manually eliminated those highly ambiguous Chinese translations and then replaced them with less ambiguous or ideally monosemous Chinese translations. This process changed roughly half of the translations and took about five hours. We compared the basic system with this manually improved one. The results are presented in section 3.2.

Using translations as queries, the sense examples were automatically extracted from *the Chinese Gigaword Corpus* (CGC), distributed by the LDC[7], which contains 2.7GB newswire text, of which 900MB are sourced from *Xinhua News Agency of Beijing*, and 1.8GB are drawn from *Central News* from Taiwan. A small percentage of words have different meanings in these two Chinese dialects, and since the Chinese-English dictionary (*LDC Mandarin-English Translation Lexicon Version 3.0*) we use later is compiled with Mandarin usages in mind, we mainly retrieve data from *Xinhua News*. We set a threshold of 100, and only when the amount of snippets retrieved from *Xinhua News* is smaller than 100, do we turn to *Central News* to collect more data. Specifically, for 48 out of the 223 (22%) Chinese queries, the system retrieved less than 100 instances from *Xinhua News* so it extracted more data from *Central News*. In theory, if the training data is still not enough, one could always turn to other text resources, such as the Web.

To decide the optimal length of text snippets to retrieve, we carried out pilot experiments with two length settings: 250 ($\approx$ 110 English words) and 400 ($\approx$ 175 English words) Chinese characters, and found that more context words helped improve WSD performance (results not shown). Therefore, we retrieve text snippets with a length of 400 characters.

We then segmented all text snippets, using an application *ICTCLAS*[8]. After the segmentor marked

[5]The task has two variations: one to disambiguate fine-grained senses and the other to coarse-grained ones. We evaluated our sense examples on the former variation, which is obviously more difficult.

[6]A commercial electronic dictionary application. We used the free on-line version at: http://cb.kingsoft.com.

[8]See: http://mtgroup.ict.ac.cn/~zhp/ICTCLAS

all word boundaries, the system automatically translated the text snippets word by word using the electronic *LDC Mandarin-English Translation Lexicon 3.0*. As expected, the lexicon does not cover all Chinese words. We simply discarded those Chinese words that do not have an entry in this lexicon. We also discarded those Chinese words with multiword English translations. Since the discarded words can be informative, one direction of our research in the future is to find an up-to-date wide coverage dictionary, and to see how much difference it will make. Finally, we filtered the sense examples with a stop-word list, to ensure only content words were included.

We ended up with 223 sets of sense examples for all senses of the 44 nouns and adjectives in the test dataset. Each sense example contains a set of words that were translated from a Chinese text snippet, whose content should closely relate to the English word sense in question. Words in a sense example are unordered, because in this work we only used bag-of-words information. Except for the very small amount of manual work described above to map WordNet glosses to those in English-Chinese dictionaries, the whole process is automatic.

3.2 WSD Experiments on Senseval-2 Lexical Sample dataset

The Senseval-2 English Lexical Sample Dataset consists of manually sense-tagged training and test instances for nouns, adjectives and verbs. We only tested our system on nouns and adjectives because verbs often have finer sense distinctions, which would mean more manual work would need to be done when mapping WordNet synsets to English-Chinese dictionary glosses. This would involve us in a rather different kind of enterprise since we would have moved from an almost-unsupervised to a more supervised setup.

We did not use the training data supplied with the dataset. Instead, we train a classifier on our automatically built sense examples and test it on the test data provided. In theory, any machine learning classifier can be applied. We chose the Naïve Bayes algorithm with kernel estimation[9] (John and Langley, 1995) which outperformed a few other classifiers in our pilot experiments on other datasets (results not shown). The average length of a sense example is 35 words, which is much shorter than the length of the text snippets, which was set to 400 Chinese characters (≈ 175 English words). This is because function words and words that are not listed in the *LDC Mandarin-English* lexicon were eliminated. We did not apply any weighting to the features because performance went down in our pilot experiments when we applied a TF.IDF weighting scheme (results not shown). We also limited the maximum number of

Table 1. WSD accuracy on words in the English Senseval-2 Lexical Sample dataset. The left most column shows words, their POS tags and how many senses they have. "Sys A" and "Sys B" are our systems, and "MW" denotes a multi-word detection module was used in conjunction with the "Basic" system. For comparison, it also shows two baselines: "RB" is the random baseline and "MFB" is the most-frequent-sense baseline. "UNED" is one of the best unsupervised participants in the Senseval-2 competition and "Lesk(U)" is the highest unsupervised-baseline set in the workshop. All accuracies are expressed as percentages.

[9]We used the implementation in the Weka machine learning package, available at: http://www.cs.waikato.ac.nz/~ml/weka.

training sense examples to 6000, for efficiency purposes. We attempted to tag every test data instance, so our coverage (on nouns and adjectives) is 100%.

To assess the influence of ambiguous Chinese translations, we prepared two sets of training data. As described in section 3.1: sense examples in the first set were prepared without taking ambiguity in Chinese text into consideration, while those in the second set were prepared with a little more human effort involved trying to reduce ambiguity by using less ambiguous translations. We call the system trained on the first set "Sys A" and the one trained on the second "Sys B".

In this lexical sample task, multiwords are expected to be picked out by participating WSD systems. For example, the answer *art collection* should be supplied when this multiword occurs in a test instance. It would be judged wrong if one tagged the *art* in *art collection* as the *artworks* sense, even though one could argue that this was also a correct answer. To deal with multiwords, we implemented a very simple detection module, which tries to match multiword entries in WordNet to the ambiguous word and its left and right neighbours. For example, if the module finds *art collection* is an entry in WordNet, it tags all occurrences of this multiword in the test data, regardless of the prediction by the classifier.

The results are shown in Table 1. Our "Sys B" system, with and without the multiword detection module, outperformed "Sys A", which shows that sense examples acquired with less ambiguous Chinese translations contain less noise and therefore boost WSD performance. For comparison, the table also shows various baseline performance figures and a system that participated in Senseval-2[10]. Considering that the manual work involved in our approach is negligible compared with manual sense-tagging, we classify our systems as unsupervised and we should aim to beat the random baseline. This all four of our systems do easily. We also easily beat another unsupervised baseline – the Lesk (1986) baseline, which disambiguates words using WordNet definitions. The MFB baseline is actually a 'supervised' baseline, since an unsupervised system does not have such prior knowledge beforehand. McCarthy et al. (2004) argue that this is a very tough baseline for an unsupervised WSD system to beat. Our "Sys B" with multiword detection exceeds it. "Sys B" also exceeds the performance of UNED (Fernández-Amorós et al., 2001), which was the second-best ranked[11] unsupervised systems in the Senseval-2 competition.

There are a number of factors that can influence WSD performance. The distribution of training data for senses is one. In our experiments, we used all sense examples that we built for a sense (with an upper bound of 6000). However, the distribution of senses in English text often does not match the distribution of their corresponding Chinese translations in Chinese text. For example, suppose an English word w has two senses: s_1 and s_2, where s_1 rarely occurs in English text, whereas sense s_2 is used frequently. Also suppose s_1's Chinese translation is much more frequently used than s_2's translation in Chinese text. Thus, the distribution of the two senses in English is different from that of the translations in Chinese. As a result, the numbers of sense examples we would acquire for the two senses would be distributed as if they were in Chinese text. A classifier trained on this data would then tend to predict unseen test instances in favour of the wrong distribution. The word *nation*, for example, has three senses, of which the *country* sense is used more frequently in English. However, in Chinese, the *country* sense and the *people* sense are almost equally distributed, which might be the reason for its WSD accuracy being lower with our systems than most of the other words. A possible way to alleviate this problem is to select training sense examples according to an estimated distribution in natural English text, which can be done by analysing available sense-tagged corpora with help of smoothing techniques, or with the unsupervised approach of (McCarthy et al., 2004).

Cultural differences can cause difficulty in retrieving sufficient training data. For example, translations of senses of *church* and *hearth* appear only infrequently in Chinese text. Thus, it is hard to build sense examples for these words. Another problem,

[10]Accuracies for each word and averages were calculated by us, based on the information on Senseval-2 Website. See: http://www.sle.sharp.co.uk/senseval2/.

[11]One system performed better but their answers were not on the official Senseval-2 website so that we could not do the comparison. Also, that system did not attempt to disambiguate as many words as UNED and us.

as mentioned above, is that translations of English senses can be ambiguous in Chinese. For example, Chinese translations of the words *vital*, *natural*, *local* etc. are also ambiguous to some extent, and this might be a reason for their low performance. One way to solve this, as we described, is to manually check the translations. Another automatic way is that, before retrieving text snippets, we could segment or even parse the Chinese corpora, which should reduce the level of ambiguity and lead to better sense examples.

3.3 Further WSD Experiments

One of the strengths of our approach is that training data come cheaply and relatively easily. However, the sense examples are acquired automatically and they inevitably contain a certain amount of noise, which may cause problems for the classifier. To assess the relationship between accuracy and the size of training data, we carried out a series of experiments, feeding the classifier with different numbers of sense examples as training data.

For these experiments, we used another standard WSD dataset, the TWA dataset. This is a manually sense-tagged corpus (Mihalcea, 2003), which contains 2-way sense-tagged text instances, drawn from the British National Corpus, for 6 nouns. We first built sense examples for all the 12 senses using the approach described above, then trained the same Naïve Bayes algorithm (NB) on different numbers of sense examples.

In detail, for all of the 6 words, we did the following: given a word w_i, we randomly selected n sense examples for each of its senses s_i, from the total amount of sense examples built for s_i. Then the NB algorithm was trained on the $2 * n$ examples and tested on w_i's test instances in TWA. We recorded the accuracy and repeated this process 200 times and calculated the mean and variance of the 200 accuracies. Then we assigned another value to n and iterated the above process until n took all the predefined values. In our experiments, n was taken from {*50, 100, 150, 200, 400, 600, 800, 1000, 1200*} for words *motion*, *plant* and *tank* and from {*50, 100, 150, 200, 250, 300, 350*} for *bass*, *crane* and *palm*, because there were less sense example data available for the latter three words. Finally, we used the t-test ($p = 0.05$) on pairwise sets of means and variances to see if improvements were statistically significant.

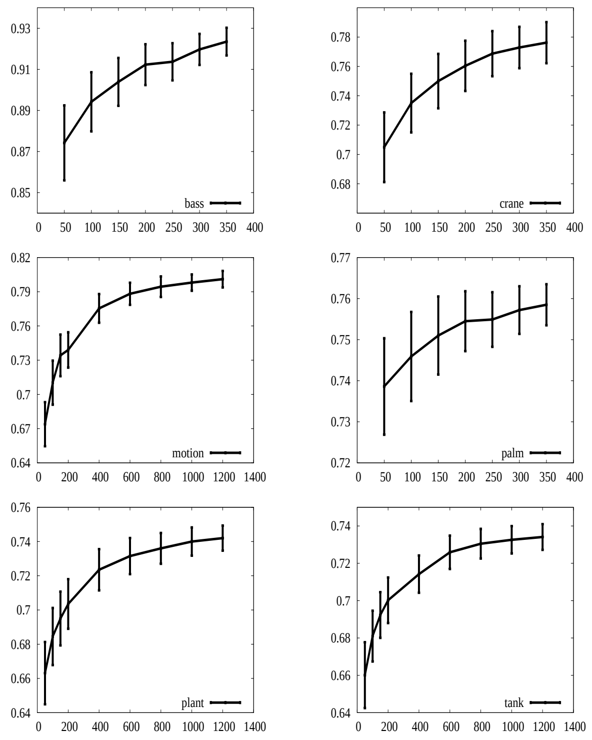

Figure 2. Accuracy scores with increasing number of training sense examples. Each bar is a standard deviation.

The results are shown in Figure 2[12]. 34 out of 42 t-scores are greater than the t-test critical values, so we are fairly confident that the more training sense examples used, the more accurate the NB classifier becomes on this disambiguation task.

4 Conclusions and Future Work

We have presented WSD systems that use sense examples as training data. Sense examples are acquired automatically from large quantities of Chinese text, with the help of Chinese-English and English-Chinese dictionaries. We have tested our WSD systems on the English Senseval-2 Lexical Sample dataset, and our best system outperformed comparable state-of-the-art unsupervised systems. Also, we found that increasing the number of the sense examples significantly improved WSD performance. Since sense examples can be obtained very cheaply from any large Chinese text collection, in-

[12]These experiments showed that our systems outperformed the most-frequent-sense baseline and Mihalcea's unsupervised system (2003).

cluding the Web, our approach is a way to tackle the knowledge acquisition bottleneck.

There are a number of future directions that we could investigate. Firstly, instead of using a bilingual dictionary to translate Chinese text snippets back to English, we could use machine translation software. Secondly, we could try this approach on other language pairs, Japanese-English, for example. This is also a possible solution to the problem that ambiguity may be preserved between Chinese and English. In other words, when a Chinese translation of an English sense is still ambiguous, we could try to collect sense examples using translation in a third language, Japanese, for instance. Thirdly, it would be interesting to try to tackle the problem of Chinese WSD using sense examples built using English, the reverse process to the one described in this paper.

Using MONA for Querying Linguistic Treebanks

Stephan Kepser[*]
Collaborative Research Centre 441
University of Tübingen
Tübingen, Germany
kepser@sfs.uni-tuebingen.de

Abstract

MONA is an automata toolkit providing a compiler for compiling formulae of monadic second order logic on strings or trees into string automata or tree automata. In this paper, we evaluate the option of using MONA as a treebank query tool. Unfortunately, we find that MONA is not an option. There are several reasons why the main being unsustainable query answer times. If the treebank contains larger trees with more than 100 nodes, then even the processing of simple queries may take hours.

1 Introduction

In recent years large amounts of electronic texts have become available providing a new base for empirical studies in linguistics and offering a chance to linguists to compare their theories with large amounts of utterances from "the real world". While tagging with morphosyntactic categories has become a standard for almost all corpora, more and more of them are nowadays annotated with refined syntactic information. Examples are the Penn Treebank (Marcus et al., 1993) for American English annotated at the University of Pennsylvania, the French treebank (Abeillé and Clément, 1999) developed in Paris, the TIGER Corpus (Brants et al., 2002) for German annotated at the Universities of Saarbrücken and Stuttgart, and the Tübingen Treebanks (Hinrichs et al., 2000) for Japanese, German and English from the University of Tübingen. To make these rich syntactic annotations accessible for linguists, the development of powerful query tools is an obvious need and has become an important task in computational linguistics.

Consequently, a number of treebank query tools have been developed. Probably amongst the most important ones are CorpusSearch (Randall, 2000), ICECUP III (Wallis and Nelson, 2000), fsq (Kepser, 2003), TGrep2 (Rohde, 2001), and TIGERSearch (König and Lezius, 2000). A common feature of these tools is the relatively low expressive power of their query languages. Explicit or implicit references to nodes in a tree are mostly interpreted existentially. The notable exception is fsq, which employs full first order logic as its query language.

The importance of the expressive power of the query language is a consequence of the sizes of the available treebanks, which can contain several ten-thousand trees. It is clearly impossible to browse these treebanks manually searching for linguistic phenomena. But a query tool that does not permit the user to specify the sought linguistic phenomenon quite precisely is not too helpful, either. If the user can only approximate the phenomenon he seeks answer sets will be very big, often containing several hundred to thousand trees. Weeding through answer sets of this size is cumbersome and not really fruitful. If the task is to gain small answer sets, then query languages must be powerful. The reason why the above mentioned query tools still offer query languages of limited expressive power is the fear that

[*] This research was funded by a German Science Foundation grant (DFG SFB441-6).

there may be a price to be paid for offering a powerful query language, namely longer query answer times due to more complex query evaluation algorithms.

At least on a theoretical level, this fear is not necessarily justified. As was recently shown by Kepser (2004), there exists a powerful query language with a query evaluation algorithm of low complexity. The query language is monadic second-order logic (MSO henceforth), an extension of first-order logic that additionally allows for the quantification over *sets* of tree nodes. The fact that makes this language so appealing beyond its expressive power is that the evaluation time of an MSO query on a tree is only linear in the size of the tree. The query evaluation algorithm proceeds in two steps. In the first step, a query is compiled into an equivalent tree automaton. In the second, the automaton is run on each tree of the treebank. Since a run of an automaton on a tree is linear in the size of the tree, the evaluation of an MSO query is linear in the size of a tree.

There has sometimes been the question whether the expressive power of MSO is really needed. Beyond the statements above about retrieving small answer sets there is an important argument concerning the expressive power of the grammars underlying the annotation of the treebanks. A standard assumption in the description of the syntax of natural languages is that at least context-free string grammars are required. On the level of trees, these correspond to regular tree grammars (Gécseg and Steinby, 1997). It is natural to demand that the expressive power of the query language matches the expressive power of the underlying grammar. Otherwise there can be linguistic phenomena annotated in the treebank for which a user cannot directly query. The query language which exactly matches the expressive power of regular tree grammars is MSO. In other words, a set of trees is definable by a regular tree grammar iff there is an MSO formula that defines this set of trees (Gécseg and Steinby, 1997). Hence MSO is a natural choice of query language under the given assumption that the syntax of natural language is (at least) context-free on the string or token level.

Since the use of MSO as a query language for treebanks is – at least on a theoretical level – quite appealing, it is worth trying to develop a query system that brings these theoretical concepts to practise. The largest and most demanding subpart of this enterprise is the development of a tree automata toolkit, a toolkit that compiles formulae into tree automata and performs standard operations on tree automata such as union, intersection, negation, and determination. Since this task is very demanding, it makes sense to investigate whether one could use existing tree automata toolkits before starting to develop a new one. To the authors' knowledge, there exists only one of-the-shelf usable tree automata toolkit, and that is MONA (Klarlund, 1998). It is the aim of this paper to give an evaluation of using MONA for querying linguistic treebanks.

2 The Tree Automata Toolkit MONA

Tree automata are generalisations of finite state automata to trees. For a general introduction to tree automata, we refer the reader to (Gécseg and Steinby, 1997). There exists a strong connection between tree automata and MSO. A set of trees is definable by an MSO formula if and only if there exists a tree automaton accepting this set. This equivalence is constructive, there is an algorithm that constructs an automaton from a given MSO formula.

MONA is an implementation of this relationship. It is being developed by Nils Klarlund, Anders Møller, and Michael Schwartzbach. Its intended main uses are hardware and program verification. MONA is actually an implementation of the compilation of monadic second order logic on *strings and* trees into finite state automata or tree automata, respectively. But we focus exclusively on the tree part here. As we will see later, MONA was not developed with linguistic applications in mind.

2.1 The Language of MONA

The language of MONA is pure monadic second order logic of two successors. We will only mention the part of the language that is needed for describing trees. There are first-order and second-order terms. A first-order variable is a first-order term. The constant *root* is a first-order term denoting the root node of a tree. If t is a first-order term and s is a non-empty sequence of 0's and 1's, then $t.s$ is a first-order term. 0 denotes the left daughter, and 1 the right daughter of a node. A sequence of 0's and 1's denotes a path in the tree. The term *root*.011, e.g., denotes the node that is reached from the root by first going to the left daughter and then going twice down to the right daughter. A set variable is a second-order term. If $t_1,\dots,t_k$ are first-order terms then $\{t_1,\dots,t_k\}$ is a second-order term. We consider the following formulae. Let t,t' be first-order terms and T,T' be second order terms. Atomic formulae are

- $t = t'$ – Equality of nodes,
- $T = T'$ – Equality of node sets,
- t `in` T – t is a member of set T,
- `empty`(T) – Set T is empty.

Formulae are constructed from atomic formulae using the boolean connectives and quantification. Let ϕ and ψ be formulae. Then we define complex formulae as

- $\sim \phi$ – Negation of ϕ,
- ϕ & ψ – Conjunction of ϕ and ψ,
- $\phi \mid \psi$ – Disjunction of ϕ and ψ,
- ϕ `=>` ψ – Implication of ϕ and ψ,
- `ex1` $x : \phi$ – First-order existential quantification of x in ϕ,
- `all1` $x : \phi$ – First-order universal quantification of x in ϕ,
- `ex2` $X : \phi$ – Existential quantification of set X in ϕ,
- `all2` $X : \phi$ – Universal quantification of set X in ϕ.

We note that there is no way to extend this language. This has three important consequences. Firstly, we are restricted to using *binary* trees only. And secondly, we cannot accommodate linguistic labels in a direct way. We have to find some coding. Finally, and this is a significant drawback that may exclude the use of MONA for many applications, we cannot code the tokens, the word sequence at the leaves of a tree. Hence we can neither query for particular words or sequences of words. We can only query the structure of a tree – including the labels.

2.2 The MONA Compiler

The main program of MONA is a compiler that compiles formulae in the above described language into tree automata. The input is a file containing the formulae. The output is an analysis of the automaton that is constructed. In particular, it is stated whether the formula is satisfiable at all, i.e., whether an automaton can be constructed.

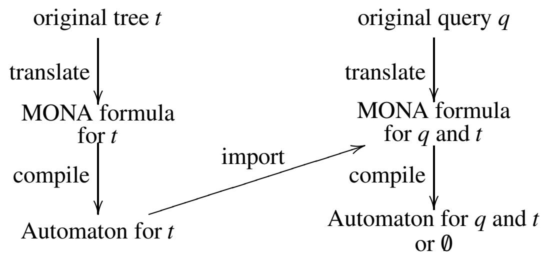

Figure 1: Method of using MONA for querying.

MONA does not provide a method to execute an automaton on a tree. But if a formula can be compiled into an automaton, this automaton can be output to file. And a file containing an automaton can be imported into a file containing a formula. We therefore use the following strategy to query treebanks using MONA. Each tree from the treebank is translated into a formula in the MONA language. How this can be done, will be described later. The formula representing the tree is then compiled into an automaton and written to file. Now the treebank exists as a set of automata files. A query to the original treebank will also be translated into a MONA formula. For each tree of the treebank, this formula is extended by an import statement for the automaton representing the tree. If and only if the extended formula representing query and tree can be compiled into an automaton, then the tree is a match for the original query. This way we can use MONA to query the treebank. The method is depicted in Figure 1.

3 The Tübingen Treebanks

In order to evaluate the usability of MONA as a query tool we had to chose some treebank to do our evaluation on. We opted for the Tübingen Treebank of spoken German. The Tübingen Treebanks, annotated at the University of Tübingen, comprise a German, an English and a Japanese treebank consisting of spoken dialogs restricted to the domain of arranging business appointments. For our evaluation, we focus on the German treebank (TüBa-D/S) (Stegmann et al., 2000; Hinrichs et al., 2000) that contains approximately 38.000 trees.

The treebank is part-of-speech tagged using the Stuttgart-Tübingen tag set (STTS) developed by

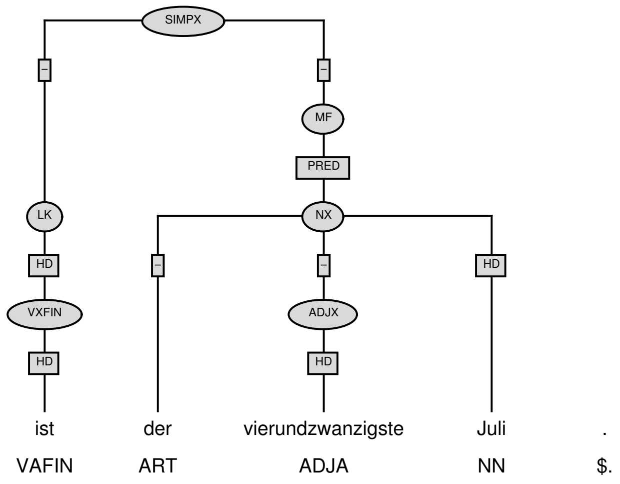

Figure 2: An example tree from TüBa-D/S.

Schiller et al. (1995). One of the design decisions for the development of the treebank was the commitment to reusability. As a consequence, the choice of the syntactic annotation scheme should not reflect a particular syntactic theory but rather be as theory-neutral as possible. Therefore a surface-oriented scheme was adopted to structure German sentences that uses the notion of topological fields in a sense similar to that of Höhle (1985). The verbal elements have the categories `LK` (*linke Klammer*) and `VC` (*verbal complex*); roughly everything preceeding the `LK` forms the "Vorfeld" `VF`, everything between `LK` and `VC` forms the "Mittelfeld" `MF`, and the material following the `VC` forms the "Nachfeld" `NF`.

The treebank is annotated with syntactic categories as node labels, grammatical functions as edge labels and dependency relations. The syntactic categories follow traditional phrase structure and the theory of topological fields. An example of a tree can be found in Figure 2. To cope with the characteristics of spontaneous speech, the data structures in the Tübingen Treebanks are of a more general form than trees. For example, an entry may consist of several tree structures. It may also contain completely disconnected nodes. In contrast to TIGER or the Penn Treebank, there are neither crossing branches nor empty categories.

There is no particular reason why we chose this treebank. Many others could have been used as well for testing the applicability of MONA.

4 Converting Trees into Automata

4.1 Translating Trees into Tree Descriptions

When translating trees from the treebank into MONA formulae describing these trees we consider proper trees only. Many treebanks, including TüBa-D/S, contain more complex structures than proper trees. For the evaluation purpose here we simplify these structures as follows. We ignore the secondary relations. And we introduce a new super root. All disconnected subparts are connected to this super root. Note that we employ this restriction for the evaluation purpose only. The general method does not require these restrictions, because even more complex tree-like structures can be recoded into proper binary trees, as is shown in (Kepser, 2004).

As stated above, the translation of trees into formulae has to perform two tasks. The trees, which are arbitrarily branching, must be transformed into binary trees. And the linguistic labels, i.e., the node categories and grammatical functions, have to be coded. For the transformation into binary trees, we employ the First-Daughter-Next-Sibling encoding, a rather standard technique. Consider an arbitrary node x in the tree. If x has any daughters, its leftmost daughter will become the left daughter of x in the transformed tree. If x has any sisters, then its leftmost sister will become the right daughter of x in the transformed tree. This transformation is applied recursively to all nodes in the tree. For example, the tree in Figure 2 is transformed into the binary tree in Figure 3.

Note how the disconnected punctuation node at the lower right corner in Figure 2 becomes the right daughter of the SIMPX node in Figure 3. Note also that we have both category and grammatical function as node labels for those nodes that have a grammatical function.

Such a binary tree is now described by a several formulae. The first formula, called *Carcase*, collects the addresses of all nodes in the tree to describe the tree structure without any labels. For our example tree, the formula would be

$$\text{Carcase} = \{root, root.0, root.00, root.000, root.0000, root.01, root.001, root.0010, root.00100, root.001001, root.0010010, root.0010011\}.$$

A syntactic category or grammatical function is coded as the set of nodes in the tree that are labelled

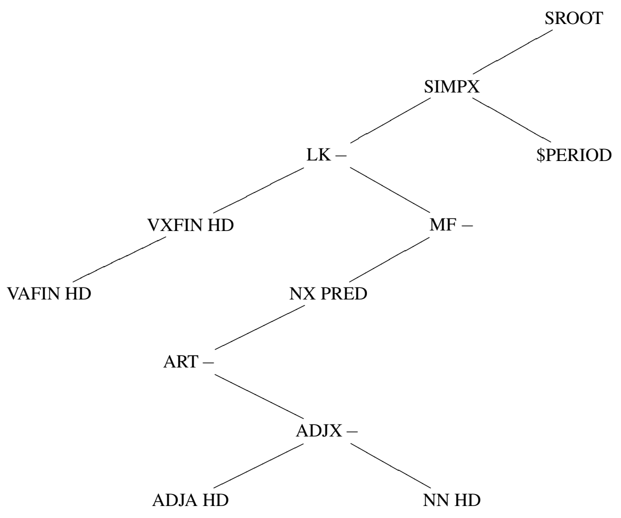

Figure 3: Binary recoding of the tree in Figure 2.

with this category or function. This is the way to circumvent the problem that we cannot extend the language of MONA. Here are some formulae for some labels of the example tree.
LK $= \{root.00\}$, ART $= \{root.00100\}$, HD $= \{root.000, root.0000, root.0010010, root.0010011\}$.

For all category or function labels that are not present at a particular tree, but part of the label set of the treebank, we state that the corresponding sets are empty. For example, the description of the example tree contains the formula `empty`(VC).

We implemented a program that actually performs this translation step. The input is a fraction of the TüBa-D/S treebank in NEGRA export format (Brants, 1997). The output is a file for each tree containing the MONA formulae coding this tree. In this way, we get a set of MONA formulae describing each tree.

4.2 Compiling Tree Descriptions into Automata

As mentioned above, the next step consists in compiling each tree description into an equivalent automaton. This is the first part of the evaluation. We tested whether MONA can actually perform this compilation. Astonishingly, the answer is not as simple as one might expect. It turns out that the computing power required to perform the compilation is quite high. To start, we chose a very small subset of the TüBa-D/S, just 1000 trees. Some of these trees contain more than 100 nodes, one more than 200 nodes. Processing descriptions of these large trees actually requires a lot of computing power.

It seems it is *not* possible to perform this compilation step on a desktop machine. We used an AMD 2200 machine with 2GB Ram for a try, but aborted the compilation of the 1000 trees after 15 hours. At that time, only 230 trees had been compiled.

To actually get through the compilation of the treebank we transfered the task to a cluster computer. On this cluster we used 4 nodes each equipped with two AMD Opteron 146 (2GHz, 4GB Ram) in parallel. Parallelisation is simple since each tree description can be compiled independently of all the others. The parallelisation was done by hand. Using this equipment we could compile 999 trees in about 4 hours. These 4 hours are the time needed to complete the whole task, not pure processing time. The tree containing more than 200 nodes could still not be compiled. Its compilation terminated unsuccessfully after 6 hours. We decided to drop this tree from the sample.

It is obvious that this is a major obstacle for using MONA. It is difficult to believe that many linguists will have access to a cluster computers and sufficient knowledge to use it. And we expect on the base of our experiences that a compilation on an ordinary desktop machine can take several days, provided the machine is equipped with large amounts of memory. Otherwise it will fail. One still has to consider that 1000 trees are not much. The TIGER corpus and the TüBa-D/S have each about 40.000 trees. Thus one may argue that this fact alone makes MONA unsuitable for use by linguists. But the compilation step has to be performed only once. The files containing the resulting automata are machine independent. Hence a corpus provider could at least in theory provide his corpus as a collection of MONA automata. This labour would be worth trying, if the resulting automata could be used for efficient querying.

5 Querying the Treebank

In order to query the treebank we designed a query language that has MSO as its core but contains features desirable for treebank querying. Naturally the language is designed to query the original trees, not their codings. It is therefore necessary to translate a query into an equivalent MONA formula that respects the translation of the trees.

5.1 The Query Language

The query language is defined as follows. The language has a LISP-like syntax. First-order variables ($x, y, \ldots$) range over nodes, set variables ($X, Y, \ldots$) range over sets of nodes. The atomic formulae are

- `(cat x NX)` – Node x is of category `NX`,
- `(fct x HD)` – Node x is of grammatical function `HD`,
- `(> x y)` – Node x is the mother of node y,
- `(>+ x y)` – Node x properly dominates y,
- `(. x y)` – Node x is immediately to the left of y,
- `(.. x y)` – Node x is to the left of y,
- `(= x y)` – Node x and y are identical,
- `(= X Y)` – Node sets X and Y are identical,
- `(in x X)` – Node x is a member of set X.

Complex formulae are constructed by boolean connectives and quantification. Let x be a node variable, X a set variable, and ϕ and ψ formulae. Then we have

- `(!` ϕ`)` – Negation of ϕ,
- `(&` ϕ ψ`)` – Conjunction of ϕ and ψ,
- `(|` ϕ ψ`)` – Disjunction of ϕ and ψ,
- `(->` ϕ ψ`)` – Implication of ϕ and ψ,
- `(E x` ϕ`)` – Existential quantification of x in ϕ,
- `(A x` ϕ`)` – Universal quantification of x in ϕ,
- `(E2 X` ϕ`)` – Existential quantification of set variable X in ϕ,
- `(A2 X` ϕ`)` – Universal quantification of set variable X in ϕ.

5.2 Translating the Query Language

The next step consists of translating queries in this language into MONA formulae. As is simple to see, the translation of the complex formulae is straight forward, because they are essentially the same in both languages. The more demanding task is connected with the translation of formulae on category and function labels and the tree structure, i.e., dominance and precedence.

As described above, categories and functions are coded as sets. Hence a query for a category or function is translated into a formula expressing set membership in the relevant set. For example, the query `(cat x SIMPX)` is translated into `(x in SIMPX)`.

The translations of dominance and precedence are the most complicated ones, because we transformed the treebank trees into binary trees. Now we have to reconstruct the original tree structures out of these binary trees. In the first step we have to define dominance on coded binary trees. The MONA language contains formulae for the left and right daughter of a node, but there is no formula for dominance, the transitive closure of the daughter relation. That we can define dominance at all is a consequence of the expressive power of MSO. As was shown by Courcelle (1990), the transitive closure of any MSO-definable binary relation is also MSO-definable. Let R be an MSO-definable binary relation. Then

$$\forall X \ (\forall z, w(z \in X \wedge R(z,w) \rightarrow w \in X) \wedge \\ \forall z(R(x,z) \rightarrow z \in X)) \rightarrow y \in X$$

is a formula with free variables x and y that defines the transitive closure of R. If we now take $R(x,y)$ in the above formula to be $(x.0 = y \mid x.1 = y)$ we define dominance (*dom*). In a similar fashion we can define that y is on the rightmost branch of x ($rb(x,y)$) by taking $R(x,y)$ to be $(x.1 = y)$.

Now for immediate dominance, if node x is the mother of y in the original tree, we have to distinguish to cases. In the simpler case, y is the leftmost daughter of x, so after transformation, y is the left daughter of x. Or y is not the leftmost daughter of x, in that case it is a sister of the leftmost daughter z of x. All sisters of z are found on the rightmost branch of z in the transformed trees. Hence `(> x y)` is translated into $(x.0 = y \mid \texttt{ex1}\ z : x.0 = z \,\&\, rb(z,y))$.

Proper dominance is treated similarly. If we iterate the above argument that the daughters of a node x in the original tree become the left daughter z of x and the rightmost successors of z, we can see that z and all the nodes dominated by z in the translated tree are actually all the nodes dominated by x in the original tree. Hence `(>+ x y)` is translated into $(x.0 = y \mid \texttt{ex1}\ z : x.0 = z \,\&\, dom(z,y))$.

For precedence, consider a node x in a coded binary tree. By definition the left daughter of x and all her successors are nodes that preceed the right daughter of x and her successors in the original tree. Thus `(.. x y)` is translated into

$$(x.1 = y \mid (\ \texttt{ex1}\ z,w,v : z.0 = w \,\&\, z.1 = v \,\& \\ (w = x \mid dom(w,x)) \,\& \\ (v = y \mid dom(v,y)))).$$

Immediate precedence can be expressed using precedence. Node x immediately precedes y if x precedes y there is no node z that is preceeded by x and precedes y.

There is a small issue in the translation of quantified formulae. In the translation of a first-order quantification (existential or universal) of a variable x we have to make sure that x actually ranges over the nodes in a particular tree. Otherwise MONA may construct an automaton that contains the coded tree as a substructure, but is more general. In such a case we could no longer be certain that a solution found by MONA actually represents a proper match of the original query on the original tree. To solve this problem, we add (x `in Carcase`) to the translation of `(E x` ϕ`)` or `(A x` ϕ`)`. E.g., `(E x` ϕ`)` translates to (`ex1` x : x `in Carcase` & ϕ') where ϕ' is the translation of ϕ. The same holds – mutatis mutandis – for set variable quantification.

5.3 Performing a Query

We implemented a small program that performs the above described translation of queries. It actually does a little bit more. It adds the defining formulae for *dom* and *rb*. Furthermore, as mentioned above, MONA allows to include a precompiled automaton into a set of MONA formulae via a special import declaration. Such an import declaration is used to include the automata representing the (coded) trees from the treebank. Thus the set of MONA formulae to evaluate a query consist of the translation of the query, the formulae for *dom* and *rb*, and an import declaration for one tree from the treebank. This set of MONA formulae can now be fed into MONA to try to compile it into an automaton. If the compilation is successful, there exists an automaton that at the same time represents the translation of the query and the translation of the given tree. Hence the tree is a match for the query. If there is no automaton, the tree is no match for the query. To perform the query on the whole treebank there is a loop that stepwise imports every tree and calls MONA to check if an automaton can be compiled. The result is the set of tree IDs that identify the trees that match the query.

We tested this method on our small treebank of 999 trees from TüBa-D/S. Unfortunately it turned out that the reloading of large precompiled automata (representing large trees) also requires enormous computational resources. We experimented with a very simple query: $\exists x\, \mathrm{NX}(x)$ (or `(E x (cat x NX)))`. On our desktop machine (AMD 2200, 2GB Ram), it took 6 hours and 9 minutes to process this query. If we pose the same query on the whole treebank TüBa-D/S (with about 38.000 trees) using established query tools like TIGERSearch or fsq, processing time is about 5 seconds. Hence the method of using MONA is clearly *not appropriate* for desktop computers.

Even access to larger computing power does not solve the problem. We processed the same query on one processor (AMD Opteron 146, 2GHz, 4GB Ram) of the cluster computer mentioned above. There it took 1 minute and 30 seconds. About the same query answer time was required for a second, more complex query that asked for two different NX nodes and a third SIMPX node. These query answer times are still too long, because we queried only about one fortieth of the whole treebank. Since each tree is queried separately, we can expect a linear time increase in the query time in the number of trees. In other words, evaluating the query on the whole treebank would probably take about 1 hour. And that on a computer with such massive computing power. TIGERSearch and fsq are 720 times faster, and they run on desktop computers.

6 Conclusions

Despite the many reported successful applications of MONA in other areas, we have to state that MONA is clearly *not* a choice for querying linguistic treebanks. Firstly, we cannot use MONA to query for tokens (or words). Secondly, the compilation of a treebank into a set of automata is extremely difficult and resources consuming, if not impossible. And finally, practical query answer times are way too long. Apparently, reloading precompiled automata representing large trees takes too much time, because the automata representing these large trees are themselves huge.

We note that this is unfortunately not the first negative experience of trying to apply MONA to computational linguistics tasks. Morawietz and Cornell (1999), who try to use MONA to compile logical formalisations of GB-theory, also report that automata get too large to work with.

The general problem behind these two unsuccessful applications of MONA to problems in computational linguistics seems to be that MONA does not allow users to define their own signatures. Hence linguistic labels have to be coded in an indirect fashion. Though this coding works in theory, the resulting automata can become huge. The reason for this explosion in automata size, though, remains mysterious.

The negative experience we made with MONA does on the other hand not mean that the whole enterprise of using tree automata for querying treebanks is deemed to fail. It seems that it is rather this particular deficit of MONA of providing no direct way to cope with labelled trees that causes the negative result. It could therefore well be worth trying to implement tree automata for labelled trees and use these for treebank querying.

KnowItNow: Fast, Scalable Information Extraction from the Web

Michael J. Cafarella, Doug Downey, Stephen Soderland, Oren Etzioni
Department of Computer Science and Engineering
University of Washington
Seattle, WA 98195-2350
{mjc,ddowney,soderlan,etzioni}@cs.washington.edu

Abstract

Numerous NLP applications rely on search-engine queries, both to extract information from and to compute statistics over the Web corpus. But search engines often limit the number of available queries. As a result, query-intensive NLP applications such as Information Extraction (IE) distribute their query load over several days, making IE a slow, offline process.

This paper introduces a novel architecture for IE that obviates queries to commercial search engines. The architecture is embodied in a system called KNOWITNOW that performs high-precision IE in minutes instead of days. We compare KNOWITNOW experimentally with the previously-published KNOWITALL system, and quantify the tradeoff between recall and speed. KNOWITNOW's extraction rate is two to three orders of magnitude higher than KNOWITALL's.

1 Background and Motivation

Numerous modern NLP applications use the Web as their corpus and rely on queries to commercial search engines to support their computation (Turney, 2001; Etzioni et al., 2005; Brill et al., 2001). Search engines are extremely helpful for several linguistic tasks, such as computing usage statistics or finding a subset of web documents to analyze in depth; however, these engines were not designed as building blocks for NLP applications. As a result, the applications are forced to issue literally millions of queries to search engines, which limits the speed, scope, and scalability of the applications. Further, the applications must often then fetch some web documents, which at scale can be very time-consuming.

In response to heavy programmatic search engine use, Google has created the "Google API" to shunt programmatic queries away from Google.com and has placed hard quotas on the number of daily queries a program can issue to the API. Other search engines have also introduced mechanisms to limit programmatic queries, forcing applications to introduce "courtesy waits" between queries and to limit the number of queries they issue.

To understand these efficiency problems in more detail, consider the KNOWITALL information extraction system (Etzioni et al., 2005). KNOWITALL has a generate-and-test architecture that extracts information in two stages. First, KNOWITALL utilizes a small set of domain-independent extraction patterns to *generate* candidate facts (*cf.* (Hearst, 1992)). For example, the generic pattern "NP1 such as NPList2" indicates that the head of each simple noun phrase (NP) in NPList2 is a member of the class named in NP1. By instantiating the pattern for class `City`, KNOWITALL extracts three candidate cities from the sentence: "We provide tours to cities such as Paris, London, and Berlin." Note that it must also fetch each document that contains a potential candidate.

Next, extending the PMI-IR algorithm (Turney, 2001), KNOWITALL automatically *tests* the plausibility of the candidate facts it extracts using *pointwise mutual information* (PMI) statistics computed from search-engine hit counts. For example, to assess the likelihood that "Yakima" is a city, KNOWITALL will compute the PMI between Yakima and a set of k *discriminator phrases* that tend to have high mutual information with city names (*e.g.*, the simple phrase "city"). Thus, KNOWITALL requires at least k search-engine queries for every candidate extraction it assesses.

Due to KNOWITALL's dependence on search-engine queries, large-scale experiments utilizing KNOWITALL *take days and even weeks to complete*, which makes research using KNOWITALL slow and cumbersome. Private access to Google-scale infrastructure would provide sufficient access to search queries, but at prohibitive cost, and the problem of fetching documents (even if from a cached copy) would remain (as we discuss in Section 2.1). Is there a feasible alternative Web-based IE system? If so, what size Web index and how many machines are required to achieve reasonable levels of precision/recall? What would the architecture of this IE system look like, and how fast would it run?

To address these questions, this paper introduces a novel architecture for web information extraction. It consists of two components that supplant the generate-and-test mechanisms in KNOWITALL. To generate extractions rapidly we utilize our own specialized search engine, called the Bindings Engine (or BE), which efficiently returns bindings in response to variabilized queries. For example, in response to the query *"Cities such as ProperNoun(Head(⟨NounPhrase⟩))"*, BE will return a list of proper nouns likely to be city names. To assess these extractions, we use URNS, a combinatorial model, which estimates the probability that each extraction is correct without using any additional search engine queries.[1] For further efficiency, we introduce an approximation to URNS, based on frequency of extractions' occurrence in the output of BE, and show that it achieves comparable precision/recall to URNS.

Our contributions are as follows:

1. We present a novel architecture for Information Extraction (IE), embodied in the KNOWITNOW system, which does not depend on Web search-engine queries.

2. We demonstrate experimentally that KNOWITNOW is the first system able to extract tens of thousands of facts from the Web in minutes instead of days.

3. We show that KNOWITNOW's extraction rate is two to three orders of magnitude greater than KNOWITALL's, but this increased efficiency comes at the cost of reduced recall. We quantify this tradeoff for KNOWITNOW's 60,000,000 page index and extrapolate how the tradeoff would change with larger indices.

Our recent work has described the BE search engine in detail (Cafarella and Etzioni, 2005), and also analyzed the URNS model's ability to compute accurate probability estimates for extractions (Downey et al., 2005). However, this is the first paper to investigate the composition of these components to create a fast IE system, and to compare it experimentally to KNOWITALL in terms of time, recall, precision, and extraction rate. The frequency-based approximation to URNS and the demonstration of its success are also new.

The remainder of the paper is organized as follows. Section 2 provides an overview of BE's design. Section 3 describes the URNS model and introduces an efficient approximation to URNS that achieves similar precision/recall. Section 4 presents experimental results. We conclude with related and future work in Sections 5 and 6.

2 The Bindings Engine

This section explains how relying on standard search engines leads to a bottleneck for NLP applications, and provides a brief overview of the Bindings Engine (BE)—our solution to this problem. A comprehensive description of BE appears in (Cafarella and Etzioni, 2005).

Standard search engines are computationally expensive for IE and other NLP tasks. IE systems issue multiple queries, downloading all pages that potentially match an extraction rule, and performing expensive processing on each page. For example, such systems operate roughly as follows on the query ("cities such as ⟨*NounPhrase*⟩"):

1. Perform a traditional search engine query to find all URLs containing the non-variable terms (*e.g.*, "cities such as")

2. For each such URL:
   (a) obtain the document contents,
   (b) find the searched-for terms ("cities such as") in the document text,
   (c) run the noun phrase recognizer to determine whether text following "cities such as" satisfies the linguistic type requirement,
   (d) and if so, return the string

We can divide the algorithm into two stages: obtaining the list of URLs from a search engine, and then processing them to find the ⟨*NounPhrase*⟩ bindings. Each stage poses its own scalability and speed challenges. The first stage makes a query to a commercial search engine; while the number of available queries may be limited, a single one executes relatively quickly. The second stage fetches a large number of documents, each fetch likely resulting in a random disk seek; this stage executes slowly. Naturally, this disk access is slow regardless of whether it happens on a locally-cached copy or on a remote document server. The observation that the second stage is slow, even if it is executed locally, is important because it shows that merely operating a "private" search engine does not solve the problem (see Section 2.1).

The Bindings Engine supports queries containing *typed variables* (such as *NounPhrase*) and

[1]In contrast, PMI-IR, which is built into KNOWITALL, requires multiple search engine queries to assess each potential extraction.

string-processing functions (such as "head(X)" or "ProperNoun(X)") as well as standard query terms. BE processes a variable by returning every possible string in the corpus that has a matching type, and that can be substituted for the variable and still satisfy the user's query. If there are multiple variables in a query, then all of them must simultaneously have valid substitutions. (So, for example, the query "<*NounPhrase*> is located in <*NounPhrase*>" only returns strings when noun phrases are found on both sides of "is located in".) We call a string that meets these requirements a *binding* for the variable in question. These queries, and the bindings they elicit, can usefully serve as part of an information extraction system or other common NLP tasks (such as gathering usage statistics). Figure 1 illustrates some of the queries that BE can handle.

president Bush <*Verb*>
cities such as *ProperNoun(Head(<NounPhrase>))*
<*NounPhrase*> is the CEO of <*NounPhrase*>

Figure 1: **Examples of queries that can be handled by** BE**. Queries that include typed variables and string-processing functions allow NLP tasks to be done efficiently without downloading the original document during query processing.**

BE's novel *neighborhood index* enables it to process these queries with $O(k)$ random disk seeks and $O(k)$ serial disk reads, where k is the number of non-variable terms in its query. As a result, BE can yield orders of magnitude speedup as shown in the asymptotic analysis later in this section. The neighborhood index is an augmented inverted index structure. For each term in the corpus, the index keeps a list of documents in which the term appears and a list of positions where the term occurs, just as in a standard inverted index (Baeza-Yates and Ribeiro-Neto, 1999). In addition, the neighborhood index keeps a list of left-hand and right-hand *neighbors* at each position. These are adjacent text strings that satisfy a recognizer for one of the target types, such as *NounPhrase*.

As with a standard inverted index, a term's list is processed from start to finish, and can be kept on disk as a contiguous piece. The relevant string for a variable binding is included directly in the index, so there is no need to fetch the source document (thus causing a disk seek). Expensive processing such as part-of-speech tagging or shallow syntactic parsing is performed only once, while building the index, and is not needed at query time. It is important to note that simply preprocessing the corpus and placing the results in a database would not avoid disk seeks, as we would still have to explicitly fetch these results. The run-time efficiency of the neighborhood index comes from integrating the results of corpus processing with the inverted index (which determines which of those results are relevant).

	Query Time	Index Space
BE	$O(k)$	$O(N)$
Standard engine	$O(k+B)$	$O(N)$

Table 1: BE **yields considerable savings in query time over a standard search engine. k is the number of concrete terms in the query, B is the number of variable bindings found in the corpus, and N is the number of documents in the corpus. N and B are typically extremely large, while k is small.**

The neighborhood index avoids the need to return to the original corpus, but it can consume a large amount of disk space, as parts of the corpus text are folded into the index several times. To conserve space, we perform simple dictionary-lookup compression of strings in the index. The storage penalty will, of course, depend on the exact number of different types added to the index. In our experiments, we created a useful IE system with a small number of types (including *NounPhrase*) and found that the neighborhood index increased disk space only four times that of a standard inverted index.

Asymptotic Analysis:

In our asymptotic analysis of BE's behavior, we count query time as a function of the number of random disk seeks, since these seeks dominate all other processing tasks. Index space is simply the number of bytes needed to store the index (not including the corpus itself).

Table 1 shows that BE requires only $O(k)$ random disk seeks to process queries with an arbitrary number of variables whereas a standard engine takes $O(k + B)$, where k is the number of concrete query terms, and B is the number of bindings found in a corpus of N documents. Thus, BE's performance is the same as that of a standard search engine for queries containing only concrete terms. For variabilized queries, N may be in the billions and B will tend to grow with N. In our experiments, eliminating the B term from our query processing time has resulted in speedups of two to three orders of magnitude over a standard search engine. The speedup is at the price of a small constant multiplier to index size.

2.1 Discussion

While BE has some attractive properties for NLP computations, is it necessary? Could fast, large-scale information extraction be achieved merely by operating a "private" search engine?

The release of open-source search engines such as Nutch[2], coupled with the dropping price of CPUs and

[2]http://lucene.apache.org/nutch/

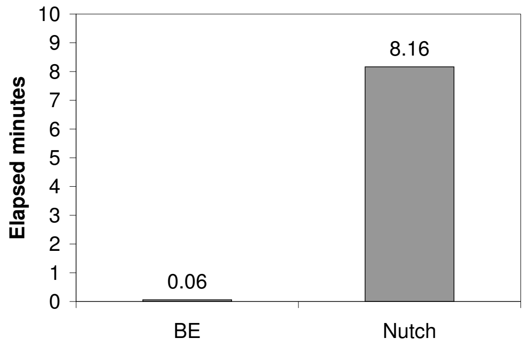

Figure 2: **Average time to return the relevant bindings in response to a set of queries was 0.06 CPU minutes for BE, compared to 8.16 CPU minutes for the comparable processing on Nutch. This is a 134-fold speed up. The CPU resources, network, and index size were the same for both systems.**

disks, makes it feasible for NLP researchers to operate their own large-scale search engines. For example, Turney operates a search engine with a terabyte-sized index of Web pages, running on a local eight-machine Beowulf cluster (Turney, 2004). Private search engines have two advantages. First, there is no query quota or need for "courtesy waits" between queries. Second, since the engine is local, network latency is minimal.

However, to support IE, we must also execute the second stage of the algorithm (see the beginning of this section). In this stage, each document that matches a query has to be retrieved from an arbitrary location on a disk.[3] Thus, the number of random disk seeks scales linearly with the number of documents retrieved. Moreover, many NLP applications require the extraction of strings matching particular syntactic or semantic types from each page. The lack of linguistic data in the search engine's index means that many pages are fetched only to be discarded as irrelevant.

To quantify the speedup due to BE, we compared it to a standard search index built on the open-source Nutch engine. All of our Nutch and BE experiments were carried out on the same corpus of 60 million Web pages and were run on a cluster of 23 dual-Xeon machines, each with two local 140 Gb disks and 4 Gb of RAM. We set all configuration values to be exactly the same for both Nutch and BE. BE gave a 134-fold speed up on average query processing time when compared to the same queries with the Nutch index, as shown in Figure 2.

[3]Moving the disk head to an arbitrary location on the disk is a mechanical operation that takes about 5 milliseconds on average.

3 The URNS Model

To realize the speedup from BE, KNOWITNOW must also avoid issuing search engine queries to validate the correctness of each extraction, as required by PMI computation. We have developed a probabilistic model obviating search-engine queries for assessment. The intuition behind this model is that correct instances of a class or relation are likely to be extracted repeatedly, while random errors by an IE system tend to have low frequency for each distinct incorrect extraction.

Our probabilistic model, which we call URNS, takes the form of a classic "balls-and-urns" model from combinatorics. We think of IE abstractly as a generative process that maps text to extractions. Each extraction is modeled as a labeled ball in an urn. A *label* represents either an instance of the target class or relation, or represents an error. The information extraction process is modeled as repeated draws from the urn, with replacement.

Formally, the parameters that characterize an urn are:

- C – the set of unique target labels; $|C|$ is the number of unique target labels in the urn.
- E – the set of unique error labels; $|E|$ is the number of unique error labels in the urn.
- $num(b)$ – the function giving the number of balls labeled by b where $b \in C \cup E$. $num(B)$ is the multi-set giving the number of balls for each label $b \in B$.

The goal of an IE system is to discern which of the labels it extracts are in fact elements of C, based on repeated draws from the urn. Thus, the central question we are investigating is: *given that a particular label x was extracted k times in a set of n draws from the urn, what is the probability that $x \in C$?* We can express the probability that an element extracted k of n times is of the target relation as follows.

$$P(x \in C | x \, \text{appears} \, k \, \text{times in} \, n \, \text{draws}) = \frac{\sum_{r \in num(C)} (\frac{r}{s})^k (1 - \frac{r}{s})^{n-k}}{\sum_{r' \in num(C \cup E)} (\frac{r'}{s})^k (1 - \frac{r'}{s})^{n-k}} \quad (1)$$

where s is the total number of balls in the urn, and the sum is taken over possible repetition rates r.

A few numerical examples illustrate the behavior of this equation. Let $|C| = |E| = 2,000$ and assume for simplicity that all labels are repeated on the same number of balls ($num(c_i) = R_C$ for all $c_i \in C$, and $num(e_i) = R_E$ for all $e_i \in E$). Assume that the extraction rules have precision $p = 0.9$, which means that $R_C = 9 \times R_E$ — target balls are nine times as common in the urn as error balls. Now, for $k = 3$ and $n = 10,000$ we have $P(x \in C) = 93.0\%$. Thus, we see that a small number of repetitions can yield high confidence in an extraction. However, when the sample size increases so that

$n = 20,000$, and the other parameters are unchanged, then $P(x \in C)$ drops to 19.6%. On the other hand, if C balls repeat much more frequently than E balls, say $R_C = 90 \times R_E$ (with $|E|$ set to 20,000, so that p remains unchanged), then $P(x \in C)$ rises to 99.9%.

The above examples enable us to illustrate the advantages of URNS over the noisy-or model used in previous work. The noisy-or model assumes that each extraction is an independent assertion that the extracted label is "true," an assertion that is correct a fraction p of the time. The noisy-or model assigns the following probability to extractions:

$$P_{noisy-or}(x \in C | x \text{ appears } k \text{ times}) = 1 - (1-p)^k$$

Therefore, the noisy-or model will assign the same probability — 99.9% — in *all three* of the above examples, although this is only correct in the case for which $n = 10,000$ and $R_C = 90 \times R_E$. As the other two examples show, for different sample sizes or repetition rates, the noisy-or model can be highly inaccurate. This is not surprising given that the noisy-or model ignores the sample size and the repetition rates.

URNS uses an EM algorithm to estimate its parameters, and currently the algorithm takes roughly three minutes to terminate.[4] Fortunately, we determined experimentally that we can approximate URNS's precision and recall using a far simpler frequency-based assessment method. This is true because good precision and recall merely require an appropriate *ordering* of the extractions for each relation, and not accurate probabilities for each extraction. For unary relations, we use the simple approximation that items extracted more often are more likely to be true, and order the extractions from most to least extracted. For binary relations like CapitalOf(X,y), in which we extract several different candidate capitals y for each known country X, we use a smoothed frequency estimate to order the extractions. Let $freq(\mathtt{R(X,y)})$ denote the number of times that the binary relation $\mathtt{R(X,y)}$ is extracted; we define:

$$smoothed\_freq(\mathtt{R(X,y)}) = \frac{freq(\mathtt{R(X,y)})}{\max_{y'} freq(\mathtt{R(X,y')}) + 1}$$

We found that sorting by smoothed frequency (in descending order) performed better than simply sorting by $freq$ for relations $\mathtt{R(X,y)}$ in which different known X values may have widely varying Web presence.

Unlike URNS, our frequency-based assessment does not yield accurate probabilities to associate with each extraction, but for the purpose of returning a ranked list of high-quality extractions it is comparable to URNS (see Figures 3 through 6), and it has the advantage of being much faster. Thus, in the experiments reported on below, we use frequency-based assessment as part of KNOWITNOW.

[4]This code has not been optimized at all. We believe that we can easily reduce its running time to less than a minute on average, and perhaps substantially more.

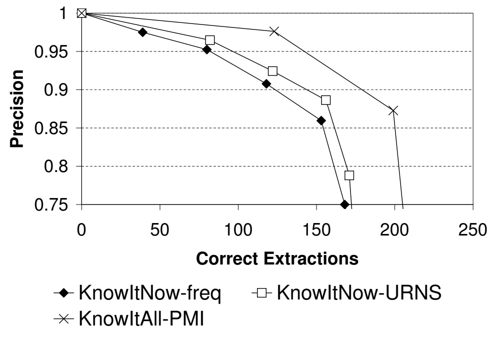

Figure 3: Country: **KNOWITALL maintains somewhat higher precision than KNOWITNOW throughout the recall-precision curve.**

4 Experimental Results

This section contrasts the performance of KNOWITNOW and KNOWITALL experimentally. Before considering the experiments in detail, we note that a key advantage of KNOWITNOW is that it does not make *any* queries to Web search engines. As a result, KNOWITNOW's scale is not limited by a query quota, though it is limited by the size of its index.

We report on the following metrics:

- **Recall:** how many distinct extractions does each system return at high precision?[5]
- **Time:** how long did each system take to produce and rank its extractions?
- **Extraction Rate:** how many distinct high-quality extractions does the system return per minute? The extraction rate is simply recall divided by time.

We contrast KNOWITALL and KNOWITNOW's precision/recall curves in Figures 3 through 6. We compared KNOWITNOW with KNOWITALL on four relations: Corp, Country, CeoOf(Corp,Ceo), and CapitalOf(Country,City). The unary relations were chosen to examine the difference between a relation with a small number of correct instances (Country) and one with a large number of extractions (Corp). The binary relations were chosen to cover both functional relations (CapitalOf) and set-valued relations (CeoOf— we treat former CEOs as correct instances of the relation).

[5]Since we cannot compute "true recall" for most relations on the Web, the paper uses the term "recall" to refer to the size of the set of facts extracted.

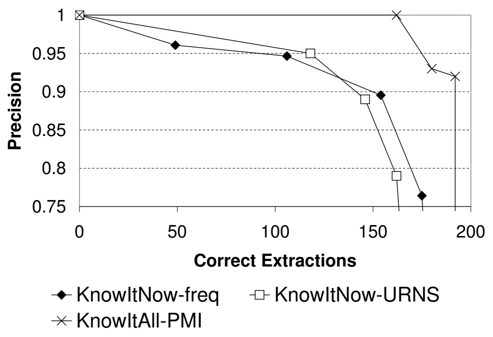

Figure 4: `CapitalOf`: KNOWITNOW **does nearly as well as** KNOWITALL**, but has more difficulty than** KNOWITALL **with sparse data for capitals of more obscure countries.**

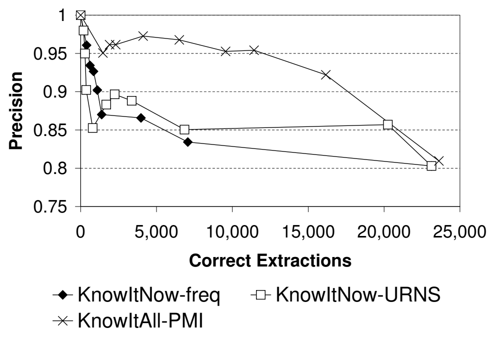

Figure 5: `Corp`: KNOWITALL**'s PMI assessment maintains high precision.** KNOWITNOW **has low recall up to precision 0.85, then catches up with** KNOWITALL**.**

For the two unary relations, both systems created extraction rules from eight generic patterns. These are hyponym patterns like "NP1 {,} such as NPList2" or "NP2 {,} and other NP1", which extract members of NPList2 or NP2 as instances of NP1. For the binary relations, the systems instantiated rules from four generic patterns. These are patterns for a generic "of" relation. They are "NP1 , rel of NP2", "NP1 the rel of NP2", "rel of NP2 , NP1", and "NP2 rel NP1". When rel is instantiated for `CeoOf`, these patterns become "NP1 , CEO of NP2" and so forth.

Both KNOWITNOW and KNOWITALL merge extractions with slight variants in the name, such as those differing only in punctuation or whitespace, or in the presence or absence of a corporate designator. For binary extractions, CEOs with the same last name and same company were also merged. Both systems rely on the OpenNlp maximum-entropy part-of-speech tagger and chunker (Ratnaparkhi, 1996), but KNOWITALL applies them to pages downloaded from the Web based on the results of Google queries, whereas KNOWITNOW applies them once to crawled and indexed pages.[6] Overall, each of the above elements of KNOWITALL and KNOWITNOW are the same to allow for controlled experiments.

Whereas KNOWITNOW runs a small number of variabilized queries (one for each extraction pattern, for each relation), KNOWITALL requires a stopping criterion. Otherwise, KNOWITALL will continue to query Google and download URLs found in its result pages over many days and even weeks. We allowed a total of 6 days of search time for KNOWITALL, allocating more search for the relations that continued to be most productive. For `CeoOf` KNOWITNOW returned all pairs of `Corp,Ceo` in its corpus; KNOWITALL searched for CEOs of a random selection of 10% of the corporations it found, and we projected the total extractions and search effort for all corporations. For `CapitalOf`, both KNOWITNOW and KNOWITALL looked for capitals of a set of 195 countries.

Table 2 shows the number of queries, search time, distinct correct extractions at precision 0.8, and extraction rate for each relation. Search time for KNOWITNOW is measured in seconds and search time for KNOWITALL is measured in hours. The number of extractions per minute counts the distinct correct extractions. Since we limit KNOWITALL to one Google query per second, the time for KNOWITALL is proportional to the number of queries. KNOWITNOW's extraction rate is from 275 to 4,707 times that of KNOWITALL at this level of precision.

While the number of distinct correct extractions from KNOWITNOW at precision 0.8 is roughly comparable to that of 6 days search effort from KNOWITALL, the situation is different at precision 0.9. KNOWITALL's PMI assessor is able to maintain higher precision than KNOWITNOW's frequency-based assessor. The number of correct corporations for KNOWITNOW drops from 23,128 at precision 0.8 to 1,116 at precision 0.9. KNOWITALL is able to identify 17,620 correct corporations at precision 0.9. Even with the drop in recall, KNOWITNOW's extraction rate is still 305 times higher than KNOWITALL's. The reason for KNOWITNOW's difficulty at precision 0.9 is due to extraction errors that occur with high frequency, particularly generic references to companies ("the Seller is a corporation ...", "corporations such as Banks", etc.) and truncation of certain company names by the extraction rules. The more expensive PMI-based assessment was not fooled by these systematic extraction errors.

Figures 3 through 6 show the recall-precision curves for KNOWITNOW with URNS assessment, KNOWITNOW with the simpler frequency-based assessment, and

[6]Our time measurements for KNOWITALL are not affected by the tagging and chunking time because it is dominated by time required to query Google, waiting a second between queries.

	Google Queries		Time		Extractions		Extractions per minute		
	NOW	ALL	NOW (sec)	ALL (hrs)	NOW	ALL	NOW	ALL	ratio
Corp	0 (16)	201,878	42	56.1	23,128	23,617	33,040	7.02	4,707
Country	0 (16)	35,480	42	9.9	161	203	230	0.34	672
CeoOf	0 (6)	263,646	51	73.2	2,402	5,823	2,836	1.33	2,132
CapitalOf	0 (6)	17,216	55	4.8	169	192	184	0.67	275

Table 2: **Comparison of KNOWITNOW with KNOWITALL for four relations, showing number of Google queries (local BE queries in parentheses), search time, correct extractions at precision 0.8, and extraction rate (the number of correct extractions at precision 0.8 per minute of search). Overall, KNOWITNOW took a total of slightly over 3 minutes as compared to a total of 6 days of search for KNOWITALL.**

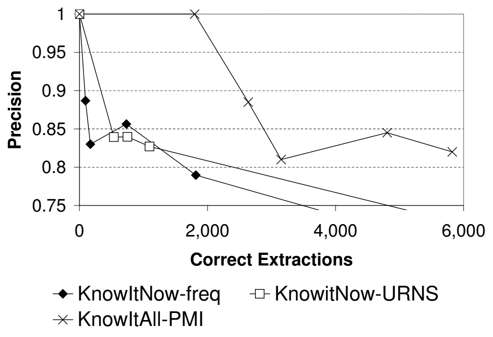

Figure 6: `CeoOf`: **KNOWITNOW has difficulty distinguishing low frequency correct extractions from noise. KNOWITALL is able to cope with the sparse data more effectively.**

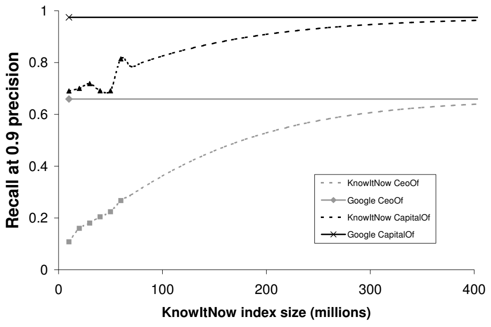

Figure 7: **Projections of recall (at precision 0.9) as a function of KNOWITNOW index size. At 400 million pages, KNOWITNOW's recall rapidly approaches the recall achieved by KNOWITALL using roughly 300,000 Google queries.**

KNOWITALL with PMI-based assessment. For each of the four relations, PMI is able to maintain a higher precision than either frequency-based or URNS assessment. URNS and frequency-based assessment give roughly the same levels of precision.

For the relations with a small number of correct instances, `Country` and `CapitalOf`, KNOWITNOW is able to identify 70-80% as many instances as KNOWITALL at precision 0.9. In contrast, `Corp` and `CeoOf` have a huge number of correct instances and a long tail of low frequency extractions that KNOWITNOW has difficulty distinguishing from noise. Over one fourth of the corporations found by KNOWITALL had Google hit counts less than 10,500, a sparseness problem that was exacerbated by KNOWITNOW's limited index size.

Figure 7 shows projected recall from larger KNOWITNOW indices, fitting a sigmoid curve to the recall from index size of 10M, 20M, up to 60M pages. The curve was fitted using logistic regression, and is restricted to asymptote at the level reported for Google-based KNOWITALL for each relation. We report recall at precision 0.9 for capitals of 195 countries and CEOs of a random selection of the top 5,000 corporations as ranked by PMI. Recall is defined as the percent of countries with a correct capital or the number of correct CEOs divided by the number of corporations.

The curve for `CeoOf` is rising steeply enough that a 400 million page KNOWITNOW index may approach the same level of recall yielded by KNOWITALL when it uses 300,000 Google queries. As shown in Table 2, KNOWITALL takes slightly more than three days to generate these results. KNOWITNOW would operate over a corpus 6.7 times its current one, but the number of required random disk seeks (and the asymptotic run time analysis) would remain the same. We thus expect that with a larger corpus we can construct a KNOWITNOW system that reproduces KNOWITALL levels of precision and recall while still executing in the order of a few minutes.

5 Related Work

There has been very little work published on how to make NLP computations such as PMI-IR and IE fast for large corpora. Indeed, extraction rate is not a metric typically used to evaluate IE systems, but we believe it is an important metric if IE is to scale.

Hobbs *et al.* point out the advantage of fast text processing for rapid system development (Hobbs et al., 1992). They could test each change to system parameters and domain-specific patterns on a large sample of documents, having moved from a system that took 36 hours to process 100 documents to FASTUS, which took only 11 minutes. This allowed them to develop one of the highest performing MUC-4 systems in only one month.

While there has been extensive work in the IR and Web communities on improvements to the standard inverted index scheme, there has been little work on efficient large-scale search to support natural language applications. One exception is Resnik's Linguist's Search Engine (Elkiss and Resnik, 2004), a tool for searching large corpora of parse trees. There is little published information about its indexing system, but the user manual suggests its corpus is a combination of indexed sentences and user-specific document collections driven by the user's AltaVista queries. In contrast, the BE system has a single index, constructed just once, that serves all queries. There is no published performance data available for Resnik's system.

6 Conclusions and Future Directions

In previous work, statistical NLP computation over large corpora has been a slow, offline process, as in KNOWITALL (Etzioni et al., 2005) and also in PMI-IR applications such as sentiment classification (Turney, 2002). Technology trends, and open source search engines such as Nutch, have made it feasible to create "private" search engines that index large collections of documents; but as shown in Figure 2, firing large numbers of queries at private search engines is still slow.

This paper described a novel and practical approach towards substantially speeding up IE. We described KNOWITNOW, which extracts thousands of facts in minutes instead of days. Furthermore, we sketched URNS, a probabilistic model that both obviates the need for search-engine queries and outputs more accurate probabilities than PMI-IR. Finally, we introduced a simple, efficient approximation to URNS, whose probability estimates are not as good, but which has comparable precision/recall to URNS, making it an appropriate assessor for KNOWITNOW.

The speed and massively improved extraction rate of KNOWITNOW come at the cost of reduced recall. We quantified this tradeoff in Table 2, and also argued that as KNOWITNOW's index size increases from 60 million to 400 million pages, KNOWITNOW would achieve in minutes the same precision/recall that takes KNOWITALL days to obtain. Of course, a hybrid approach is possible where KNOWITNOW has, say, a 100 million page index and, when necessary, augments its results with a limited number of queries to Google. Investigating the extraction-rate/recall tradeoff in such a hybrid system is a natural next step.

While our experiments have used the Web corpus, our approach transfers readily to other large corpora; experimentation with other corpora is another topic for future work. In conclusion, we believe that our techniques transform IE from a slow, offline process to an online one. They could open the door to a new class of interactive IE applications, of which KNOWITNOW is merely the first.

Abstract

In the past decade, several researchers have started reinvestigating the use of sub-phonetic models for lexical representations within automatic speech recognition systems. Lest history repeat itself, it may be instructive to mine the further past for models of lexical representations in the lexical access literature. In this work, we re-evaluate the model of Briscoe (1989), in which a hybrid strategy of lexical representation between phones and manner classes is promoted. While many of Briscoe's assumptions do not match up with current ASR processing models, we show that his conclusions are essentially correct, and that reconsidering this structure for ASR lexica is an appropriate avenue for future ASR research.

1 Introduction

Almost every state-of-the-art large vocabulary automatic speech recognition (ASR) system requires the sharing of sub-word units in order to achieve the desired vocabulary coverage. Traditionally, these sub-word units are determined by the phones or phonemes of a language (depending on desired detail of representation). However, phonetic (or phonemic) representation has its pitfalls (*cf*. (Ostendorf, 1999)). Among the problems cited in the literature are that (1) segments are often difficult for machines to recognize from the acoustic cues alone, because the acoustic cues to a particular phoneme are multi-faceted, and (2) the intended words and phrases are not always recoverable even from correctly recognized segments, because speakers themselves will also fail to articulate words with the dictionary-listed phonemes. The first of these problems refers to the *discriminability* of phonemes within an inventory; the second to the *reliability* of (actual) phone sequences mapping to the canonical phonemic representations of words. This is particularly true in conversational speech (such as that found in the Switchboard corpus), where pragmatic context and conversational conventions assist human comprehension (but not current ASR systems).

A common approach for handling pronunciation variation is to introduce alternative entries into the lexicon. However, phones that are perceived as non-canonical (for example, when an /eh/ is heard as an /ih/ by linguistic transcribers) often are closer in acoustic space to the Gaussian means of the canonical phones, rather than the perceived phones (Saraçlar et al., 2000). This insight suggests that acoustic models need to be cognizant of potential pronunciation changes. Thus the lexical and acoustic models should work hand in hand.

Another way to model this type of pronunciation variation is to find the commonalities that the canonical and perceived phone share in terms of a sub-phonetic representation. In the past decade, a significant community in acoustic-phonetic ASR research has been turning to distinctive features (Jakobson et al., 1952) for building ASR lexica. While an exhaustive description of these approaches is beyond the scope of this paper, estimates of phonological feature probabilities have been combined to obtain phone probabilities (Kirchhoff, 1998), or incorporated into "feature bundles" that allow representation of phonological processes (Finke et al., 1999).

More recent work has integrated phonological features into graphical models (Livescu et al., 2003) and landmark based systems (Juneja and Espy-Wilson, 2004). The common thread among this research is the notion that acoustic models should be sensitive to sub-phonetic information. With this trend in phonological representation research, it is time to re-examine some older hypotheses about lexical access and speech processing in order to gain some insight in this current featural renaissance.

Sub-phonetic ASR research is also driven by the fact that deviations from canonical pronunciation and from correct perception of phones is far from random; indeed, there have been a number of studies demonstrating that both of these variations have defined, modelable trends. Deviations from canonical pronunciation can be described by phonological rules, and errors in perception also tend to conform to phonological patterns. By and large, confusions occur (at least in humans) between phones with phonological features in common (e.g., (Miller and Nicely, 1955)). In particular, three features (voicing, manner, and place) have been postulated as relatively invariant (see e.g., (Stevens, 1981), quoted in (Church, 1987)). It follows from this phonetic detection based on the most reliable features may handle highly variable speech more robustly than systems which demand full identity over all the features for a given phone or phone sequence.

Consequently, a number of researchers have previously suggested using certain broad classes of segments, rather than full phonemic identification, for a first pass on recognition. For instance, Shipman and Zue (1982), working on large-vocabulary isolated word recognition, used both two-way consonant-vowel distinctions and a six-way distinction based on manner in order to divide their 20,000-word dictionary into “cohorts” or groups of words. They found that this partial specification of segments reduced the search space of word candidates significantly. Carlson et al. (1985) found similar results for English and four other languages.

2 A suggested compromise: a hybrid phone-manner representation

Briscoe (1989) extended this broad-class approach to address the problem of lexical access on connected speech. However, Briscoe argues against the use of broad, manner-based classes at all times. He argues that manner cues provide no particular advantage for stressed syllables, but that all cues are sufficiently reliable in stressed syllables to justify a full segmental analysis. Working with a 30,000-word lexicon, Briscoe shows that the manner-based broad classes for weak (reduced) syllables, together with full identification of strong (unreduced) syllables constrained the set of possible candidates satisfactorily. Unfortunately, he only provides results for one sentence from his corpus.

This approach proposes to adjust the granularity of recognition dynamically, depending on the stress level of the current syllable. The details of how this would be managed are left somewhat vague. As it stands, it would seem to depend crucially on first detecting the stress of each frame, so as to determine which alphabet of symbols to apply to incoming input. Alternatively, it could recognize the broad class as a first pass, and then refine this into a full phonemic analysis for stressed syllables in a second pass, at the cost of multiplying passes through the speech data. It is not possible in this system to recover from the miscategorization of stress.

One possible remedy is to bypass a hard decision on stress and run both a manner-based broad-class detector and a traditional phonemic system in parallel. These then may be combined according to the probability of lexical stress, such that those frames judged less likely to be stressed weight the broad-class analysis more heavily, and those judged more likely to be stressed weight the narrow phonemic analysis more heavily. Its advantage is that a full phonemic analysis is recoverable for each frame and phone, but those in weak syllables (and hence less likely to be accurate) weigh in less heavily.

Briscoe’s analysis is in terms of lexical access activations: taking a cue from the lexical access community, he assumes that any “partially activated” word (e.g., “boat” and “both” being active after processing “bo”) will contribute linearly to the processing time in ASR. However, most large-vocabulary ASR systems today use a tree-based lexicon where common phonetic prefixes of words are processed only once, thus invalidating this conjecture. Briscoe experimented with several triggers for starting a new word — at every phone, at the beginnings of syllables, at the beginnings of syllables with unreduced vowels, and at the beginnings of word boundaries.

Category	Example (Vietnamese)	Cohorts
# of Words		6247
Stress pattern only (lower bound)	0001	84
Identify phones in stressed syllables	0001:m_iy_z	4709
+CV pattern of unstressed syllables	0001:CV:VC:CV:m_iy_z	5609
+manner pattern of unstressed syllables	0001:FV:CS:NV:m_iy_z	6076
Phonetic prons. (upper bound)	v iy . eh t . n aa . m iy z	6152

Table 1: Cohorts for varied lexical representations

However, the latter three require oracle information as to where word or syllable boundaries can occur. A more appropriate measure commensurate with current ASR practice would be to only allow words to start where a previous word hypothesis ends.

In the remainder of the paper, we seek to validate (or invalidate) Briscoe's claim that a hybrid phonetic and feature model is appropriate for ASR processing. In the 15 years since Briscoe's paper, the ASR community has developed large phonetically transcribed corpora and more advanced computational tools (such as the AT&T Finite-State Toolkit (Mohri et al., 2001)) that we can apply to this problem.

3 Experiment 1: Effective Partitioning by Manner-based Broad Classes

Our first experiment explores various types of broad classes to determine the effects of these encodings on cohort size within a sample 6,000 word dictionary.[1] Here we use the lexical stress-marked dictionary provided with the TIMIT database (Garofolo et al., 1993), which was syllabified using the NIST Tsylb2 syllabifier (Fisher, 1996).

Rather than calculate cohort size directly, we calculate the number of cohorts into which our dictionary is partitioned, a measure which Carlson et al. (1985) showed to correlate well with expected cohort size. (Note that this is an inverse correlation.) This describes the static *discriminability* of the lexicon: systems that have words with the same lexical representation will not be able to discriminate between these two words acoustically and must rely on the language model to discriminate between them.

[1]"Cohort size" is used here (as with Shipman and Zue (1982)) to mean the number of distinct vocabulary items that match a particular broad-class encoding. It is not intended to imply a particular theory of lexical access.

Before proceeding, it may useful to set upper and lower bounds for this exercise (Table 1). An obvious upper bound is the full phonemic disambiguation of every word. Of the 6247 words in the dictionary, 6152 unique pronunciations are found (a few cohorts consisting of sets of homophones). A convenient lower bound is the lexical stress pattern of the word, devoid of any segmental information: e.g., "unidirectional" has its stress on the 4th of 6 syllables; hence, 000100 is its lexical-stress profile. 84 unique lexical-stress profiles exist in the dictionary.

Between these two bounds, three variant broad-class partitions were explored for isolated word recognition. All three use the lower-bound stress profile as a starting place, combined with full phonemic information for the syllable with primary stress. The first, with no additional segmental information, produces 4709 distinct cohorts. The second adds a consonant-vowel (CV) profile for the unstressed syllables, which boosts the number of distinct cohorts to 5609. The final partition replaces the CV profile with a six-class manner-based broad-class partition (Nasals, Stops, Fricatives, Glides, Liquids, and Vowels). Including a manner-class representation for unstressed vowels increases the number of cohorts to 6076, which is very close to the upper bound. Thus, there is not much loss of lexical discriminability when using this type of representation.

3.1 Caveats

Now, for this scheme to be maximally useful for recognition, several conditions must obtain. First, we have assumed that we can reliably detect lexically stressed syllables within the speech signal. Waibel (Waibel, 1988) has shown that stress correlates with various acoustic cues such as spectral change. As a side experiment, we have shown that very basic methods provide encouraging results (only sketched here due to space constraints). We re-annotated TIMIT with lexical stress markings, where all frames of each stressed syllable (including onset and coda consonants, not just the nucleus) were marked as stressed. A multi-layer perceptron with 100 hidden units was trained to predict $P(\mathrm{Stress}|\mathrm{Acoustics})$ with a nine-frame context window. No additional phonetic information besides the binary label stressed/unstressed was used in training. Frame-by-frame results on the TIMIT test set were 75% accurate (chance: 52%), and when

MLP output was greater than 0.9, a precision of 89% was obtained (recall: 20%). While far from perfect, this result strongly suggests that even very simple methods can predict lexical stress fairly reasonably.

A second assumption in the above analysis was that words occur in isolation. It is clear that in connected speech, there are a larger number of potential lexical confusions. A third assumption is that those features we are relying upon in our partitions (namely, all features within stressed syllables, and manner of articulation for unstressed syllables) are perfectly reliable and discriminable. In the next two sections, we relax these assumptions by applying extensions of this method to connected speech.

4 Experiment 2: What does a hybrid representation buy you?

As Experiment 1 shows, the hybrid phone/feature representation does not drastically decrease the discriminability of the (albeit small) lexicon. It is also possible that such a representation reduces pronunciation variation, by allowing the canonical representation to more closely match actual pronunciations. For example, we have demonstrated that for common ASR corpora (Switchboard and TIMIT), segments in unstressed syllables were much more likely to deviate from their canonical lexical representation (Fosler-Lussier et al., 1999). If phones that deviate from canonical still keep the same manner class, then a dictionary built with Briscoe-esque representations should more closely match the actual pronunciations of words in running speech (as transcribed by a phonetician).

4.1 Method

In order to test this theory, we used phonetic data from (Fosler-Lussier et al., 1999) in which the ICSI phonetic transcripts of the Switchboard corpus (Greenberg et al., 1996; NIST, 1992) were aligned to a syllabified version of the Pronlex dictionary (Linguistic Data Consortium (LDC), 1996), which has 71014 entries for 66293 words. In this alignment, for every canonical phone given by the lexicon, there were zero or more corresponding realized phones. From these data we extracted the canonical and realized pronunciation of each word token, for a total of 38,527 tokens. Generally, high-frequency function words show the most variation, so they may benefit most from a manner-based representation.

Lexicon type	Strict matching	Matching w/ deletion
1) Phonetic units	37.0%	50.1%
2) Manner-based function words	50.2%	69.6%
3) + Manner for unstressed syls	53.4%	74.6%
4) + Manner for secondary stress	55.7%	77.9%
5) Manner for all syls	60.7%	85.2%

Table 2: Percent of words pronounced canonically for phonetic and hybrid lexical representations

Given these word pronunciation data, we can examine how many word tokens have transcriptions that match their dictionary-listed pronunciations, given the broad-class mappings for various sets of syllables. We built lexica and mapped phonetic transcriptions according to five different criteria:

1. Every segment is phone based (no classes).
2. Function words use manner-based classes.
3. Unstressed syllables and function words use manner only.
4. Secondary stressed syllables also use manner. (Primary stressed syllables are phone based.)
5. Every segment uses manner-based classes.

We noted in the data (as others have done) that a large proportion of the pronunciation variation was due to phone deletion (29% of words) — which would not be handled by the manner-based lexicon. However, it is likely that not every phone deletion leads to an ASR error (as attested by the fact that state-of-the-art Switchboard ASR error rates are typically less than 29%). Often there is enough residual phonetic evidence of the deleted phone, or enough phonetic evidence in other parts of the word, to recognize a word correctly despite the deletion. Thus, we decided to use a two-part strategy in calculating canonical pronunciation (Table 2). The first column, "strict matching", allows no insertions or deletions when comparing the canonical and realized pronunciation. "Matching with deletion" reports the ideal situation where phone deletions were perfectly recoverable in their canonical form. Including and ignoring deletions provides upper and lower bounds on the true lexical access results. (Insertions are relatively rare and not anticipated to affect the results significantly, and hence are not examined.)

4.2 Results and Discussion

In Table 2, we see that a standard ASR lexicon approach (strict matching 1), does not match the transcribed data very well, with only 37% of words pronounced according to the dictionary. The strict matching hybrid scenario on line 3 most closely resembles Briscoe's experiment, and shows a marked improvement in matching the dictionary and realized pronunciations; comparing the two, we see that using manner-based broad classes reduces mismatch by 25% of the total error (from 63% error to 47%), most of which comes from improved modeling of function words (line 2). Whether this gain in representation is worthwhile will depend of course on the cost in terms of the increased hypothesis space.

By allowing for perfect deletion recovery (which will of necessity entail another large expansion of the hypothesis space), a somewhat more optimistic is obtained. Comparing the "matching with deletion" columns of lines 1 and 3, we see that a little over half of the non-deletion pronunciation variation is due to manner changes in unstressed syllables. Again, a good chunk of this is in function words. By moving to manner class for stressed syllables as well would bring the hypothetical error from 25% to 15%, but at the cost of a huge explosion in the hypothesis space (as Briscoe rightly points out and as discussed in the next section).

One interesting implication of this data is that over all types of segments (stressed and unstressed), roughly three-quarters of word pronunciation variants differ from the canonical only in terms of within-manner variation and phonetic deletion.

The moral of this story is that manner-based broad classes may be a useful type of back off from truly reduced and variable syllables (particularly function words), but the full benefit of such a maneuver would only be realized after a reasonable solution for recovering large-scale deletions is found. This may come from predicting with increased specificity where deletions are likely to occur (e.g., complex codas), and what reduced realizations (e.g., of function words) are most common.

5 Experiment 3: What is the cost of a hybrid representation?

Briscoe measured the cost of hybrid representation in terms of the number of lexical activations that a partially-completed word creates (see Section 2). Yet Briscoe's methodology has several shortcomings when applied to today's ASR technology; a summary of the arguments presented above are: (1) Tree-based lexica now share processing for words with identical prefixes. (2) New words are activated only when other word hypotheses end. (3) We now have a large amount of phonetically transcribed, spontaneous speech. (4) Perfect stress detection is not really achievable.

Given criticism 1, a better measure of potential processing requirements is to generate a lattice of hypothesized words and count the number of arcs in the lattice. This lattice can be constructed in such a way that criticism 2 is satisfied. In the next section, we present a finite state machine formalism for generating such a lattice.

We apply this technique to the phonetic transcription of the Switchboard corpus (thus alleviating criticism 3). However, this introduces several problems. As Experiment 2 shows, many words have pronunciations that do not appear in the dictionary. Thus, we must find a way to alleviate the mismatch between the phonetic transcription and the dictionary in a way that is plausible for ASR processing.

We can address criticism 4 by creating phone-based and manner-based transcriptions that will run in parallel; thus, the lattice generator would be free to choose whichever representation allows the matching to a dictionary word.

5.1 Method

In this experiment we consider a finite-state transducer model of the strategy described above. This corresponds not to the ASR system as a whole, but rather to the pronunciation model of a traditional system. We assume that the pronunciation as given by the transcriber is correct, but we model the transformation of realized phones into canonical dictionary pronunciations. Since we are only investigating the combined acoustic-phonetic-lexical representation, we have left out the re-weighting and pruning of hypotheses due to integration of a language model, discourse model, or any other constraints.

Specifically, this model consists of three finite state transducers composed. The first FSM, **R**, encodes the representation of the **r**ealized phonetic transcription of the spoken corpus. In order to match this to dictionary pronunciations, we train a confusion matrix on all realized/canonical phone pairs, to obtain $P(\text{dictionary phone}|\text{transcribed phone})$; these confusion probabilities are encoded as a finite state transducer **C**. Thus, **C** is derived by computing the strength of all correspondences between the phonetic transcription of what was actually said at the phone level and the canonical pronunciation of the corresponding words. This confusion matrix consists of three parts, corresponding to substitutions, insertions, and deletions.

1. Pairwise substitutions are counted to yield a standard confusion matrix.

2. Where two or more realized phones correspond to a single canonical phone (a rare occurrence, as in e.g., *really* /r iy l iy/ → [r ih ax l iy]), each realized phone is allowed (independently) to be either deleted or substituted with its pairwise confusions from (1).

3. Deleted phones are assumed to be potentially recoverable (as in Experiment 2), so both an epsilon transition and the canonical pronunciation are preserved in the confusion matrix.

In each of these confusion matrices, we have always preserved the pathway from each realized utterance to its canonical representation for the whole corpus. So for this seen corpus, it is always possible in theory to recover the canonical representation, such that the right answer is always one of the possible hypotheses. While this may seem a bit strange, here we can only overestimate the potential hypothesis space (by adding the correct string and by assuming that deletions are recoverable); the point of this exercise is to see the number of total hypotheses (the search space) generated under such a system.

The third transducer, **D**, is the ASR dictionary that we wish to test. Thus, composing $\mathbf{R} \circ \mathbf{C} \circ \mathbf{D}$ will give the graph of all potential complete hypotheses in this space. Figure 1 shows a pruned hypothesis graph for the phrase "it's really sad" (the full hypothesis graph has 12216 arcs).

5.2 Results and Discussion

By choosing different sub-word representations, we can test Briscoe's contention that backing off to manner-based broad classes for certain (e.g., unstressed) syllables will reduce the search space and/or facilitate recovery of the intended word string. When a phone is substituted with a manner class, we construct **C** so that the generated confusions are over manner classes rather than phones.

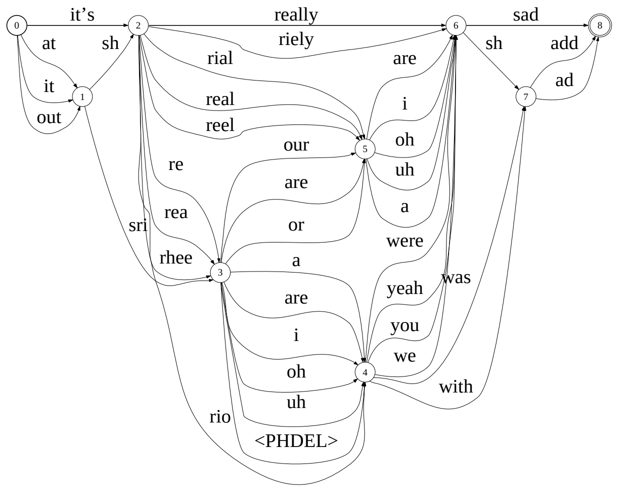

Figure 1: Pruned hypothesis graph for *It's really sad*

Figure 2 shows how the number of hypotheses per word changes as a function of the number of words in the hypothesis. Note that if the relationship were linear, we would expect to see a flat line. The figure demonstrates that that Briscoe's conclusions were correct, given the assumption that one can accurately detect lexical stress (as illustrated by the line with circles on 2). Across all utterances, the average number of hypotheses per word for the hybrid dictionary was 510 (roughly 1/3 of the phone-based average of 1429). However, when one allows for the fact that stress detection is not perfect, one sees an *increase* in the amount of necessary computation: the non-ideal hybrid dictionary has an average of 3322

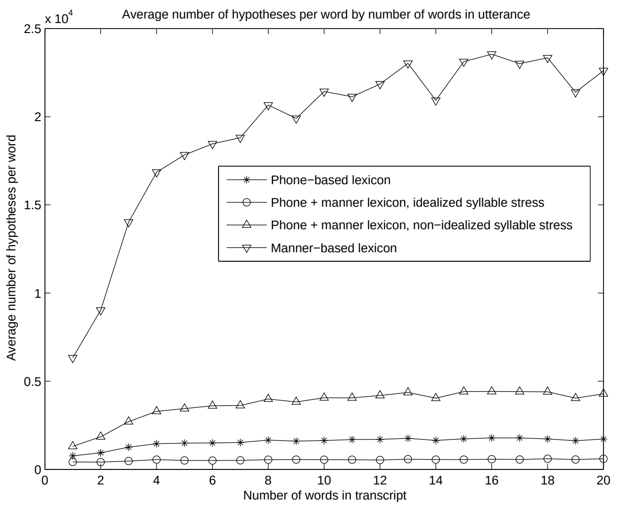

Figure 2: Average number of hypotheses per word as a function of number of words in utterance

hypotheses per word (2.3 times the phone-based average). Yet this is much lower than the potential growth of the hypothesis space given with manner-only dictionaries. This dictionary generated a hypothesis space 12 times as large as a phone based dictionary (17186 hypotheses/word average); moreover, the curve grows significantly as a function of the number of words, so longer utterances will take disproportionately more space. Thus, Briscoe's hypothesis that purely manner-based decoding is too expensive seems to be confirmed.

6 Integration into ASR

This paper has investigated hybrid representations along computational phonology lines, but we have also trained an ASR system with a hybrid lexicon for the Wall Street Journal (WSJ0) corpus. Space does not permit a full explanation of the experiment here (for more details, see (Fosler-Lussier et al., 2005)), but we include the results from this experiment as evidence of the validity of the approach.

In this experiment, we trained phonetic and manner-based acoustic models for all segments using the flat-start recipe of the HTK recognizer (Young et al., 2002). After a number of iterations of EM-training, we constructed a hybrid set of acoustic models and lexicon in which phones in unstressed syllables were replaced with manner classes (Hybrid-all). We also derived a lexicon in which the recognizer could choose whether a manner or phonetic representation was appropriate for unstressed segments (Hybrid-choice). During evaluation, we found that the Hybrid-choice lexicon degraded only slightly over a phone-based lexicon (9.9% word error vs. 9.1%), and in fact improved recognition in mild (10dB SNR) additive car noise (13.0% vs. 15.4%). The Hybrid-all was worse on clean speech (13.1% WER) but statistically the same as phone-based on noisy speech (15.8%). While not conclusive, this suggests that hybrid models may provide an interesting avenue for robustness research.

7 Conclusion

Our studies verify to some degree Briscoe's claim that a hybrid representation for lexical modeling, with stressed syllables receiving full phonetic representation and unstressed syllables represented by manner classes, can improve ASR processing. However, our analysis shows that the argument for this hypothesis plays out along very different lines than in Briscoe's study. A hybrid phone-manner lexicon can theoretically benefit ASR because (a) the discriminative power of the lexicon is not reduced greatly, (b) such a representation is a much better model of the types of pronunciation variation seen in spontaneous speech corpora such as Switchboard, and (c) the theoretical average hypothesis space increases only by a little over a factor of 2. This last fact is contrary to Briscoe's finding that the search space would be reduced because it incorporates more realistic assumptions about the detection of stressed versus unstressed syllables.

These experiments were designed primarily to investigate the validity of Briscoe's claims, and thus we attempted to remain true to his model. However, it is clear that our analysis can be extended in several ways. We have begun experimenting with pruning the hypothesis graph to remove unlikely arcs – this would give a more accurate model of the ASR processing that would occur. However, this only makes sense if language model constraints are integrated into the processing, since some word sequences in the graph would be discarded as unlikely. This analysis could also benefit from a more accurate model of the ASR system's transformation between realized phones and lexical representations. This could be achieved by comparing the Gaussian acoustic model distributions in an HMM system or sampling the acoustic model's space (McAllaster et al., 1998). Both of these extensions will be considered in future work.

The results clearly indicate that further investigation and development of a hybrid lexical strategy in an ASR system is worthwhile, particularly for spontaneous speech corpora where the problem of pronunciation variation is most rampant.

Abstract

In addition to information, text contains attitudinal, and more specifically, emotional content. This paper explores the *text-based emotion prediction problem* empirically, using supervised machine learning with the SNoW learning architecture. The goal is to classify the emotional affinity of sentences in the narrative domain of children's fairy tales, for subsequent usage in appropriate expressive rendering of text-to-speech synthesis. Initial experiments on a preliminary data set of 22 fairy tales show encouraging results over a naïve baseline and BOW approach for classification of emotional versus non-emotional contents, with some dependency on parameter tuning. We also discuss results for a tripartite model which covers emotional valence, as well as feature set alternations. In addition, we present plans for a more cognitively sound sequential model, taking into consideration a larger set of basic emotions.

1 Introduction

Text does not only communicate informative contents, but also attitudinal information, including emotional states. The following reports on an empirical study of *text-based emotion prediction*.

Section 2 gives a brief overview of the intended application area, whereas section 3 summarizes related work. Next, section 4 explains the empirical study, including the machine learning model, the corpus, the feature set, parameter tuning, etc. Section 5 presents experimental results from two classification tasks and feature set modifications. Section 6 describes the agenda for refining the model, before presenting concluding remarks in 7.

2 Application area: Text-to-speech

Narrative text is often especially prone to having emotional contents. In the literary genre of fairy tales, emotions such as HAPPINESS and ANGER and related cognitive states, e.g. LOVE or HATE, become integral parts of the story plot, and thus are of particular importance. Moreover, the story teller reading the story interprets emotions in order to orally convey the story in a fashion which makes the story come alive and catches the listeners' attention.

In speech, speakers effectively express emotions by modifying prosody, including pitch, intensity, and durational cues in the speech signal. Thus, in order to make text-to-speech synthesis sound as natural and engaging as possible, it is important to convey the emotional stance in the text. However, this implies first having identified the appropriate emotional meaning of the corresponding text passage.

Thus, an application for emotional text-to-speech synthesis has to solve two basic problems. First, what emotion or emotions most appropriately describe a certain text passage, and second, given a text passage and a specified emotional mark-up, how to render the prosodic contour in order to convey the emotional content, (Cahn, 1990). The *text-based emotion prediction* task (TEP) addresses the first of these two problems.

3 Previous work

For a complete general overview of the field of *affective computing*, see (Picard, 1997). (Liu, Lieberman and Selker, 2003) is a rare study in text-based inference of sentence-level emotional affinity. The authors adopt the notion of *basic emotions*, cf. (Ekman, 1993), and use six emotion categories: ANGER, DISGUST, FEAR, HAPPINESS, SADNESS, SURPRISE. They critique statistical NLP for being unsuccessful at the small sentence level, and instead use a database of common-sense knowledge and create affect models which are combined to form a representation of the emotional affinity of a sentence. At its core, the approach remains dependent on an emotion lexicon and hand-crafted rules for conceptual polarity. In order to be effective, emotion recognition must go beyond such resources; the authors note themselves that lexical affinity is fragile. The method was tested on 20 users' preferences for an email-client, based on user-composed text emails describing short but colorful events. While the users preferred the emotional client, this evaluation does not reveal emotion classification accuracy, nor how well the model generalizes on a large data set.

Whereas work on emotion classification from the point of view of natural speech and human-computer dialogues is fairly extensive, e.g. (Scherer, 2003), (Litman and Forbes-Riley, 2004), this appears not to be the case for text-to-speech synthesis (TTS). A short study by (Sugimoto et al., 2004) addresses sentence-level emotion recognition for Japanese TTS. Their model uses a composition assumption: the emotion of a sentence is a function of the emotional affinity of the words in the sentence. They obtain emotional judgements of 73 adjectives and a set of sentences from 15 human subjects and compute words' emotional strength based on the ratio of times a word or a sentence was judged to fall into a particular emotion bucket, given the number of human subjects. Additionally, they conducted an interactive experiment concerning the acoustic rendering of emotion, using manual tuning of prosodic parameters for Japanese sentences. While the authors actually address the two fundamental problems of emotional TTS, their approach is impractical and most likely cannot scale up for a real corpus. Again, while lexical items with clear emotional meaning, such as *happy* or *sad*, matter, emotion classification probably needs to consider additional inference mechanisms. Moreover, a naïve compositional approach to emotion recognition is risky due to simple linguistic facts, such as context-dependent semantics, domination of words with multiple meanings, and emotional negation.

Many NLP problems address attitudinal meaning distinctions in text, e.g. detecting *subjective* opinion documents or expressions, e.g. (Wiebe et al, 2004), measuring *strength* of subjective clauses (Wilson, Wiebe and Hwa, 2004), determining word *polarity* (Hatzivassiloglou and McKeown, 1997) or texts' attitudinal valence, e.g. (Turney, 2002), (Bai, Padman and Airoldi, 2004), (Beineke, Hastie and Vaithyanathan, 2003), (Mullen and Collier, 2003), (Pang and Lee, 2003). Here, it suffices to say that the targets, the domain, and the intended application differ; our goal is to classify emotional text passages in children's stories, and eventually use this information for rendering expressive child-directed storytelling in a text-to-speech application. This can be useful, e.g. in therapeutic education of children with communication disorders (van Santen et al., 2003).

4 Empirical study

This part covers the experimental study with a formal problem definition, computational implementation, data, features, and a note on parameter tuning.

4.1 Machine learning model

Determining emotion of a linguistic unit can be cast as a multi-class classification problem. For the flat case, let T denote the text, and s an embedded linguistic unit, such as a sentence, where $s \in T$. Let k be the number of emotion classes $E = \{em_1, em_2, .., em_k\}$, where em_1 denotes the special case of *neutrality*, or absence of emotion. The goal is to determine a mapping function $f : s \rightarrow em_i$, such that we obtain an ordered labeled pair (s, em_i). The mapping is based on $F = \{f_1, f_2, .., f_n\}$, where F contains the features derived from the text.

Furthermore, if multiple emotion classes can characterize s, then given $E' \subset E$, the target of the mapping function becomes the ordered pair (s, E'). Finally, as further discussed in section 6, the hierarchical case of label assignment requires a sequential model that further defines levels of coarse versus fine-grained classifiers, as done by (Li and Roth, 2002) for the *question classification* problem.

4.2 Implementation

Whereas our goal is to predict finer emotional meaning distinctions according to emotional categories in speech; in this study, we focus on the basic task of recognizing emotional passages and on determining their valence (i.e. positive versus negative) because we currently do not have enough training data to explore finer-grained distinctions. The goal here is to get a good understanding of the nature of the TEP problem and explore features which may be useful.

We explore two cases of flat classification, using a variation of the Winnow update rule implemented in the SNoW learning architecture (Carlson et al., 1999),[1] which learns a linear classifier in feature space, and has been successful in several NLP applications, e.g. semantic role labeling (Koomen, Punyakanok, Roth and Yih, 2005). In the first case, the set of emotion classes E consists of EMOTIONAL versus non-emotional or NEUTRAL, i.e. $E = \{N, E\}$. In the second case, E has been incremented with emotional distinctions according to the valence, i.e. $E = \{N, PE, NE\}$. Experiments used 10-fold cross-validation, with 90% train and 10% test data.[2]

4.3 Data

The goal of our current data annotation project is to annotate a corpus of approximately 185 children stories, including Grimms', H.C. Andersen's and B. Potter's stories. So far, the annotation process proceeds as follows: annotators work in pairs on the same stories. They have been trained separately and work independently in order to avoid any annotation bias and get a true understanding of the task difficulty. Each annotator marks the sentence level with one of eight *primary emotions*, see table 1, reflecting an extended set of *basic emotions* (Ekman, 1993). In order to make the annotation process more focused, emotion is annotated from the point of view of the text, i.e. the *feeler* in the sentence. While the primary emotions are targets, the sentences are also marked for other affective contents, i.e. background *mood*, *secondary* emotions via *intensity*, *feeler*, and *textual* cues. Disagreements in annotations are resolved by a second pass of tie-breaking by the first author, who chooses one of the competing labels. Eventually, the completed annotations will be made available.

Table 1: Basic emotions used in annotation

Abbreviation	Emotion class
A	ANGRY
D	DISGUSTED
F	FEARFUL
H	HAPPY
Sa	SAD
Su+	POSITIVELY SURPRISED
Su-	NEGATIVELY SURPRISED

Emotion annotation is hard; interannotator agreement currently range at $\kappa = .24 - .51$, with the ratio of observed annotation overlap ranging between 45-64%, depending on annotator pair and stories assigned. This is expected, given the subjective nature of the annotation task. The lack of a clear definition for emotion vs. non-emotion is acknowledged across the emotion literature, and contributes to dynamic and shifting annotation targets. Indeed, a common source of confusion is NEUTRAL, i.e. deciding whether or not a sentence is emotional or non-emotional. Emotion perception also depends on which character's point-of-view the annotator takes, and on extratextual factors such as annotator's personality or mood. It is possible that by focusing more on the training of annotator pairs, particularly on joint training, agreement might improve. However, that would also result in a bias, which is probably not preferable to actual perception. Moreover, what agreement levels are needed for successful expressive TTS remains an empirical question.

The current data set consisted of a preliminary annotated and tie-broken data set of 1580 sentence, or 22 Grimms' tales. The label distribution is in table 2. NEUTRAL was most frequent with 59.94%.

Table 2: Percent of annotated labels

A	D	F	H
12.34%	0.89%	7.03%	6.77%
N	SA	SU+	SU.-
59.94%	7.34%	2.59%	3.10%

[1] Available from http://l2r.cs.uiuc.edu/∼cogcomp/

[2] Experiments were also run for Perceptron, however the results are not included. Overall, Perceptron performed worse.

Table 3: % EMOTIONAL vs. NEUTRAL examples

E	N
40.06%	59.94%

Table 4: % POSITIVE vs. NEGATIVE vs. NEUTRAL

PE	NE	N
9.87%	30.19%	59.94%

Next, for the purpose of this study, all emotional classes, i.e. A, D, F, H, SA, SU+, SU-, were combined into one emotional superclass E for the first experiment, as shown in table 3. For the second experiment, we used two emotional classes, i.e. positive versus negative emotions; PE={H, SU+} and NE={A, D, F, SA, SU-}, as seen in table 4.

4.4 Feature set

The feature extraction was written in python. SNoW only requires active features as input, which resulted in a typical feature vector size of around 30 features. The features are listed below. They were implemented as boolean values, with continuous values represented by ranges. The ranges generally overlapped, in order to get more generalization coverage.

1. First sentence in story
2. Conjunctions of selected features (see below)
3. Direct speech (i.e. whole quote) in sentence
4. Thematic story type (3 top and 15 sub-types)
5. Special punctuation (! and ?)
6. Complete upper-case word
7. Sentence length in words (0-1, 2-3, 4-8, 9-15, 16-25, 26-35, $>$35)
8. Ranges of story progress (5-100%, 15-100%, 80-100%, 90-100%)
9. Percent of JJ, N, V, RB (0%, 1-100%, 50-100%, 80-100%)
10. V count in sentence, excluding participles (0-1, 0-3, 0-5, 0-7, 0-9, $>$ 9)
11. Positive and negative word counts ($\geq$ 1, $\geq$ 2, $\geq$ 3, $\geq$ 4, $\geq$ 5, $\geq$ 6)
12. WordNet emotion words
13. Interjections and affective words
14. *Content BOW*: N, V, JJ, RB words by POS

Feature conjunctions covered pairings of counts of positive and negative words with range of story progress or interjections, respectively.

Feature groups 1, 3, 5, 6, 7, 8, 9, 10 and 14 are extracted automatically from the sentences in the stories; with the SNoW POS-tagger used for features 9, 10, and 14. Group 10 reflects how many verbs are active in a sentence. Together with the quotation and punctuation, verb domination intends to capture the assumption that emotion is often accompanied by increased action and interaction. Feature group 4 is based on Finish scholar Antti Aarne's classes of folk-tale types according to their informative thematic contents (Aarne, 1964). The current tales have 3 top story types (ANIMAL TALES, ORDINARY FOLK-TALES, and JOKES AND ANECDOTES), and 15 subtypes (e.g. *supernatural helpers* is a subtype of the ORDINARY FOLK-TALE). This feature intends to provide an idea about the story's general affective *personality* (Picard, 1997), whereas the feature reflecting the story progress is hoped to capture that some emotions may be more prevalent in certain sections of the story (e.g. the happy end).

For semantic tasks, words are obviously important. In addition to considering 'content words', we also explored specific word lists. Group 11 uses 2 lists of 1636 positive and 2008 negative words, obtained from (Di Cicco et al., online). Group 12 uses lexical lists extracted from WordNet (Fellbaum, 1998), on the basis of the primary emotion words in their adjectival and nominal forms. For the adjectives, Py-WordNet's (Steele et al., 2004) SIMILAR feature was used to retrieve similar items of the primary emotion adjectives, exploring one additional level in the hierarchy (i.e. similar items of all senses of all words in the synset). For the nouns and any identical verbal homonyms, synonyms and hyponyms were extracted manually.[3] Feature group 13 used a short list of 22 interjections collected manually by browsing educational ESL sites, whereas the affective word list of 771 words consisted of a combination of the non-neutral words from (Johnson-Laird and Oatley, 1989) and (Siegle, online). Only a subset of these lexical lists actually occurred.[4]

[3]Multi-words were transformed to hyphenated form.

[4]At this point, neither stems and bigrams nor a list of onomatopoeic words contribute to accuracy. Intermediate resource processing inserted some feature noise.

The above feature set is henceforth referred to as *all features*, whereas *content BOW* is just group 14. The *content BOW* is a more interesting baseline than the naïve one, *P(Neutral)*, i.e. always assigning the most likely NEUTRAL category. Lastly, emotions blend and transform (Liu, Lieberman and Selker, 2003). Thus, emotion and background mood of immediately adjacent sentences, i.e. the *sequencing*, seems important. At this point, it is not implemented automatically. Instead, it was extracted from the manual emotion and mood annotations. If *sequencing* seemed important, an automatic method using sequential target activation could be added next.

4.5 Parameter tuning

The Winnow parameters that were tuned included promotional α, demotional β, activation threshold θ, initial weights ω, and the regularization parameter, S, which implements a margin between positive and negative examples. Given the currently fairly limited data, results from 2 alternative tuning methods, applied to *all features*, are reported.

- For the condition called *sep-tune-eval*, 50% of the sentences were randomly selected and set aside to be used for the parameter tuning process only. Of this subset, 10% were subsequently randomly chosen as test set with the remaining 90% used for training during the automatic tuning process, which covered 4356 different parameter combinations. Resulting parameters were: $\alpha = 1.1$, $\beta = 0.5$, $\theta = 5$, $\omega = 1.0$, $S = 0.5$. The remaining half of the data was used for training and testing in the 10-fold cross-validation evaluation. (Also, note the slight change for *P(Neutral)* in table 5, due to randomly splitting the data.)
- Given that the data set is currently small, for the condition named *same-tune-eval*, tuning was performed automatically on all data using a slightly smaller set of combinations, and then manually adjusted against the 10-fold cross-validation process. Resulting parameters were: $\alpha = 1.2$, $\beta = 0.9$, $\theta = 4$, $\omega = 1$, $S = 0.5$. All data was used for evaluation.

Emotion classification was sensitive to the selected tuning data. Generally, a smaller tuning set resulted in pejorative parameter settings. The random selection could make a difference, but was not explored.

5 Results and discussion

This section first presents the results from experiments with the two different confusion sets described above, as well as feature experimentation.

5.1 Classification results

Average accuracy from 10-fold cross validation for the first experiment, i.e. classifying sentences as either NEUTRAL or EMOTIONAL, are included in table 5 and figure 1 for the two tuning conditions on the main feature sets and baselines. As expected,

Table 5: Mean classification accuracy: N vs. E, 2 conditions

	same-tune-eval	sep-tune-eval
P(Neutral)	59.94	60.05
Content BOW	61.01	58.30
All features except BOW	64.68	63.45
All features	68.99	63.31
All features + sequencing	69.37	62.94

degree of success reflects parameter settings, both for *content BOW* and *all features*. Nevertheless, under these circumstances, performance above a naïve baseline and a BOW approach is obtained. Moreover, *sequencing* shows potential for contributing in one case. However, observations also point to three issues: first, the current data set appears to be too small. Second, the data is not easily separable. This comes as no surprise, given the subjective nature of the task, and the rather low interannotator agreement, reported above. Moreover, despite the schematic narrative plots of children's stories, tales still differ in their overall affective orientation, which increases data complexity. Third and finally, the EMOTION class is combined by basic emotion labels, rather than an original annotated label.

More detailed averaged results from 10-fold cross-validation are included in table 6 using *all features* and the separated tuning and evaluation data condition *sep-tune-eval*. With these parameters, approximately 3% improvement in accuracy over the naïve baseline *P(Neutral)* was recorded, and 5% over the *content BOW*, which obviously did poorly with these parameters. Moreover, precision is

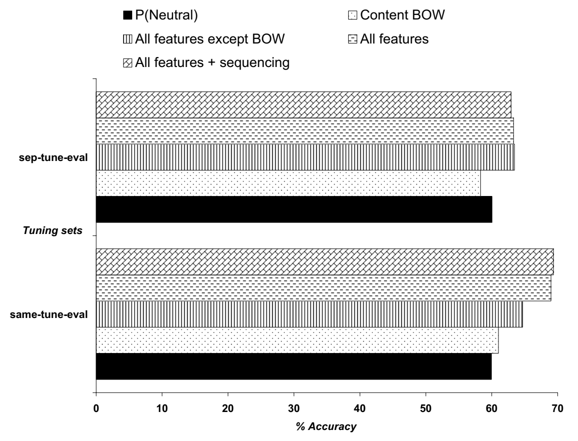

Figure 1: Accuracy under different conditions (in %)

Table 6: Classifying N vs. E (*all features*, *sep-tune-eval*)

Measure	N	E
Averaged accuracy	0.63	0.63
Averaged error	0.37	0.37
Averaged precision	0.66	0.56
Averaged recall	0.75	0.42
Averaged F-score	0.70	0.47

higher than recall for the combined EMOTION class. In comparison, with the *same-tune-eval* procedure, the accuracy improved by approximately 9% over *P(Neutral)* and by 8% over *content BOW*.

In the second experiment, the emotion category was split into two classes: emotions with positive versus negative valence. The results in terms of precision, recall, and F-score are included in table 7, using *all features* and the *sep-tune-eval* condition. The decrease in performance for the emotion classes mirrors the smaller amounts of data available for each class. As noted in section 4.3, only 9.87% of the sentences were annotated with a positive emotion, and the results for this class are worse. Thus, performance seems likely to improve as more annotated story data becomes available; at this point, we are experimenting with merely around 12% of the total texts targeted by the data annotation project.

5.2 Feature experiments

Emotions are poorly understood, and it is especially unclear which features may be important for their recognition from text. Thus, we experimented

Table 7: N, PE, and NE (*all features*, *sep-tune-eval*)

	N	NE	PE
Averaged precision	0.64	0.45	0.13
Averaged recall	0.75	0.27	0.19
Averaged F-score	0.69	0.32	0.13

Table 8: Feature group members

Word lists	interj., WordNet, affective lists, pos/neg
Syntactic	length ranges, % POS, V-count ranges
Story-related	% story-progress, 1st sent., story type
Orthographic	punctuation, upper-case words, quote
Conjunctions	Conjunctions with pos/neg
Content BOW	Words (N,V,Adj, Adv)

with different feature configurations. Starting with all features, again using 10-fold cross-validation for the separated tuning-evaluation condition *sep-tune-eval*, one additional feature group was removed until none remained. The feature groups are listed in table 8. Figure 2 on the next page shows the accuracy at each step of the cumulative subtraction process. While some feature groups, e.g. syntactic, appeared less important, the removal order mattered; e.g. if syntactic features were removed first, accuracy decreased. This fact also illustrated that features work together; removing any group degraded performance because features interact and there is no true independence. It was observed that features' contributions were sensitive to parameter tuning. Clearly, further work on developing features which fit the TEP problem is needed.

6 Refining the model

This was a “first pass” of addressing TEP for TTS. At this point, the annotation project is still on-going, and we only had a fairly small data set to draw on. Nevertheless, results indicate that our learning approach benefits emotion recognition. For example, the following instances, also labeled with the same valence by both annotators, were correctly classified both in the binary (N vs. E) and the tripartite polarity task (N, NE, PE), given the separated tuning and evaluation data condition, and using *all features*:

(1a) E/NE: Then he offered the dwarfs money, and prayed and besought them to let him take her away; but they said, ”We will not part with her for all the gold in the world.”

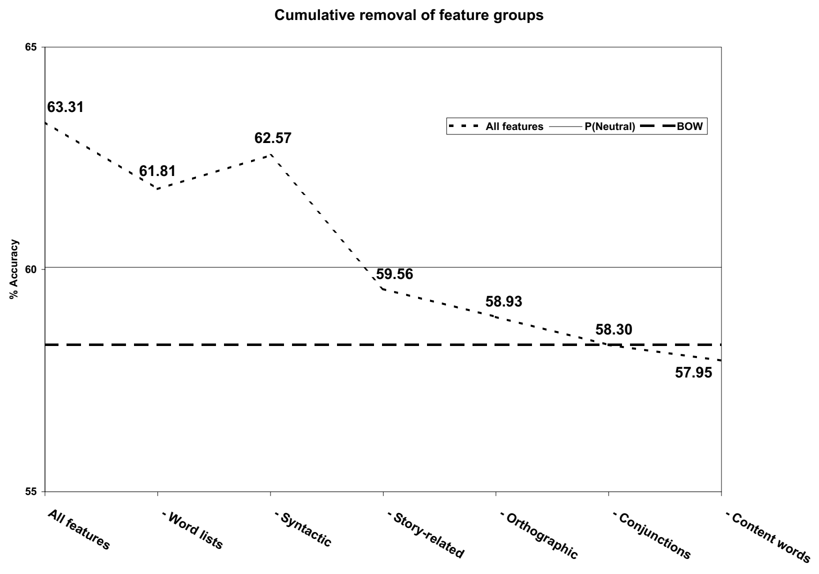

Figure 2: Averaged effect of feature group removal, using *sep-tune-eval*

(1b) N: And so the little girl really did grow up; her skin was as white as snow, her cheeks as rosy as the blood, and her hair as black as ebony; and she was called Snowdrop.

(2a) E/NE: "Ah," she answered, "have I not reason to weep?

(2b) N: Nevertheless, he wished to try him first, and took a stone in his hand and squeezed it together so that water dropped out of it.

Cases (1a) and (1b) are from the well-known FOLK TALE *Snowdrop*, also called *Snow White*. (1a) and (1b) are also correctly classified by the simple *content BOW* approach, although our approach has higher prediction confidence for E/NE (1a); it also considers, e.g. direct speech, a fairly high verb count, advanced story progress, connotative words and conjunctions thereof with story progress features, all of which the BOW misses. In addition, the simple *content BOW* approach makes incorrect predictions at both the bipartite and tripartite levels for examples (2a) and (2b) from the JOKES AND ANECDOTES stories *Clever Hans* and *The Valiant Little Tailor*, while our classifier captures the affective differences by considering, e.g. distinctions in verb count, interjection, POS, sentence length, connotations, story subtype, and conjunctions.

Next, we intend to use a larger data set to conduct a more complete study to establish mature findings. We also plan to explore finer emotional meaning distinctions, by using a hierarchical sequential model which better corresponds to different levels of cognitive difficulty in emotional categorization by humans, and to classify the full set of basic level emotional categories discussed in section 4.3. Sequential modeling of simple classifiers has been successfully employed to question classification, for example by (Li and Roth, 2002). In addition, we are working on refining and improving the feature set, and given more data, tuning can be improved on a sufficiently large development set. The three subcorpora in the annotation project can reveal how authorship affects emotion perception and classification.

Moreover, arousal appears to be an important dimension for emotional prosody (Scherer, 2003), especially in storytelling (Alm and Sproat, 2005). Thus, we are planning on exploring degrees of emotional intensity in a learning scenario, i.e. a problem similar to measuring strength of opinion clauses (Wilson, Wiebe and Hwa, 2004).

Finally, emotions are not discrete objects; rather they have transitional nature, and blend and overlap along the temporal dimension. For example, (Liu, Lieberman and Selker, 2003) include parallel estimations of emotional activity, and include smoothing techniques such as interpolation and decay to capture sequential and interactive emotional activity. Observations from tales indicate that some emotions are more likely to be prolonged than others.

7 Conclusion

This paper has discussed an empirical study of the *text-based emotion prediction* problem in the domain of children's fairy tales, with child-directed expressive text-to-speech synthesis as goal. Besides reporting on encouraging results in a first set of computational experiments using supervised machine learning, we have set forth a research agenda for tackling the TEP problem more comprehensively.

8 Acknowledgments

We are grateful to the annotators, in particular A. Rasmussen and S. Siddiqui. We also thank two anonymous reviewers for comments. This work was funded by NSF under award ITR-#0205731, and NS ITR IIS-0428472. The annotation is supported by UIUC's Research Board. The authors take sole responsibility for the work.

Abstract

This paper studies how to go beyond relevance and enable a filtering system to learn more interesting and detailed data driven user models from multiple forms of evidence. We carry out a user study using a real time web based personal news filtering system, and collect extensive multiple forms of evidence, including explicit and implicit user feedback. We explore the graphical modeling approach to combine these forms of evidence. To test whether the approach can help us understand the domain better, we use graph structure learning algorithm to derive the causal relationships between different forms of evidence. To test whether the approach can help the system improve the performance, we use the graphical inference algorithms to predict whether a user likes a document based on multiple forms of evidence. The results show that combining multiple forms of evidence using graphical models can help us better understand the filtering problem, improve filtering system performance, and handle various data missing situations naturally.

1 Introduction

An adaptive personal information filtering system is an autonomous agent that delivers information to the user in a dynamic environment over a period of time. A common filtering approach is adapting existing text classification/retrieval algorithms to classify incoming documents as either relevant or non relevant using user profiles learned from explicit user feedback on documents the user has seen. However, there are other important criteria for the user besides relevance, such as readability (Collins-Thompson and Callan, 2004), novelty (Harman, 2003), and authority (Kleinberg, 1998). Besides, much information about the user and the document can be collected by a filtering system. These suggest a way to improve the current filtering system: going beyond relevance and using multiple forms of evidence.

Unfortunately, there is no standard evaluation data set for this research, and there is not much work on finding a good theory to combine various forms of evidence. To solve the first problem, we designed a user study and collect thousands of cases with multiple forms of evidence, including the content of a document, explicit and implicit user feedback, such as a user's mouse usage, key board usage, document length, novelty, relevance, readability, authority, user profile characteristics, news source information, and whether a user likes a document or not. Solving the second problem is very challenging. A good model should have the representation power to combine multiple forms of evidence; it should be able to help us understand the relationships between various forms of evidence; it should use the evidence to improve filtering system performance; and it should handle various problems like missing data in an operational environment robustly.

On the other hand, researchers have identified three major advantages of graphical modeling approach: 1) it provides inference tools to naturally handle situations of missing data entry because of the conditional dependencies encoded in the graph structure; 2) it can learn causal relationships in the domain, thus help us to understand the problem and to predict the consequences of intervention; and 3) it can easily combine prior knowledge (such as partial information about the causal relationship) with data in this framework. This approach has been applied to model computer software users (Horvitz et al., 1998), car drivers (Pynadath and Wellman, 1995), and students (Conati et al., 1997). Motivated by the prior work, we choose to use graphical models as our solution. To understand relationships between various forms of evidence, we use the causal graph structure learning algorithms (advantage 2), together with some prior knowledge of the domain (advantage 3), to derive the causal relationships between different user feedback, actions and user context. To improve the existing filtering system, especially in the situation of missing data, we use statistical inference tools to predict how a user will like a document, using information available in different missing evidence situations (advantage 1). We also try linear regression as an alternative approach.

The following sections describe our efforts towards

*This research was done while at the Language Technologies Institute, Carnegie Mellon University.

Figure 1: The user study system structure. The structured information, such as user feedback and crawler statistics, are kept in the database. The content of each web page crawled is saved in the news repository.

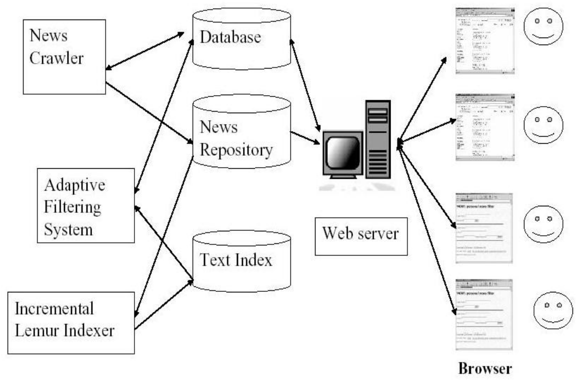

Figure 2: Web interface after a user logged in.

collecting data and customizing the graphical modeling approach to combine multiple forms of evidence for filtering. We begin with a description of the user study in Section 2, followed by some preliminary data analysis on the data collected in Section 3. Section 4 explores causal structure learning algorithm to understand the relationships between various forms of evidence from the data and Section 5 explores how to improve the system performance using multiple forms of evidence. Section 6 discusses related work and how this work differs from existing work, and Section 7 concludes.

2 User Study

No existing filtering database contains the level of detail that we needed for our study, so we developed a web based news story filtering system to collect an evaluation data set (Figure 1). This system constantly gathers and recommends information to the users. The system includes a crawler with 8000 candidate RSS news feeds (Pilgrim, 2002) to crawl every day. The Lemur indexer indexes the crawled document stream incrementally, and an adaptive filtering system recommends documents to the users using a modified logistic regression algorithm (Zhang, 2004). Users read and evaluate what the system has delivered to them. An example of the web interface after user login is in Figure 2.

More than 20 paid subjects from 19 different programs at Carnegie Mellon University, who are otherwise not affiliated with our research, participated in the study for 4 weeks. We expected to collect enough data for evaluation over this period of time. The subjects were required to read the news for about 1 hour per day and provide explicit feedback for each page they visited. [1] 28 users tried this system. However, only 21 users are official paid subjects, among which one worked only for 2 weeks and 20 worked for about 4 weeks.

2.1 Data collected

We have collected 7881 feedback entries from all 28 users, among which 7839 were from the 21 official participants. Each entry contains several different forms of evidence for a news story a user clicked.[2] Our intention to collect the evidence is not to be exhaustive, but representative. The evidence can be roughly classified into the following five categories listed in Tables 1 to 5.[3]

Explicit user feedback After finishing reading a news story, a user clicks a button on the toolbar of the browser to bring up an evaluation interface shown in Figure 3. Through this interface, the user provided the explicit feedback to tell the hidden properties about current story, including the topics the news belongs to ($classes$), how the user likes this news

[1]In the last week of the study, some subjects read 2 hours per day. They are encouraged but not required to do so.

[2]Each entry is for a <document, user class, time> tuple.

[3]The forms of evidence are listed in the first column and we will get the the other columns later in Section 3.

($user\_likes$), how relevant the news is related to the class(es) ($relevant$), how novel the news is ($novel$), whether the news matches the readability level of the user ($readable$), and whether the news is authoritative ($authoritative$). $user\_likes$, $relevant$ and $novel$ are recorded as integers ranging from 1 (least) to 5 (most). $readable$ and $authoritative$ are recorded as 0 or 1. A user has the option to provide partial instead of all explicit feedback. A user can create new classes, and choose multiple classes for one documents.

User actions The browser adapted from (Claypool et al., 2001) recorded some user actions, such as mouse activities, scroll bar activities, and keyboard activities (Table 2). TimeOnPage is the number of seconds the user spent on a page, and EventOnScroll is the number of clicks on the scroll bars. When the mouse is out of the browser window or when the browser window is not focused, the browser does not capture any activities. More details about the actions are in (Le and Waseda, 2000).

Topic information Each participant filled out an exit questionnaire and answered several topic/class[4] specific questions for each of his/her most popular 10 topics and other topics with more than 20 evaluated documents each (Table 3). The questions include how familiar the user is with the topic before the study (*topic_familiar_before*), how the user likes this topic ($topic\_like$), and how confident the user is with respect to the answers he/she provided ($topic\_confidence$). We include this information as evidence, because they may be collected when a topic is created and used by filtering systems. Whether collecting them in exit questionnaire affects the answers needs further investigation.

News Source Information For each news source (RSS feed), we collected the number of web pages that link to it (*RSS_link*), the number of pages that link to the server that provided it ($host\_link$), and the speed of the server that hosts it.

Content based evidence Three pieces of evidence are collected to represent the content of each document: the relevance score, the readability score and the number of words in the document (doc_len) (Table 5). To estimate the relevance score of a document, the system processes all the documents a user put into a class ordered by the feedback time and adaptively learns a topic specific relevance model using the relevance feedback the user provided. The relevance score of a documents is estimated using a modified logistic regression model learned from all feedback before it (Zhang, 2004). To estimate the readability score of document, the system processes all the documents in all users' classes ordered by the feedback time and adaptively learns a user independent readability model using a logistic regression algorithm.

[4]"topic" and "class" are used interchangeably in the paper.

Table 1: Basic descriptive statistics about explicit feedbacks.

Variable	Mean	variance	corr	miss
user likes	3.5	1.2	1	0.05
relevant	3.5	1.3	0.73	0.005
novel	3.6	1.33	0.70	0.008
authoritative	0.88	0.32	0.50	0.065
readable	0.90	0.30	0.54	0.012

3 Preliminary data analysis

The means and variances of all variables are in Tables 1 to 5. These basic descriptive statistics are very diverse. The values of some evidence may be missing; only the user actions and news source information were always collected. Out of the 7991 entries, only 4522 (57%) entries contain no missing value. The missing rate of each form of evidence is also reported in the tables. There are several reasons for missing data. For example, the explicit feedback is missing because users didn't always follow instructions, the relevance score is missing for the first story in a class, and the $topic\_familiar\_before$ values for many topics are missing because we only collected the topic specific answers for larger topics. We expect missing data to be common in operational environments.

The correlation coefficient between each evidence and the explicit feedback $user\_likes$ is also listed (corr). The high correlation coefficients between $user\_likes$ and other forms of explicit feedback are not very interesting because we can only get explicit feedback after a user reads the document. The correlation coefficient between relevance score and $user\_likes$ is 0.37, the highest among all forms of evidence that the system can get before delivering a document. This is not surprising since most filtering systems only consider relevance and use relevance score to make decisions.

The correlation coefficients between $user\_likes$ and the topic information (Table 3) are relatively high. This suggests collecting $topic\_familiar\_before$ or $topic\_like$ in a real filtering system, since they are informative and collecting them requires less user effort (a user only needs to provide information on the class level instead of document level). Section 5 will show how to use it with other forms of evidence in a filtering system. The correlation coefficients between the news source in-

Table 5: Basic descriptive statistics about documents. The length of the document does not include HTML tags.

variable	mean	variance	corr	miss
doc_length	837	1.2×10^3	0.04	0.05
relevant_score	0.49	0.42	0.37	0.18
readability_score	0.52	0.16	0.25	0.11

formation and $user\_likes$ are weaker (Table 4). The correlation coefficient between $user\_likes$ and each user action (Table 2) is even lower (Table 1). Some actions, such as $TimeOnPage$, are more correlated with $user\_likes$ than other refined actions, such as $NumOfPageDown$. This finding agrees with (Claypool et al., 2001).

4 Understanding the domain using causal structure learning

Correlation analysis in Section 3 has helped us to get some initial idea about the data collected. However, in order to better understand the underlying truth of the domain, we need to go beyond correlation and uncover the causal relationships between different variables.

To do that, we first specify N nodes, one for each form of evidence to be included in the model. Then PC algorithm is used (Spirtes et al., 2000) to search the causal relationships between multiple forms of evidence from the data collected. To make the search space smaller, some prior domain knowledge, such as forbidden edges, required edges or temporal tiers, can be introduced before searching. In our experiments, we manually specified some prior knowledge based on the first authors' experience and intuition as the following 5-tier temporal tier: [5] 1) $Topic\ info\ =$ (familiar_topic_before), $RSS\ info$ =(RSS_link, host_link), document length ($doc\,len$); 2) hidden criteria, such as $relevant$, $novel$, $authoritative$, and $readable$; 3) system generated scores, such as *relevance score* and *readability score*; 4) $user\_likes$; 5) user actions, such as seconds spent on a page (TimeOnPage) or the number of clicks on the $\downarrow$ key (NumOfDownArrow). This informs the learning algorithm that $\rightarrow$ from a higher level to lower level is prohibited.

It is very encouraging to see that the structure learned automatically looks reasonable (Figure 4). According to the graph, $novel$, $relevant$, $authoritative$, $readabilty$ of a document and whether a user is familiar with the topic before using the system ($familar\_topic\_before$) are direct causes of the user's preference for a document ($user\_likes$) . How familiar with this topic a user is before participating the study ($topic\_familiar\_before$) and the number of web links to the news source (RSS_link) directly affect the user's $relevant$ and $authoritative$ feedback and $readability\ score$. $Relevant$, $authoritative$, $familiar\_topic\_before$ and $host\_link$ influence a user's actions, such as the $EventOnScroll$.

Comparing Tables 2 to 5 with Figure 4, one may ask why some variables are correlated with *user likes* although there is no direct links between them and *user likes*. For example, why the correlation between *relevance score* and *user likes* is 0.39, while there is no direct link between them. Does Figure 4 contradict Table 5? The answer is "no". In fact the indirect causal relationship between them tells us why *relevance score* and *user likes* are correlated: *relevance score* and *user likes* have a common cause *relevant*. Most of the refined actions, such as the number of pressing page up key ($NumOfPageUp$), are far away from $user\_likes$. This implies that these refined actions are not very informative if we want to use the learned model to predict whether a user likes a document or not. This finding agree with (Claypool et al., 2001) and Table 2.

The node $authoritative$ is directly linked to $readability\ score$ and $host\ link$. The link between $host\_link$ and $authoritative$ confirms the existing approaches that use the web link structure to estimate the

[5]Other priors are also possible.

Figure 4: User independent causal graphical structure learned using PC algorithm. $X \rightarrow Y$ means X is a direct cause of Y. $X - Y$ means the algorithm cannot tell if X causes Y or if Y causes X. $X \longleftrightarrow Y$ means the algorithm found some problem, which may happen due to a latent common cause of X and Y, a chance pattern in the sample, or other violations of assumptions.

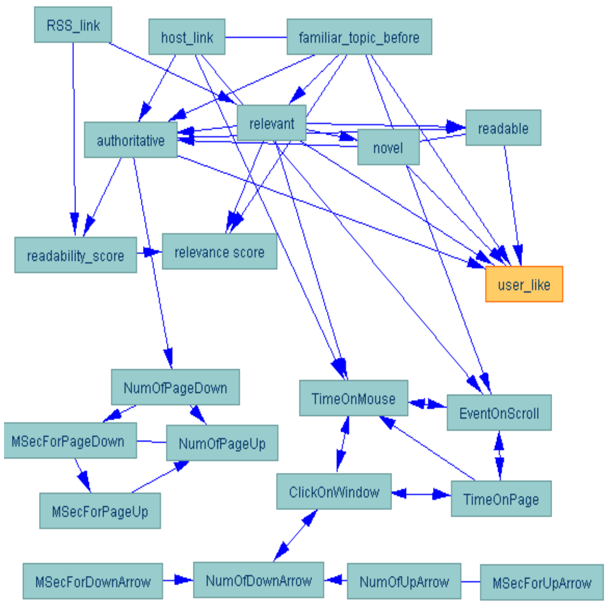

Figure 5: Structure of GM_complete.

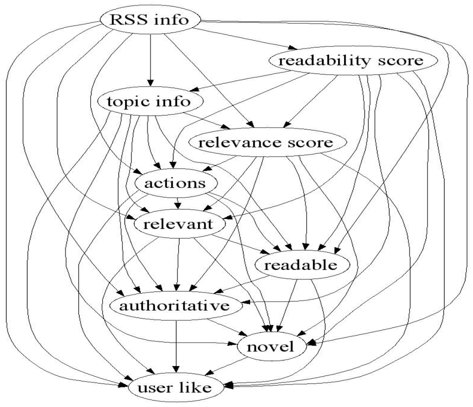

Figure 6: Structure of GM_causal.

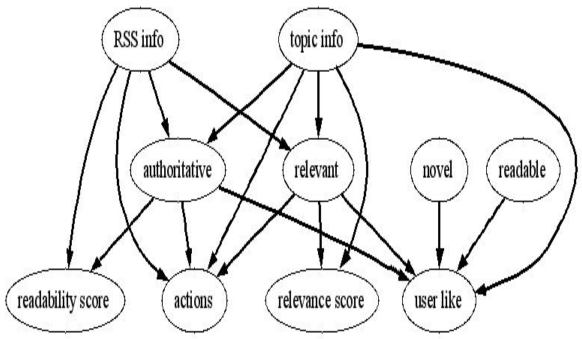

authority of a page (Kleinberg, 1998). The links between $readability\ score$, $readable$ and $authoritative$ are very interesting. They suggest the difficulty to understand a page may make the user feel it is not authoritative. Further investigation shows that although the percentage of un-authoritative news is less than 15% in general, among the 187 news stories some users identified as "difficult" using class labels, 73% were also rated as not authoritative. Besides some successful web page authority algorithms that only use hyper links, the estimation of authority may be further improved using the content of a page.

There are links among *relevant*, *novel*, *readable* and *authoritative*. Although the algorithm failed to tell the causal direction between some pairs of variables, it suggests that the four variables influence each other. This may be an inherent property of the document; or because a user is likely to rate one aspect of the document higher than he/she should if the other aspects are good.

One may ask why the structure in Figure 4 contains no link between $readable$ and $readability\ score$, since intuitively it should exist. To answer this question, one needs to understand that the causal relationships learned automatically are what the algorithm "believes" based on the evidence of the data, the assumptions it makes, and the prior constraints we engineered. They may have errors, because the data is noisy, or the assumptions and the prior constraints may be wrong. For example, the PC algorithm do statistical test about the independence relationships among variables using the data and the final results are subject to the error of the statistical test. The PC algorithm assumes no hidden variables, however besides *relevant, novel, authoritative, and readable*, other hidden variables, such as *whether a document is up-to-date, interesting, misleading, etc.* (Schamber and Bateman, 1996), may exist and influence a user's preference for a document. Thus it is not surprising that some of the causal relationships, such as the link between $readable$ and $readability\ score$, are missed in the final graph because of the limitation of the learning algorithms. The model learned only sheds some light on the relationships between the variables instead of uncovering the whole truth. It only serves as a starting point for us. To further understand the domain, we may want to break down some variables in the current graph further and relate them to either the user or document properties. In general, causal discovery is inherently difficult and far from solved.

5 Improving system performance using inference algorithms

A primary task of a filtering system is to predict user preference ($user\_likes$) for a document so that the system can decide whether to deliver it to the user. To tell whether combining multiple forms of evidence using graphical models can improve system performance, we evaluate the proposed solution on the task of predicting $user\_likes$ while filtering.

To predict $user\_likes$, the system needs to learn a graphical model: the combination of a graph structure and a set of local conditional probability functions or potential functions. Doing inference over the causal structure learned in the previous section is difficult because of the circles and a mixture of directed and undirected links on the graph. So, we tried the following directed acyclic graphical models.

GM_complete, an almost complete Bayesian network: In this graph, we order the nodes from top to bottom, and the parents of a node are all the nodes above it, such as in Figure 5. For this structure, the order of the nodes is not very important when using Gaussian distributions.

GM_causal, a graphical model inspired by causal models: We manually modify the causal structure in Figure 4 to make it a directed acyclic graph as in Figure 6.

In the graphs, *RSS info=(RSS_link, host_link)* and *Topic info=topic_familiar_before, topic_like)* are 2 dimensional vectors representing the information about the news source and the topic in Table 4 and Table 3. $actions = (TimeOnPage, ...)$ is a 12 dimensional vector representing the user actions in Table 1. $user\_likes$ is the target variable the system wants to predict.

Before learning the parameters of the model, we need to choose a specific conditional form for the probability function associated with each node. We chose Gaussian distributions. If the parents of node X are Y, $P(X|Y) = N(m + W \times Y, \Sigma)$, where $N(\mu, \Sigma)$ is a gaussian distribution with mean μ and covariance Σ. This is a commonly used distribution for continuous valued nodes. It assumes the joint distribution of these variables is multivariate Gaussian, which may be wrong. Nevertheless, because of the mathematical convenience, the existence of efficient learning and inference algorithms for Gaussian networks, and the availability of modeling tools, we chose this distribution. Using the BNT Toolbox (Murphy, 2001), the maximum likelihood estimations of the parameters (m, W, Σ) were learned using EM algorithm and junction tree inference engine(Cowell et al., 1999) over the graphical models, with whatever information was available on the first $2/3$ of the data.

An alternative approach to combine multiple forms of evidence is linear regression. We tried two special methods to solve the missing evidence problem while using linear regression: 1) building a model that does not use the evidence that is missing for each missing situation (*LR_different*); or 2)*mean substitution*: replacing each missing value for an evidence with the average of the observed evidence (LR_mean). For K different forms of evidence, the system may need to handle 2^K different evidence missing situations. A large number of linear regression models need to be learned if we use the first approach, considering K is higher than 15 in some of our experiments. Building 2^{15} models is almost impossible for us, so a heuristic approach, which is discussed later, was used to make the experiments possible.

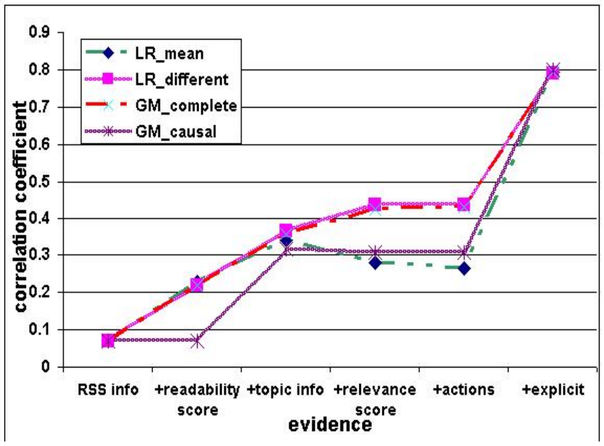

Figure 7: Comparison of the prediction power of different models using 7952 cases for evaluation. The vertical axis is the correlation coefficient between the predicted value of $user\_likes$ using the model and the true explicit feedback provided by the users. The order of different forms of evidence is set manually, based on how easy it is to collect each evidence.

Not all 7991 cases collected in the user study were used in the experiments. We conducted two sets of experiments. For the first set of experiments, we use 7952 cases for which $user\_likes$ is not missing. For the other set of runs, we use only cases without missing value. In this task, the value of each variable is continuous and normalized to variance one. Each model is learned using all information available on the first $2/3$ of the cases, and tested on the remaining $1/3$ of the cases. The correlation coefficient between the predicted value of $user\_likes$ and the true explicit $user\_likes$ feedback provided by the users is used as the evaluation measure. Our baseline is using $relevance\ score$ alone, which has a correlation coefficient of 0.367 with 95% confidence interval 0.33-0.40 on the last 1/3 of the 7952 cases.

5.1 Experimental results and discussions

Figure 7 shows the effectiveness of different models at different testing conditions as indicated by the horizontal axis. From left to right, additional sources of evidence are given when testing. At the very left of the figure (x=$RSS\ info$), a model predicts the value of $user\_likes$ only given the value of $RSS\ info$ at testing time. "+explicit" means the explicit feedback (except $user\_likes$) about the current document is given besides the value of $actions$, $relevance\ score$, $readability\ score$, $RSS\ info$, and $TopicInfo$. The graphical models and LR_mean model were trained with all evidence/features, and the learned models are independent of the testing condition. *LR_different* models were only trained with features that are also provided at testing time, so there is one model per testing condition. [6]

The results show that $GM\_complete$ performs similarly to *LR_different*. This is not surprising. Theoretically, if there is no missing entries in training data, $GM\_complete$'s estimation of the conditional distribution of $P(user\ likes|available\ evidence)$ would be the same as that of *LR_different* on a testing case with missing evidence.

Comparing the correlation coefficients under different testing conditions when using *LR_different* or $GM\_complete$, we can see that as more forms of evidence are available, the performance improves. If only the news source information of a document ($RSS\ info$) is given, all models perform poorly. The $readability\ score$ improves the system performance significantly. This is nice and interesting, because the evidence is user independent and can be estimated efficiently for each document. The performance keeps improving as $topic\ info$ and $relevance\ score$ were added. To collect them, we needs user feedback on previous documents. The performance improvement is not very obvious with $actions$ added. This means that given other evidence ($RSS\ info$, $topic\ info$, $relevance\ score$ and $readability\ score$), the system won't improve its prediction of the document much by observing these actions. However, this is only true when we use a model learned for all users and other forms of evidence are available. It does not mean the actions are useless if we learn user specific model, or if other forms of evidence (such as $relevance\ score$) are not available. All models perform very good with *explicit feedback* added. However, this is a "cheating" condition of less interest to us.

The performances of LR_mean and GM_causal do not increase monotonically as more forms of evidence are added. They perform much worse than *LR_different* and $GM\_complete$. Why does a structure that looks more causally reasonable not perform well as the simple $GM\_complete$? We may answer this question better by comparing the underlying assumptions of these algorithms. $GM\_complete$ only assumes the joint distribution of all variables is multivariate Gaussian. GM_causal makes much stronger independence assumptions by removing some links between variables. As mentioned before, the causal relationships learned automatically are not perfect, which may cause the poor performance of GM_causal. LR_mean also suffers from the strong conditional independent assumptions.

[6]However, for a specific testing condition, the training data and testing data contain cases where some evidence that is supposed to be available is missing. These cases in training data were ignored and not used to learn a $LR\_different$ model. However, ignoring such kind of cases in testing data makes comparison of different runs difficult. So we used mean substitution approach to fill the required missing features in testing data while using $LR\_different$.

Model	Cond.	corr	RLow	RUp
LR_mean	+R	0.2783	0.2426	0.3132
LR_different	+R	0.4372	0.4058	0.4677
GM_complete	+R	0.4247	0.3928	0.4555
GM_causal	+R	0.3078	0.2728	0.342
LR_mean	+A	0.2646	0.2286	0.2998
LR_different	+A	0.4375	0.406	0.4679
GM_complete	+A	0.4315	0.3999	0.4622
GM_causal	+A	0.3086	0.2736	0.3428

Table 6: A comparison of different models on all data under the $+relevance\ score$ (+R) and $+action$ (+A) conditions. Corr is the correlation coefficient between the predicted value of $user\_likes$ using the model and the true explicit feedback provided by the users. RLO and RUP are the lower and upper bounds for a 95% confidence interval for each coefficient.

Table 6 reports the performance together with the confidence intervals of all the models under the $+relevance\ score$ and $+actions$ conditions. Under both conditions, $GM\_complete$ and *LR_different* are statistically significantly better than the baseline 0.367. LR_mean and GM_causal are significantly worse. It means using multiple forms of evidence may hurt some models and benefit others. Further analysis about the $+actions$ runs shows that LR_mean gave *explicit feedback* too much weight and overlooked other less strong evidence. At testing time, it did not handle the problem of missing *explicit feedback* well and thus performed poorly. Although $GM\_complete$ also gave very high weights to *explicit feedback*, it could infer the missing values based on other available evidence at testing time, thus performed better than LR_mean. *LR_different* didn't consider *explicit feedback* for training, thus it didn't overlook other forms of evidence and suffer from the problem less. LR_mean may work reasonably if explicit variables are not included, however the large difference on how informative each evidence is will still hurt the performance of LR_mean to some extent when some strong evidence is missing. For $GM\_complete$ approach, a single model is needed to handle various evidence missing situations. If we use *LR_different* approach, several models are needed. As we mentioned before, there are 2^K

Model	Cond.	Corr	RLow	RUp
LR_mean	+R	0.13	0.08	0.18
LR_different	+R	0.41	0.37	0.45
GM_complete	+R	0.41	0.37	0.45
GM_causal	+R	0.41	0.375	0.45
LR_mean	+A	0.11	0.061	0.16
LR_different	+A	0.42	0.38	0.46
GM_complete	+A	0.42	0.38	0.46
GM_causal	+A	0.38	0.33	0.42

Table 7: The performance on 4522 no missing value cases under the $+relevance\ score$ (+R) and $+action$ (+A) conditions.

different evidence missing combinations, and 2^K linear regression models are needed in order to handle all these situations using *LR_different* approach. *LR_different* may be preferred if K is small, while graphical modeling using $GM\_complete$ may be a better approach to handle different data missing situations if K is big.

So far, all results are based on 7952 cases where some evidence may be missing. We also compared the models under different testing conditions using the 4522 cases that do not have any missing value (Table 7). GM_causal performs significantly better than before. We need to be very careful with the structures while using the graphical modeling approach, since a structure that looks more reasonable may work poorly on the inference task. However, we couldn't not draw any conclusion on whether $GM\_complete$ is better in general, because the answer may be different with different conditional probability distributions, different data sets, or a better structure learning algorithm.

6 Related Work

There has been some research on news filtering using time-coded implicit feedback (Lang, 1995; Morita and Shinoda, 1994). We noticed that an independent work uses a different graphical modeling approach, dependency network, to understand the relationships between implicit measures and explicit satisfaction while user were conducting their web searches and viewing results, and then uses decision tree to predict user satisfaction with results (Fox et al., 2005). Our work differs from the previous work in the goal of the task, the range of evidence considered, the modeling approach we took, and the findings reached.

There has been a lot of related research on using implicit feedback (Kelly and Teevan, 2003). The user actions we collected are based on (Claypool et al., 2001). There is much work about how to handle missing data. (Schafer and Graham, 2002) discussed several approaches such as case deletion, mean substitution, and recommended maximum likelihood (ML) and Bayesian multiple imputation (MI). LR_mean uses mean substitution, *LR_different* uses case deletion, and graphical models follow the ML approach.

There has been some research on criteria beyond topic relevance (Carbonell and Goldstein, 1998) (Zhang et al., 2002) (Collins-Thompson and Callan, 2004) (Kleinberg, 1998). (Schamber and Bateman, 1996) identified criteria underlying users' relevance judgements and explored how users employed the criteria in making evaluations by asking users to interpret and sort criteria independent of document manually. In the literature, the word "relevant" is used ambiguously, either as a narrow definition of "related to the matter at hand (aboutness)" or a broader definition of "having the ability to satisfy the needs of the user". When it is used by the second definition, such as in (Schamber and Bateman, 1996), researchers are usually studying what we refer to as *user likes*. In this paper, we use "relevant" as is defined in the first definition and use the phrase "user likes" for the second definition. Despite the vocabulary difference, our work is motivated by the early research. The major contributions of our work in this area are: 1) we model the *user likes* and other criteria as hidden variables; 2) we quantify the importance of various criteria based on probabilistic reasoning; and 3) we have explored the new methodology for combining these criteria with implicit and explicit user feedback.

7 CONCLUSION

We have explored how to combine multiple forms of evidence using the graphical modeling approach. This work is significant because it addresses some long-standing issues in the adaptive information filtering community: the integration of a wider range of user-specific and user-independent evidence, and handling situations like missing data that occur in operational environments.

We have analyzed the user study data using graphical models, as well as linear regression algorithms. The experimental results show that the graphical modeling approach can help us to understand the causal relationships between multiple forms of evidence in the domain and explain the real world scenario better. It can also help the filtering system to predict user preference more accurately with multiple forms of evidence compared to using a relevance model only.

As more forms of evidence are added, missing data is a common problem because of system glitches or because users will not behave as desired. A real system needs to handle missing data by either ignoring it or by estimating it based on what is known. The graphical modeling approach addresses this problem naturally. *LR_different* handles the problem by building many different models to be used at different data missing conditions. *LR_different* and $GM\_complete$ perform similarly. When the types of evidence is few, *LR_different* probably is preferable because of the simplicity. However, as more forms of evidence are added, a more powerful model, such as $GM\_complete$, may be preferred because of the computation and space efficiency.

We only collected data for documents users clicked. Further investigation is needed to look at data not clicked, which is a critical step to see whether the improvement on prediction accuracy of user preference will help the system serve the user better in a real system. This is the first step towards using graphical models to combine multiple forms of evidence while filtering. The proposed solution, especially the data analyzing methodology used in this paper, can also be used in other IR tasks besides filtering, such as context-based retrieval.

Abstract

Traditional question answering systems adopt the following framework: parsing questions, searching for relevant documents, and identifying/generating answers. However, this framework does not work well for questions with hidden assumptions and implicatures. In this paper, we describe a novel idea, a cascading guidance strategy, which can not only identify potential traps in questions but further guide the answer extraction procedure by recognizing whether there are multiple answers for a question. This is the first attempt to solve implicature problem for complex QA in a cascading fashion using N-gram language models as features. We here investigate questions with implicatures related to biography facts in a web-based QA system, PowerBio. We compare the performances of Decision Tree, Naïve Bayes, SVM (Support Vector Machine), and ME (Maximum Entropy) classification methods. The integration of the cascading guidance strategy can help extract answers for questions with implicatures and produce satisfactory results in our experiments.

1 Motivation

Question Answering has emerged as a key area in natural language processing (NLP) to apply question parsing, information extraction, summarization, and language generation techniques (Clark et al., 2004; Fleischman et al., 2003; Echihabi et al., 2003; Yang et al., 2003; Hermjakob et al., 2002; Dumais et al., 2002). Traditional question answering systems adopt the framework of parsing questions, searching for relevant documents, and then pinpointing and generating answers. However, this framework includes potential dangers. For example, to answer the question "when did Beethoven get married?", a typical QA system would identify the question target to be a "Date" and would apply techniques to identify the date Beethoven got married. Since Beethoven never married, this direct approach is likely to deliver wrong answers. The trick in the question is the implicature that Beethoven got married. In the main task of QA track of TREC 2003, the performances of most systems on providing "NIL" when no answer is possible range from only 10% to 30% (Voorhees, 2003).

Just as some questions have no answer, others may have multiple answers. For instance, with "who was Ronald Reagan's wife?", a QA system may give only "Nancy Davis" as the answer. However, there is another correct answer: Jane Wyman. The problem here is the implicature in the question that Reagan only got married once.

An implicature is anything that is inferred from an utterance but that is not a condition for the truth of the utterance (Gazdar, 1979; Levinson, 1983). Implicatures in questions either waste computational effort or impair the performance of a QA system or both. Therefore, when answering questions, it is prudent to identify the questions with implicatures before processing starts.

In this paper, we describe a novel idea to solve the problem: a strategy of cascading guidance. This is the first attempt to solve implicature problem for complex QA in a cascading fashion using N-gram language models as features. The cascading guidance part is designed to be inserted immediately before the search procedure to handle questions with implicatures. It can not only first identify the potential "no answer" traps but also identify whether multiple answers for this question are likely.

To investigate the performance of the cascading guidance strategy, we here study two types of questions related to biography facts in a web-based biography QA system, PowerBio. This web-based QA system extracts biographical facts from the web obtained by querying a web search engine (Google in our case). Figure 1 provides the two types of questions we selected, which we refer to as SPOUSE_QUESTION and CHILD_QUESTION.

```
I. SPOUSE_QUESTION
   E.g. Who is <PERSON>'s wife?
        Who is <PERSON>'s husband?
        Whom did <PERSON> marry?
         …
II. CHILD_QUESTION
   E.g. Who is <PERSON>'s son?
        Who is <PERSON>'s daughter?
        Who is <PERSON>'s child?
         …
```

Figure 1. SPOUSE_QUESTION and CHILD_QUESTION

Both types of questions have implicatures to justify the use of the cascading guidance strategy. Intuitively, to answer these questions, we have two issues related to implicatures to clarify:

- Does the person have a spouse/child?
- What's the number of answers for this question? (One or many?)

We therefore create two successive classification engines in the cascading classifier.

For learning, our approach queries the search engine with every person listed in the training set, extracts related features from the documents, and trains the cascading classifiers. For application, when a new question is given, the cascading classifier is applied before activation of the search subsystem. We compare the performances of four popular classification approaches in the cascading classifier, namely Decision Tree, Naïve Bayes, SVM (Support Vector Machine), and ME (Maximum Entropy) classifications.

The paper is structured as follows: related work is discussed in Section 2. We introduce our cascading guidance technique in Section 3, including Decision Tree, Naïve Bayes and SVM (Support Vector Machine) and ME (Maximum Entropy) classifications. The experimental results are presented in Section 4. We discuss related issues and future work in Section 5.

2 Related Work

Question Answering has attracted much attention from the areas of Natural Language Processing, Information Retrieval and Data Mining (Fleischman et al., 2003; Echihabi et al., 2003; Yang et al., 2003; Hermjakob et al., 2002; Dumais et al., 2002; Hermjakob et al., 2000). It is tested in several venues, including the TREC and CLEF Question Answering tracks (Voorhees, 2003; Magnini et al., 2003). Most research efforts in the Question Answering community have focused on factoid questions and successful Question Answering systems tend to have similar underlying pipelines structures (Prager et al., 2004; Xu et al., 2003; Hovy et al., 2000; Moldovan et al., 2000).

Recently more techniques for answer extraction, answer selection, and answer validation have been proposed (Lita et al., 2004; Soricut and Brill, 2004; Clark et al., 2004).

Prager et al. (2004) proposed applying constraint satisfaction obtained by asking auxiliary questions to improve system performance. This approach requires the creation of auxiliary questions, which may be complex to automate.

Ravichandran and Hovy (2002) proposed automatically learning surface text patterns for answer extraction. However, this approach will not work if no explicit answers exist in the source. The first reason is that in that situation the anchors to learn the patterns cannot be determined. Secondly, most of the facts without explicit values are not expressed with long patterns including anchors. For example, the phrase "the childless marriage" gives enough information that a person has no child. But it is almost impossible to learn such surface text patterns following (Ravichandran and Hovy, 2002).

Reported work on question processing focuses mainly on the problems of parsing questions, determining the question target for search subsystem

(Pasca and Harabagiu, 2001; Hermjakob et al., 2000). Saquete et al. (2004) decompose complex temporal questions into simpler ones based on the temporal relationships in the question.

To date, there has been little published work on handling implicatures in questions. Just-In-Time Information Seeking Agents (JITISA) was proposed by Harabagiu (2001) to process questions in dialogue and implicatures. The agents are created based on pragmatic knowledge. Traditional answer extraction and answer fusion approaches assume the question is always correct and explicit answers do exist in the corpus. Reported work attempts to rank the candidate answer list to boost the correct one into top position. This is not enough when there may not be an answer for the question posed.

For biographical fact extraction and generation, Zhou et al. (2004) and Schiffman et al. (2001) use summarization techniques to generate human biographies. Mann and Yarowsky (2005) propose fusing the extracted information across documents to return a consensus answer. In their approach, they did not consider multiple values or no values for biography facts, although multiple facts are common for some biography attributes, such as multiple occupations, children, books, places of residence, etc. In these cases a consensus answer is not adequate.

Our work differs from theirs because we are not only working on information/answer extraction; the focus in this paper is the guidance for answer extraction of questions (or IE task for values) with implicatures. This work can be of great help for immediate biographical information extraction.

We describe details of the cascading guidance technique and investigate how it will help for question answering in Section 3.

3 Cascading Guidance Technique

We turn to the Web by querying a web search engine (Google in our case) to find evidence to create guidance for answer extraction.

3.1 Classification Procedure

The cascading classifier is applied after the name of the person and the answer types are identified. Figure 2 gives the pipeline of the classification procedure.

With the identified person name, we query the search engine (Google) to obtain the top N web pages/documents. A simple data cleaning program only keeps the content texts in the web page, which is broken up into separate sentences. Following that, topic sentences are identified with the keyword topic identification technique. For each topic we provide a list of possible related keywords and any sentences containing both the person's name (or reference) and at least one of the keywords will be selected. The required features are extracted from the topic sentences and passed to the cascading classifier as supporting evidence to generate guidance for answer extraction.

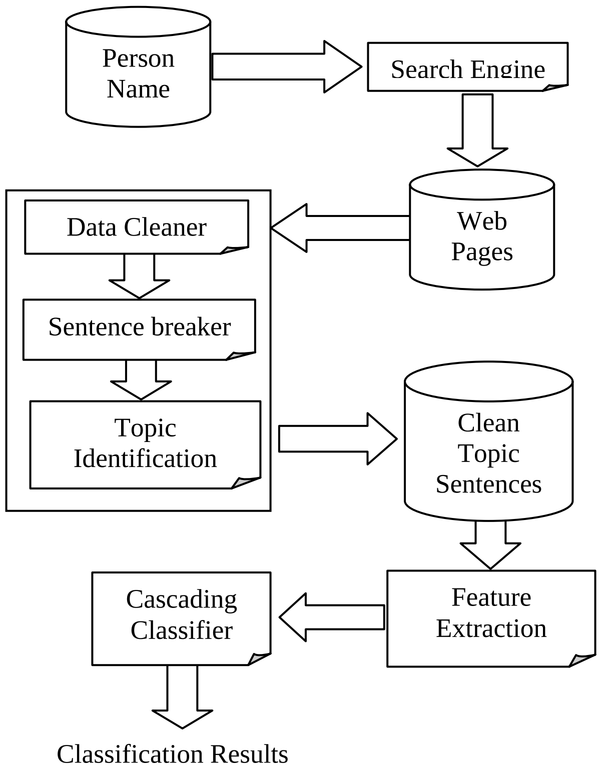

Figure 2. Procedure of Cascading Classifier

3.2 Feature Extraction

Intuitively, sentences elaborating a biographical fact in a given topic should have similar styles (short patterns) of organizing words and phrases. Here, topic means an aspect of biographical facts, e.g., marriage, children, birthplace, and so on. Inspired by this, we consider taking N-grams in sentences as our features. However, N-gram features not closely related to the topic will bring more noise into the system. Therefore, we only take the N-grams within a fixed-length window around the topic keywords for features calculation, and pass them as evidence to cascading classifier.

For N-grams, instead of using the multiplication of conditional probabilities of each word in the N-gram, we only consider the last conditional probability (see below). The reason is that the last conditional probability is a strong sign of the pattern's importance and how this sequence of words is organized. Simply multiplying all the conditional probabilities will decrease the value and require normalization. Realizing that in a set of documents the frequency of each N-gram is very important information, we combine the last conditional probability with the frequency.

The computation for each feature of unigram, bigram and trigram are defined as the following formulas:

$$f_{unigram} = p(w_i) * freq(w_i) \quad (1)$$

$$f_{bigram} = p(w_i \mid w_{i-1}) * freq(w_{i-1}, w_i) \quad (2)$$

$$f_{trigram} = p(w_i \mid w_{i-2}, w_{i-1}) * freq(w_{i-2}, w_{i-1}, w_i) \quad (3)$$

We here investigate four kinds of classifiers, namely Decision Tree, Naïve Bayes, Support Vector Machine (SVM), and Maximum Entropy (ME).

3.3 Classification Approaches

The cascading classifier is composed of two successive parts. Given the set of extracted features, the classification result could lead to different responses to the question, either answering with "no value" with strong confidence or directing the answer extraction model how many answers should be sought.

For text classification, there are several well-studied classifiers in the machine learning and natural language processing communities.

Decision Tree Classification

The Decision Tree classifier is simple and matches human intuitions perfectly while it has been proved efficient in many application systems. The basic idea is to break up the classification decision into a union of a set of simpler decisions based on N-gram features. Due to the large feature set, we use C5.0, the decision tree software package developed by RuleQuest Research (Quinlan, 1993), instead of C4.5.

Naïve Bayes Classification

The Naïve Bayes classifier utilizes Bayes' rule as follows. Supposing we have the feature set $F = \{f_1, f_2, ..., f_n\}$, the probability that person p belongs to a class c is given as:

$$c = \arg\max_{c'} P(c' \mid F) \quad (4)$$

Based on Bayes' rule, we have

$$\begin{aligned} c &= \arg\max_{c'} P(c' \mid F) \\ &= \arg\max_{c'} \frac{P(F \mid c')P(c')}{P(F)} \quad (5) \\ &= \arg\max_{c'} P(F \mid c')P(c') \end{aligned}$$

This was used for both successive classifiers of the cascading engine.

SVM Classification

SVM (Support Vector Machines) has attracted much attention since it was introduced in (Boser et al., 1992). As a special and effective approach for kernel based methods, SVM creates non-linear classifiers by applying the kernel trick to maximum-margin hyperplanes.

Suppose $p_i, i = 1, ..., n$ represent the training set of persons, and the classes for classifications are $C = \{c_1, c_2\}$ (for simplicity, we represent the classes with $C = \{-1, 1\}$). Then the classification task requires the solution of the following optimization problem (Hsu et al., 2003):

$$\begin{aligned} &\min_{\omega, b, \xi} \ \frac{1}{2}\omega^T \omega + M \sum_{i=1}^{n} \xi_i \\ &subject\ \ to \ \ c_i(\omega^T \phi(p_i) + b) \geq 1 - \xi_i \quad (6) \\ &\qquad \xi_i \geq 0 \end{aligned}$$

We use the SVM classification package LIBSVM (Chang and Lin, 2001) in our problem.

ME Classification

ME (Maximum Entropy) classification is used here to directly estimate the posterior probability for classification.

Suppose p represents the person and the classes for classifications are $C = \{c_1, c_2\}$, we have M feature functions $h_m(c, p), m = 1, ..., M$. For each feature function, we have a model parameter $\lambda_m, m = 1, ..., M$. The classification with maximum likelihood estimation can be defined as follows (Och and Ney, 2002):

$$P(c \mid p) = p_{\lambda_1^M}(c \mid p) = \frac{\exp[\sum_{m=1}^{M} \lambda_m h_m(c, p)]}{\sum_{c'} \exp[\sum_{m=1}^{M} \lambda_m h_m(c', p)]} \quad (7)$$

The decision rule to choose the most probable class is (Och and Ney, 2002):

$$\hat{c} = \arg\max_c \{P(c \mid p)\} = \arg\max_c \left\{ \sum_{m=1}^{M} \lambda_m h_m(c, p) \right\} \quad (8)$$

We use the published package YASMET[1] to conduct parameters training and classification. YASMET requires supervised learning for the training of maximum entropy model.

The four classification approaches are assembled in a cascading fashion. We discuss their performance next.

4 Experiments and Results

4.1 Experimental Setup

We download from infoplease.com[2] and biography.com[3] two corpora of people's biographies, which include 24,975 and 24,345 bios respectively. We scan each whole corpus and extract people having spouse information. To create the data set, we manually check and categorize each person as having multiple spouses, only one spouse, or no spouse. Similarly, we obtained another list of persons having multiple children, only one child, and no child. The sizes of data extracted are given in Table 1.

Type	Child	Spouse
No_value	25	20
One_value	35	32
Multiple_values	107	43

Table 1. Extracted experimental data

For the cascading classification, in the first step, when classifying whether a person has a spouse/child or not, we merge the last two subsets with one value and multiple values into one. Table 2 presents the data used for each level of classification.

	class	Child	Spouse
First-level Classification	No_value	25	20
	With_value	142	75
Second-level Classification	One_value	35	32
	Multiple_value	107	43

Table 2. Data set used for classification

To investigate the performances of our cascading classifiers, we divided the two sets into training set and testing set, with half of them in the training set and half in the testing set.

4.2 Empirical Results

For each situation of the two questions, when the answer type has been determined to be the child or spouse of a person, we send the person's name to Google and collect the top N documents. As described in Figure 2, topic sentences in each document are selected by keyword matching. A window with the length of *w* is applied to the sentence. All word sequences in the window are selected for feature calculation. We take all the three N-gram language models (unigram, bigram, and trigram) in the window for feature computation. Table 3 gives the sizes of the bigram feature sets for first-level classification as we take more and more documents into the system.

Top N Docs	Child	Spouse
1	3468	1958
10	27733	12325
20	46431	27331
30	61057	36637
40	76687	43771
50	87020	50868
60	96393	61632
70	108053	67712
80	118947	73306
90	130526	77370
100	139722	82339

Table 3. Sizes of feature sets

As described in Section 3, the feature values are applied in the classifiers. Tables 4 and 5 give the best performances of the 4 classifiers in the two situations when we select the top N articles using N-gram probability for feature computation.

Due to the large size of the feature set, C5.0, SVM, and ME packages will not work at some

[1] http://www.fjoch.com/YASMET.html
[2] http://www.infoplease.com/people.html
[3] http://www.biography.com/search/index.jsp

point as more documents are encountered. The Naïve Bayes classification is more scalable as we use intermediate file to store probability tables.

Precision	First-level Classification	Second-level Classification
C5.0	82.90%	65.70%
Naïve Bayes	87.80%	72.86%
SVM	84.15%	75.71%
ME	86.59%	75.71%

Table 4. Precision scores for child classification

Precision	First-level Classification	Second-level Classification
C5.0	80.90%	56.80%
Naïve Bayes	83.00%	59.46%
SVM	78.72%	54.05%
ME	78.72%	51.35%

Table 5. Precision scores for spouse classification

Feature	# of times identified (out of 75)	$p(w_i \mid w_{i-2}, w_{i-1})$
and his wife	35	0.6786
her husband ,	33	0.3082
and her husband	26	0.5476
was married to	20	0.8621
with his wife	14	0.875
her second husband	13	0.6667
her marriage to	13	0.5
ex - wife	12	0.3333
ex - husband	11	0.6667
her first husband	10	0.75
second husband ,	10	1
his first wife	8	0.3333
first husband ,	7	0.6667
second wife ,	7	0.3333
his first marriage	5	0.1667
s second wife	5	0.75

Table 6. Example trigram features for second-level classification for Spouse (one or multiple values)

The feature set has a large number of features. However, not all of them will be used for each person. We studied the number of times features are identified/used in the training and testing sets and their probabilities. Table 6 presents a list of some trigram features for second-level classification (one or multiple values) for Spouse. Obviously, indicating features have a large probability as expected. The second column gives the number of times the feature is used out of the training and testing set (75 persons in total).

Will more complex N-gram features work better?

Intuitively, being less ambiguous, more complex N-gram features carry more precise information and therefore should work better than simple ones. We studied the performances for different N-gram language model features. Below are the results of Naïve Bayes first-level classification for Child, using different N-gram features.

Top N Docs	Unigram	Bigram	Trigram
1	34.78%	54.35%	**67.39%**
10	30.48%	79.27%	**86.59%**
20	26.83%	82.93%	**85.37%**
30	24.39%	81.71%	**86.59%**

Table 7. Comparisons of classification precisions using different N-gram features for child

From Table 7, we can infer that bigram features work better than unigram features, and trigram features work better than bigrams when we select different numbers of top N documents. Trigram features actually bring enough evidence in classification. However, when we investigated 4-grams language features in the collected data, most of them are very sparse in the feature space of all the cases. Applying 4-grams or higher may not help in our task.

Will more data/documents help?

The performance of corpus-based statistical approaches usually depends on the size of corpus. A traditional view for most NLP problems is that more data will help to improve the system's performance. However, for data collected from a search engine, this may not be the case, since web data is usually ambiguous and noisy. We therefore investigate the data size's effect on system performance. Figure 3 gives the precision curves of the Naïve Bayes classifier for the first-level classification for Child.

Except for the case of top 1, where the top document alone may not contain too much useful information on selected topics, precision scores only have slight variations for increasing numbers of documents. For bigram features, over the top 50 through top 70 documents, the precision scores even get a little worse.

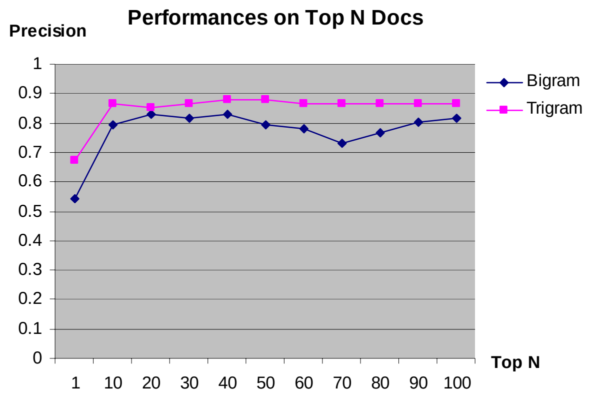

Figure 3. Performance on top N documents

4.3 Examples

Equipped with the cascading guiding strategy, we are able to handle questions containing implicatures. In our system, when we can determine the answer type is child or spouse, the cascading guiding system will help the answer extraction part to extract answers from the designated corpus. Figure 4 gives two examples of the strategy.

Q1: *Who is Sophia Smith's spouse?*
Classified: <NO_SPOUSE>
Answer: *She did not marry.*

Q2: *Who is John Ritter's child?*
Classified: <HAVING_CHILD>
Classified: <MULTIPLE_VALUES>
…

Figure 4. Classification Example for question

For the first question, the classifier recognizes there is no spouse for the target person and returns information for the answer generation. The features used here are the first-level classification result for SPOUSE_QUESTION. For the second question, the classifier recognizes the target person has a child first, followed by recognizing that the answer has multiple values. In this way, the strategy integrated to the question answering system can improve the system's performance by handling questions with implicatures.

5 Discussion and Future Work

Questions may have implicatures due to the flexibility of human language and conversation. In real question-answering systems, failure to handle them may either waste huge computation cost or impair system's performance. The traditional QA framework does not work well for questions containing implicatures. We describe a novel idea in this paper to identify potential traps in biographical questions and recognize whether there are multiple answers for a question.

Question-Answering systems, even when focused upon biographies, have to handle many facts, such as birth date, birth place, parents, training, accomplishments, etc. These values can be extracted using typical text harvesting approaches. However, when there are no values for some biographical information, the task becomes much more difficult because text seldom explicitly states a negative. For example, the following two questions require schools attended:

- *Where did <person> graduate from?*
- *What university did <person> attend?*

Our program scanned the two corpora of bios and found only 2 out 49320 bios explicitly stating that the subject never attended any school. Therefore, for some types of information, it will be much harder to identify null values through evidence from text. Some more complicated reasoning and inference may be required. Classifiers for some biographical facts may need to incorporate extra knowledge from other resources. The inherent relations between biography facts can also be used to validate each other. For example, the relations of marriage and child, birth place and childhood home, etc. may provide clues for cross-validation. We plan to investigate these problems in the future.

Abstract

A reading comprehension (RC) system attempts to understand a document and returns an answer sentence when posed with a question. RC resembles the *ad hoc* question answering (QA) task that aims to extract an answer from a collection of documents when posed with a question. However, since RC focuses only on a single document, the system needs to draw upon external knowledge sources to achieve deep analysis of passage sentences for answer sentence extraction. This paper proposes an approach towards RC that attempts to utilize external knowledge to improve performance beyond the baseline set by the bag-of-words (BOW) approach. Our approach emphasizes matching of metadata (i.e. verbs, named entities and base noun phrases) in passage context utilization and answer sentence extraction. We have also devised an automatic acquisition process for Web-derived answer patterns (AP) which utilizes question-answer pairs from TREC QA, the Google search engine and the Web. This approach gave improved RC performances for both the Remedia and ChungHwa corpora, attaining *HumSent* accuracies of 42% and 69% respectively. In particular, performance analysis based on Remedia shows that relative performances of 20.7% is due to metadata matching and a further 10.9% is due to the application of Web-derived answer patterns.

1. Introduction

A reading comprehension (RC) system attempts to understand a document and returns an answer sentence when posed with a question. The RC task was first proposed by the MITRE Corporation which developed the Deep Read reading comprehension system (Hirschman et al., 1999). Deep Read was evaluated on the Remedia Corpus that contains a set of stories, each with an average of 20 sentences and five questions (of types *who, where, when, what* and *why*). The MITRE group also defined the *HumSent* scoring metric, i.e. the percentage of test questions for which the system has chosen a correct sentence as the answer. *HumSent* answers were compiled by a human annotator, who examined the stories and chose the sentence(s) that best answered the questions. It was judged that for 11% of the Remedia test questions, there is no single sentence in the story that is judged to be an appropriate answer sentence. Hence the upper bound for RC on Remedia should by 89% *HumSent* accuracy. (Hirschman et al. 1999) reported a *HumSent* accuracy of 36.6% on the Remedia test set. Subsequently, (Ng et al., 2000) used a machine learning approach of decision tree and achieved the accuracy of 39.3%. Then (Riloff and Thelen, 2000) and (Charniak et al., 2000) reported improvements to 39.7% and 41%, respectively. They made use of handcrafted heuristics such as the WHEN rule:

if contain(S, TIME), then Score(S)+=4

i.e. WHEN questions reward candidate answer sentences with four extra points if they contain a name entity TIME.

RC resembles the ad hoc question answering (QA) task in TREC.[1] The QA task finds answers to a set of questions from a *collection* of documents, while RC focuses on a single

[1] http://www.nist.gov.

document. (Light et al. 1998) conducted a detailed compared between the two tasks. They found that the answers of most questions in the TREC QA task appear more than once within the document collection. However, over 80% of the questions in the Remedia corpus correspond to answer sentences that have a single occurrence only. Therefore an RC system often has only one shot at finding the answer. The system is in dire need of extensive knowledge sources to help with deep text analysis in order to find the correct answer sentence.

Recently, many QA systems have exploited the Web as a gigantic data repository in order to help question answering (Clarke et al., 2001; Kwok et al., 2001; Radev et al., 2002). Our current work attempts to incorporate a similar idea in exploiting Web-derived knowledge to aid RC. In particular, we have devised an automatic acquisition process for Web-derived answer patterns. Additionally we propose to emphasize the importance of *metadata* matching in our approach to RC. By metadata, we are referring to automatically labeled verbs, named entities as well as base noun phrases in the passage. It is important to achieve a metadata match between the question and a candidate answer sentence before the candidate is selected as the final answer. The candidate answer sentence may be one with a high degree of word overlap with the posed question, or it may come from other sentences in the neighboring context. We apply these different techniques step by step and obtain better results than have ever previously been reported. Especially, we give experiment analysis for understanding the results.

In the rest of this paper, we will first describe three main aspects of our approach towards RC – (i) metadata matching, (ii)automatic acquisition of Web-derived answer patterns and (iii) the use of passage context. This will be followed by a description of our experiments, analysis of results and conclusions.

2. Metadata Matching

A popular approach in reading comprehension is to represent the information content of each question or passage sentence as a bag of words (BOW). This approach incorporates stopword removal and stemming. Thereafter, two words are considered a match if they share the same morphological root. Given a question, the BOW approach selects the passage sentence with the maximum number of matching words as the answer. However, the BOW approach does not capture the fact that the *informativeness* of a word about a passage sentence varies from one word to another. For example, it has been pointed out by (Charniak et al. 2000) that the verb seems to be especially important for recognizing that a passage sentence is related to a specific question. In view of this, we propose a representation for questions and answer sentences that emphasizes three types of metadata:

(i) **Main Verbs (MVerb)**, identified by the link parser (Sleator and Temperley 1993);
(ii) **Named Entities (NE)**, including names of locations (LCN), persons (PRN) and organizations (ORG), identified by a home-grown named entity identification tool; and
(iii) **Base Noun Phrases (BNP)**, identified by a home-grown base noun phrase parser respectively.

We attempt to quantify the relative importance of such metadata through corpus statistics obtained only from the training set of the Remedia corpus, which has 55 stories. The Remedia test set, which contains 60 stories, is set aside for evaluation. On average, each training story has 20 sentences and five questions. There are 274 questions in all in the entire training set. Each question corresponds to a marked answer sentence within the story text. We analyzed all the questions and divided them into three question sets (Q_SETS) based on the occurrences of MVerb, NE and BNP identified with the tools mentioned above. The following are illustrative examples of the Q_SETS as well as their sizes:

Q_SET$_{\text{Mverb}}$ (Count:169)	*Who <u>helped</u> the Pilgrims?*
Q_SET$_{\text{NE}}$ (Count:62)	*When was the first merry-go-round built in <u>the United States</u>?*
Q_SET$_{\text{BNP}}$ (Count:232)	*Where are <u>the northern lights</u>?*

Table 1. Examples and sizes of question sets (Q_SETS) with different metadata – main verb (MVerb), named entity (NE) and base noun phrase (BNP).

It may also occur that a question belongs to multiple Q_SETS. For example:

Q_SET$_{MVerb}$	*When was the first merry-go-round built in the United States?*
Q_SET$_{NE}$	*When was the first merry-go-round built in the United States?*
Q_SET$_{BNP}$	*When was the first merry-go-round built in the United States?*

Table 2. An example sentence that belongs to multiple Q_SETS.

As mentioned earlier, each question corresponds to an answer sentence, which is annotated in the story text by MITRE. Hence we can follow the Q_SETS to divide the answer sentences into three answer sets (A_SETS). Examples of A_SETS that correspond to Table 1 include:

A_SET$_{MVerb}$	*An Indian named Squanto came to help them.*
A_SET$_{NE}$	*The first merry-go-round in the United States was built in 1799.*
A_SET$_{BNP}$	*Then these specks reach the air high above the earth.*

Table 3. Examples of the answer sets (A_SETS) corresponding to the different metadata categories, namely, main verb (MVerb), named entity (NE) and base noun phrase) (BNP).

In order to quantify the relative importance of matching the three kinds of metadata between Q_SET and A_SET for reading comprehension, we compute the following relative weights based on corpus statistics:

$$Weight_{Metadata} = \frac{|S_{Metadata}|}{|A\_SET_{Metadata}|} \quad \text{.....Eqn (1)}$$

where $S_{Metadata}$ is the set of answer sentences in $|A\_SET_{Metadata}|$ that contain the metadata of its corresponding question. For example, referring to Tables 2 and 3, the question in Q_SET$_{NE}$ *"When was the first merry-go-round built in the United Sates?"* contains the named entity (underlined) which is also found in the associated answer sentence from A_SET$_{NE}$, *"The first merry-go-round in the United States was built in 1799." Hence this answer sentence belongs to the set* S$_{NE}$. Contrarily, the question in Q_SET$_{BNP}$ *"Where are the northern lights?"* contains the base noun phrase (underlined) but it is not found in the associated answer sentence from A_SET$_{BNP}$, *"Then these specks reach the air high above the earth."* Hence this answer sentence does not belong to the set S$_{BNP}$. Based on the three sets, we obtain the metadata weights:

$Weight_{MVerb}$=0.64, $Weight_{NE}$=0.38, $Weight_{BNP}$=0.21

To illustrate how these metadata weights are utilized in the RC task, consider again the question, "*Who helped the Pilgrims?*" together with three candidate answers that are "equally good" with a single word match when the BOW approach is applied. We further search for matching metadata among these candidate answers and use the metadata weights for scoring.

Question	*Who helped the Pilgrims?* MVerb identified: "help" BNP identified: "the Pilgrams"
Candidate Sentence 1	*An Indian named Squanto came to help.* Matched MVerb (underlined) Score= $Weight_{MVerb}$=0.64
Candidate Sentence 2	*By fall, the Pilgrims had enough food for the winter.* Matched BNP (underlined) Score= $Weight_{BNP}$=0.21
Candidate Sentence 3	*Then the Pilgrims and the Indians ate and played games.* Matched BNP (underlined) Score= $Weight_{BNP}$=0.21

Table 4. The use of metadata matching to extend the bag-of-words approach in reading comprehension.

3. Web-derived Answer Patterns

In addition to using metadata for RC, the proposed approach also leverages knowledge sources that are external to the core RC resources – primarily the Web and other available corpora. This section describes our approach that attempts to automatically derive answer patterns from the Web as well as score useful answer patterns to aid RC. We utilize the open domain question-answer pairs (2393 in all) from the Question Answering track of TREC (TREC8-TREC12) as a basis for automatic answer pattern acquisition.

3.1 Deriving Question Patterns

We define a set of question tags (Q_TAGS) that extend the metadata above in order to represent *question patterns*. The tags include one for main verbs (Q_MVerb), three for named entities (Q_LCN, Q_PRN and Q_ORG) and one for base noun phrases (Q_BNP). We are also careful to ensure that noun phrases tagged as named entities are not further tagged as base noun phrases.

A question pattern is expressed in terms of Q_TAGS. A question pattern can be used to represent multiple questions in the TREC QA resource. An example is shown in Table 5. Tagging the TREC QA resource provides us with a set of question patterns $\{QP_i\}$ and for each pattern, up to m_i example questions.

Question Pattern (QP_i): When do Q_PRN Q_MVerb Q_BNP?
Represented questions: Q_1: *When did Alexander Graham Bell invent the telephone?* Q_2: *When did Maytag make Magic Chef refrigerators?* Q_3: *When did Amumdsen reach the South Pole?* (m_i example questions in all)

Table 5. A question pattern and some example questions that it represents.

3.2 Deriving Answer Patterns

For each question pattern, we aim to derive answer patterns for it automatically from the Web. The set of answer patterns capture possible ways of embedding a *specific* answer in an answer sentence. We will describe the algorithm for deriving answer patterns as following and illustrate with the following question answer pair from TREC QA:

Q: *When did Alexander Graham Bell invent the telephone?*
A: *1876*

1. **Formulate the Web Query**
   The question is tagged and the Web query is formulated as "Q_TAG"+ "ANSWER", i.e.
   Question: "*When did Alexander Graham Bell invent the telephone?*"
   QP: When do Q_PRN Q_MVerb Q_BNP ?
   where Q_PRN= "*Alexander Graham Bell*", Q_MVerb= "*invent*", and Q_BNP= "*the telephone*"
   hence Web query: "*Alexander Graham Bell*"+ "*invent*" + "*the telephone*" + "*1876*"
2. **Web Search and Snippet Selection**
   The Web query is submitted to the search engine Google using the GoogleAPI and the top 100 snippets are downloaded. From each snippet, we select up to ten contiguous words to the left as well as to the right of the "ANSWER" for answer pattern extraction. The selected words must be continuous and do not cross the snippet boundary that Google denotes with '…'.
3. **Answer Pattern Selection**
   We label the terms in each selected snippet with the Q_TAGs from the question as well as the answer tag <A>. The shortest string containing all these tags (underlined below) is extracted as the answer pattern (AP). For example:

Snippet 1: *1876, Alexander Graham Bell invented the telephone in the United States…*
AP 1: <A>, Q_PRN Q_MVerb Q_BNP.
(N.B. The answer tag <A> denotes "*1876*" in this example).

Snippet 2: *…which has been invented by Alexander Graham Bell in 1876…*
AP 2: Q_MVerb by Q_PRN in <A>.

As may be seen in above, the acquisition algorithm for Web-derived answer questions calls for specific answers, such as a factoid in a word or phrase. Hence the question-answer pairs from TREC QA are suitable for use. On the other hand, Remedia is less suitable here because it contains labelled answer *sentences* instead of factoids. Inclusion of whole answer sentences in Web query formulation generally does not return the answer pattern that we seek in this work.

3.3 Scoring the Acquired Answer Patterns

The answer pattern acquisition algorithm returns *multiple* answer patterns for every question-answer pair submitted to the Web. In this subsection we present an algorithm for deriving scores for these answer patterns. The methodology is motivated by the concept of *confidence* level, similar to that used in data mining. The algorithm is as follows:

1. **Formulate the Web Query**
   For each question pattern QP_i (see Table 5) obtained previously, randomly select an example question among the m_i options that belongs to this pattern. The question is tagged and the Web query is formulated in terms of the Q_TAGs only. (Please note that the corresponding *answer is excluded* from Web query formulation here, which differs from the answer pattern acquisition algorithm). E.g.,
   Question: "*When did Alexander Graham Bell invent the telephone?*"
   Q_TAGs: Q_PRN Q_MVerb Q_BNP
   Web query: "*Alexander Graham Bell*"+ "*invent*" + "*the telephone*"
2. **Web Search and Snippet Selection**
   The Web query is submitted to the search engine

Google and the top 100 snippets are downloaded.

3. Scoring each Answer Pattern AP_{ij} relating to QP_i

Based on the question, its pattern QP_i, the answer and the retrieved snippets, totally the following counts for each answer pattern AP_{ij} relating to QP_i .

c_{ij} – # snippets matching AP_{ij} and for which the tag <A> matches the correct answer.

n_{ij} – # snippets matching AP_{ij} and for which the tag <A> matches any term

Compute the ratio $r_{ij}= c_{ij} / n_{ij}$..........Eqn(2)

Repeat steps 1-3 above for another example question randomly selected from the pool of m_i example under QP_i. We arbitrarily set the maximum number of iterations to be $k_i = \left\lceil \frac{2}{3} m_i \right\rceil$ in order to achieve decent coverage of the available examples. The confidence for AP_{ij}.is computed as

$$Confidence\ (AP_{ij}) = \frac{\sum_{i=1}^{k} r_{ij}}{k} \text{......Eqn(3)}$$

Equation (3) tries to assign high confidence values to answer patterns AP_{ij} that choose the correct answers, while other answer patterns are assigned low confidence values. E.g.:

<A>, Q_PRN Q_MVerb Q_BNP (Confidence=0.8)
Q_MVerb by Q_PRN in <A>. (Confidence=0.76)

3.4 Answer Pattern Matching in RC

The Web-derived answer patterns are used in the RC task. Based on the question and its QP, we select the related AP to match among the answer sentence candidates. The candidate that matches the highest-scoring AP will be selected. We find that this technique is very effective for RC as it can discriminate among candidate answer sentences that are rated "equally good" by the BOW or metadata matching approaches, e.g.:

Q: *When is the Chinese New Year?*
QP: When is the Q_BNP?
where Q_BNP=*Chinese New Year*
Related AP: Q_BNP is <A> (Confidence=0.82)
Candidate answer sentences 1: *you must wait a few more weeks for the Chinese New Year.*
Candidate answer sentences 2: *Chinese New Year is most often between January 20 and February 20.*

Both candidate answer sentences have the same number of matching terms – "Chinese", "New" and "Year" and the same metadata, i.e. Q_BNP=*Chinese New Year*. The term "is" is excluded by stopword removal. However the Web-derived answer pattern is able to select the second candidate as the correct answer sentence.

Hence our system gives high priority to the Web-derived AP – if a candidate answer sentence can match an answer pattern with confidence > 0.6, the candidate is taken as the final answer. No further knowledge constraints will be enforced.

4. Context Assistance

During RC, the initial application of the BOW approach focuses the system's attention on a small set of answer sentence candidates. However, it may occur the true answer sentence is not contained in this set. As was observed by (Riloff and Thelen, 2000) and (Charniak et al., 2000), the correct answer sentence often precedes/follows the sentence with the highest number of matching words. Hence both the preceding and following context sentences are searched in their work to find the answer sentence especially for *why* questions.

Our proposed approach references this idea in leveraging contextual knowledge for RC. Incorporation of contextual knowledge is very effective when used in conjunction with named entity (NE) identification. For instance, *who* questions should be answered with words tagged with Q_PRN (for persons). If the candidate sentence with the highest number of matching words does not contain the appropriate NE, it will not be selected as the answer sentence. Instead, our system searches among the *two* preceding and *two* following context sentences for the appropriate NE. Table 6 offers an illustration. Data analysis Remedia training set shows that the context window size selected is appropriate for *when*, *who* and *where* questions.

Football Catches On Fast (LATROBE, PA., September 4, 1895) - The new game of football is catching on fast, and each month new teams are being formed. *Last night was the first time that a football player was paid. The man's name is John Brallier, and he was paid $10 to take the place of someone who was hurt.…*
Question: *Who was the* first *football player to be paid?* **Sentence with maximum # matching words:** *Last night was the first time that a football player was paid.* **Correct answer sentence:** *The man's name is John Brallier, and he was paid $10 to take the place of someone who was hurt.*

Table 6. An example illustrating the use of contextual knowledge in RC.

As for *why* questions, a candidate answer sentence is selected from the context window if its first word is one of *"this"*, *"that"*, *"these"*, *"those"*, *"so"* or *"because"*. We did not utilize contextual constraints for *what* questions.

5. Experiments

RC experiments are run on the Remedia corpus as well as the ChungHwa corpus. The Remedia training set has 55 stories, each with about five questions. The Remedia test set has 60 stories and 5 questions per story. The ChungHwa corpus is derived from the book, *"English Reading Comprehension in 100 days,"* published by Chung Hwa Book Co., (H.K.) Ltd. The ChungHwa training set includes 100 English stories and each has four questions on average. The ChungHwa testing set includes 50 stories and their questions. We use *HumSent* as the prime evaluation metric for reading comprehension.

The three kinds of knowledge sources are used incrementally in our experimental setup and results are labeled as follows:

Result	Technique
Result_1	BOW
Result_2	BOW+MD
Result_3	BOW+MD+AP
Result_4	BOW+MD+AP+Context

Table 7. Experimental setup in RC evaluations. Abbrievations are: bag-of-words (BOW), metadata (MD), Web-derived answer patterns (AP), contextual knowledge (Context).

5.1 Results on Remedia

Table 8 shows the RC results for various question types in the Remedia test set.

	When	Who	What	Where	Why
Result_1	32.0%	30.0%	31.8%	29.6%	18.6%
Result_2	40.0%	28.0%	39.0%	38.0%	20.0%
Result_3	52.6%	42.8%	40.6%	38.4%	21.0%
Result_4	55.0%	48.0%	40.6%	36.4%	27.6%

Table 8. *HumSent* accuracies for the Remedia test set.

We observe that the *HumSent* accuracies vary substantially across different interrogatives. The system performs best for *when* questions and worst for *why* questions. The use of Web-derived answer patterns brought improvements to all the different interrogatives. The other knowledge sources, namely, meta data and context, bring improvements for some question types but degraded others.

Figure 1 shows the overall RC results of our system. The relative incremental gains due to the use of metadata, Web-derived answer patterns and context are 20.7%, 10.9% and 8.2% respectively. We also ran pairwise *t*-tests to test the statistical significance of these improvements and results are shown in Table 9. The improvements due to metadata matching and Web-derived answer patterns are statistically significant (p<0.05) but the improvement due to context is not.

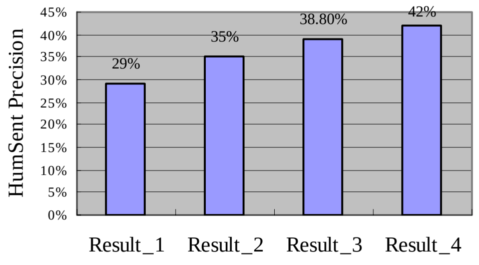

Figure 1. *HumSent* accuracies for Remedia.

Pairwise Comparison	Result_1 & Result_2	Result_2 & Result_3	Result_3 & Result_4
t-test Results	t(4)=2.207, p=0.046	t(4)=2.168, p=0.048	t(4)=1.5, p=0.104

Table 9. Tests of statistical significance in the incremental improvements over BOW among the use of metadata, Web-derived answer patterns and context.

We also compared our results across various interrogatives with those previously reported in (Riloff and Thelen, 2000). Their system is based on handcrafted rules with deterministic algorithms. The comparison (see Table 10) shows that our approach which is based on data-driven patterns and statistics can achieve comparable performance.

Question Type	Riloff &Thelen 2000	Result_4
When	55%	55.0%
Who	41%	48.0%
What	28%	40.6%
Where	47%	36.4%
Why	28%	27.6%
Overall	**40%**	**42.0%**

Table 10. Comparison of *HumSent* results with a heuristic based RC system (Riloff & Thelen 00).

5.2 Results on ChungHwa

Experimental results for the ChungHwa corpus are presented in Figure 2. The *HumSent* accuracies obtained are generally higher than those with

Remedia. We observe similar trends as before, i.e. our approach in the use of metadata, Web-derived answer patterns and context bring incremental gains to RC performance. However, the actual gain levels are much reduced.

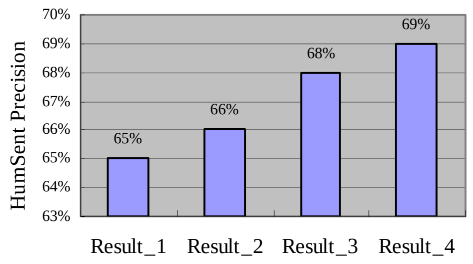

Figure 2. *HumSent* accuracies for ChungHwa.

5.3. Analyses of Results

In order to understand the underlying reason for reduced performance gains as we migrated from Remedia to Chunghwa, we analyzed the question lengths as well as the degree of word match between questions and answers among the two corpora. Figure 3 shows that the average length of questions in Chunghwa are longer than Remedia. Longer questions contain more information which is beneficial to the BOW approach in finding the correct answer.

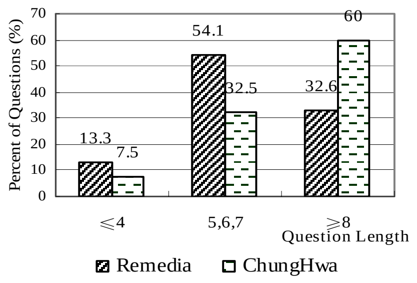

Figure 3. Distribution of question lengths among the Remedia and ChungHwa corpora.

The degree of word match between questions and answers among the two corpora is depicted in Figure 4. We observe that ChungHwa has a larger proportion of questions that have a *match- size* (i.e. number of matching words between a question and its answer) larger than 2. This presents an advantage for the BOW approach in RC. It is also observed that approximately 10% of the Remedia questions have no correct answers (i.e. match-size=-1) and about 25% have no matching words with the correct answer sentence. This explains the overall discrepancies in *HumSent* accuracies between Remedia and ChungHwa.

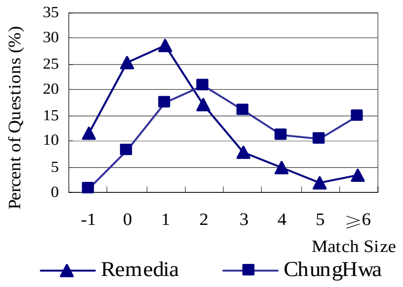

Figure 4. Distribution of match-sizes (i.e. the number of matching words between questions and their answers) in the two corpora.

While our approach has leveraged a variety of knowledge sources in RC, we still observe that our system is unable to correctly answer 58% of the questions in Remedia. An example of such elusive questions is:

Question: *When do the French celebrate their freedom?*

Answer Sentence: *To the French, July 14 has the same meaning as July 4th does to the United States.*

6. Conclusions

A reading comprehension (RC) system aims to understand a single document (i.e. story or passage) in order to be able to automatically answer questions about it. The task presents an information retrieval paradigm that differs significantly from that found in Web search engines. RC resembles the question answering (QA) task in TREC which returns an answer for a given question from a collection of documents. However, while a QA system can utilize the knowledge and information in a *collection* of documents, RC systems focuses only on a *single* document only. Consequently there is a dire need to draw upon a variety of knowledge sources to aid deep analysis of the document for answer generation. This paper presents our initial effort in designing an approach for RC that leverages a variety of knowledge sources beyond the context of the passage, in an attempt to improve RC performance beyond the baseline set by the bag-of-words (BOW) approach. The knowledge sources include the use of metadata (i.e. verbs, named entities and base noun phrases). Metadata matching is applied in our approach in answer sentence extraction as well as use of contextual sentences. We also devised an automatic acquisition algorithm for Web-derived answer patterns. The acquisition process utilizes question-answer pairs from TREC QA, the Google search engine and the Web. These answer patterns capture important structures for answer sentence extraction in RC. The use of metadata matching and Web-derived answer patterns improved reading comprehension performances for the both Remedia and ChungHwa corpora. We obtain improvements over previously reported results for Remedia, with an overall HumSet accuracy of 42%. In particular, a relative gain of 20.7% is due to metadata matching and a further 10.9% is due to application of Web-derived answer patterns.

Abstract

This paper uses human verb associations as the basis for an investigation of verb properties, focusing on semantic verb relations and prominent nominal features. First, the lexical semantic taxonymy GermaNet is checked on the types of classic semantic relations in our data; verb-verb pairs not covered by GermaNet can help to detect missing links in the taxonomy, and provide a useful basis for defining non-classical relations. Second, a statistical grammar is used for determining the conceptual roles of the noun responses. We present prominent syntax-semantic roles and evidence for the usefulness of co-occurrence information in distributional verb descriptions.

1 Introduction

This paper presents an examination of a collection of semantic associates evoked by German verbs in a web experiment. We define semantic associates here as those concepts spontaneously called to mind by a stimulus word. In the current investigation, we assume that these evoked concepts reflect highly salient linguistic and conceptual features of the stimulus word. Given this assumption, identifying the types of information provided by speakers and distinguishing and quantifying the relationships between stimulus and response can serve a number of purposes for NLP applications.

First, the notion of semantic verb relations is crucial for many NLP tasks and applications such as verb clustering (Pereira et al., 1993; Merlo and Stevenson, 2001; Lin, 1998; Schulte im Walde, 2003), thesaurus extraction (Lin, 1999; McCarthy et al., 2003), word sense discrimination (Schütze, 1998), text indexing (Deerwester et al., 1990), and summarisation (Barzilay et al., 2002). Different applications incorporate different semantic verb relations, varying with respect to their demands. To date, limited effort has been spent on specifying the range of verb-verb relations. Morris and Hirst (2004) perform a study on lexical semantic relations which ensure text cohesion. Their relations are not specific to verb-verb pairs, but include e.g. descriptive noun-adjective pairs (such as *professors/brilliant*), or stereotypical relations (such as *homeless/drunk*). Chklovski and Pantel (2004) address the automatic acquisition of verb-verb pairs and their relations from the web. They define syntagmatic patterns to cover strength, enablement and temporal relations in addition to synonymy and antonymy, but they do not perform an exhaustive study. We suggest that an analysis of human verb-verb associations may identify the range of semantic relations which are crucial in NLP applications. We present a preparatory study where the lexical semantic taxonymy GermaNet (Kunze, 2000; Kunze, 2004) is checked on the types of classical semantic verb relations[1] in our data; verb-verb pairs not covered by GermaNet can help to detect missing links in the taxonomy, and provide an empirical basis for defining non-classical relations.

[1]We follow Morris and Hirst (2004) and refer to the paradigmatic WordNet relations as the ”classical” relations.

Second, in data-intensive lexical semantics, words are commonly modelled by distributional vectors, and the relatedness of words is measured by vector similarity. The features in the distributional descriptions can be varied in nature: words co-occurring in a document, in a context window, or with respect to a word-word relationship, such as syntactic structure, syntactic and semantic valency, etc. Most previous work on distributional similarity has either focused on a specific word-word relation (such as Pereira et al. (1993) referring to a direct object noun for describing verbs), or used any dependency relation detected by the chunker or parser (such as Lin (1999; 1998), and McCarthy et al. (2003)). Little effort has been spent on varying the (mostly nominal) types of verb features. We assume that the noun associates in our verb experiment are related to conceptual roles of the respective verbs, and investigate the linguistic functions that are realised by the response nouns with respect to the target verb, based on an empirical grammar model (Schulte im Walde, 2003). Even though the usage of the distributional features depends on the respective application, we present prominent roles and evidence for the usefulness of co-occurrence information in distributional verb descriptions.

2 Web Experiment

This section introduces our web experiment, as the data source for the explorations to follow. The web experiment asked native speakers to provide associations to German verbs.

2.1 Experiment Method

Material: 330 verbs were selected for the experiment. They were drawn from a variety of semantic classes including verbs of self-motion (e.g. *gehen* 'walk', *schwimmen* 'swim'), transfer of possession (e.g. *kaufen* 'buy', *kriegen* 'receive'), cause (e.g. *verbrennen* 'burn', *reduzieren* 'reduce'), experiencing (e.g. *hassen* 'hate', *überraschen* 'surprise'), communication (e.g. *reden* 'talk', *beneiden* 'envy'), etc. Drawing verbs from different categories was intended only to ensure that the experiment covered a wide variety of verb types; the inclusion of any verb in any particular verb class was achieved in part with reference to prior verb classification work (e.g. Levin (1993)) but also on intuitive grounds. It is not critical for the subsequent analyses. The target verbs were divided randomly into 6 separate experimental lists of 55 verbs each. The lists were balanced for class affiliation and frequency ranges (0, 100, 500, 1000, 5000), such that each list contained verbs from each grossly defined semantic class, and had equivalent overall verb frequency distributions. The frequencies of the verbs were determined by a 35 million word newspaper corpus; the verbs showed corpus frequencies between 1 and 71,604.

Procedure: The experiment was administered over the Internet. When participants loaded the experimental page, they were first asked for their biographical information, such as linguistic expertise, age and regional dialect. Next, the participant was presented with the written instructions for the experiment and an example item with potential responses. In the actual experiment, each trial consisted of a verb presented in a box at the top of the screen. All stimulus verbs were presented in the infinitive. Below the verb was a series of data input lines where participants could type their associations. They were instructed to type at most one word per line and, following German grammar, to distinguish nouns from other parts of speech with capitalisation. [2] Participants had 30 sec. per verb to type as many associations as they could. After this time limit, the program automatically advanced to the next trial.

Participants and Data: 299 native German speakers participated in the experiment, between 44 and 54 for each data set. 132 of the individuals identified themselves as having had a linguistics education and 166 rated themselves as linguistic novices. In total, we collected 81,373 associations from 16,445 trials; each trial elicited an average of 5.16 associate responses with a range of 0-16.

2.2 Data Preparation

Each completed data set contains the background information of the participant, followed by the list of target verbs. Each target verb is paired with a list of associations in the order in which the participant provided them. For the analyses to follow, we preprocessed all data sets in the following way: For each target verb, we quantified over all responses in

[2]Despite these instructions, some participants failed to use capitalisation, leading to some ambiguity.

the experiment, disregarding the participant's background and the order of the associates. Table 1 lists the 10 most frequent responses for the verb *klagen* 'complain, moan, sue'. 64% of all responses were provided more than once for a target verb, and 36% were idiosyncratic, i.e. given only once. The verb responses were not distinguished according to polysemic senses of the verbs.

klagen 'complain, moan, sue'		
Gericht	'court'	19
jammern	'moan'	18
weinen	'cry'	13
Anwalt	'lawyer'	11
Richter	'judge'	9
Klage	'complaint'	7
Leid	'suffering'	6
Trauer	'mourning'	6
Klagemauer	'Wailing Wall'	5
laut	'noisy'	5

Table 1: Association frequencies for target verb.

3 Linguistic Analyses of Experiment Data

The verb associations are investigated on three linguistic dimensions:

1. In a preparatory step, we distinguish the responses with respect to the major part-of-speech tags: nouns, verbs, adjectives, adverbs.
2. For each verb associate, we look up the semantic relation between the target and response verbs using the lexical taxonomy GermaNet.
3. For each noun associate, we investigate the kinds of linguistic functions that are realised by the noun with respect to the target verb. The analysis is based on an empirical grammar.

For expository purposes, the paper is organised into three analysis sections, with discussions following each analysis.

3.1 *Excursus:* Empirical Grammar Model

The quantitative data in the analyses to follow are derived from an empirical grammar model (Schulte im Walde, 2003): a German context-free grammar was developed with specific attention towards verb subcategorisation. The grammar was lexicalised, and the parameters of the probabilistic version were estimated in an unsupervised training procedure, using 35 million words of a large German newspaper corpus from the 1990s. The trained grammar model provides empirical frequencies for word forms, parts-of-speech tags and lemmas, and quantitative information on lexicalised rules and syntax-semantics head-head co-occurrences.

3.2 Morpho-Syntactic Analysis

The morpho-syntactic analysis is a preparatory step for the analyses to follow. Each associate of the target verb is assigned its (possibly ambiguous) part-of-speech by our empirical grammar dictionary. Originally, the dictionary distinguished approx. 50 morpho-syntactic categories, but we disregard fine-grained distinctions such as case, number and gender features and consider only the major categories verb (V), noun (N), adjective (ADJ) and adverb (ADV). Ambiguities between these categories arise e.g. in the case of nominalised verbs (such as *Rauchen* 'smoke', *Vergnügen* 'please/pleasure'), where the experiment participant could have been referring either to a verb or a noun, or in the case of past participles (such as *verschlafen*) and infinitives (such as *überlegen*), where the participant could have been referring either to a verb ('sleep' or 'think about', for the two examples respectively) or an adjective ('drowsy' or 'superior', respectively). In total, 4% of all response types are ambiguous between multiple part-of-speech tags.

Having assigned part-of-speech tags to the associates, we can distinguish and quantify the morpho-syntactic categories of the responses. In non-ambiguous situations, the unique part-of-speech receives the total target-response frequency; in ambiguous situations, the target-response frequency is split over the possible part-of-speech tags. As the result of this first analysis, we can specify the frequency distributions of the part-of-speech tags for each verb, and also in total. Table 2 presents the total numbers and specific verb examples. Participants provided noun associates in the clear majority of token instances, 62%; verbs were given in 25% of the responses, adjectives in 11%, adverbs almost never (2%).[3] The part-of-speech distribution for response words is correlated with target verb frequency. The rate of verb and adverb

[3]All of our analyses reported in this paper are based on response tokens; the type analyses show the same overall pictures.

responses is positively correlated with target verb frequency, Pearson's *r*(328)=.294, *p*<.001 for verbs and *r*(328)=.229, *p*<.001 for adverbs, while the rate of noun and adjective responses is inversely correlated with verb frequency, Pearson's *r*(328)=-.155, *p*<.005 for nouns and *r*(328)=.114, *p*<.05 for adjectives. The distribution of responses over part-of-speech also varies across verb classes. For example, aspectual verbs, such as *aufhören* 'stop', received more verb responses, *t*(12)=3.11, *p*<.01, and fewer noun responses, *t*(12)=3.84, *p*<.002, than creation verbs, such as *backen* 'bake', although the verb sets have comparable frequencies, *t*(12)=1.1, *p*<.2.

	V	N	ADJ	ADV
Total Freq	19,863	48,905	8,510	1,268
Total Prob	25%	62%	11%	2%
aufhören 'stop'	49%	39%	4%	6%
aufregen 'be upset'	22%	54%	21%	0%
backen 'bake'	7%	86%	6%	1%
bemerken 'realise'	52%	31%	12%	2%
dünken 'seem'	46%	30%	18%	1%
flüstern 'whisper'	19%	43%	37%	0%
nehmen 'take'	60%	31%	3%	2%
radeln 'bike'	8%	84%	6%	2%
schreiben 'write'	14%	81%	4%	1%

Table 2: Part-of-speech tags.

3.3 Semantic Verb Relations

For each verb associate, we look up the semantic relation between the target and response verbs using the lexical semantic taxonomy GermaNet (Kunze, 2000; Kunze, 2004), the German counterpart to WordNet (Fellbaum, 1998). The lexical database is inspired by psycholinguistic research on human lexical memory. It organises nouns, verbs, adjectives and adverbs into classes of synonyms (synsets), which are connected by lexical and conceptual relations. The GermaNet version from October 2001 contains 6,904 verbs and defines the paradigmatic semantic relations *synonymy, antonymy, hypernymy/hyponymy* as well as the non-paradigmatic relations *entailment, cause,* and *also see* between verbs or verb synsets. (*Also see* is an underspecified relation, which captures relationships other than the preceding ones. For example, *sparen* 'save' is related to *haushalten* 'budget' by *also see*.) Words with several senses are assigned to multiple synsets.

Based on the GermaNet relations, we can distinguish between the different kinds of verb associations elicited from speakers. Our analysis proceeds as follows. For each pair of target and response verbs, we look up whether any kind of semantic relation is defined between any of the synsets the verbs belong to. For example, if the target verb *rennen* 'run' is in synsets a and b, and the response verb *bewegen* 'move' is in synsets c and d, we determine whether there is any semantic relation between the synsets a and c, a and d, b and c, b and d. Two verbs belonging to the same synset are synonymous. The semantic relations are quantified by the target-response verb frequencies, e.g. if 12 participants provided the association *bewegen* for *rennen*, the hypernymy relation is quantified by the frequency 12. If the target and the response verb are both in GermaNet, but there is no relation between their synsets, then the verbs do not bear any kind of semantic relation, according to GermaNet's current status. If either of them is not in GermaNet, we cannot make any statement about the verb-verb relationship. Table 3 shows the number of semantic relations encoded in our GermaNet version, and the frequencies and probabilities of our response tokens found among them.[4] For example, there are 9,275 verb-verb instances where GermaNet defines a hypernymy-hyponymy relation between their synsets; for 2,807 of our verb-verb pairs (verb response tokens with respect to target verbs) we found a hypernymy relation among the GermaNet definitions, which accounts for 14% of all our verb responses.

The distribution of target-response relations is also correlated with target verb frequency. The proportion of associate responses captured by the respective relations of synonym, antonym and hyponym increases as a function of target verb frequency, *r*(323)=.147 for synonymy, *r*(328)=.341 for antonymy and *r*(328)=.243 for hyponymy (all *p*<.01); the proportion of hypernym relations is not correlated with verb frequency. The distribution of relations also varies by verb class. For example, aspectual target verbs like *aufhören* 'stop' received significantly more antonymic responses like *anfangen* 'begin' or *weitermachen* 'go on' than creation verbs such as *backen* 'bake', *t*(12)=3.44, *p*<.05.

[4]Note that the number of encoded relations in GermaNet differs strongly, which influences the number of verb-verb tokens that can potentially be found.

	GermaNet	Freq	Prob
Synonymy	4,633	1,194	6%
Antonymy	226	252	1%
Hypernymy	9,275	2,807	14%
Hyponymy	9,275	3,016	16%
Cause	95	49	0%
Entailment	8	0	0%
Also see	1	0	0%
No relation	-	10,509	54%
Unknown cases	-	1,726	9%

Table 3: Semantic relations.

An interesting piece of information is provided by the verb-verb pairs for which we do not find a relationship in GermaNet. The minority of such cases (9%) is due to part-of-speech confusion based on capitalisation errors by the participants, cf. footnote 2; e.g. the non-capitalised noun *wärme* ‘warmth’ was classified as a verb because it is the imperative of the verb *wärmen* ‘warm’. A remarkable number of verb-verb associations (54%) do not show any kind of semantic relation according to GermaNet despite both verbs appearing in the taxonomy. On the one hand, this is partly due to the GermaNet taxonomy not being finished yet; we find verb associations such as *weglaufen* ‘run away’ for *abhauen* ‘walk off’ (12 times), or *untersuchen* ‘examine’ for *analysieren* ‘analyse’ (8 times) where we assume (near) synonymy not yet coded in GermaNet; or *weggehen* ‘leave’ for *ankommen* ‘arrive’ (6 times), and *frieren* ‘be cold’ for *schwitzen* ‘sweat’ (2 times) where we assume antonymy not yet coded in GermaNet. For those cases, our association data provides a useful basis for detecting missing links in GermaNet, which can be used to enhance the taxonomy. However, a large proportion of the ”no relation” associations represent instances of verb-verb relations not targeted by GermaNet. For example, *adressieren* ‘address’ was associated with the temporally preceding *schreiben* ‘write’ (15 times) and the temporally following *schicken* ‘send’ (6 times); *schwitzen* ‘sweat’ was associated with a consequence *stinken* ‘stink’ (8 times) and with a cause *laufen* ‘run’ (5 times); *setzen* ‘seat’ was associated with the implication *sitzen* ‘sit’ (2 times), *erfahren* ‘get to know’ with the implication *wissen* ‘know’ (8 times). Those examples represent instantiations of non-classical verb relations and could be subsumed under *also see* relations in GermaNet, but it is obvious that one would prefer more fine-grained distinctions. We are specifically interested in those cases, because we expect that human associations cover the range of possible semantic verb relations to a large extent, and we believe that they represent an excellent basis for defining an exhaustive set, as alternative to e.g. text-based relations (Morris and Hirst, 2004). Again, the diversity of semantic verb relations is a crucial ingredient for NLP tasks such as thesaurus extraction, summarisation, and question answering.

Window Look-up We have argued above that an investigation into the types of semantic relations instantiated by verb-verb associations could be relevant in NLP. Thus, we are interested in whether paradigmatically related verb-verb pairs co-occur in texts. To evaluate this point, we perform a window look-up, in order to determine the distance between two associated verbs. We use our complete newspaper corpus, 200 million words, and check whether the response verbs occur in a window of 5/20/50 words to the left or to the right of the relevant target word. For paradigmatically related verb pairs, namely those whose relation we could determine with GermaNet (37%), we find 85/95/97% in the respective windows. For those whose relation is unspecified in GermaNet (63%), we find lower co-occurrence rates, 61/74/79%. The fact that the distances between verbs and the co-occurrance rates differ with respect to the category of semantic relation, e.g. paradigmatic or not, is useful for NLP applications such as summarisation, where both the distances between salient words and their semantic relations are crucial. More precise conditions (e.g. different window sizes, structural sentence/paragraph distinctions, quantification of window matches by their frequencies) shall be specified in future work.

3.4 Syntax-Semantic Noun Functions

In a third step, we investigate the kinds of linguistic functions that are realised by noun associates of the target verbs. Our hypothesis is that the properties of the elicited noun concepts provide insight into conceptual features for distributional verb descriptions.

The analysis utilises the empirical grammar model, cf. Section 3.1. With respect to verb subcategorisation, the grammar defines frequency distributions of verbs for 178 subcategorisation frame types, including prepositional phrase information, and frequency distributions of verbs for nominal argument fillers. For example, the verb *backen* 'bake' appeared 240 times in our training corpus. In 80 of these instances it was parsed as intransitive, and in 109 instances it was parsed as transitive subcategorising for a direct object. The most frequent nouns subcategorised for as direct objects are *Brötchen* 'rolls', *Brot* 'bread', *Kuchen* 'cake', *Plätzchen* 'cookies', *Waffel* 'waffle'.

We use the grammar information to look up the syntactic relationships which exist between a target verb and a response noun. For example, the nouns *Kuchen* 'cake', *Brot* 'bread', *Pizza* and *Mutter* 'mother' were produced in response to the target verb *backen* 'bake'. The grammar look-up tells us that *Kuchen* 'cake' and *Brot* 'bread' appear not only as the verb's direct objects (as illustrated above), but also as intransitive subjects; *Pizza* appears only as a direct object, and *Mutter* 'mother' appears only as transitive subject. The verb-noun relationships which are found in the grammar are quantified by the verb-noun association frequency, divided by the number of different relationships (to account for the ambiguity represented by multiple relationships). For example, the noun *Kuchen* was elicited 45 times in response to *bake*; the grammar contains the noun both as direct object and as intransitive subject for that verb, so both functions are assigned a frequency of 22.5. In a second variant of the analysis, we also distributed the verb-noun association frequencies over multiple relationships according to the empirical proportions of the respective relationships in the grammar, e.g. of the total association frequency of 45 for *Kuchen*, 15 would be assigned to the direct object of *backen*, and 30 to the intransitive subject if the empirical grammar evidence for the respective functions of *backen* were one vs. two thirds.

In a following step, we accumulate the association frequency proportions with respect to a specific relationship, e.g. for the direct objects of *backen* 'bake' we sum over the frequency proportions for *Kuchen, Brot, Plätzchen, Brötchen*, etc. The final result is a frequency distribution over linguistic functions for each target verb, i.e. for each verb we can determine which linguistic functions are activated by how many noun associates. For example, the most prominent functions for the inchoative-causative verb *backen* 'bake' are the transitive direct object (8%), the intransitive subject (7%) and the transitive subject (4%).

By generalising over all verbs, we discover that only 11 frame-slot combinations are activated by at least 1% of the nouns: subjects in the intransitive frame, the transitive frame (with direct/indirect object, or prepositional phrase) and the ditransitive frame; the direct object slot in the transitive, the ditransitive frame and the direct object plus PP frame; the indirect object in a transitive and ditransitive frame, and the prepositional phrase headed by *Dat:in*, dative (locative) 'in'. The frequency and probability proportions are illustrated by Table 4; the function is indicated by a slot within a frame (with the relevant slot in bold font); 'S' is a subject slot, 'AO' an accusative (direct) object, 'DO' a dative (indirect) object, and 'PP' a prepositional phrase. The activation of the functions differs only slightly with the analysis variant distributing the association frequencies with respect to grammar evidence, see above.

Interestingly, different verb classes are associated to frame slots to varying degrees. For example, verbs of creation like *backen* 'bake' elicited direct object slot fillers significantly more often than aspectual verbs like *aufhören* 'stop', *t*(12)=2.24, *p*<.05.

Function		Freq	Prob
S	**S** V	1,793	4%
	S V AO	1,065	2%
	S V DO	330	1%
	S V AO DO	344	1%
	S V PP	510	1%
AO	S V **AO**	2,298	5%
	S V **AO** DO	882	2%
	S V **AO** PP	706	1%
DO	S V **DO**	302	1%
	S V AO **DO**	597	1%
PP	S V **PP-Dat:in**	418	1%
Unknown noun		10,663	22%
Unknown function		24,536	50%

Table 4: Associates as slot fillers.

In total, only 28% of all noun associates were identified by the statistical grammar as frame-slots fillers. However, the analysis of noun functions shows that a range of linguistic functions might be considered as prominent, e.g. 11 functions are activated by more than 1% of the associates. Our hope is that these frame-role combinations are candidates for defining distributional verb descriptions. As mentioned before, most previous work on distributional similarity has focused either on a specific word-word relation (such as Pereira et al. (1993) referring to a direct object noun for describing verbs), or used any syntactic relationship detected by the chunker or parser (such as Lin (1999; 1998) and McCarthy et al. (2003)). Naturally, the contribution of distributional features depends on the distributional objects and the application, but our results suggest that it is worth determining a task-specific set of prominent features.

The majority of noun responses were not found as slot fillers. 22% of the associates are missing because they do not appear in the grammar model at all. These cases are due to (i) lemmatisation in the empirical grammar dictionary, where noun compounds such as *Autorennen* ‘car racing’ are lemmatised by their lexical heads, creating a mismatch between the full compound and its head; (ii) domain and size of training corpus, which underrepresents slang responses like *Grufties* ‘old people’, dialect expressions such as *Ausstecherle* ‘cookie-cutter’ as well as technical expressions such as *Plosiv* ‘plosive’. The remaining 50% of the nouns are represented in the grammar but do not fill subcategorised-for linguistic functions; clearly the conceptual roles of the noun associates are not restricted to the subcategorisation of the target verbs. In part what is or is not covered by the grammar model can be characterised as an argument/adjunct contrast. The grammar model distinguishes argument and adjunct functions, and only arguments are included in the verb subcategorisation and therefore found as linguistic functions. Adjuncts such as the instrument *Pinsel* ‘brush’ for *bemalen* ‘paint’ (21 times), *Pfanne* ‘pan’ for *erhitzen* ‘heat’ (2), or clause-internal information such as *Aufmerksamkeit* ‘attention’ for *bemerken* ‘notice’ (6) and *Musik* ‘music’ for *feiern* ‘celebrate’ (10) are not found. These associates fulfill scene-related roles which are not captured by subcategorisation in the grammar model. In addition, we find associates which capture clause-external scene-related information or refer to world knowledge which is not expected to be found in the context at all. For example, the association *Trockner* ‘dryer’ as the instrument for *trocknen* ‘dry’ (11 times) is not typically mentioned with the verb; similarly *Wasser* ‘water’ for *auftauen* ‘defrost’ (14), *Freude* ‘joy’ for *überraschen* ‘surprise’ (24), or *Verantwortung* ‘responsibility’ for *leiten* ‘guide’ (4) reflect world knowledge and may not be found in the immediate context of the verb.

Window Look-up Of course, the distinction between arguments, adjuncts, scene-related roles and world knowledge reflects a continuum. As a follow-up experiment, we perform a window look-up on the verb-noun pairs, in order to determine what portion of the nouns co-occur in the context of the verb and what portion is missing. This should provide us with a rough idea of the conceptual roles which are world knowledge and not found in the context. We again use our complete newspaper corpus, 200 million words, and check whether the response nouns are in a window of 5/20/50 words to the left or to the right of the relevant target verb. Naturally, most noun associates which were found as slot fillers in the functional analysis also appear in the window (since they are part of the subcategorisation): 99/99/100%. Of those cases which are not argument slot-fillers in the preceding functional analysis, we find 55/69/75% in our large corpus, i.e. more than half of the 72% missing noun tokens are in a window of 5 words from the verb, three quarters are captured by a large window of 50 words, one quarter is still missing. We conclude that, in addition to the conceptual roles referring to verb subcategorisation roles, the associations point to scene-related information and world knowledge, much of which is not explicitly mentioned in the context of the verb. With respect to a distributional feature description of verbs, we suggest that a set of prominent functions is relevant, but in addition it makes sense to include window-based nouns, which refer to scene information rather than intra-sentential syntactic functions. This is an interesting finding, since the window approach has largely been disregarded in recent years, in comparison to using syntactic functions.

4 Summary

This paper presented a study to identify, distinguish and quantify the various types of semantic associations provided by humans, and to illustrate their usage for NLP. For the approx. 20,000 verb associates, we specified classical GermaNet relations for 37% of the verb-verb pairs, and demonstrated that the co-occurrence distance between two verbs varies with respect to their semantic relation. Verb-verb pairs with no relation in GermaNet provide an empirical basis for detecting missing links in the taxonomy. Non-classical verb-verb relations such as temporal order, cause, and consequence are represented in a large proportion of the verb-verb pairs. These data represent an excellent basis for defining an exhaustive set of non-classical relations, a crucial ingredient for NLP applications.

For the approx. 50,000 noun associates, we investigated the kinds of linguistic functions that are realised by the verb-noun pairs. For 28% of the noun tokens, we found prominent frame-role combinations which speakers have in mind; our hope is that these conceptual roles represent features which contribute to distributional verb descriptions. Window-based nouns also contribute to verb descriptions by encoding scene information, rather than intra-sentential functions. This finding supports the integration of window-based approaches into function-based approaches.

Future work will establish a set of non-classical verb-verb relations, and then apply variations of verb feature descriptions in order to find dependencies between feature descriptions and verb relations. Such dependencies would improve the application of distributional verb descriptions significantly, knowing which relations are addressed by which kinds of features. In addition, we assume that the (morphological, syntactic, semantic) kinds of associates provided for a verb are indicators for its semantic class. Further investigations into the varied distributions of associate types across semantic classes will enhance the automatic acquisition of such classes. We plan to investigate this issue in more detail.

Abstract

In this paper, we extend an existing parser to produce richer output annotated with function labels. We obtain state-of-the-art results both in function labelling and in parsing, by automatically relabelling the Penn Treebank trees. In particular, we obtain the best published results on semantic function labels. This suggests that current statistical parsing methods are sufficiently general to produce accurate shallow semantic annotation.

1 Introduction

With recent advances in speech recognition, parsing, and information extraction, some domain-specific interactive systems are now of practical use for tasks such as question-answering, flight booking, or restaurant reservation (Stallard, 2000). One of the challenges ahead lies in moving from hand-crafted programs of limited scope to robust systems independent of a given domain. While this ambitious goal will remain in the future for some time to come, recent efforts to develop language processing systems producing richer semantic outputs will likely be the cornerstone of many successful developments in natural language understanding.

In this paper, we present a parser that outputs labels indicating the syntactic or semantic function of a constituent in the tree, such as NP-SBJ or PP-TMP shown in bold face in the tree in Figure 1. These labels indicate that the NP is the subject of the sentence and that the PP conveys temporal information. (Labels in parentheses will be explained later in the paper.) Output annotated with such informative labels underlies all domain-independent question answering (Jijkoun et al., 2004) or shallow semantic interpretation systems (Collins and Miller, 1998; Ge and Mooney, 2005). We test the hypothesis that a current statistical parser can output such richer information without any degradation of the parser's accuracy on the original parsing task. Briefly, our method consists in augmenting a state-of-the-art statistical parser (Henderson, 2003), whose architecture and properties make it particularly adaptive to new tasks. We achieve state-of-the-art results both for parsing and function labelling.

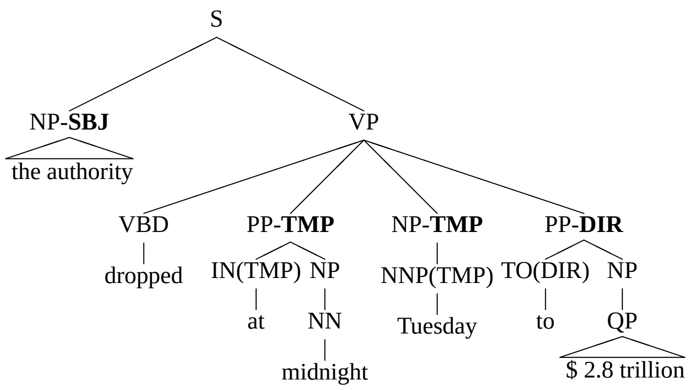

Figure 1: A sample syntactic structure with function labels.

Statistical parsers trained on the Penn Treebank (PTB) (Marcus et al., 1993) produce trees annotated with bare phrase structure labels (Collins, 1999; Charniak, 2000). The trees of the Penn Treebank, however, are also decorated with function labels. Figure 1 shows the simplified tree representation with function labels for a sample sentence from the Penn Treebank corpus (section 00) *The Government's borrowing authority dropped at midnight Tuesday to 2.8 trillion from 2.87 trillion.* Table 1 illustrates the complete list of function labels in the Penn Treebank. Unlike phrase structure labels, func-

tion labels are context-dependent and encode a shallow level of phrasal and lexical semantics, as observed first in (Blaheta and Charniak, 2000).[1] To a large extent, they overlap with semantic role labels as defined in PropBank (Palmer et al., 2005).

Current statistical parsers do not use this richer information because performance of the parser usually decreases considerably, since a more complex task is being solved. (Klein and Manning, 2003), for instance report a reduction in parsing accuracy of an unlexicalised PCFG from 77.8% to 72.9% if using function labels in training. (Blaheta, 2004) also reports a decrease in performance when attempting to integrate his function labelling system with a full parser. Conversely, researchers interested in producing richer semantic outputs have concentrated on two-stage systems, where the semantic labelling task is performed on the output of a parser, in a pipeline architecture divided in several stages (Gildea and Jurafsky, 2002). See also the common task of (CoNLL, 2004 2005; Senseval, 2004).

Our approach maintains state-of-the-art results in parsing, while also reaching state-of-the-art results in function labelling, by suitably extending a Simple Synchrony Network (SSN) parser (Henderson, 2003) into a single integrated system. This is an interesting result, as a task combining function labelling and parsing is more complex than simple parsing. While the function of a constituent and its structural position are often correlated, they sometimes diverge. For example, some nominal temporal modifiers occupy an object position without being objects, like *Tuesday* in the tree above. Moreover, given current limited availability of annotated tree banks, this more complex task will have to be solved with the same overall amount of data, aggravating the difficulty of estimating the model's parameters due to sparse data.

[1](Blaheta and Charniak, 2000) talk of function *tags*. We will instead use the term function *label*, to indicate function identifiers, as they can decorate any node in the tree. We keep the word *tag* to indicate only those labels that decorate preterminal nodes in a tree – part-of-speech tags– as is standard use.

2 Method

Successfully addressing function parsing requires accurate parsing models and training data. Understanding the causes and the relevance of the observed results requires appropriate evaluation measures. In this section, we describe the methodology that will be used to assess our main hypothesis.

2.1 The Basic Parsing Architecture

Our main hypothesis says that function labels can be successfully and automatically recovered while parsing, without affecting negatively the performance of the parser. It is possible that attempting to solve the function labelling and the parsing problem at the same time would require modifying existing parsing models, since their underlying independence assumptions might no longer hold. Moreover, many more parameters are to be estimated. It is therefore important to choose a statistical parser that can model our augmented labelling problem. We use a family of statistical parsers, the Simple Synchrony Network (SSN) parsers (Henderson, 2003), which crucially do not make any explicit independence assumptions, and learn to smooth across rare feature combinations. They are therefore likely to adapt without much modification to the current problem. This architecture has shown state-of-the-art performance and is very adaptive to properties of the input.

The architecture of an SSN parser comprises two components, one which estimates the parameters of a stochastic model for syntactic trees, and one which searches for the most probable syntactic tree given the parameter estimates. As with many other statistical parsers (Collins, 1999; Charniak, 2000), the model of parsing is history-based. Its events are derivation moves. The set of well-formed sequences of derivation moves in this parser is defined by a Predictive LR pushdown automaton (Nederhof, 1994), which implements a form of left-corner parsing strategy.[2]

The probability of a phrase-structure tree is equated to the probability of a finite (but unbounded) sequence of derivation moves. To bound the number of parameters, standard history-based models partition the set of prefixes of well-formed sequences of transitions into equivalence classes. While such a partition makes the problem of searching for the most probable parse polynomial, it introduces hard independence assumptions: a derivation move only depends on the equivalence class to which its history belongs. SSN parsers, on the other hand, do not state any explicit independence assumptions: they induce a finite history representation of an unbounded sequence of moves, so that the representation of a move $i-1$ is included in the inputs to the representation of the next move i, as explained in more detail in (Henderson, 2003). SSN parsers only impose soft inductive biases to capture relevant properties of the derivation, thereby exhibiting adaptivity to the input. The art of designing SSN parsers consists in selecting and introducing such biases. To this end, it is sufficient to specify features that extract some information relevant to the next derivation move from previous ones, or some set of nodes that are structurally local to the node on top of the stack. These features and these nodes are input to the computation of a hidden history representation of the sequence of previous derivation moves. Given the hidden representation of a derivation, a log-linear distribution over possible next moves is computed. Thus, the set D of structurally local nodes and the set f of predefined features determine the inductive bias of an SSN system. Unless stated otherwise, for each of the experiments reported here, the set D that is input to the computation of the history representation of the derivation moves $d_1, \ldots, d_{i-1}$ includes the following nodes: top_i, the node on top of the pushdown stack before the ith move; the left-corner ancestor of top_i; the leftmost child of top_i; and the most recent child of top_i, if any. The set of features f includes the last move in the derivation, the label or tag of top_i, the tag-word pair of the most recently shifted word, the leftmost tag-word pair that top_i dominates.

[2]The derivation moves include: projecting a constituent with a specified label, attaching one constituent to another, and shifting a tag-word pair onto the pushdown stack.

2.2 The Set of Function Labels

The bracketting guidelines for the Penn Treebank II list 20 function labels, shown in Table 1 (Bies et al., 1995). Based on their description in the Penn Treebank guidelines, we partition the set of function labels into four classes, as indicated in the table. Following (Blaheta and Charniak, 2000), we refer to the first class as syntactic function labels, and to the second class as semantic function labels. In the rest of the paper, we will ignore the other two classes, for they do not intersect with PropBank labels, and they do not form natural classes. Like previous work (Blaheta and Charniak, 2000), we complete the sets of syntactic and semantic labels by labelling constituents that do not bear any function label with a NULL label.[3]

2.3 Evaluation

To evaluate the performance of our function parsing experiments, we will use several measures. First of all, we apply the standard Parseval measures of labelled recall and precision to a parser whose training data contains the Penn Treebank function labels, to assess how well we solve the standard phrase structure parsing problem. We call these figures FLABEL-less figures in the tables below and we will call the task the (simple) parsing task in the rest of the paper. Second, we measure the accuracy of this parser with an extension of the Parseval measures of labelled precision and recall applied to the set of complex labels —the phrase structure non-terminals augmented with function labels— to evaluate how well the parser solves this complex parsing problem. These are the FLABEL figures in the tables below. We call this task the function parsing task. Finally, we also assess function labelling performance on its own. Note that the maximal precision or recall score of function labelling is strictly smaller than one-hundred percent if the precision or the recall of

[3]Strictly speaking, this label corresponds to two NULL labels: SYN-NULL and SEM-NULL. A node bearing the SYN-NULL label is a node that does not bear any other syntactic label. Analogously, the SEM-NULL label completes the set of semantic labels. Note that both the SYN-NULL label and the SEM-NULL are necessary, since both a syntactic and a semantic label can label a given constituent.

		ASSIGNED LABELS										
		ADV	BNF	DIR	EXT	LOC	MNR	NOM	PRP	TMP	SEM-NULL	SUM
ACTUAL LABELS	ADV	143	0	0	0	0	0	0	1	3	11	158
	BNF	0	0	0	0	0	0	0	0	0	1	1

	MNR	0	0	0	0	3	35	0	0	16	40	94
	NOM	2	0	0	0	0	0	88	0	0	4	94
	PRP	0	0	0	0	0	0	0	54	1	33	88
	TMP	18	0	1	0	24	11	0	1	479	105	639
	SEM-NULL	12	0	13	5	81	28	12	24	97	20292	20564
	SUM	175	0	54	42	456	81	100	80	612	20702	22302

Table 2: Confusion matrix for simple baseline model, tested on the validation set (section 24 of PTB).

the parser is less than one-hundred percent. Following (Blaheta and Charniak, 2000), incorrectly parsed constituents will be ignored (roughly 11% of the total) in the evaluation of the precision and recall of the function labels, but not in the evaluation of the parser. Of the correctly parsed constituents, some bear function labels, but the overwhelming majority do not bear any label, or rather, in our notation, they bear a NULL label. To avoid calculating excessively optimistic scores, constituents bearing the NULL label are not taken into consideration for computing overall recall and precision figures. NULL-labelled constituents are only needed to calculate the precision and recall of other function labels. (In other words, NULL-labelled constituents never contribute to the numerators of our calculations.) For example, consider the confusion matrix M in Table 2, which reports scores for the semantic labels recovered by the baseline model described below. Precision is computed as $\frac{\sum_{i\in\{\text{ADV}\cdots\text{TMP}\}} M[i,i]}{\sum_{j\in\{\text{ADV}\cdots\text{TMP}\}} M[\text{SUM},j]}$. Recall is computed analogously. Notice that $M[n,n]$, that is the $[\text{SEM-NULL},\text{SEM-NULL}]$ cell in the matrix, is never taken into account.

3 Learning Function Labels

In order to assess the complexity of the task of predicting function labels while parsing, we run first the SSN on the function parsing task, without modifications to the parser. The confusion matrix for semantic function labels of this simple baseline model is illustrated in Table 2.

It is apparent that the baseline model's largest cause of error is confusion between the labels and the NULL label. These misclassfications affect recall in particular. Consider, for example, the MNR label, where 40 out of 94 occurrences are not given a function label. We add two augmentations to the parser to alleviate this problem.

The simple baseline parser treats NULL labels like other labels, and it does not distinguish subtypes of NULL labels. Our first augmentation of the parser is designed to discriminate among constituents with these NULL labels. We hypothesize that the label NULL (ie. SYN-NULL and SEM-NULL) is a mixture of types, which will be more accurately learnt separately. If the label NULL is learnt more precisely, the recall of the other labels will increase. The NULL label in the training set was automatically split into the mutually exclusive labels CLR, OBJ and OTHER. Constituents were assigned the OBJ label according to the conditions stated in (Collins, 1999).[4]

Another striking property of the simple baseline function parser is that the SSN tends to project NULL labels more than any other label. Since SSNs decide the label of a non-terminal at projection, this behaviour indicates that the parser does not have enough information at this point in the parse to project the correct function label. We hypothesize that finer-grained labelling will improve parsing performance. This observation is consistent with results reported in (Klein and Manning, 2003), who showed that part-of-speech tags occurring in the Treebank are not fine-grained enough to discriminate between

[4]Roughly, an OBJ non-terminal is an NP, SBAR or S whose parent is an S, VP or SBAR. Any such non-terminal must not bear either syntactic or semantic function labels, or the CLR label. In addition, the first child following the head of a PP is marked with the OBJ label.

preterminals. For example, the tag TO labels both the preposition *to* and the infinitival marker. Extending (Klein and Manning, 2003)'s technique to function labelling, we split some part-of-speech tags into tags marked with semantic function labels. More precisely, we concentrate on the function labels DIR, LOC, MNR, PRP or TMP, which appear to cause the most trouble to the parser, as illustrated in Table 2.

The label attached to a non-terminal was propagated down to the pre-terminal tag of its head. The labels in parentheses in Figure 1 illustrate the effect of this lowering of the labels. The goal of this tag-splitting is to indicate more clearly to the parser what kind of label to project on reading a word-tag pair in the input. To this end, re-labelling is applied only if the non-terminal dominates the pre-terminal immediately. This constraint guarantees that only those non-terminals that are actual projections of the pre-terminal are affected by this tag-splitting method. Linguistically, we are trying to capture the notion of maximal projection. [5] This augmented model has a total of 188 non-terminals to represent labels of constituents, instead of the 33 of the original SSN parser. As a result of lowering the five function labels, 83 new part-of-speech tags were introduced to partition the original tagset of the Treebank. There are 819 tag-word pairs in this model, while the original SSN parser has a vocabulary size of 508 tag-word pairs. These augmented tags as well as the 155 new non-terminals are included in the set f of features input to parsing decisions as described in section 2.1.

SSN parsers do not tag their input sentences. To provide the augmented model with tagged input sentences, we trained an SVM tagger whose features and parameters are described in detail in (Gimenez and Marquez, 2004). Trained on section 2-21, the tagger reaches a performance of 95.8% on the test set (section 23) of the PTB using our new tag set.

4 Experiments

In this section, we report the results of the experiments testing hypotheses concerning our function parser. All SSN function parsers were trained on sections 2-21 from the Penn Treebank, validated on section 24, and tested on section 23. All models are trained on parse trees whose labels include function labels. Both results taking function labels into account (FLABEL) and results not taking them into account (FLABEL-less) are reported. All our models, as well as the parser described in (Henderson, 2003), are run only once. [6] These results are reported in Table 3.

	FLABEL			FLABEL-less		
	F	R	P	F	R	P
	Validation Set					
Base	83.4	82.8	83.9	87.7	87.1	88.2

	Test Set					
Aug	86.1	85.8	86.5	88.9	88.6	89.3
H03				88.6	88.3	88.9

Table 3: Percentage F-measure (F), recall (R), and precision (P) of the SSN baseline (Base) and augmented (Aug) parsers. H03 indicates the model illustrated in (Henderson, 2003).

Our hypothesis states that we can perform function labelling and parsing at the same time, without loss in parsing performance. For this to be an interesting statement, we need to show that function labelling is not a straightforward extension of simple parsing. If simple parsing could be easily applied to function parsing, we should not have a degradation of an SSN parser model evaluated on the complex labels, compared to the same SSN parser evaluated only on phrase structure labels. As the results on the validation set indicate, our baseline model with function labels (FLABEL) is indeed lower than the performance of the parser when function labels are not taken into account (FLABEL-less), indicating that the function parsing task is more difficult than the simple parsing task.

Since the function parsing problem is more difficult than simple parsing, it is then interesting to observe that performance of the augmented parser increases significantly (FLABEL column) ($p < .001$) without losing accuracy on the parsing task

[5] This condition was relaxed in a few cases to capture constructs such as coordinated PPs (e.g. [PP-LOC[PP[IN*at*] ...][CC*and*][PP[IN*in*] ...] ...] or infinitival clauses (e.g. [S-PRP[VP[TO*to*][VP[VB...] ...] ...]).

[6] This explains the little difference in performance between our results for H03 and those cited in (Henderson, 2003), where the best of three runs on the validation set is chosen.

(FLABEL-less column), compared to the initial parsing performance (as indicated by the performance of H03). Notice that, numerically, we do in fact a little better than H03, but this difference is not significant.[7]

Beside confirming that learning function labels does not increase parsing errors, we can also confirm that the nature of the errors remains the same. A separate comparison of labelled and unlabelled scores of our complex function parser indicates that unlabelled results are roughly 1% better than labelled results (F measure 89.8% on the validation set). The original SSN parser exhibits the same differential. This shows that, like other simple parsers, the function parser makes mostly node attachment mistakes rather than labelling mistakes.

A separate experiment only discriminating NULL labels indicates that this modification is indeed useful, but not as much as introducing new tags, on which we concentrate to explain the results. There is converging evidence indicating that the improvement in performance is due to having introduced new tag-word pairs, and not simply new words. First of all, of the 311 new tag-word pairs only 122 introduce truly new words. The remaining pairs are constituted by words that were already in the original vocabulary and have been retagged, or by tags associated to unknown words.

Second, this interpretation of the results is confirmed by comparing different ways of enlarging the vocabulary size input to the SSN. (Henderson, 2003) tested the effect of larger input vocabulary on SSN performance by changing the frequency cut-off that selects the input tag-word pairs. A frequency cut-off of 200 yields a vocabulary of 508 pairs, while a cut-off of 20 yields 4242 pairs, 3734 of which comprise new words. This difference in input size does not give rise to an appreciable difference in performance. On the contrary, we observe that introducing 122 new words and 83 new tags improves results considerably. This leads us to conclude that the performance of the augmented model is not simply due to a larger vocabulary.

We think that our tag-word pairs are effective because they are selected by a linguistically meaningful criterion and are more informative exemplars for the parser. Instead, simply decreasing the frequency cut-off adds mostly types of words for which the parser already possesses enough evidence (in general, nouns). Our method of lowering function labels acts as a finer-grained classification that partitions different kinds of complements based on their lexical semantic characteristics, yielding classes that are relevant to constituent structure. For instance, it is well known that lexical semantic properties of arguments of verbs are related to the verb's argument structure, and consequently to the parse tree that the verb occurs in. Partitioning a verb's complements into function classes could influence attachment decisions beneficially. We also think that the parser we use is particularly able to take advantage of these subclasses. One of the main properties of SSN parsers is that they do not need large vocabularies, because the SSN is good at generalising item-specific properties into an internal hidden representation of word classes.

	Syntactic Labels			Semantic Labels		
	F	R	P	F	R	P

Table 4: Percentage F-measure (F), recall (R), and precision (P) function labelling, separated for syntactic and semantic labels, for our models and Blaheta and Charniak's (BC00) and Blaheta's models (B04 FT, B04 KP). The feature trees (FT) and kernel perceptrons (KP) are optimised separately for the two different sets of labels.

Finally, to provide a meaningful and complete evaluation of the parser, it is necessary to examine the level of performance on the function labels for those constituents that are correctly parsed according to the usual Parseval measure, i.e. for those constituents for which the phrase structure labels and the string covered by the label have been correctly

[7]Significance was measured with the randomized significance test described in (Yeh, 2000).

	Baseline		Augmented	
	P	R	P	R
ADV	81.7	90.5	87.9	81.0
DIR	72.2	39.8	77.0	48.5
EXT	88.1	68.5	86.8	63.5
LOC	75.7	67.4	78.9	74.6
MNR	43.2	37.2	74.0	55.7
NOM	88.0	93.6	88.7	93.1
PRP	67.5	61.4	74.4	65.9
TMP	78.3	75.0	89.6	83.7

Table 5: Percentage F-measure (F), recall (R), and precision (P) function labelling, separated for individual semantic labels, for validation set.

recovered. Clearly, our parsing results would be uninteresting if our recall on function labels were very low. In that case, we would have failed to learn the function parsing task, and that would trivially yield a good performance on the simple parsing task. Table 4 reports the aggregated numbers for the baseline and the augmented model, while Table 5 reports separate figures for each semantic function label. These tables show that we also perform well on the labelling task alone. [8] Comparison to other researchers (last three lines of Table 4) shows that we achieve state-of-the-art results with a single integrated model that is jointly optimised for all the different types of function labels and for parsing, while previous attempts are optimised separately for the two different sets of labels. In particular, our method performs better on semantic labels.

5 Related Work

As far as we are aware, there is no directly comparable work, as nobody has so far attempted to fully merge function labelling or semantic role labelling into parsing. We will therefore discuss separately those pieces of work that have made limited use of function labels for parsing (Klein and Manning, 2003), and those that have concentrated on recovering function labels as a separate task (Blaheta and Charniak, 2000; Blaheta, 2004). We cannot discuss here the large recent literature on semantic role labelling for reasons of space, apart from work that also recovers function labels (Jijkoun and de Rijke, 2004) and work that trains a parser on Propbank labels as the first stage of a semantic role labelling pipeline (Yi and Palmer, 2005).

(Klein and Manning, 2003) and, to a much more limited extent, (Collins, 1999) are the only researchers we are aware of who used function labels for parsing. In both cases, the aim was actually to improve parser performance, consequently only few carefully chosen labels were used. (Klein and Manning, 2003) suggest the technique of tag splitting for the constituent bearing the label TMP. They also speculate that locative labels could be fruitfully percolated down the tree onto the preterminals. Results in Table 5 indicate more precisely that lowering locative labels does indeed bring about some improvement, but not as much as the MNR and TMP labels.

In work that predates the availability of Framenet and Propbank, (Blaheta and Charniak, 2000) define the task of function labelling for the first time and highlight its relevance for NLP. Their method is in two-steps. First, they parse the Penn Treebank using a state-of-the-art parser (Charniak, 2000). Then, they assign function labels using features from the local context, mostly limited to two levels up the tree and only one next label. (Blaheta, 2004) extends on this method by developing specialised feature sets for the different subproblems of function labelling and slightly improves the results, as reported in Table 4. (Jijkoun and de Rijke, 2004) approach the problem of enriching the output of a parser in several steps. The first step applies memory-based learning to the output of a parser mapped to dependency structures. This step learns function labels. Only aggregated results for all function labels, and not only for syntactic or semantic labels, are provided. Although they cannot be compared directly to our results, it is interesting to notice that they are slightly better in F-measure than Blaheta's (F=88.5%). (Yi and Palmer, 2005) share the motivation of our work, although they apply it to a different task. Like the current work, they observe that the distributions of semantic labels could potentially interact with the distributions of syntactic labels and redefine the boundaries of constituents, thus yielding trees that reflect generalisations over both these sources of information.

[8]See also (Musillo and Merlo, 2005) for more detail and comparisons on the labelling task.

6 Conclusions

In this paper we have presented a technique to extend an existing parser to produce richer output, annotated with function labels. We show that both state-of-the-art results in function labelling and in parsing can be achieved. Application of these results are many-fold, such as information extraction or question answering where shallow semantic annotation is necessary. The technique illustrated in this paper is of wide applicability to all other semantic annotation schemes available today, such as Propbank and Framenet, and can be easily extended. Work to extend this technique to Propbank annotation is underway. Since function labels describe dependence relations between the predicative head and its complements, whether they be arguments or adjuncts, this paper suggests that a left-corner parser and its probabilistic model, which are defined entirely on configurational criteria, can be used to produce a dependency output. Consequences of this observation will be explored in future work.

Abstract

We use logical inference techniques for recognising textual entailment. As the performance of theorem proving turns out to be highly dependent on not readily available background knowledge, we incorporate model building, a technique borrowed from automated reasoning, and show that it is a useful robust method to approximate entailment. Finally, we use machine learning to combine these deep semantic analysis techniques with simple shallow word overlap; the resulting hybrid model achieves high accuracy on the RTE testset, given the state of the art. Our results also show that the different techniques that we employ perform very differently on some of the subsets of the RTE corpus and as a result, it is useful to use the nature of the dataset as a feature.

1 Introduction

Recognising textual entailment (RTE) is the task to find out whether some text T entails a hypothesis H. This task has recently been the focus of a challenge organised by the PASCAL network in 2004/5.[1] In Example 1550 H follows from T whereas this is not the case in Example 731.

[1]All examples are from the corpus released as part of the RTE challenge. It is downloadable from `http://www.pascal-network.org/Challenges/RTE/`. The example numbers have also been kept. Each example is marked for entailment as TRUE if H follows from T and FALSE otherwise. The dataset is described in Section 4.1.

Example: 1550 (TRUE)

T: In 1998, the General Assembly of the Nippon Sei Ko Kai (Anglican Church in Japan) voted to accept female priests.

H: The Anglican church in Japan approved the ordination of women.

Example: 731 (FALSE)

T: The city Tenochtitlan grew rapidly and was the center of the Aztec's great empire.

H: Tenochtitlan quickly spread over the island, marshes, and swamps.

The recognition of textual entailment is without doubt one of the ultimate challenges for any NLP system: if it is able to do so with reasonable accuracy, it is clearly an indication that it has some thorough understanding of how language works. Indeed, recognising entailment bears similarities to Turing's famous test to assess whether machines can think, as access to different sources of knowledge and the ability to draw inferences seem to be among the primary ingredients for an intelligent system. Moreover, many NLP tasks have strong links to entailment: in summarisation, a summary should be entailed by the text; paraphrases can be seen as mutual entailment between T and H; in IE, the extracted information should also be entailed by the text.

In this paper, we discuss two methods for recognising textual entailment: a shallow method relying mainly on word overlap (Section 2), and deep semantic analysis, using state-of-the-art off-the-shelf inference tools, namely a theorem prover and a model builder (Section 3). These tools rely on Discourse Representation Structures for T and H as well as lexical and world knowledge. To our knowledge, few approaches to entailment currently use theorem provers and none incorporate model building (see

Section 5 for a discussion of related work).

Both methods are domain-independent to increase transferrability and have not been tailored to any particular test suite. In Section 4 we test their accuracy and robustness on the RTE datasets as one of the few currently available datasets for textual inference. We also combine the two methods in a hybrid approach using machine learning. We discuss particularly the following questions:

- Can the methods presented improve significantly over the baseline and what are the performance differences between them? Does the hybrid system using both shallow and deep semantic analysis improve over the individual use of these methods?
- How far does deep semantic analysis suffer from a lack of lexical and world knowledge and how can we perform logical inference in the face of potentially large knowledge gaps?
- How does the design of the test suite affect performance? Are there subsets of the test suite that are more suited to any particular textual entailment recognition method?

2 Shallow Semantic Features

We use several shallow surface features to model the text, hypothesis and their relation to each other.

Most importantly, we expect some dependency between surface string similarity of text and hypothesis and the existence of entailment. Our string similarity measure uses only a form of extended word overlap between text and hypothesis, taking into account equality of words, synonymy and morphological derivations. WordNet (Fellbaum, 1998) is used as the knowledge source for synonymy and derivations. The exact procedure is as follows:

Both text and hypothesis are tokenised and lemmatised. A lemma l_1 in the hypothesis is said to be *related* to a lemma l_2 in the text iff l_1 and l_2 are equal, belong to the same WordNet synset (e.g., "murder" and "slay"), are related via WordNet derivations (e.g. "murder" and "murderer") or are related via a combination of synonymy and derivations (e.g. "murder" via "murderer" to "liquidator"). No word sense disambiguation is performed and *all* synsets for a particular lemma are considered.

In addition, each lemma in the hypothesis is assigned its inverse document frequency, accessing the Web as corpus via the GoogleAPI, as its weight. This standard procedure allows us to assign more importance to less frequent words.

The overlap measure `wnoverlap` between text and hypothesis is initialised as zero. Should a lemma in the hypothesis be related to a lemma in the text, its weight is added to `wnoverlap`, otherwise it is ignored. In the end `wnoverlap` is normalised by dividing it by the sum of all weights of the lemmas in the hypothesis. This ensures that `wnoverlap` is always a real number between 0 and 1 and also ensures independence of the length of the hypothesis.

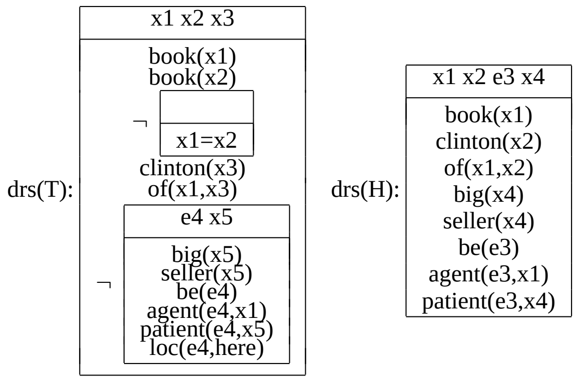
Apart from `wnoverlap` we take into account length (as measured by number of lemmas) of text and hypothesis, because in most of the observed cases for true entailments the hypothesis is shorter than the text as it contains less information. This is covered by three numerical features measuring the length of the text, of the hypothesis and the relative length of hypothesis with regard to the text.

3 Deep Semantic Analysis

3.1 Semantic Interpretation

We use a robust wide-coverage CCG-parser (Bos et al., 2004) to generate fine-grained semantic representations for each T/H-pair. The semantic representation language is a first-order fragment of the DRS-language used in Discourse Representation Theory (Kamp and Reyle, 1993), conveying argument structure with a neo-Davidsonian analysis and including the recursive DRS structure to cover negation, disjunction, and implication. Consider for example:

Example: 78 (FALSE)
T: Clinton's new book is not big seller here.
H: Clinton's book is a big seller.



Proper names and definite descriptions are treated as anaphoric, and bound to previously introduced discourse referents if possible, otherwise accommodated. Some lexical items are specified as presupposition triggers. An example is the adjective 'new' which has a presuppositional reading, as shown by the existence of two different "book" entities in drs(T). Scope is fully specified.

To check whether an entailment holds or not, we use two kinds of automated reasoning tools: Vampire, a theorem prover (Riazanov and Voronkov, 2002), and Paradox, a model builder (Claessen and Sörensson, 2003). Both tools are developed to deal with inference problems stated in first-order logic. We use the standard translation from DRS to first-order logic (Kamp and Reyle, 1993) to map our semantic representation onto the format required by the inference tools.

3.2 Theorem Proving

Given a T/H pair, a theorem prover can be used to find answers to the following conjectures:

1. T implies H (shows entailment)
2. T+H are inconsistent (shows no entailment)

Assume that the function DRS denotes the DRS corresponding to T or H, and FOL the function that translates a DRS into first-order logic. Then, if the theorem prover manages to find a proof for

$$\text{FOL}(\text{DRS}(T)) \rightarrow \text{FOL}(\text{DRS}(H)) \qquad \text{(A)}$$

we know that we are dealing with a true entailment. In addition, to use a theorem prover to detect inconsistencies in a T/H pair, we give it:

$$\neg\text{FOL}(\text{DRS}(T);\text{DRS}(H)) \qquad \text{(B)}$$

If the theorem prover returns a proof for (B), we know that T and H are inconsistent and T definitely doesn't entail H (assuming that T and H are themselves consistent).

Examples The theorem prover will find that T implies H for the following examples:

Example: 1005 (TRUE)
T: Jessica Litman, a law professor at Michigan's Wayne State University, has specialized in copyright law and Internet law for more than 20 years.
H: Jessica Litman is a law professor.

Example: 1977 (TRUE)
T: His family has steadfastly denied the charges.
H: The charges were denied by his family.

Example: 898 (TRUE)
T: After the war the city was briefly occupied by the Allies and then was returned to the Dutch.
H: After the war, the city was returned to the Dutch.

Example: 1952 (TRUE)
T: Crude oil prices soared to record levels.
H: Crude oil prices rise.

These examples show how deep semantic analysis deals effectively with apposition, active-passive alternation, coordination, and can integrate lexical knowledge.

The RTE dataset only contains a few inconsistent T/H pairs. Even although Example 78 might look like a case in point, it is not inconsistent: It would be if the T in the example would have been *Clinton's new book is not a big seller*. The addition of the adverb *here* makes T+H consistent.

3.3 Background Knowledge

The theorem prover needs background knowledge to support its proofs. Finding a proof for Example 1952 above is only possible if the theorem prover knows that soaring is a way of rising.

How does it know this? Because in addition to the information from T and H alone, we also supply relevant background knowledge in the form of first-order axioms. Instead of giving just FOL(DRS(T);DRS(H)) to the theorem prover, we supply it with (BK $\wedge$ FOL(DRS(T);DRS(H))) where BK is short for the relevant background knowledge.

We generate background knowledge using three kinds of sources: generic knowledge, lexical knowledge, and geographical knowledge. Axioms for generic knowledge cover the semantics of possessives, active-passive alternation, and spatial knowledge. There are about 20 different axioms in the current system and these are the only manually generated axioms. An example is

$$\forall e \forall x \forall y(\text{event}(e) \wedge \text{agent}(e,x) \wedge \text{in}(e,y) \rightarrow \text{in}(x,y))$$

which states that if an event is located in y, then so is the agent of that event.

Lexical knowledge is created automatically from WordNet. A hyponymy relation between two synsets A and B is converted into ∀x(A(x)→B(x)). Two synset sisters A and B are translated into ∀x(A(x)→ ¬B(x)). Here the predicate symbols from the DRS are mapped to WordNet synsets using a variant of Lesk's WSD algorithm (Manning and Schuetze, 1999). Examples 78 and 1952 would be supported by knowledge similar to:

∀x(clinton(x)→person(x))	∀x(book(x)→artifact(x))
∀x(artifact(x)→ ¬person(x))	∀x(soar(x)→rise(x))

Finally, axioms covering geographical knowledge about capitals, countries and US states are extracted automatically from the CIA factbook. An example:

∀x∀y(paris(x)∧france(y)→in(x,y))

3.4 Model Building

While theorem provers are designed to prove that a formula *is* a theorem (i.e., that the formula is true in any model), they are generally not good at deciding that a formula is *not* a theorem. Model builders are designed to show that a formula is true in at least one model. To exploit these complementary approaches to inference, we use both a theorem prover and a model builder for any inference problem: the theorem prover attempts to prove the input whereas the model builder simultaneously tries to find a model for the negation of the input. If the model builder finds a model for

$$\neg\text{FOL}(\text{DRS}(T))\rightarrow\text{FOL}(\text{DRS}(H)) \qquad (= \neg A)$$

we know that there can't be a proof for its negation (hence no entailment). And if the model builder is able to generate a model for

$$\text{FOL}(\text{DRS}(T);\text{DRS}(H)) \qquad (= \neg B)$$

we know that T and H are consistent (maybe entailment). (In practice, this is also a good way to terminate the search for proofs or models: if the theorem prover finds a proof for $\neg\phi$, we can halt the model builder to try and find a model for ϕ (because there won't be one), and vice versa.)

Another attractive property of a model builder is that it outputs a model for its input formula (only of course if the input is satisfiable). A model is here the logical notion of a model, describing a situation in which the input formula is true. Formally, a model is a pair $\langle D, F\rangle$ where D is the set of entities in the domain, and F a function mapping predicate symbols to sets of domain members. For instance, the model returned for fol(drs(T)) in Example 78 is one where the domain consists of three entities (domain size = 3):

```
D = {d1,d2,d3}      F(loc) = {}
F(book) = {d1,d2}   F(seller) = {}
F(clinton) = {d3}   F(be) = {}
F(of) = {(d1,d3)}   F(agent) = {}
F(big) = {}         F(patient) = {}
```

Model builders like Paradox generate finite models by iteration. They attempt to create a model for domain size 1. If they fail, they increase the domain size and try again, until either they find a model or their resources run out. Thus, although there are infinitely many models satisfying fol(drs(T)), model builders generally build a model with a minimal domain size. (For more information on model building consult (Blackburn and Bos, 2005)).

3.5 Approximating Entailment

In an ideal world we calculate all the required background knowledge and by either finding a proof or a countermodel, decide how T and H relate with respect to entailment. However, it is extremely hard to acquire all the required background knowledge. This is partly due to the limitations of word sense disambiguation, the lack of resources like WordNet, and the lack of general knowledge in a form suitable for automatic inference tasks.

To introduce an element of robustness into our approach, we use the models as produced by the model builders to measure the "distance" from an entailment. The intuition behind it is as follows. If H is entailed by T, the model for T+H is not informative compared to the one for T, and hence does not introduce new entities. Put differently, the domain size for T+H would equal the domain size of T. In contrast, if T does not entail H, H normally introduce some new information (except when it contains negated information), and this will be reflected in the domain size of T+H, which then is larger than the domain size of T. It turns out that this difference between the domain sizes is a useful way of measuring the likelihood of entailment. Large differences are mostly not entailments, small differences mostly are. Consider the following example:

Example: 1049 (TRUE)

T: Four Venezuelan firefighters who were traveling to a training course in Texas were killed when their sport utility vehicle drifted onto the shoulder of a highway and struck a parked truck.

H: Four firefighters were killed in a car accident.

Although this example is judged as a true entailment, Vampire doesn't find a proof because it lacks the background knowledge that one way of causing a car accident is to drift onto the shoulder of the highway and strike something. It generates a model with domain size 11 for fol(drs(T)), and a model with domain size 12 for fol((drs(T);drs(H))). The absolute difference in domain sizes is small, and therefore likely to indicate an entailment. Apart from the absolute difference we also compute the difference relative to the domain size. For the example above the relative domain size yields $1/12 = 0.083$.

The domain size only tells us something about the number of entities used in a model—not about the number of established relations between the model's entities. Therefore, we also introduce the notion of model size. The model size is defined here by counting the number of all instances of two-place relations (and three-place relations, if there are any) in the model, and multiplying this with the domain size. For instance, the following model

```
D = {d1,d2,d3}
F(cat) = {d1,d2}
F(john) = {d3}
F(of) = {(d1,d3)}
F(like) = {(d3,d1),(d3,d2)}
```

has a domain size of 3 and 3 instantiated two-place relations, yielding a model size of $3 * 3 = 9$.

3.6 Deep Semantic Features

Given our approach to deep semantic analysis, we identified eight features relevant for recognising textual entailment. The theorem prover provides us with two features: `entailed` determining whether T implies H, and `inconsistent` determining whether T together with H is inconsistent. The model builder gives us six features: `domainsize` and `modelsize` for T+H as well as the absolute and relative difference between the sizes of T and T+H, both for the size of the domains (`domainsizeabsdif`, `domainsizereldif`) and the size of the models (`modelsizeabsdif`, `modelsizereldif`).

4 Experiments

There are not many test suites available for textual inference. We use throughout this section the dataset made available as part of the RTE challenge.

4.1 Dataset Design and Evaluation Measures

The organisers released a development set of 567 sentence pairs and a test set of 800 sentence pairs. In both sets, 50% of the sentence pairs were annotated as TRUE and 50% as FALSE, leading to a 50% most frequent class baseline for automatic systems. The examples are further distinguished according to the way they were designed via a so-called *Task* variable. For examples marked CD (Comparable Documents), sentences with high lexical overlap in comparable news articles were selected, whereas the hypotheses of examples marked QA (Question Answering) were formed by translating questions from e.g., TREC into statements. The other subsets are IE (Information extraction), MT (Machine Translation) RC (Reading Comprehension), PP (Paraphrase Acquisition) and IR (Information Retrieval). The different examples and subsets cover a wide variety of different aspects of entailment, from incorporation of background knowledge to lexical to syntactic entailment and combinations of all these. For a more exhaustive description of dataset design we refer the reader to (Dagan et al., 2005).

4.2 Experiment 1: Human Upper bound

To establish a human upper bound as well as investigate the validity of the datasets issued, one of the authors annotated all 800 examples of the test set for entailment, using the short RTE annotation rules. The annotation was performed before the release of the gold standard annotation for the test set and was therefore independent of the organisers' annotation. The organisers' and the author's annotation yielded a high percentage agreement of 95.25%. However, 33% of the originally created examples were already filtered out of the corpus before release by the organisers because of agreement-related problems. Therefore we expect that human agreement on textual entailment in general is rather lower.

4.3 Decision trees for entailment recognition

We expressed each example pair as a feature vector, using different subsets of the features described in Section 2 and Section 3 for each experiment. We then trained a decision tree for classification into TRUE and FALSE entailment on the development set, using the Weka machine learning tool (Witten and Frank, 2000), and tested on the test set. Apart from a classification, Weka also computes a confidence value for each decision, dependent on the leaf in the tree that the classified example falls into: if the leaf covers x examples in the training set, of which y examples are classified wrongly, then the error rate is y/x and the confidence value is $1 - y/x$.

Our evaluation measures are accuracy (acc) as the percentage of correct judgements as well as confidence-weighted average score (cws), which rewards the system's ability to assign a higher confidence score to correct judgements than wrong ones (Dagan et al., 2005): after the n judgements are sorted in decreasing order by their confidence value, the following measure is computed:

$$cws = \frac{1}{n}\sum_{i=1}^{n}\frac{\text{\#correct-up-rank-}i}{i}$$

All evaluation measures are computed over the whole test set as well as on the 7 different subsets (CD, IE, etc.). The results are summarised in Table 1. We also computed precision, recall and F-measure for both classes TRUE and FALSE and will discuss the results in the text whenever of interest.

Experiment 2: Shallow Features In this experiment only the shallow features (see Section 2) were used. The overall accuracy of 56.9% is significantly higher than the baseline.[2]

Column 2 in Table 1 shows that this decent performance is entirely due to excellent performance on the CD subset. (Recall that the CD set was designed explicitly with examples with high lexical overlap in mind.) In addition, the method overestimates the number of true entailments, achieving a Recall of 0.926 for the class TRUE, but a precision of only 0.547 on the same class. In contrast, it has good precision (0.761) but low recall (0.236) for the FALSE class. Thus, there is a correspondence between low word overlap and FALSE examples (see Example 731 in the Introduction, where important words in the hypothesis like "swamps" or "marshes" are not matched in the text); high overlap, however, is normally necessary but not sufficient for TRUE entailment (see also Example 78 in Section 3).

Experiment 3: Strict entailment To test the potential of entailment as discovered by theorem proving alone, we now use only the `entailment` and `inconsistent` features. As to be expected, the decision tree shows that, if a proof for T implies H has been found, the example should be classified as TRUE, otherwise as FALSE.[3] The precision (0.767) for the class TRUE is reasonably high: if a proof is found, then an entailment is indeed very likely. However, recall is very low (0.058) as only 30 proofs were found on the test set (for some examples see Section 3). This yields an F-measure of only 0.10 for the TRUE class. Due to the low recall, the overall accuracy of the system (0.52, see Table 1) is not significantly higher than the baseline.

Thus, this feature behaves in the opposite way to shallow lexical overlap and overgenerates the FALSE class. Missing lexical and background knowledge is the major cause for missing proofs.

Experiment 4: Approximating entailment As discussed in Section 3.5 we now try to compensate for missing knowledge and improve recall for TRUE entailments by approximating entailment with the features that are furnished by the model builder. Thus, Experiment 4 uses all eight deep semantic analysis features, including the features capturing differences in domain- and modelsizes. The recall for the TRUE class indeed jumps to 0.735. Although, unavoidably, the FALSE class suffers, the resulting overall accuracy (0.562, see Column 4 in Table 1) is significantly higher than when using the features provided by the theorem prover alone (as in Experiment 3). The confidence weighted score also rises substantially from 0.548 to 0.608. The approximation achieved can be seen in the different treatment of Example 1049 (see Section 3.5) in Experiments 3 and 4. In Experiment 3, this example

[2]We used the z-test for the difference between two proportions to measure whether the difference in accuracy between two algorithms or an algorithm and the baseline is statistically significant at the 5% level.

[3]The `inconsistent` feature was not used by the decision tree as very few examples were covered by that feature.

Table 1: Summary of Results for Experiments 1 to 6

Exp	1: Human		2: Shallow		3: Strict		4: Deep		5: Hybrid		6: Hybrid+Task

all	0.951	n/a	0.569	0.624	0.520	0.548	0.562	0.608	0.577	0.632	**0.612**	**0.646**

is wrongly classified as FALSE as no proof can be found; in Experiment 4, it is correctly classified as TRUE due to the small difference between domain- and modelsizes for T and T+H.

There is hardly any overall difference in accuracy between the shallow and the deep classifier. However, it seems that the shallow classifier in its current form has very little potential outside of the CD subset whereas the deep classifier shows a more promising performance for several subsets.

Experiment 5: Hybrid classification As shallow and deep classifiers seem to perform differently on differently designed datasets, we hypothesized that a combination of these classifiers should bring further improvement. Experiment 5 therefore used all shallow and deep features together. However, the overall performance of this classifier (see Column 5 in Table 1) is not significantly better than either of the separate classifiers. Closer inspection of the results reveals that, in comparison to the shallow classifier, the hybrid classifier performs better or equally on all subsets but CD. In comparison to the deep classifier in Column 4, the hybrid classifier performs equally well or better on all subsets apart from MT. Overall, this means more robust performance of the hybrid classifier over differently designed datasets and therefore more independence from dataset design.

Experiment 6: Dependency on dataset design As Eperiment 5 shows, simple combination of methods, while maybe more robust, will not necessarily raise overall performance if the system does not know when to apply which method. To test this hypothesis further we integrated the subset indicator as a feature with the values CD, IE, MT, RC, IR, PP, QA into our hybrid system. Indeed, the resulting overall accuracy (0.612) is significantly better than either shallow or deep system alone. Note that using both a combination of methodologies *and* the subset indicator is necessary to improve on individual shallow and deep classifiers for this corpus. We integrated the subset indicator also into the shallow and deep classifier by themselves, yielding classifiers Shallow+Task and Deep+Task, with no or only very small changes in accuracy (these figures are not included in Table 1).

5 Related Work

Our shallow analysis is similar to the IDF models proposed by (Monz and de Rijke, 2003; Saggion et al., 2004). We have expanded their approach by using other shallow features regarding text length.

The basic idea of our deep analysis, using a detailed semantic analysis and first-order inference, goes back to (Blackburn and Bos, 2005). It is similar to some of the recent approaches that were proposed in the context of the PASCAL RTE workshop, i.e. using the OTTER theorem prover (Akhmatova, 2005; Fowler et al., 2005), using EPILOG (Bayer et al., 2005), or abduction (Raina et al., 2005).

None of these systems, however, incorporate model building as a central part of the inference mechanism. We have shown that solely relying on theorem proving is normally insufficient due to low recall, and that using model builders is a promising way to approximate entailment.

Results of other approaches to determining textual entailment indicate that it is an extremely hard task. The aforementioned RTE workshop revealed that participating systems reached accuracy figures ranging between 0.50 and 0.59 and cws scores between 0.50 and 0.69 (Dagan et al., 2005). Comparing this with our own results (accuracy 0.61 and cws 0.65) shows how well our systems performs on the same data set. This is partly due to our hybrid approach which is more robust across different datasets.

6 Conclusions

Relying on theorem proving as a technique for determining textual entailment yielded high precision but low recall due to a general lack of appropriate background knowledge. We used model building as an innovative technique to surmount this problem to a certain extent. Still, it will be unavoidable to incorporate automatic methods for knowledge acquisition to increase the performance of our approach. Future work will be directed to the acquisition of targeted paraphrases that can be converted into background knowledge in the form of axioms.

Our hybrid approach combines shallow analysis with both theorem proving and model building and achieves high accuracy scores on the RTE dataset compared to other systems that we are aware of. The results for this approach also indicate that (a) the choice of entailment recognition methods might have to vary according to the dataset design and/or application and (b) that a method that wants to achieve robust performance across different datasets might need the integration of several different entailment recognition methods as well as an indicator of design methodology or application.

Thus, although test suites establish a controlled way of assessing textual entailment detection systems, the importance of being able to predict textual entailment in NLP might be better justified using task-based evaluation. This can be achieved by incorporating them in QA or summarisation systems.

A Self-Learning Context-Aware Lemmatizer for German

Praharshana Perera and **René Witte**
Institute for Program Structures and Data Organization (IPD)
Universität Karlsruhe, Germany
perera|witte@ipd.uka.de

Abstract

Accurate lemmatization of German nouns mandates the use of a lexicon. Comprehensive lexicons, however, are expensive to build and maintain. We present a self-learning lemmatizer capable of automatically creating a full-form lexicon by processing German documents.

1 Introduction

Lemmatization is the process of deriving the base form, or *lemma*, of a word from one of its inflected forms. For morphologically complex languages like German this is not a simple task that can be solved solely through a rule-based algorithm: Performing an accurate lemmatization for German requires a lexicon. This can be either a lexicon containing all inflected forms of a word together with its base form *(full-form lexicon)*, or just the lemma together with a set of rules for creating its inflected forms *(base-form lexicon)* (Hausser, 2000).

Creating such a lexicon by hand, however, is expensive and time-consuming. Perhaps because of this there are currently no freely available lexical resources for German that include full case and inflection information.[1] Moreover, even a full-scale commercial lexicon can fail when encountering specialized terminology.

As a consequence, most systems processing German texts currently perform the much simpler task of *stemming*, which often generates stem forms of words that might not actually exist in the language (so-called *overstemming*). Stemming is frequently used for information retrieval (IR) tasks, an example being the German stemmer contained in the full-text search engine *Lucene*,[2] which is based on the algorithm described in (Caumanns, 1999). While overstemming is a feasible approach for text retrieval, a *text mining* system often needs to obtain a more precise lemma, for example, in order to perform a gazetteer lookup to identify named entities or for description logic (DL) queries within an ontology.

The goal of our work, therefore, is to allow the semi-automatic generation of a lexicon by mining full-text documents. Since there are currently no free lemmatization systems for German available,[3] all components have been developed for release as free, open-source software.

2 Lemmatization Algorithm

Our lemmatization system has two main components, an algorithm and a lexicon. The algorithm lemmatizes German nouns depending on morphological classes. The lexicon, which is described in Section 3, is generated from the nouns that have been processed by this algorithm, with some additional capabilities for self-correction.

The lemmatization algorithm considers the context and grammatical features of the language to lemmatize German words. It requires an additional POS tagger and an NP chunker, which are used as resources to extract the features of words and their surrounding context. It has been developed primarily for nouns but can also be extended to lemmatize adjectives and verbs.

2.1 Inflection of German Nouns

In German there are seven declensional suffixes for nouns: *-s*, *-es*, *-e*, *-n*, *-er*, and *-ern* (Caumanns, 1999). These suffixes are due to the morphological

[1]The free online dictionary *Wiktionary* (http://de.wiktionary.org/) had at the time of writing (May 2005) less than 5000 entries for German.

[2]http://lucene.apache.org/

[3]The *Morphy* system (Lezius et al., 1998) is described as "freely available," but in fact is closed-source, binary-only, nonchangeable software. It is also no longer being maintained.

Class	Features	Remove Suffix
I	$\{Sg\} \wedge \sim \{Gen\}$	
	$\wedge\{Masc \vee Fem \vee Neut\}$	none
II	$\{Sg\} \wedge \{Gen\}$	
	$\wedge\{Masc \vee Neut\}$	*-es* or *-s*
III	$\{Pl\} \wedge \sim \{Dat\}$	
	$\wedge\{Masc \vee Fem \vee Neut\}$	*-e*, *-n*, *-en*, *-er*, or *-s*
IV	$\{Pl\} \wedge \{Dat\}$	
	$\wedge\{Masc \vee Fem \vee Neut\}$	*-n*, *-en*, *-ern*, or *-s*

Table 1: Lemmatization of German nouns based on morphological classes

features such as gender, number, and case (Vilares et al., 2004). A basic lemmatization algorithm would reduce the suffixes by analyzing these morphological features. The existence of these suffixes is caused by the following: (1) genitive form of the singular, masculine, or neuter nouns have the declensional suffixes *-es*, *-en*, or *-s*, e.g., *Kind → Kindes*; (2) plural nouns have the declensional suffixes *-en*, *-ern*, *-n*, or *-s*, e.g., *Frau → Frauen*; and (3) dative forms of plural nouns have the declensional suffixes *-s*, *-n*, *-en*, or *-ern*, like in *Kind → Kindern*.

A simple lemmatization algorithm has been developed to cutoff these suffixes taking the morphological features such as number, gender, and case into consideration. The values of these features often cannot be uniquely determined from the word form (Evert, 2004). Therefore, we developed an algorithm to classify the nouns into four different morphological classes, as shown in Table 1. Lemmatization can then be performed based on these morphological classes (Table 1, right column).

We now discuss the first step, finding the proper class for each noun.

2.2 Lemmatization Classes

The currently available POS taggers for German do not capture more complex morphological features like number or case. Thus, in order to lemmatize German nouns it is necessary to first categorize them into the classes defined above. Our algorithm achieves this by analyzing the grammatical features of a noun, based on the German grammar (Duden, 1995). Additionally, a stochastic case tagger has been developed as an additional resource to support the algorithm in the classification of nouns.

2.2.1 Nouns with a Determiner

Table 2 shows statistics for German noun phrases for different corpora (the size of each corpus can be found in Section 5). The percentage of nouns that have a determiner is around 34% (25% determiner only + 9% determiner and modifier). The morphological information that can be extracted from a determiner preceding a noun is very ambiguous. For example, the determiner *die* can be either singular or plural in number, nominative or accusative in case, and masculine, feminine, or neuter in gender. But some determiners can be used to classify nouns into morphological classes.

Corpus	Det Only	Mod Only	Det+Mod	None
Negra	25%	13%	9%	53%
Die Welt	26%	14%	9%	51%
AvFIS	22%	16%	8%	53%
Wikipedia	28%	15%	9%	48%

Table 2: Distribution of German noun phrases

Table 3 describes our algorithm for nouns that have a determiner. In the first step, we consider determiners that are singular and non-genitive. Therefore, they belong to class I and do not need to be lemmatized. Examples are *das Haus → Haus*, *dem Mann → Mann*, *eine Frau → Frau*.

Determiners in the second step are singular and genitive and the gender can be masculine or neuter. These nouns belong to class II and to find the lemma, the suffix *-s* or *-es* must be removed. Examples are *des Hauses → Haus*, *des Vaters → Vater*.

Determiners in the third step can be either singular or plural. The only possible way to differentiate this is when the noun has both a determiner and a modifier. The plurals have modifiers ending with *-en* and singulars with *-e*.

In the other steps, nouns cannot be directly classified. In the fourth step we apply additional heuristics and in the last step the statistical case tagger (described in Section 2.4) is being used.

In German, genitive is mostly used as the case of nominal modifiers and complement of prepositions (Hinrichs and Trushkina, 1996), which is used as a heuristic to find the singular determiners in the fourth step and in the same way another heuristic has been applied which finds singular determiners when they are followed by dative prepositions.

The determiner *den* in German can be either accusative or dative. In the dative case it is plural and in the accusative case it is singular and masculine in gender. Examples are *den Kindern* (dative plural)

Step	Determiner	Class
1	das, dem, ein, einem, ..., ihr, ihrem	Class I
2	des, eines, meines, deines, ..., ihres	Class II
3	die, meine, deine, ..., ihre	If modifier has the suffix *-e* → Class I If modifier has the suffix *-en* → Class III
4	der, meiner, deiner, ..., ihrer	If determiner is not followed by a genitive preposition or a noun phrase → Class I If determiner is followed by a dative preposition → Class I
5	den, meinen, deinen, ..., ihren	If case tagged by case tagger is accusative → Class I If case is dative → Class IV

Table 3: Lemmatizing German nouns that appear with a determiner

and *den Salat* (accusative singular). The fifth step has determiners that have this ambiguity, which is resolved using information given by the case tagger.

2.2.2 Nouns with a Modifier only

The morphological features of a noun that can be extracted from a modifier are less than those based on a determiner. According to the statistics in Table 2, around 14% of noun phrases come with a modifier only. However, it is sometimes possible to lemmatize nouns by looking at the modifiers' suffixes and the case information as given by the case tagger. Table 4 describes our algorithm for nouns that come solely with a modifier.

In German, when a noun exists without a determiner but with a modifier, the ending of the modifier changes according to the morphological features of the noun. For example, the noun phrase *dem kleinen Kind* without determiner becomes *kleinem Kind*. The suffix *-em* appears only for singular nouns, which do not need to be lemmatized.

A modifier with the suffix *-es* can be genitive, accusative, or nominative. A good example for this feature is *kleines Kind* and *kleines Kindes*. In the first case it is nominative or accusative and in the second case genitive. Here, we use the case information given by the case tagger to classify the noun.

Modifiers with the suffix *-en* are similar to the step with the determiner *den*. A modifier with suffix *-en* can be either singular or plural. In singular case it is accusative and in plural case dative; examples

Step	Modifier Suffix	Action
1	*-em*	Class I
2	*-es*	If case is not genitive → Class I If case is genitive → Class II
3	*-en*	If case is accusative → Class I If case is dative → Class IV
4	*-er*	If case is dative or nominative → Class I

Table 4: Lemmatizing German nouns with a modifier but without a determiner

for these cases are *guten Mann* (accusative, singular) and *guten Männern* (dative, plural).

Modifiers that have the suffix *-er* can be both genitive or non-genitive. In the non-genitive case they are singular and need not to be lemmatized. Examples for this are *kleiner Katze* (dative, singular), *kleiner Katze* (genitive, singular), and *kleiner Katzen* (genitive, plural).

2.2.3 Nouns without Modifier or Determiner

Nouns without modifier or determiner account for 51% of all NPs (Table 2). Most of these nouns cannot be directly lemmatized using methods as they have been applied above. The main reason for this is the unavailability of a tagger providing number and gender information for such nouns. Using only the case tagger it is not possible to classify all the nouns in this set. However, it is possible to capture some nouns in this set by applying a heuristic:

If a noun follows the preposition *zum, zur, am, im, ins,* or *ans* ⟶ Class I.

The main idea behind this heuristic is a grammatical feature of the German language. In German, there exists a set of prepositions that are connected with a determiner, for example, *zum Bahnhof*, *zur Party*, and *ins Bett*. The main feature of nouns following such a preposition is that they are singular and thus do not need to be lemmatized.

2.2.4 POS-based Lemmatization

To maximize the number of nouns that can be lemmatized a heuristic has been added to capture nominative nouns, using the POS tagger *TreeTagger* (Schmid, 1995). The main idea behind this heuristic is to find the subject and main verb of a sentence. In German, the subject is always nominative and by looking at the suffix of the main verb, it is possible to determine the number of the subject.

This heuristic first finds the subject of the sentence based on the case tagger information. Then, based on the information from the POS tags the main verb is identified and checked whether it is a plural verb. The corresponding plural nouns are then lemmatized, whereas singular nouns remain unchanged.

2.3 Optimizations

To avoid some errors in the lemmatization algorithm and to increase the accuracy of lemmatization additional optimizations are needed. In German, many plural forms are built by changing a vowel to an Umlaut (Caumanns, 1999), like in *das Land* and *die Länder*. But this is not a static rule because there are some cases where the noun already has an Umlaut, like in *die Affäre* and *die Affären*. Here, it would not be correct to lemmatize *Affären* to **Affare*. As a solution, several possible lemma candidates are generated, for example, *Länder* → **Länd* and *Land*.

Another feature of German are nouns that are made up from adjectives. These nouns have different suffixes when they appear with definite or indefinite determiners and without determiners. An example is the noun *Abgeordnete*; in singular form it can appear in two ways, *der Abgeordnete* and *ein Abgeordneter*. It is also tricky in the dative singular case, where it has three forms, *Abgeordnetem*, *Abgeordneter* and *dem/der/einem/einer Abgeordneten*. Our algorithm thus generates the possible lemma candidates: *Abgeordneter* → *Abgeordneter*, *Abgeordnete*.

The main reason to generate lemma candidates for these nouns above is to store them in the lexicon. The correct lemma can then later be identified and the lexicon updated when the noun appears again in a different context.

2.4 The Case Tagger

As an additional resource to the lemmatizer we developed a stochastic case tagger. It has been built using the POS tags as features to train the model in order to predict the case of nouns. From the standard STTS tagset for German (Schiller et al., 1995), which has 54 POS tags, 38 tags[4] have been identified to train the model, based on an analysis of the grammatical structure of German sentences as defined in the German grammar (Duden, 1995).

[4]These POS tags define the structure of the grammatical case in German sentences, for example, verbs and prepositions.

2.4.1 Model

We apply a standard Hidden Markov Model (HMM), designed for the structure of the German language. A German sentence can be represented as a set of variable states, which can be nominative, accusative, dative, or genitive and a set of fixed states like finite verbs and conjunctions. For example, in the sentence *Die Mutter gibt den kleinen Kindern den Salat*, the phrases *Die Mutter* (nominative), *den kleinen Kindern* (dative) and *den Salat* (accusative) are the variable states and the finite verb *gibt* is a fixed state. In this manner, the whole sentence can be represented with the state sequence *nominative VVFIN* (finite verb) *dative accusative*. From the 38 tags that have been chosen for training, 10 tags[5] have been integrated with the nouns as variable states.

2.4.2 Tagging Algorithm

As an HMM tagger, our case tagger chooses the best sequence of tags for a given sequence of states (Jurafsky and Martin, 2000). In this model this can be expressed as choosing the best sequence of tags for the variable states in the sequence. The first stage of the algorithm selects the set of tags from the POS tags that are used for calculation and then it orders these tags into fixed and non-fixed states with respect to the grammatical case. The second stage of the algorithm calculates the most probable tag sequence using the Viterbi algorithm. The model is smoothed to avoid zero probabilities. In the worst case the complexity of this algorithm is $O(N^3)$ but here $N = 4$, the four grammatical cases.

3 Lexicon Generation

As discussed above, the lemmatization algorithm cannot be used alone to lemmatize all German nouns, as it cannot capture every noun in a text. However, a noun that could not be lemmatized within one text may well have enough context information for a precise lemmatization within another. Thus, our main idea here is to create a self-learning lexicon that evolves with the nouns processed by the algorithm, continuously learning the correct values for each lexical entry.

[5]Like for nouns, grammatical case is a morphological feature of these POS tags, for example, pronouns and adjectives.

3.1 Lexicon Entries

The lexicon stores the full form of a word with its base form and possible morphological features like number, gender, and case. This is different from a lexicon as it has been used for lemmatization, which only stores the base form for each word together with its inflection class (Lezius et al., 1998).

For example, the lexicon entries for the noun *Kind* are represented as:

Noun	Number	Gender	Case	Lemma
Kind	Sg	Neut	Nom.Akk	Kind
Kindes	Sg	Neut	Gen	Kind
Kinder	Pl	Neut	Nom.Akk	Kind
Kindern	Pl	Neut	Dat	Kind

3.2 Lexicon Generation

The lexicon grows by updating itself from the nouns that have been processed by the lemmatization algorithm. Additional functionality has been implemented in the lexicon, to allow it to evolve by assigning the correct lemma to the words that are inflected from the same lemma and correcting some errors that have been generated by the algorithm.

3.2.1 Evolving the Lexicon

If a word is scheduled for addition to the lexicon, it first checks whether it already exists. If this is the case, it compares each feature of the new word with the one already in the lexicon. If there is any difference, for example, if the word in the lexicon shows the number *Sg* and the new word has the number *Pl*, it adds both features to the lexicon entry. If a new word does not already exist in the lexicon it will just be added as a new entry. The following example illustrates this process:

Current state of the lexicon				
Menschen	Sg	Masc	Akk	Mensch
Mensch	Sg	Masc	Nom	Mensch

New Entry				
Menschen	Pl	Masc	Nom	Mensche.Mensch

State of the lexicon after update				
Menschen	Sg.Pl	Masc	Akk.Nom	Mensch
Mensch	Sg	Masc	Nom	Mensch

The assignment of the correct lemma *Mensch* is done by a procedure that will be discussed next.

3.2.2 Updating Lemmas

If a new word lemmatized by the algorithm that has more than one lemma candidate is to be added, the lexicon tries to assign the correct lemma for this new word by looking at the lemmas that are already in the lexicon. If one of the lemma candidates in the new word matches with a lemma stored in the lexicon, the lemma of the new word will be updated with the new information. This process is illustrated in the following example:

Current state of the lexicon (lemma only)	
Land	Land
Landes	Land

New Entry	
Länder	Lände.Länd.Lande.Land

State of the lexicon after update	
Land	Land
Landes	Land
Länder	Land

In the same way, if a new word that has been correctly lemmatized is to be entered to the lexicon, the lexicon tries to update the words in the lexicon that have more than one lemma using the lemma of the new word. If one of the lemma candidates of a word in the lexicon matches with the lemma of the new word, then the lemma of the word in the lexicon will be updated with the lemma of the new word:

Current state of the lexicon (lemma only)	
Länder	Lände.Länd.Lande.Land
Ländern	Länder.Lände.Länd.Lander.Lande.Land

New Entry	
Landes	Land

State of the lexicon after update	
Landes	Land
Länder	Land
Ländern	Land

3.2.3 Automatic Error Correction

The lemmatization algorithm may produce errors, for example, a plural noun wrongly tagged as singular may not be lemmatized, resulting in a wrong entry. While the lexicon evolves, such errors produced by the algorithm are corrected automatically.

As shown in the example below, the lexicon can have wrong entries and entering a word with more than one lemma, which is an inflectional form of a word that has a wrong entry, will not be assigned with the correct lemma because the procedure that updates the lemma will assign possible lemma candidates to this word. If a word that has a wrong entry in the lexicon will be entered again with the correct lemma, the word itself and all its inflectional forms will be updated with the correct lemma:

Current state of the lexicon (lemma only)	
Jahr	Jahr
Jahre	Jahre **(wrong)**
New Entry	
Jahren	Jahre.Jahr
State of the lexicon after update	
Jahr	Jahr
Jahre	Jahre **(wrong)**

4 Implementation

The lemmatization algorithm and the lexicon have been implemented based on the GATE architecture (Cunningham et al., 2002). GATE provides an infrastructure for developing and deploying software components that process human language. For the German POS tagger we currently use the TreeTagger (Schmid, 1995). The other main resource is a multi-lingual base NP chunker implemented within the JAPE language.

The Negra corpus version 2 (Skut et al., 1998) based on approximately 70 000 tokens tagged with morphological features has been used to train the case tagger. This corpus has been split into 50 000 training tokens and 20 000 tokens used for testing.

5 Evaluation

Evaluation was performed over four collections of texts: (1) a set of 350 articles from “Die Welt” newspaper containing 190 868 tokens (40 104 nouns); (2) the electronic version of the book “AvFIS”[6] containing 120 212 tokens (22 039 nouns); (3) six manually for lemma, case, and number annotated articles from the German *Wikipedia* containing 6580 tokens (1536 nouns); (4) 20 000 tokens (5023 nouns) from the Negra corpus version 2 (Skut et al., 1998), which contains morphological tags for case and number.

The lemmatization of German texts has been evaluated using both the algorithm and the lexicon separately and combined. Since the first two collections of texts are not annotated with lemmatization information, we evaluated the lemma produced by our algorithm or lexicon by comparing it with the one produced by the TreeTagger, which is based on an internal dictionary. Since the TreeTagger cannot produce the lemma for all nouns, we evaluated only that percentage of nouns for which the TreeTagger was able to produced a lemma, which is 88% for both “Die Welt” and the “AvFIS” book. In order to also evaluate our lemmatization independently from the lemma produced by the TreeTagger, we compared its results to a manually annotated set of articles from the Wikipedia.

Corpus	Nouns	Algorithm Only		Lexicon Only	
		Lemm.	Acc.	Lemm.	Acc.
Die Welt	35531	49%	0.88	67%	0.96
AvFIS	19394	40%	0.88	70%	0.97
Wikipedia	1536	49%	0.87	54%	0.97

Table 5: Lemmatization results, algorithm and lexicon tested in isolation

Finally, the case and number taggers have also been evaluated separately using the manually annotated articles from the Wikipedia and the Negra corpus. For this evaluation, the lemmatization accuracy has been calculated by $accuracy = \frac{n(correct)}{n(lemmatized)}$.

5.1 Algorithm Evaluation

Table 5 shows the results of lemmatization using only the lemmatization algorithm (i.e., no lexicon).

The number of nouns that our algorithm can lemmatize is just below 50%. This is mainly due to the large number of nouns, as shown in Table 2, that appear without a determiner or modifier, as well as some ambiguous cases where NPs with determiners and modifiers cannot be lemmatized directly.[7]

The accuracy of lemmatization based on this approach shows the irregular morphological features of the German language. 75% of the errors are due to irregular morphological variations in German. The algorithm does not change the vowels with Umlauts, therefore, all nouns which have a vowel with an Umlaut in plural are not lemmatized correctly. For example, the noun *Ländern* is lemmatized by the algorithm to **Länd* but the correct lemma is *Land*. Another peculiarity that causes errors in lemmatization are nouns that have been formed by adjectives. For example, a noun with a determiner like *ein Ab-*

[7]E.g., in the sentence *Ich sehe die Kinder der Frau* the two nouns *Kinder* and *Frau* cannot be lemmatized by the algorithm because in this context these nouns could be singular or plural.

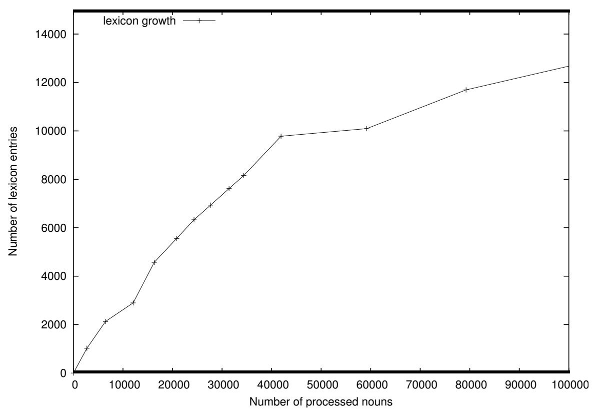

Figure 1: Lexicon growth

geordneter would not be lemmatized by the algorithm because it is singular and non-genitive. However, the correct lemma of this word is *Abgeordnete*. German also has nouns where the plural and the singular forms are equal. This is a situation in which the algorithm fails to generate the correct lemma. For example, the noun *Arbeiter* has the same singular *der Arbeiter* and plural *die Arbeiter* form. The algorithm lemmatizes *die Arbeiter* to **Arbeit* whereas the correct lemma is *Arbeiter*.

The remaining errors are due to mis-tagging, mainly by the case tagger, which can result in an error in lemmatization. For example, *den Kindern* has been tagged by the case tagger as **Akk* (correct *Dat*), so the lemmatization algorithm does not lemmatize this noun to *Kind* because the case is accusative and hence assumed to be singular.

5.2 Lexicon Evaluation

The lexicon was initially generated by applying the lemmatization algorithm on the "Die Welt" collection of texts. We then evaluated lemmatization based solely on the lexicon (not applying the algorithm) for these documents. Table 5 also shows the results for this collection of texts. The growth of the lexicon is shown in Figure 1; when we performed the evaluation it contained 12 858 entries for 10 251 lemmas.

The next test for lexicon evaluation has been done in two stages. First, the electronic book "AvFIS" (2) has been lemmatized using only the lexicon. Afterwards, we applied the lemmatization algorithm on the same book, generating new entries, and then evaluated the extended lexicon again on this book. Before processing the book, the lexicon was able to lemmatize 40% of all nouns with an accuracy of 0.98, whereas afterwards the lemmatization coverage increased to 70% with the accuracy dropping slightly to 0.97.

Both tests above have been done against the lemma generated by the TreeTagger. Additionally, we evaluated the lexicon on our manually annotated set of articles from the Wikipedia, which is also shown in Table 5.

As can be seen, in all tests the accuracy of lemmatization based on the lexicon is higher than that of the algorithm. The reason for this is the self-correcting feature of the lexicon discussed above: While the lexicon evolves it increasingly assigns the correct lemma for each noun.

Although the lexicon performs with a high accuracy, the remaining errors are due to various forms of the construction of words in German. For example, consider the two nouns *Sieger* (lemma *Sieger*) and *Sieg* (lemma *Sieg*). As the lexicon evolves, it assigns *Sieger* the lemma **Sieg* because it already exists as a lemma in the lexicon whereas the correct lemma is *Sieger*. Some remaining incorrect entries in the lexicon also result in errors. Such cases will need to be corrected manually.

The percentage of lemmatization is obviously high for texts which have been used to generate the lexicon. The difference can be clearly seen in the book example, where the number of nouns that could be lemmatized increased significantly after enhancing the lexicon from the same set of nouns.

5.3 Lexicon and Algorithm Evaluation

We evaluated lemmatization using both algorithm and lexicon combined on the same set of texts (Table 6, right side). The number of lemmatized nouns has clearly increased in the combined method. Here, a lemma produced by the lexicon takes precedence over the algorithms' one, if both were able to produce a lemma. Table 6 also shows the contribution of each method for lemmatization in the combined method (left side). The number of nouns lemmatized

Corpus	Contribution			Results	
	Lex.	Alg.	Both	Lemm.	Acc.
Die Welt	27%	10%	39%	76%	0.94
AvFIS	33%	3%	37%	73%	0.96
Wikipedia	24%	19%	30%	73%	0.93

Table 6: Results using both algorithm and lexicon

by the lexicon is relatively higher than the algorithm on the first two texts because these texts were used to initially generate the lexicon.

When both algorithm and lexicon were able to produce a lemma, it agrees in 92% of all cases with an accuracy of 0.98.

One special case both fail to lemmatize correctly are foreign (e.g., Latin) words that do not follow German morphological rules (e.g., *Lexika* → *Lexikon*). These require manual correction or the development of specialized heuristics.

Finally, we evaluated the performance of the case and number taggers. While a detailed discussion of these results cannot be presented in this paper, the case tagger reaches an accuracy of 0.92 on the training data, 0.8 on the testing data, and 0.79 on the Wikipedia, while the number tagger has an accuracy of 0.93 on the training data, 0.9 on the testing data, and 0.91 on the Wikipedia corpus.

6 Conclusions and Future Work

In this paper we demonstrated a new algorithm for the lemmatization of German nouns. An important feature is the automatic construction of a lexicon from the processed documents, allowing it to continuously improve in both coverage and accuracy. The lemmatization system as well as a lexicon will be made available as free, open-source software, which will fill an important gap for the development of NLP systems dealing with German.[8]

The automatic generation and self-correction of a lexicon is a huge time-saver. Compared to the German Wiktionary, whose users needed a year to manually curate less than 5000 entries, we were able to compile the same amount of nouns within a matter of days.[9] Human intervention can be limited to the inspection and correction of wrong entries, which will allow the creation of specialized lexicons even for groups with limited resources. To increase the coverage of our lexicon, we currently employ a web crawler, which daily scans several German news sources for texts, which are then processed for lexical entries.

In the future, we plan to enhance the system to also deal with verbs, adjectives, and adverbs, as well as compound nouns.

Acknowledgments. This work is funded through the DFG project “Entstehungswissen.”

[8]Dictionaries that are only accessible online, like Canoo.net (`http://www.canoo.net`) or Wortschatz Lexikon (`http://wortschatz.uni-leipzig.de`) we do not consider freely available, as the underlying databases and tools cannot be downloaded, modified, or integrated into NLP systems.

[9]The Wiktionary does have more information for each entry, however, some of these could also be automatically created in a similar fashion.

A Robust Combination Strategy for Semantic Role Labeling

Lluís Màrquez, Mihai Surdeanu, Pere Comas, and Jordi Turmo

{lluism,surdeanu,pcomas,turmo}@lsi.upc.edu

Abstract

This paper focuses on semantic role labeling using automatically-generated syntactic information. A simple and robust strategy for system combination is presented, which allows to partially recover from input parsing errors and to significantly boost results of individual systems. This combination scheme is also very flexible since the individual systems are not required to provide any information other than their solution. Extensive experimental evaluation in the CoNLL-2005 shared task framework supports our previous claims. The proposed architecture outperforms the best results reported in that evaluation exercise.

1 Introduction

The task of Semantic Role Labeling (SRL), i.e. the process of detecting basic event structures such as *who* did *what* to *whom*, *when* and *where*, has received considerable interest in the past few years (Gildea and Jurafsky, 2002; Surdeanu et al., 2003; Xue and Palmer, 2004; Pradhan et al., 2005a; Carreras and Màrquez, 2005). It was shown that the identification of such event frames has a significant contribution for many Natural Language Processing (NLP) applications such as Information Extraction (Surdeanu et al., 2003) and Question Answering (Narayanan and Harabagiu, 2004).

Most current SRL approaches can be classified in one of two classes: approaches that take advantage of complete syntactic analysis of text, pioneered by Gildea and Jurafsky (2002), and approaches that use partial syntactic analysis, championed by previous evaluations performed within the Conference on Computational Natural Language Learning (CoNLL) (Carreras and Màrquez, 2004). The wisdom extracted from this volume of work indicates that full syntactic analysis has a significant contribution to the SRL performance, *when using hand-corrected syntactic information*.

On the other hand, when only automatically-generated syntax is available, the quality of the information provided through full syntax decreases because the state-of-the-art of full parsing is less robust and performs worse than the tools used for partial syntactic analysis. Under such real-world conditions, the difference between the two SRL approaches (with full or partial syntax) is not that high. More interestingly, *the two SRL strategies perform better for different semantic roles*. For example, models that use full syntax recognize better agent and theme roles, whereas models based on partial syntax are better at recognizing explicit patient roles, which tend to be farther from the predicate and accumulate more parsing errors (Màrquez et al., 2005).

The above observations motivate the work presented in this paper. We introduce a novel semantic role labeling approach that combines several individual SRL systems. Intuitively, our approach can be separated in two stages: a *candidate generation* phase, where the solutions provided by several individual models are combined into a pool of candidate arguments, and an *inference* phase, where the candidates are filtered using a binary classifier, and possi-

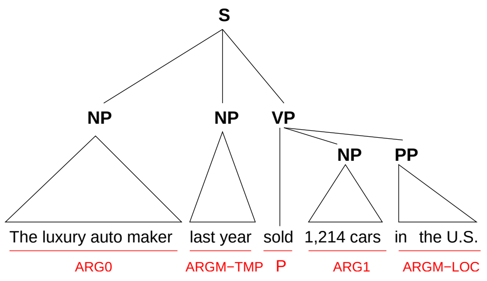

Figure 1: Sample PropBank sentence.

ble conflicts with domain knowledge constraints are resolved to obtain the final solution.

For robustness, the inference model uses only global attributes extracted from the solutions provided by the individual systems, e.g., the sequence of role labels generated by each system for the current predicate. We do not use any attributes specific to the individual models, not even the confidence assigned by the individual classifiers. Besides simplicity, the consequence of this decision is that our approach does not impose any restrictions on the individual SRL strategies, as long as one solution is provided for each predicate. On the other hand, probabilistic inference processes, which have been successfully used for SRL (Koomen et al., 2005), mandate that each individual candidate argument be associated with its raw activation, or confidence, in the given model. However, this information is not directly available in two out of three of our individual models, which classify argument chunks and not entire arguments.

Despite its simplicity, our approach obtains encouraging results: the combined system outperforms any of the individual systems and, using exactly the same data, it is also competitive with the best SRL systems that participated in the latest CoNLL shared task evaluation (Carreras and Màrquez, 2005).

2 Semantic Corpora

In this paper we report results using PropBank, an approximately one-million-word corpus annotated with predicate-argument structures (Kingsbury et al., 2002). To date, PropBank addresses mainly predicates lexicalized by verbs and a small number of predicates lexicalized by verb nominalizations and adjectives.

The arguments of each predicate are numbered sequentially from `ARG0` to `ARG5`. Generally, `ARG0` stands for *agent*, `ARG1` for *theme* or *direct object*, and `ARG2` for *indirect object*, *benefactive* or *instrument*, but mnemonics tend to be verb specific. Additionally, predicates might have "adjunctive arguments", referred to as `ARGM`s. For example, `ARGM-LOC` indicates a locative and `ARGM-TMP` indicates a temporal. Figure 1 shows a sample sentence where one predicate ("sold") has 4 arguments.

In a departure from "traditional" SRL approaches that train on the hand-corrected syntactic trees associated with PropBank, we do not use any syntactic information from PropBank. Instead, we develop our models using automatically-generated syntax and named-entity (NE) labels, made available by the CoNLL shared task evaluation (Carreras and Màrquez, 2005). From the CoNLL data, our individual models based on full syntactic analysis use the trees generated by the Charniak parser. The partial-syntax model uses the chunk – i.e. basic syntactic phrase – labels and clause boundaries. All individual models make use of the provided NE labels.

Following the CoNLL-2005 setting we evaluated our system also on a fresh test set, derived from the Brown corpus. This second evaluation allows us to re-enforce our robustness claim.

3 Approach Overview

The proposed architecture, summarized in Figure 2, consists of two stages: a *candidate generation* phase and an *inference* stage.

In the candidate generation step, we merge the solutions of three individual SRL models into a unique pool of candidate arguments. The proposed models range from complete reliance on full parsing to using only partial syntactic information. The first two models, Model 1 and 2, are developed as sequential taggers (using the BIO tagging scheme) on a shared framework. The major difference between the two models is that Model 1 uses only partial syntactic information (basic phrases and clause boundaries), whereas Model 2 uses complete syntactic information. To maximize diversity, Model 3 implements a different strategy: it models only arguments that map into exactly one syntactic constituent. Section 4 details all three individual models.

The inference stage starts with *candidate filtering*,

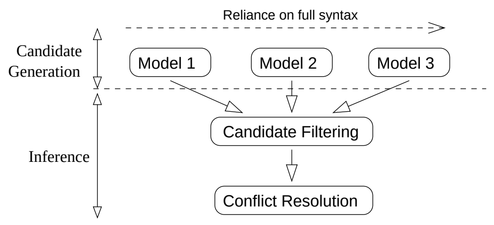

Figure 2: Architecture of the proposed system.

which reduces the number of candidate arguments in the pool using a single binary classifier. Using this classifier's confidence values and a number of domain-specific constraints, e.g. no two arguments can overlap, the *conflict resolution* component enforces the consistency of the final solution using a straightforward greedy strategy. The complete inference model is detailed in Section 5.

4 Individual SRL Models

Models 1 and 2. These models approach SRL as a sequential tagging task. In a pre-process step, the input syntactic structures are traversed in order to select a subset of constituents organized sequentially (i.e. non embedding). Model 1 makes use only of the partial tree defined by base chunks and clause boundaries, while Model 2 explores full parse trees.

Precisely, the sequential tokens are selected as follows. First, the input sentence is splitted into disjoint segments by considering the clause boundaries given by the syntactic structure. Second, for each segment, the set of top-most non-overlapping syntactic constituents completely falling inside the segment are selected as tokens. Note that this strategy provides a set of sequential tokens covering the complete sentence. Also, it is independent of the syntactic annotation explored, given it provides clause boundaries — see (Màrquez et al., 2005) for more details.

Due to this pre-processing stage, the upper-bound recall figures are 95.67% for Model 1 and 90.32% for Model 2 using the datasets defined in Section 6.

The nodes selected are labeled with B-I-O tags (depending if they are at the beginning, inside, or outside of a predicate argument) and they are converted into training examples by considering a rich set of features, mainly borrowed from state-of-the-art systems. These features codify properties from: (a) the argument constituent, (b) the target predicate,

Constituent *type* and *head*: extracted using common head-word rules. If the first element is a PP chunk, then the head of the first NP is extracted.
First and last words and POS tags of the constituent.
POS sequence: if it is less than 5 tags long. *2/3/4-grams* of the POS sequence.
Bag-of-words of nouns, adjectives, and adverbs.
TOP sequence: sequence of types of the top-most syntactic elements in the constituent (if it is less than 5 elements long). In the case of full parsing this corresponds to the right-hand side of the rule expanding the constituent node. *2/3/4-grams* of the TOP sequence.
Governing category as in (Gildea and Jurafsky, 2002).
NamedEnt, indicating if the constituent embeds or strictly matches a named entity along with its type.
TMP, indicating if the constituent embeds or strictly matches a temporal keyword (extracted from `AM-TMP` arguments of the training set).
Previous and following words and POS of the constituent.
The same features characterizing focus constituents are extracted for the *two previous and following tokens*, provided they are inside the clause boundaries of the codified region.

Table 1: Constituent structure features: Models 1/2

Predicate *form*, *lemma*, and *POS tag*.
Chunk type and *type of verb phrase* in which verb is included: single-word or multi-word.
The predicate *voice*. We currently distinguish five voice types: active, passive, copulative, infinitive, and progressive.
Binary flag indicating if the verb is a *start/end* of a clause.
Sub-categorization rule, i.e. the phrase structure rule that expands the predicate immediate parent.

Table 2: Predicate structure features: Models 1/2

and (c) the distance between the argument and predicate. The three feature sets are listed in Tables 1, 2, and 3, respectively.[1]

Regarding the learning algorithm, we used generalized AdaBoost with real-valued weak classifiers, which constructs an ensemble of decision trees of fixed depth (Schapire and Singer, 1999). We considered a one-vs-all decomposition into binary problems to address multi-class classification. AdaBoost binary classifiers are then used for *labeling* test sequences, from left to right, using a recurrent sliding window approach with information about the tag assigned to the preceding token. This tagging module enforces some basic constraints, e.g., BIO correct structure, arguments cannot overlap with clause nor chunk boundaries, discard `ARG0-5` arguments not present in PropBank frames for a certain verb, etc.

[1]Features extracted from partial parsing and Named Entities are common to Model 1 and 2, while features coming from full parse trees only apply to Model 2.

Relative position, *distance* in words and chunks, and *level of embedding* (in #clause-levels) with respect to the constituent.
Constituent path as described in (Gildea and Jurafsky, 2002) and all *3/4/5-grams* of path constituents beginning at the verb predicate or ending at the constituent.
Partial parsing path as described in (Carreras et al., 2004) and all *3/4/5-grams* of path elements beginning at the verb predicate or ending at the constituent.
Syntactic frame as described by Xue and Palmer (2004)

Table 3: Predicate–constituent features: Models 1/2

The *syntactic label* of the candidate constituent.
The constituent *head word*, *suffixes* of length 2, 3, and 4, *lemma*, and *POS tag*.
The constituent *content word*, *suffixes* of length 2, 3, and 4, *lemma*, *POS tag*, and *NE label*. Content words, which add informative lexicalized information different from the head word, were detected using the heuristics of (Surdeanu et al., 2003).
The *first and last constituent words* and their *POS tags*.
NE labels included in the candidate phrase.
Binary features to indicate the presence of *temporal cue words*, i.e. words that appear often in `AM-TMP` phrases in training.
For each TreeBank syntactic label we added a feature to indicate the *number of such labels* included in the candidate phrase.
The *sequence of syntactic labels* of the constituent immediate children.
The phrase *label*, *head word and POS tag* of the constituent parent, left sibling, and right sibling.

Table 4: Constituent structure features: Model 3

Model 3. The third individual SRL model makes the strong assumption that each predicate argument maps to one syntactic constituent. For example, in Figure 1 `ARG0` maps to a noun phrase, `ARGM-LOC` maps to a prepositional phrase etcetera. This assumption holds well on hand-corrected parse trees and simplifies significantly the SRL process because only one syntactic constituent has to be correctly classified in order to recognize one semantic argument. On the other hand, this approach is limited when using automatically-generated syntactic trees. For example, only slightly over 91% of the arguments can be mapped to one of the syntactic constituents produced by the Charniak parser.

Using a bottom-up approach, Model 3 maps each argument to the first syntactic constituent that has the exact same boundaries and then climbs as high as possible in the tree across unary production chains. We currently ignore all arguments that do not map to a single syntactic constituent.

The predicate *word* and *lemma*.
The predicate *voice*. Same definition as Models 1 and 2.
A binary feature to indicate if the predicate is *frequent* (i.e., it appears more than twice in the training data) or not.
Sub-categorization rule. Same def. as Models 1 and 2.

Table 5: Predicate structure features: Model 3

The *path* in the syntactic tree between the argument phrase and the predicate as a chain of syntactic labels along with the traversal direction (up or down).
The *length* of the above syntactic path.
The *number of clauses* (`S*` phrases) in the path.
The *number of verb phrases* (`VP`) in the path.
The *subsumption count*, i.e. the difference between the depths in the syntactic tree of the argument and predicate constituents. This value is 0 if the two phrases share the same parent.
The *governing category*, which indicates if `NP` arguments are dominated by a sentence (typical for subjects) or a verb phrase (typical for objects).
We *generalize* syntactic paths with more than 3 elements using two templates: (a) $\texttt{Arg} \uparrow \texttt{Ancestor} \downarrow \texttt{N}_i \downarrow \texttt{Pred}$, where `Arg` is the argument label, `Pred` is the predicate label, `Ancestor` is the label of the common ancestor, and $\texttt{N}_i$ is instantiated with all the labels between `Pred` and `Ancestor` in the full path; and (b) $\texttt{Arg} \uparrow \texttt{N}_i \uparrow \texttt{Ancestor} \downarrow \texttt{Pred}$, where $\texttt{N}_i$ is instantiated with all the labels between `Arg` and `Ancestor` in the full path.
The *surface distance* between the predicate and the argument phrases encoded as: the number of tokens, verb terminals (`VB*`), commas, and coordinations (`CC`) between the argument and predicate phrases, and a binary feature to indicate if the two constituents are adjacent.
A binary feature to indicate if the argument *starts with a predicate particle*, i.e. a token seen with the `RP*` POS tag and directly attached to the predicate in training.

Table 6: Predicate–constituent features: Model 3

Once the mapping process completes, Model 3 extracts a rich set of lexical, syntactic, and semantic features. Tables 4, 5, and 6 present these features organized in the same three categories as the previous Models 1 and 2 — see (Surdeanu and Turmo, 2005) for more details.

Similarly with Models 1 and 2, Model 3 trains one-vs-all classifiers using AdaBoost for the most common argument labels. To reduce the sample space, Model 3 selects training examples (both positive and negative) only from: (a) the first clause that includes the predicate, or (b) from phrases that appear to the left of the predicate in the sentence. More than 98% of the argument constituents fall into one of these classes.

At prediction time the classifiers are combined using a simple greedy technique that iteratively assigns to each predicate the argument classified with the highest confidence. For each predicate we consider as candidates all AM attributes, but only numbered attributes indicated in the corresponding PropBank frame. Additionally, this greedy strategy enforces a limited number of domain knowledge constraints in the generated solution: (a) arguments can not overlap in any form, and (b) no duplicate arguments are allowed for ARG0-5.

5 The Inference Model

The most important component of our inference model is candidate filtering, which decides if a candidate argument should be maintained in the global solution or not. Candidate filtering is implemented as a single binary classifier that uses only features extracted from the solutions provided by the individual systems. For robustness, we do not use any features that are specific to any of the individual models, nor the confidence value of their classifiers.

Table 7 lists the features extracted from each candidate argument by the filtering classifier. For simplicity we have focused only on attributes that: (a) are readily available in the solutions proposed by the individual classifiers, and (b) allow the gathering of simple and robust statistics. For example, the filtering classifier might learn that a candidate is to be trusted if: (a) two individual systems proposed it, (b) if its label is ARG2 and it was generated by Model 1, or (c) if it was proposed by Model 2 within a certain argument sequence.

The candidate arguments that pass the filtering stage are incorporated in the global solution by the conflict resolution module, which enforces several domain specific constraints. We have currently implemented two constraints: (a) arguments can not overlap or embed other arguments; and (b) no duplicate arguments are allowed for the numbered arguments ARG0-5. Theoretically, the set of constraints can be extended with any other rules, but in our particular case, we know that some constraints, e.g. providing only arguments indicated in the corresponding PropBank frame, are already guaranteed by the individual models. Conflicts are solved with a straightforward greedy strategy: the pool of candidate arguments is inspected in descending order of the confidence values assigned by the filtering classifier, and candidates are appended to the global solution only if they do not violate any of the domain constraints with the arguments already selected. Our inference system currently has a sequential architecture, i.e. no feedback is sent from the conflict resolution module to candidate filtering.

The *label* of the candidate argument.
The *number of systems* that generated an argument with this label and span.
The *unique ids*, e.g. M1 and M2, of all the systems that generated an argument with this label and span.
The *argument sequence* for this predicate for all the systems that generated an argument with this label and span. For example, the argument sequence for the proposition illustrated in Figure 1 is: ARG0 - ARGM-TMP - P - ARG1 - ARGM-LOC.
The *number* and *unique ids* of all the systems that generated an argument with the *same span but different label*.
The *number* and *unique ids* of all the systems that generated an argument *included* in the current argument.
The *number* and *unique ids* of all the systems that generated an argument that *contains* the current argument.
The *number* and *unique ids* of all the systems that generated an argument that *overlaps* the current argument.

Table 7: Features used by the candidate filtering classifier.

6 Experimental Results

We trained the individual models using the complete CoNLL-2005 training set (PropBank/TreeBank sections 2 to 21). All models were developed using AdaBoost with decision trees of depth 4 (i.e. each branch may represent a conjunction of at most 4 basic features). Each classification model was trained for up to 2,000 rounds.

We applied some simplifications to keep training times and memory requirements inside admissible bounds: (a) we have limited the number of negative examples in Model 3 to the first 500,000; (b) we have trained only the most frequent argument labels: top 41 for Model 1, top 35 for Model 2, and top 24 for Model 3; and (c) we discarded all features occurring less than 15 times in the training set.

The models were tuned on a separate development partition (TreeBank section 24) and evaluated on two corpora: (a) TreeBank section 23, which consists of Wall Street Journal (WSJ) documents, and (b) on three sections of the Brown corpus, semantically annotated by the PropBank team for the CoNLL 2005 shared task evaluation. Table 8 sum-

WSJ	PProps	Precision	Recall	$F_{\beta=1}$
Model 1	48.45%	78.76%	72.44%	75.47 ± 0.8
Model 2	**52.04%**	79.65%	**74.92%**	**77.21** ± 0.8
Model 3	45.28%	**80.32%**	72.95%	76.46 ± 0.6
Brown	PProps	Precision	Recall	$F_{\beta=1}$
Model 1	30.85%	67.72%	58.29%	62.65 ± 2.1
Model 2	**36.44%**	71.82%	**64.03%**	**67.70** ± 1.9
Model 3	29.48%	**72.41%**	59.67%	65.42 ± 2.1

Table 8: Overall results of the individual models on the WSJ and Brown test sets.

marizes the results of the three models on the WSJ and Brown corpora. In that table we include the percentage of perfect propositions detected by each model ("PProps"), i.e. predicates recognized with all their arguments, the overall precision, recall, and $F_{\beta=1}$ measure[2].

The results summarized in Table 8 indicate that all individual systems have a solid performance. Although none of them would rank in the top 3 in this year's CoNLL evaluation (Carreras and Màrquez, 2005), their performance is comparable to the best individual systems presented at that evaluation exercise[3]. As expected, the models based on full parsing (2 and 3) perform better than the model based on partial syntax. But, interestingly, the difference is not large (e.g., less than 2 points in $F_{\beta=1}$ in the WSJ corpus), evincing that having base syntactic chunks and clause boundaries is enough to obtain a competitive performance with a simple system.

Consistently with other systems evaluated on the Brown corpus, all our models experience a severe performance drop in this corpus, due to the lower performance of the linguistic processors.

6.1 Performance of Combination Systems

We have trained the candidate filtering binary classifier on one third of the training partition. Its training data was generated using individual models trained on the other two thirds of the training partition. The classifier was developed using Support Vector Machines (SVM) with a polynomial kernel of degree 2. We trained combined models for all 4 possible combinations of our 3 individual models.

[2]The signifi cance intervals for the F_1 measure have been obtained using bootstrap resampling (Noreen, 1989). F_1 rates outside of these intervals are assumed to be signifi cantly different from the related F_1 rate ($p < 0.05$).

[3]The best performing SRL systems at CoNLL were a combination of several subsystems. See section 7 for details.

Table 9 summarizes the performance of the combined systems on the WSJ and Brown corpora.[4] The combined systems are compared against a baseline combination system, which merges *all* the arguments generated by the individual systems. For conflict resolution, the baseline uses the greedy strategy introduced in Section 5, but using as argument ordering criterion a radix sort that orders the candidate arguments in descending order of: number of models that agreed on this argument; argument length in tokens; and performance of the individual system[5].

Table 9 indicates that our combination strategy is always successful: the results of all combined systems improve upon their individual models and they are better the baseline when using the same number of individual models. As expected, the highest scoring combined system includes all three individual models. Its $F_{\beta=1}$ measure is 2.35 points higher than the best individual model (Model 2) in the WSJ test set and 1.30 points higher in the Brown test set. Somewhat surprisingly, the highest percentage of perfect propositions is not obtained by the overall best combination, but by the system that combines the two models based on full parsing (Models 2 and 3). This happens because Model 1 is the weakest performing of the bunch, hence its arguments, while providing useful information to the filtering classifier, decrease the number of perfect propositions when selected.

We consider these results encouraging given the simplicity of our inference model and the limited amount of training data used to train the candidate filtering classifier. Additionally, they compare favorably with respect to the best performing systems at CoNLL-2005 shared task (see Section 7).

6.2 Upper Limit of the Combination Strategy

To explore the potential of our approach we have constructed a hypothetical system where our candidate filtering module is replaced with a perfect classifier that selects only correct arguments and discards all others. Table 10 lists the results obtained on the WSJ and Brown corpora by this hypothetical system using all three individual models.

[4]For conciseness, in Table 9 we introduced the notation M1+2+3 to indicate the combination of Models 1, 2, and 3

[5]This combination produced the highest-scoring baseline model.

WSJ	PProps	Prec.	Recall	$F_{\beta=1}$
M1+2	51.30%	81.30%	74.13%	77.55 ± 0.7
M1+3	47.26%	81.21%	73.36%	77.08 ± 0.8
M2+3	**52.65**%	81.55%	75.30%	78.30 ± 0.7
M1+2+3	51.64%	**84.89**%	74.87%	**79.56** ± 0.7
baseline	51.09%	77.29%	**78.67**%	77.98 ± 0.7
Brown	**PProps**	**Prec.**	**Recall**	$F_{\beta=1}$
M1+2	35.95%	73.70%	62.93%	67.89 ± 2.0
M1+3	28.98%	72.83%	58.84%	65.09 ± 2.2
M2+3	**37.06**%	73.89%	63.30%	68.18 ± 2.2
M1+2+3	34.20%	**78.66**%	61.46%	**69.00** ± 2.1
baseline	33.58%	67.66%	**66.01**%	66.82 ± 1.8

Table 9: Overall results of the combination models on the WSJ and Brown test sets.

	Perfect props	Precision	Recall	$F_{\beta=1}$
WSJ	70.76%	99.12%	85.22%	91.64
Brown	51.87%	99.63%	74.32%	85.14

Table 10: Performance upper limit on the test sets.

Table 10 indicates that the upper limit of proposed approach is relatively high: the $F_{\beta=1}$ of this hypothetical system is over 12 points higher than our best combined system in the WSJ test set, and over 16 points higher in the Brown corpus. These results indicate that the potential of our combination strategy is high, especially when compared with re-ranking strategies, which are limited to the performance of the best *complete* solution in the candidate pool. By allowing the re-combination of arguments from the individual candidate solutions we raise this threshold significantly. Table 11 lists the contribution of the individual models to this upper limit on the WSJ corpus. For conciseness, we list only the "core" numbered arguments. "$\cap$ of 3" indicates the percentage of correct arguments where all 3 models agreed, "$\cap$ of 2" indicates the percentage of correct arguments where any 2 models agreed, and the other columns indicate the percentage of correct arguments detected by a single model. Table 11 indicates that, as expected, two or more individual models agreed on a large percentage of the correct arguments. Nevertheless, a significant number of correct arguments, e.g. over 22% of ARG3, come from a *single* individual system. This proves that, in order to achieve maximum performance, one has to look beyond simple voting strategies that favor arguments with high agreement between individual systems.

	$\cap$ of 3	$\cap$ of 2	M1	M2	M3
ARG0	80.45%	12.10%	3.47%	2.14%	1.84%
ARG1	69.82%	17.83%	7.45%	2.77%	2.13%
ARG2	56.04%	22.32%	12.20%	4.95%	4.49%
ARG3	56.03%	21.55%	12.93%	5.17%	4.31%
ARG4	65.85%	20.73%	6.10%	2.44%	4.88%

Table 11: Contribution of the individual systems to the upper limit, for ARG0–ARG4 in the WSJ test set.

	WSJ		Brown	
	PProps	$F_{\beta=1}$	PProps	$F_{\beta=1}$
koomen	53.79%	**79.44** ± 0.8	32.34%	**67.75** ± 1.8
haghighi	**56.52**%	78.45 ± 0.8	**37.06**%	67.71 ± 2.0
pradhan	50.14%	77.37 ± 0.7	36.44%	67.07 ± 2.0

Table 12: Results of the best combined systems at CoNLL-2005.

7 Related Work

The best performing systems at the CoNLL-2005 shared task included a combination of different base subsystems to increase robustness and to gain coverage and independence from parse errors. Therefore, they are closely related to the work of this paper. Table 12 summarizes their results under exactly the same experimental setting.

Koomen et al. (2005) used a 2 layer architecture similar to ours. The pool of candidates is generated by running a full syntax SRL system on alternative input information (Collins parsing, and 5-best trees from Charniak's parser). The combination of candidates is performed in an elegant global inference procedure as constraint satisfaction, which, formulated as Integer Linear Programming, can be solved efficiently. Interestingly, the generalized inference layer allows to include in the objective function, jointly with the candidate argument scores, a number of linguistically-motivated constraints to obtain a coherent solution. Differing from the strategy presented in this paper, their inference layer does not include learning. Also, they require confidence values from individual classifiers. This is the best performing system at CoNLL-2005.

Haghighi et al. (2005) implemented a double re-ranking model on top of the base SRL models to select the most probable solution among a set of candidates. The re-ranking is performed, first, on a set of n-best solutions obtained by the base system run on a single parse tree, and, then, on the set of best-candidates coming from the n-best parse trees. The re-ranking approach allows to define global complex features applying to complete candidate solutions to train the rankers. The main drawback, compared to our approach, is that re-ranking does not permit to combine different solutions since it is forced to select a complete candidate solution. This fact implies that the performance upper limit strongly depends on the ability of the base model to generate the complete correct solution in the set of n-best candidates.

Finally, Pradhan et al. (2005b) followed a stacking approach by learning two individual systems based on full syntax, whose outputs are used to generate features to feed the training stage of a final chunk-by-chunk SRL system. Although the fine granularity of the chunking-based system allows to recover from parsing errors, we find this combination scheme quite ad-hoc because it forces to break argument candidates into chunks in the last stage.

8 Conclusions

This paper introduces a novel, robust combination strategy for semantic role labeling. Our approach is separated in two stages: a candidate generation phase, which combines the solutions generated by several individual models into a pool of candidate arguments, followed by a simple inference model that filters the candidate arguments using a single binary classifier and then enforces an arbitrary number of domain-specific constraints.

The proposed approach has several advantages. First, because it combines the solutions provided by the individual models, the inference model can recover from errors produced in the generation phase. Second, due to the diversity of the individual models employed, the candidate pool contains a high percentage of the correct arguments. And lastly, our approach is flexible and robust: it can incorporate any SRL model in the candidate generation stage because it does not require that the individual SRL models provide any information, e.g. classification confidence values, other than an argument solution.

Our results are better than the state of the art using automatically-generated syntactic information. These results are encouraging considering the simplicity of the proposed approach.

A Methodology for Extrinsically Evaluating Information Extraction Performance

Abstract

This paper reports a preliminary study addressing two challenges in measuring the effectiveness of information extraction (IE) technology:

- Developing a methodology for extrinsic evaluation of IE; and,
- Estimating the impact of improving IE technology on the ability to perform an application task.

The methodology described can be employed for further controlled experiments regarding information extraction.

1 Introduction

Intrinsic evaluations of information extraction (IE) have a history dating back to the Third Message Understanding Conference[1] (MUC-3) and continuing today in the Automatic Content Extraction (ACE) evaluations.[2] *Extrinsic* evaluations of IE, measuring the utility of IE in a task, are lacking and needed (Jones, 2005).

In this paper, we investigate an extrinsic evaluation of IE where the task is question answering (QA) given extracted information. In addition, we propose a novel method for exploring hypothetical performance questions, e.g., if IE accuracy were x% closer to human accuracy, how would speed and accuracy in a task, e.g., QA, improve?

We plot QA accuracy and time-to-complete given eight extracted data accuracy levels ranging from the output of SERIF, BBN's state-of-the-art IE system, to manually extracted data.

2 Methodology

Figure 1 gives an overview of the methodology. The left portion of the figure shows source documents provided both to a system and a human to produce two extraction databases, one corresponding to SERIF's automated performance and one corresponding to double-annotated, human accuracy. By merging portions of those two sources in varying degrees ("blends"), one can derive several extracted databases ranging from machine quality, through varying percentages of improved performance, up to human accuracy. This method of blending databases provides a means of answering hypothetical questions, i.e., what if the state-of-the-art were x% closer to human accuracy, with a single set of answer keys.

A person using a given extraction database performs a task, in our case, QA. The measures of effectiveness in our study were time to complete the task and percent of questions answered correctly. An extrinsic measure of the value of improved IE technology performance is realized by rotating users through different extraction databases and questions sets.

In our preliminary study, databases of fully automated IE and manual annotation (the gold standard) were populated with entities, relationships, and co-reference links from 946 documents. The two initial databases representing machine extraction and human extraction respectively were then blended to produce a continuum of database qualities from machine to

Figure 1: Study Overview

human performance. ACE Value Scores[3] were measured for each database. Pilot studies were conducted to develop questions for a QA task. Each participant answered four sets of questions, each with a different extraction database representing a different level of IE accuracy. An answer capture tool recorded the time to answer each question and additional data to confirm that the participant followed the study protocol. The answers were then evaluated for accuracy and the relationship between QA performance and IE quality was established.

Each experiment used four databases. The first experiment used databases spanning the range from solely machine extraction to solely human extraction. Based on the results of this experiment, two further experiments focused on smaller ranges in database quality to study the relationship between IE and QA performance.

2.1 Source Document Selection, Annotation, and Extraction

Source documents were selected based on the availability of manual annotation. We identified 946 broadcast news and newswire articles from recent ACE efforts, all annotated by the LDC according to the ACE guidelines for the relevant year (2002, 2003, 2004). Entities, relations, and within-document co-reference were marked. Inter-document co-reference annotation was added by BBN. The 946 news articles comprised 363 articles (187,720 words) from newswire and 583 (122,216 words) from broadcast news. With some corrections to deal with errors and changes in guidelines, the annotations were loaded as the human (DB-quality 100) database.

SERIF, BBN's automatic IE system based on its predecessor, SIFT (Miller, 2000), was run on the 946 ACE documents to create the machine (DB-quality 0) database. SERIF is a statistically trained software system that automatically performs entity, co-reference, and relationship information extraction.

Intermediate IE performance was simulated by blending the human and automatically generated databases in various degrees using an interpolation algorithm developed specifically for this study. To create a blended database, DB-quality *n*, all of the entities, relationships, and co-reference links common to the human and automatically generated databases are copied into a new one. Then, *n*% of the entity mentions in the human database (100), but not in the automatic IE system output (0), are copied; and, (100 – *n*)% of the entity mentions in the automatically generated database, but not in the human database, are copied. Next, the relationships for which both of the constituent entity mentions have been copied are also copied to the blended database. Finally, co-reference links and entities for the already copied entity mentions are copied into the blended database.

For the first experiment, two intermediate extraction databases were created: DB-qualities 33 and 67. For the second experiment, two additional databases were created: 16.5 and 50. The first intermediate databases were both created using the 0 and 100 databases as seeds. The 16.5 database was created by mixing the 0 and the 33 databases in a 50% blend. The 50 database was created by doing the same with the 33 and 67 databases. For Experiment 3, 41 and 58 databases were created by mixing the 33 and 50, and 50 and 67 databases respectively.

[3] The 2004 ACE evaluation plan, available at http://www.nist.gov/speech/tests/ace/ace04/doc/ace04-evalplan-v7.pdf, contains a full description of the scoring metric used in the evaluation. Entity type weights were 1 and the level weights were NAM=1.0, NOM=0.5, and PRO=0.1.

	DB Blend															
	0 (Machine)		16.5		33		41		50		58		67		100 (Human)

Table 2: Entity, Relation and Description Counts for each DB Blend

To validate the interpolation algorithm and blending procedure, we applied NIST's 2004 ACE Scorer to the eight extraction databases. Polynomial approximations were fitted against both the entity and relation extraction curves. Entity performance was found to vary linearly with DB blend ($R^2 = .9853$) and relation performance was found to vary with the square of DB blend ($R^2 = .9961$). Table 1 shows the scores for each blend, and Table 2 shows the counts of entities, relationships, and descriptions.

2.2 Question Answering Task

Extraction effectiveness was measured by how well a person could answer questions given a database of facts, entities, and documents. Participants answered four sets of questions using four databases. They accessed the database using BBN's FactBrowser (Miller, 2001) and recorded their answers and source citations in a separate tool developed for this study, AnswerPad.

Each database represented a different database quality. In some databases, facts were missing, or incorrect facts were recorded. Consequently, answers were more accessible in some databases than in others, and participants had to vary their question answering strategy depending on the database.

Participants were given five minutes to answer each question. To ensure that they had actually located the answer rather than relied on world knowledge, they were required to provide source citations for every answer. The instructions emphasized that the investigation was a test of the system, and not of their world knowledge or web search skills. Compliance with these instructions was high. Users resorted to knowledge-based proper noun searches only one percent of the time. In addition, keyword search was disabled to force participants to rely on the database features.

2.3 Participants

Study participants were recruited through local web lists and at local colleges and universities. Participants were restricted to college students and recent graduates with PC (not Mac) experience, without reading disabilities, for whom English was their native language. No other screening was necessary because the design called for each participant to serve as his or her own control, and because opportunities to use world knowledge in answering the questions were minimized through the interface and procedures.

During the first two months of the study 23 participants were used to help develop questions, participant criteria, and the overall test procedure. Then, experiments were conducted comparing the 0, 33, 67, and 100 database blends (Experiment 1, 20 subjects); the 0, 16.5, 33, and 50 database blends (Experiment 2, 20 subjects), and the 33, 41, 50, and 58 database blends (Experiment 3, 24 subjects).

2.4 Question Selection and Validation

Questions were developed over two months of pilot studies. The goal was to find a set of questions that would be differentially supported by the 0, 33, 67, and 100 databases. We explored both "random" and "engineered" approaches. The random approach called for creating questions using only the documents, without reference to the kind of information extracted. Using a list of keywords, one person generated 86 questions involving relationships and entities pertaining to politics and the military by scanning the 946 ACE documents to find references to each keyword and devising questions based on the information she found.

The alternative, engineered approach involved eliminating questions that were not supported by the types of information extracted by SERIF, and generating additional questions to fit the desired pattern of increasing support with increased human annotation. This approach ensured that the question sets reflected the structural differences that are assumed to exist in the database, and produced psychophysical data that link degree of QA support to human performance parameters. The IE results from four of the databases (0, 33, 67 and 100) were used to develop questions that received differential support from the different quality databases. For example, such a question could be answered using the automatically extracted results, but might be more straightforwardly answered given human annotation.

Sixty-four questions, plus an additional ten practice questions, were created using the engineering approach. Additional criteria that were followed in creating the question sets were: 1) Questions had to contain at least one reasonable entry hook into all four databases, e.g., the terms U.S. and America were considered too broad to be reasonable; and, 2) For ease of scoring, list-type questions had to specify the number of answers required. Alternative criteria were considered but rejected because they correlated with the aforementioned set. The following are examples of engineered questions.

- Identify eight current or former U.S. State Department workers.
- In what two West Bank towns does Fatah have an office?
- Name two countries where Osama bin Laden has been.
- Were Lebanese women allowed to vote in municipal elections between two Shiite groups in the year 1998?

Two question lists, one with 86 questions generated by the random procedure and one with 64 questions generated by the engineered procedure, were analyzed with respect to the degree of support afforded by each of the four databases as viewed through FactBrowser. Four *a priori* criteria were established to assess degree of support – or its opposite, the degree of expected difficulty – for each question in each of the four databases. Ranked from easiest to hardest, they are listed in Table 3.

The question can be answered…
1. Directly with fact or description (answer is highlighted in FactBrowser citation)
2. Indirectly with fact or description (answer is not highlighted)
3. With name mentioned in question (long list of mentions without context)
4. Via database crawling

Table 3: *A Priori* Question Difficulty Characteristics, listed from easiest to hardest

Table 4 shows the question difficulty levels for both question types, for each of four databases. Analysis of the engineered set was done on all 64 questions. Analysis for randomly generated questions was done on a random sample of 44 of the 86 questions. Fifteen questions did not meet the question criteria, leaving 29.

The randomly generated questions showed a statistically significant, but small, variation in expected difficulty, in part due to the number of unanswerable questions. While the questions were made up with respect to information found in the documents, the process did not consider the types of extracted entities and relations. This problem might have been mitigated by limiting the search to questions involving entities and relations that were part of the extraction task.

By contrast, the engineered question set showed a highly significant decrease in expected difficulty as the percentage of human annotation in the database increased ($P < 0.0001$ for chi-square analysis). This result is not surprising, given that the questions were constructed with reference to the list of entities in the four databases. The analysis confirms that the experimental manipulation of different degrees of support provided by the four databases was achieved for this question set.

Random Question Generation

Difficulty Level (easiest to hardest)	0% Human	33% Human	67% Human	100% Human
1 Fact-Highlight	7	10	13	15
2 Fact-Indirect	14	10	8	10
3 Mention	3	5	2	1
4 Web Crawl	5	4	6	3
Total	29	29	29	29

Engineered Question Generation

Difficulty Level (from easiest to hardest)	0% Human	33% Human	67 Human	100% Human
1 Fact-Highlight	16	25	35	49
2 Fact-Indirect	23	20	18	14
3 Mention	7	14	11	1
4 Web Crawl	18	5	0	0
Total	64	64	64	64

Table 4: Anticipated Difficulty of Questions as a Function of Database Quality

Preliminary human testing with both question sets suggested that the *a priori* difficulty indicators predict human question answering performance. Experiments with the randomly generated questions, therefore, were unlikely to reveal much about the databases or about human question answering performance. On the other hand, an examination of how different levels of database quality affect human performance, in a psychophysical experiment where structure is varied systematically, promised to address the question of how much support is needed for good performance.

Based on the question difficulties, and pilot study timing and performance results, the 64 questions were grouped into four, 16-question balanced sets.

2.5 Procedure

Participants were tested individually at our site, in sessions lasting roughly four hours. Training prior to the test lasted for approximately a half hour. Training consisted of a walk-through of the interface features followed by guided practice with sample questions. The test consisted of four question sets, each with a different database. Participants were informed that they would be using a different database for each question set and that some might be easier to use than others.

Questions were automatically presented and responses were captured in AnswerPad, a software tool designed for the study. AnswerPad is shown in Figure 2.

Key features of the tool include:

- Limiting view to current question set – disallowing participants to view previous question sets
- Automatically connecting to correct db
- Logging time spent on each question
- Enforcing five-minute limit per question
- Enforcing requirement that all answers include a citation

Figure 2: AnswerPad Question Presentation and Answer Capture Interface

Participants were given written documentation as part of their training. The participants were instructed to cut-and-paste question answers and document citations from source documents into AnswerPad.

Extracted facts and entities, and source documents were accessed through FactBrowser. FactBrowser, shown in Figure 3, is web-browser based and is invoked via a button in AnswerPad. FactBrowser allows one to enter a string, which is matched against the database of entity mentions. The list of entities that have at least one mention partially matching the string are returned (e.g., “Laura Bush”) along with an icon indicating the type of the entity and the number of documents in which the entity appears. Clicking on the entity in the left panel causes the top right panel to display all of the descriptions, facts, and mentions for the entity. Selecting one of these displays citations in which the description, fact, or mention occurs. Clicking on the citation opens up a document view in the lower right corner of the screen and highlights the extracted information in the text. When a document is displayed, all of the entities detected in the document are listed down the left side of the document viewer.

Figure **3**: Browsing Tool Interface

The browsing tool was instrumented to record command invocations so that the path a participant took to answer a question could be recreated, and the participant’s adherence to protocol could be verified. Furthermore, the find function (Ctrl-F) was disabled to prevent users from performing *ad hoc* searches of the documents instead of using the extracted data.

The order of question sets and the order of database conditions were counterbalanced across participants, so that, for every four participants, every question set and database appeared once in every ordinal position, and every question set was paired once with every database. This avoided carryover effects from question order.

2.6 Data Collected

Based on the initial results from Experiment 1, a 70% target effectiveness threshold was identified to occur between the 33 and 67 database blends. To refine and verify this finding, Experiment 2 examined the 0, 16.5, 33, and 50 database blends. Experiment 3 examined the 33, 41, 50, and 58 database blends.

AnswerPad collected participant-provided answers to questions and the corresponding citations. In addition, AnswerPad recorded the time spent answering the questions. A limit of five minutes was imposed based on pilot study results. The browsing tool logged commands invoked while the user searched the fact-base for question answers. Questions were manually scored based on the answers in the provided corpus. No partial credit was given. The maximum score, for each database condition, was 16, for a total maximum score of 64.

3 Results

Figure 4 shows the question answer scores and times for each of the three individual experiments, and for Experiments 1 and 2 combined. Database quality affects both task speed (downward-sloping line) and task accuracy (upward-sloping line) in the expected direction. A logistic fit, as for a binary-response curve, was used to fit the relationship between blend percentage and accuracy in each experiment. The logistic fit Goodman-Theil quasi-R^2 was .9973 for Experiment 1, .9594 for Experiment 2, .8936 for Experiment 3, and .9959 for Experiments 1 and 2 combined.

For the target accuracy of 70%, the 95% confidence interval for the required blend is (35,56) around a predicted 46% blend for Experiment 1, and (41,56) around a predicted 49% for Experiments 1 and 2 combined.

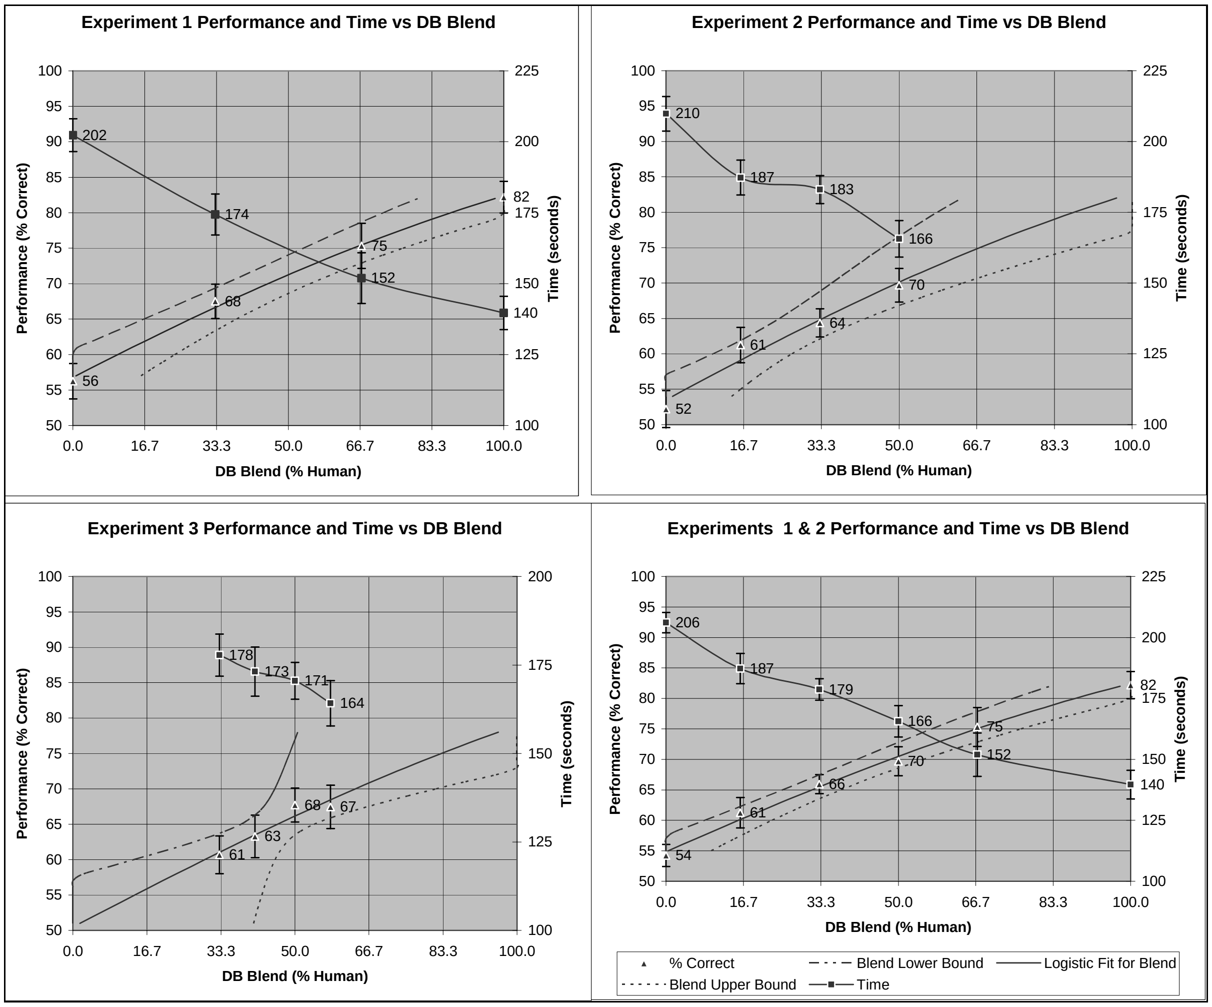

Figure 4 QA Performance (upward-sloping) and QA Time (downward-sloping) vs. Extraction Blend
Error Bars are Plus/Minus Standard Error of Mean (SEM) Within Each Blend
Upper and Lower Bounds Are Approximate 95% Confidence Intervals Based on the Logistic Fit
For the Blend (X) to Produce a Given Performance (Y)
(Read these bounds horizontally, as bounds on X, with the upper bound to the right of the lower bound.)

The downward-sloping line in each graph displays the average time to answer a question as a function of the extraction blend. For this analysis we used *strict time,* the time it took the participant to answer the question if he or she answered correctly, or the full 5 minutes allowed for any incorrectly answered question. This addresses the situation where a person quickly answers all of the questions incorrectly. The average question-answer time drops 32% as one moves from a machine generated extraction database to a human generated database. A straight-line fit to the Experiment 1 and 2 combined data predicts a drop of 6.5 seconds as the human proportion of the database increases by 10 percentage points.

A one-way repeated measures analysis of variance (ANOVA) was performed for Experiment 1 (0-33-67-100), Experiment 2 (0-16.5-33-50), and Experiment 3 (33-41-50-58). Table 5 summarizes the results. In Experiments 1 and 2 the impact of database quality on QA performance and on QA time were highly significant ($P < 0.0001$), but not for the narrower range of databases in Experiment 3. Other ANOVAs showed that the impact of trial order and question set on QA performance were both non-significant ($P > 0.05$).

Experiment	QA Performance	Strict Time
1	F(3,57) = 30.98, P < .0001	F(3, 57) = 28.36 P < .0001
2	F(3,57)= 19.32, P < .0001	F(3, 57) = 15.37, P < .0001
3	F(3,69)= 2.023, P = .1187	F(3,69)= 1.053, P = .3747

Table 5: ANOVA Analyses for QA Performance
Expt. 1 used db blends of 0, 33, 67, and 100%
Expt. 2 used db blends of 0, 16.5, 33, and 50%
Expt. 3 used db blends of 33, 41, 50, and 58%

In Experiment 1, Newman-Keuls contrasts indicate that the 0, 33, 67, and 100 databases differ significantly (P < .05) on their impact on QA quality. For Experiment 2, however, the 16.5 and 33 database qualities were not shown to be different, nor were any of the database blends in Experiment 3. The data suggest that nearly half the improvement in QA quality from 0 to 100 occurs by the 33 database blend, and more than half the improvement in QA quality from 0 to 50 occurs by the 16.5 blend: a little "human" goes a long way. Experiment 3 suggests that small differences in data blends make no practical difference in the results. Alternatively, there might be real differences that are small enough such that a larger number of participants would be required to detect them. Experiment 3 also had two participants with atypical patterns of QA against blend, which might account for the failure to detect a difference between the 33 and 50 or 58 blends as suggested by the results from Experiment 2. Furthermore, larger experiments could reveal whether the atypical participants were representatives of a subpopulation, or simply outliers. Bearing the possibility of outliers in mind, we used the combination of Experiments 1 and 2 for the combined logistic analysis.

4 Conclusions

We presented a methodology for assessing information extraction effectiveness using an extrinsic study. In addition, we demonstrated how a novel database blending (merging) strategy allows interpolating extraction quality from automated performance up through human accuracy, thereby decreasing the resources required to conduct effectiveness evaluations.

Experiments showed QA accuracy and speed increased with higher IE performance, and that the database blend percentage was a good proxy for ACE value scores. We emphasize that the study was not to show that IE supports QA better than other technologies, rather to isolate utility gains due to IE performance improvements.

QA performance was plotted against human-machine IE blend and, for example, 70% QA performance was achieved with a database blend between 41% and 46% machine extraction. This corresponded to entity and relationship value scores of roughly 74 and 47 respectively.

The logistic dose-response model provided a good fit and allowed for computation of confidence bounds for the IE associated with a particular level of performance. The constraints imposed by AnswerPad and FactBrowser ensured that world knowledge was neutralized, and the repeated-measures design (using participants as their own controls across multiple levels of database quality) excluded inter-participant variability from experimental error, increasing the ability to detect differences with relatively small sample sizes.

Abstract

In this paper, we study the impact of a group of features extracted automatically from machine-generated parse trees on coreference resolution. One focus is on designing syntactic features using the binding theory as the guideline to improve pronoun resolution, although linguistic phenomenon such as apposition is also modeled. These features are applied to the Arabic, Chinese and English coreference resolution systems and their effectiveness is evaluated on data from the Automatic Content Extraction (ACE) task. The syntactic features improve the Arabic and English systems significantly, but play a limited role in the Chinese one. Detailed analyses are done to understand the syntactic features' impact on the three coreference systems.

1 Introduction

A coreference resolution system aims to group together *mention*s referring to the same *entity*, where a mention is an instance of reference to an object, and the collection of mentions referring to the same object in a document form an *entity*. In the following example:

(I) "John believes himself to be the best student."

mentions are underlined. The three mentions "John", "himself", "the best student" are of type name, pronoun [1], and nominal, respectively. They form an *entity* since they all refer to the same person.

Syntactic information plays an important role in coreference resolution. For example, the binding theory (Haegeman, 1994; Beatrice and Kroch, 2000) provides a good account of the constraints on the antecedent of English pronouns. The theory relies on syntactic parse trees to determine the governing category which defines the scope of binding constraints. We will use the theory as a guideline to help us design features in a machine learning framework.

Previous pronoun resolution work (Hobbs, 1976; Lappin and Leass, 1994; Ge et al., 1998; Stuckardt, 2001) explicitly utilized syntactic information before. But there are unique challenges in this study: (1) Syntactic information is extracted from parse trees automatically generated. This is possible because of the availability of statistical parsers, which can be trained on human-annotated treebanks (Marcus et al., 1993; Xia et al., 2000; Maamouri and Bies, 2004) for multiple languages; (2) The binding theory is used as a guideline and syntactic structures are encoded as features in a maximum entropy coreference system; (3) The syntactic features are evaluated on three languages: Arabic, Chinese and English (one goal is to see if features motivated by the English language can help coreference resolution in other languages). All contrastive experiments are done on publicly-available data; (4) Our coreference system resolves coreferential relationships among all the annotated mentions, not just for pronouns.

Using machine-generated parse trees eliminates the need of hand-labeled trees in a coreference system. However, it is a major challenge to extract useful information from these noisy parse trees. Our approach is encoding the structures contained in a parse tree into a set of computable features, each of which is associated with a weight automatically determined by a machine learning algorithm. This contrasts with the approach of extracting rules and assigning weights to these rules by hand (Lappin and Leass, 1994; Stuckardt, 2001). The advantage of our approach is robustness: if a particular structure is helpful, it will be assigned a high weight; if a feature is extracted from a highly noisy parse tree and is not informative in coreference resolution, it will be assigned a small weight. By avoiding writing rules, we automatically incorporate useful information into our model and at the same time limit the potentially negative impact from noisy parsing output.

[1]"Pronoun" in this paper refers to both anaphor and normal pronoun.

2 Statistical Coreference Resolution Model

Our coreference system uses a binary entity-mention model $P_L(\cdot|e,m)$ (henceforth "link model") to score the action of linking a mention m to an entity e. In our implementation, the link model is computed as

$$P_L(L=1|e,m) \approx \max_{m' \in e} \hat{P}_L(L=1|e,m',m), \quad (1)$$

where m' is one mention in entity e, and the basic model building block $\hat{P}_L(L=1|e,m',m)$ is an exponential or maximum entropy model (Berger et al., 1996):

$$\hat{P}_L(L|e,m',m) = \frac{\exp\left\{\sum_i \lambda_i g_i(e,m',m,L)\right\}}{Z(e,m',m)}, \quad (2)$$

where $Z(e,m',m)$ is a normalizing factor to ensure that $\hat{P}_L(\cdot|e,m',m)$ is a probability, $\{g_i(e,m',m,L)\}$ are features and $\{\lambda_i\}$ are feature weights.

Another *start* model is used to score the action of creating a new entity with the current mention m. Since starting a new entity depends on all the partial entities created in the history $\{e_i\}_{i=1}^t$, we use the following approximation:

$$P_S(S=1|e_1,e_2,\cdots,e_t,m) \approx 1 - \max_{1\le i\le t} P_L(L=1|e_i,m) \quad (3)$$

In the maximum-entropy model (2), feature (typically binary) functions $\{g_i(e,m',m,\cdot)\}$ provide us with a flexible framework to encode useful information into the the system: it can be as simple as "$g_i(e,m',m,L=1)=1$ if m' and m have the same surface string," or "$g_j(e,m',m,L=0)=1$ if e and m differ in number," or as complex as "$g_l(e,m',m,L=1)=1$ if m' c-commands m and m' is a NAME mention and m is a pronoun mention." These feature functions bear similarity to rules used in other coreference systems (Lappin and Leass, 1994; Mitkov, 1998; Stuckardt, 2001), except that the feature weights $\{\lambda_i\}$ are automatically trained over a corpus with coreference information. Learning feature weights automatically eliminates the need of manually assigning the weights or precedence of rules, and opens the door for us to explore rich features extracted from parse trees, which is discussed in the next section.

3 Syntactic Features

In this section, we present a set of features extracted from syntactic parse trees. We discuss how we *approximately* compute linguistic concepts such as governing category (Haegeman, 1994), apposition and dependency relationships from noisy syntactic parse trees. While parsing and parse trees depend on the target language, the automatic nature of feature extraction from parse trees makes the process language-independent.

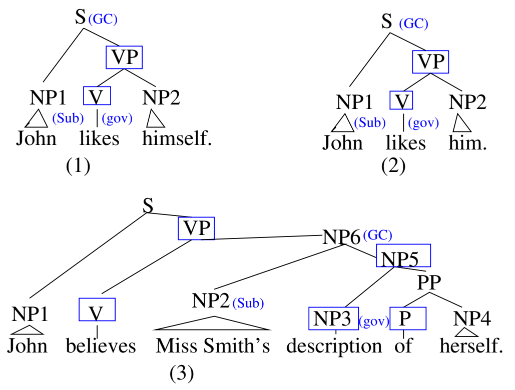

Figure 1: GC examples.

3.1 Features Inspired by Binding Theory

The binding theory (Haegeman, 1994) concerning pronouns can be summarized with the following principles:

1. A reflexive or reciprocal pronoun (e.g., "herself" or "each other") must be bound in its governing category (GC).
2. A normal pronoun must be free in its governing category.

The first principle states that the antecedent of a reflexive or reciprocal pronoun is within its GC, while the second principle says that the antecedent of a normal pronoun is outside its GC. While the two principles are simple, they all rely on the concept of governing category, which is defined as the minimal domain containing the pronoun in question, its governor, and an accessible subject.

The concept GC can best be explained with a few examples in Figure 1, where the label of a head constituent is marked within a box, and GC, accessible subject, and governor constituents are marked in parentheses with "GC", "Sub" and "gov." Noun-phrases (NP) are numbered for the convenience of referencing. For example, in sub-figure (1) of Figure 1, the governor of "himself" is "likes," the subject is "John," hence the GC is the entire sentence spanned by the root "S." Since "himself" is reflexive, its antecedent must be "John" by Principle 1. The parse tree in sub-figure (2) is the same as that in sub-figure (1), but since "him" is a normal pronoun, its antecedent, according to Principle 2, has to be outside the GC, that is, "him" cannot be coreferenced with "John.". Sentence in sub-figure (3) is slightly more complicated: the governor of "herself" is "description," and the accessible subject is "Miss Smith." Thus, the governing category is NP6. The first principle implies that the antecedent of "herself" must be "Miss Smith."

It is clear from these examples that GC is very useful in finding the antecedent of a pronoun. But the last example shows that determining GC is not a trivial matter. Not only is the correct parse tree required, but extra information is also needed to identify the head governor and the minimal constituent dominating the pronoun, its governor and an accessible subject. Determining the accessible subject itself entails checking other constraints such as number and gender agreement. The complexity of computing governing category, compounded with the noisy nature of machine-generated parse tree, prompts us to compute a set of features that characterize the structural relationship between a candidate mention and a pronoun, as opposed to explicitly identify GC in a parse tree. These features are designed to implicitly model the binding constraints.

Given a candidate antecedent or mention m_1 and a pronoun mention m_2 within a parsed sentence, we first test if they have c-command relation, and then a set of counting features are computed. The features are detailed as follows:

(1) C-command $ccmd(m_1, m_2)$: A constituent X c-commands another constituent Y in a parse tree if the first branching node dominating X also dominates Y. The binary feature $ccmd(m_1, m_2)$ is true if the minimum NP dominating m_1 c-commands the minimum NP dominating m_2. In sub-figure (1) of Figure 1, NP1 c-commands NP2 since the first branching node dominating NP1 is S and it dominates NP2.

If $ccmd(m_1, m_2)$ is true, we then define the c-command path $T(m_1, m_2)$ as the path from the minimum NP dominating m_2 to the first branching node that dominates the minimum NP dominating m_1. In sub-figure (1) of Figure 1, the c-command path T("John", "himself") would be "NP2-VP-S."

(2) $NP\_count(m_1, m_2)$: If $ccmd(m_1, m_2)$ is true, then $NP\_count(m_1, m_2)$ counts how many NPs are seen on the c-command path $T(m_1, m_2)$, excluding two endpoints. In sub-figure (1) of Figure 1, NP_count("John", "himself") $= 0$ since there is no NP on T("John", "himself").

(3) $VP\_count(m_1, m_2)$: similar to $NP\_count(m_1, m_2)$, except that this feature counts how many verb phrases (VP) are seen on the c-command path. In sub-figure (1) of Figure 1, VP_count("John", "himself") is true since there is one VP on T("John", "himself").

(4) $S\_count(m_1, m_2)$: This feature counts how many clauses are seen on the c-command path when $ccmd(m_1, m_2)$ is true. In sub-figure (1) of Figure 1, S_count("John", "himself") $= 0$ since there is no clause label on T("John", "himself").

These features are designed to capture information in the concept of governing category when used in conjunction with attributes (e.g., gender, number, reflexiveness) of individual pronouns. Counting the intermediate NPs, VPs and sub-clauses implicitly characterizes the governor of a pronoun in question; the presence or absence of a sub-clause indicates whethere or not a coreferential relation is across clause boundary.

3.2 Dependency Features

In addition to features inspired by the binding theory, a set of dependency features are also computed with the help of syntactic parse trees. This is motivated by examples such as "John is the president of ABC Corporation," where "John" and "the president" refer to the same person and should be in the same entity. In scenarios like this, lexical features do not help, while the knowledge that "John" left-modifies the verb "is" and the "the president" right-modifies the same verb would be useful.

Given two mentions m_1 and m_2 in a sentence, we compute the following dependency features:

(1)$same\_head(m_1, m_2)$: The feature compares the bilexical dependencies $\langle m_1, h(m_1)\rangle$, and $\langle m_2, h(m_2)\rangle$, where $h(x)$ is the head word which x modifies. The feature is active only if $h(m_1) = h(m_2)$, in which case it returns $h(m_1)$.

(2)$same\_POS(m_1, m_2)$: To get good coverage of dependencies, we compute a feature $same\_POS(m_1, m_2)$, which examines the same dependency as in (1) and returns the common head part-of-speech (POS) tag if $h(m_1) = h(m_2)$.

The head child nodes are marked with boxes in Figure 1. For the parse tree in sub-figure (1), $same\_head$("John", "him") would return "likes" as "John" left-modifies "likes" while "him" right-modifies "likes," and $same\_POS$("John", "him") would return "V" as the POS tag of "likes" is "V."

(3) $mod(m_1, m_2)$: the binary feature is true if m_1 modifies m_2. For parse tree (2) of Figure 1, mod("John", "him") returns false as "John" does not modify "him" directly. A reverse order feature $mod(m_2, m_1)$ is computed too.

(4) $same\_head2(m_1, m_2)$: this set of features examine second-level dependency. It compares the head word of $h(m_1)$, or $h(h(m_1))$, with $h(m_2)$ and returns the common head if $h(h(m_1)) = h(m_2)$. A reverse order feature $same\_head2(m_2, m_1)$ is also computed.

(5) $same\_POS2(m_1, m_2)$: similar to (4), except that it computes the second-level POS. A reverse order feature $same\_POS2(m_2, m_1)$ is computed too.

(6) $same\_head22(m_1, m_2)$: it returns the common second-level head if $h(h(m_1)) = h(h(m_2))$.

3.3 Apposition and Same-Parent Features

Apposition is a phenomenon where two adjacent NPs refer to the same entity, as "Jimmy Carter" and "the former president" in the following example:

(II) "$\underline{\text{Jimmy Carter}}$, $\underline{\text{the former president}}$ of US, is visiting Europe."

Note that not all NPs separated by a comma are necessarily appositive. For example, in "John called Al, Bob, and Charlie last night," "Al" and "Bob" share a same NP parent and are separated by comma, but they are not appositive.

To compute the apposition feature $appos(m_1, m_2)$ for mention-pair (m_1, m_2), we first determine the minimum dominating NP of m_1 and m_2. The minimum dominating NP of a mention is the lowest NP, with an optional modifying phrase or clause, that spans the mention. If the two minimum dominating NPs have the same parent NP, and they are the only two NP children of the parent, the value of $appos(m_1, m_2)$ is true. This would exclude "Al" and "Bob" in "John called Al, Bob, and Charlie last night" from being computed as apposition.

We also implement a feature $same\_parent(m_1, m_2)$ which tests if two mentions m_1 and m_2 are dominated by a common NP. The feature helps to prevent the system from linking "his" with "colleague" in the sentence "John called his colleague."

All the features described in Section 3.1-3.3 are computed from syntactic trees generated by a parser. While the parser is language dependent, feature computation boils down to encoding the structural relationship of two mentions, which is language independent. To test the effectiveness of the syntactic features, we integrate them into 3 coreference systems processing Arabic, Chinese and English.

4 Experimental Results

4.1 Data and System Description

All experiments are done on true mentions of the ACE (NIST, 2004) 2004 data. We reserve part of LDC-released 2004 data as the development-test set (henceforth "devtest") as follows: documents are sorted by their date and time within each data source (e.g., broadcast news (bnews) and news wire (nwire) are two different sources) and the last 25% documents of each data source are reserved as the devtest set. Splitting data on chronological order simulates the process of a system's development and deployment in the real world. The devtest set statistics of three languages (Arabic, Chinese and English) is summarized in Table 1, where the number of documents, mentions and entities is shown on row 2 through 4, respectively. The rest of 2004 ACE data together with earlier ACE data is used as training.

	Arabic	Chinese	English
#-docs	178	166	114
#-mentions	11358	8524	7008
#-entities	4428	3876	2929

Table 1: Devtest Set Statistics by Language

The official 2004 evaluation test set is used as the blind test set on which we run our system once after the system development is finished. We will report summary results on this test set.

As for parser, we train three off-shelf maximum-entropy parsers (Ratnaparkhi, 1999) using the Arabic, Chinese and English Penn treebank (Maamouri and Bies, 2004; Xia et al., 2000; Marcus et al., 1993). Arabic words are segmented while the Chinese parser is a character-based parser. The three parsers have a label F-measure of 77%, 80%, and 86% on their respective test sets. The three parsers are used to parse both ACE training and test data. Features described in Section 3 are computed from machine-generated parse trees.

Apart from features extracted from parse trees, our coreference system also utilizes other features such as lexical features (e.g., string matching), distance features characterized as quantized word and sentence distances, mention- and entity-level attribute information (e.g, ACE distinguishes 4 types of mentions: NAM(e), NOM(inal), PRE(modifier) and PRO(noun)) found in the 2004 ACE data. Details of these features can be found in (Luo et al., 2004).

4.2 Performance Metrics

The official performance metric in the ACE task is ACE-Value (NIST, 2004). The ACE-Value is an entity-based metric computed by subtracting a normalized cost from 1 (so it is unbounded below). The cost of a system is a weighted sum of costs associated with entity misses, false alarms and errors. This cost is normalized against the cost of a nominal system that outputs no entity. A perfect coreference system gets 100% ACE-Value while a system outputting many false-alarm entities could get a negative value.

The default weights in ACE-Value emphasize names, and severely discount pronouns: the relative importance of a pronoun is two orders of magnitude less than that of a name. So the ACE-Value will not be able to accurately reflect a system's improvement on pronouns[2]. For this reason, we compute an *unweighted* entity-constrained mention F-measure (Luo, 2005) and report all contrastive experiments with this metric. The F-measure is computed by first aligning system and reference entities such that the number of common mentions is maximized and each system entity is constrained to align with at most one reference entity, and vice versa. For example, suppose that a reference document contains three entities: $\{[m_1], [m_2, m_3], [m_4]\}$ while a system outputs four entities: $\{[m_1, m_2], [m_3], [m_5], [m_6]\}$, where $\{m_i : i = 1, 2, \cdots, 6\}$ are mentions, then the best alignment from reference to system would be $[m_1] \Leftrightarrow [m_1, m_2]$, $[m_2, m_3] \Leftrightarrow [m_3]$ and other entities are not aligned. The number of common mentions of the best alignment is 2

[2]Another possible choice is the MUC F-measure (Vilain et al., 1995). But the metric has a systematic bias for systems generating fewer entities (Bagga and Baldwin, 1998) – see Luo (2005). Another reason is that it cannot score single-mention entity.

(i.e., m_1 and m_3), thus the recall is $\frac{2}{4}$ and precision is $\frac{2}{5}$. Due to the one-to-one entity alignment constraint, the F-measure here is more stringent than the accuracy (Ge et al., 1998; Mitkov, 1998; Kehler et al., 2004) computed on antecedent-pronoun pairs.

4.3 Effect of Syntactic Features

We first present the contrastive experimental results on the devtest described in sub-section 4.1.

Two coreference systems are trained for each language: a baseline without syntactic features, and a system including the syntactic features. The entity-constrained F-measures with mention-type breakdown are presented in Table 2. Rows marked with N_m contain the number of mentions, while rows with "base" and "+synt" are F-measures for the baseline and the system with the syntactic features, respectively.

The syntactic features improve pronoun mentions across three languages – not surprising since features inspired by the binding theory are designed to improve pronouns. The pronoun improvement on the Arabic (from 73.2% to 74.6%) and English (from 69.2% to 72.0%) system is statistically significant (at above 95% confidence level), but change on the Chinese system is not. For Arabic, the syntactic features improve Arabic NAM, NOM and PRE mentions, probably because Arabic pronouns are sometimes attached to other types of mentions. For Chinese and English, the syntactic features do not practically change the systems' performance.

As will be shown in Section 4.5, the baseline systems without syntactic features are already competitive, compared with the results on the coreference evaluation track (EDR-coref) of the ACE 2004 evaluation (NIS, 2004). So it is nice to see that syntactic features further improve a good baseline on Arabic and English.

	Mention Type				
	NAM	NOM	PRE	PRO	Total
Arabic					
N_m	2843	3438	1291	3786	11358
base	86.8	73.2	86.7	73.2	78.2
+synt	**88.4**	**76.4**	**87.4**	**74.6**	**80.1**
Chinese					
N_m	4034	3696	-	794	8524
base	**95.4**	**77.8**	-	65.9	**85.0**
+synt	95.2	77.7	-	**66.5**	84.9
English					
N_m	2069	2173	835	1931	7008
base	92.0	73.4	**88.7**	69.2	79.6
+synt	92.0	**75.3**	87.8	**72.0**	**80.8**

Table 2: F-measure(%) Breakdown by Mention Type: NAM(e), NOM(inal), PRE(modifier) and PRO(noun). Chinese data does not have the PRE type.

4.4 Error Analyses

From the results in Table 2, we know that the set of syntactic features are working in the Arabic and English system. But the results also raise some questions: Are there interactions among the the syntactic features and other features? Why do the syntactic features work well for Arabic and English, but not Chinese? To answer these questions, we look into each system and report our findings in the following sections.

4.4.1 English System

Our system uses a group of distance features. One observation is that information provided by some syntactic features (e.g., $VP\_count(m_1, m_2)$ etc) may have overlapped with some of the distance features. To test if this is the case, we take out the distance features from the English system, and then train two systems, one with the syntactic features, one without. The results are shown in Table 3, where numbers on the row "b-dist" are F-measures after removing the distance features from the baseline, and numbers on the row "b-dist+synt" are with the syntactic features.

	Mention Type				
	NAM	NOM	PRE	PRO	Total
b-dist	84.2	68.8	74.6	63.3	72.5
b-dist+synt	**90.7**	**74.2**	**87.8**	**69.0**	**79.3**

Table 3: Impact of Syntactic Features on English System After Taking out Distance Features. Numbers are F-measures(%).

As can be seen, the impact of the syntactic features is much larger when the distance features are absent in the system: performance improves across all the four mention types after adding the syntactic features, and the overall F-measure jumps from 72.5% to 79.3%. The PRE type gets the biggest improvement since features extracted from parse trees include apposition, same-parent test, and dependency features, which are designed to help mention pairs in close distance, just as in the case of PRE mentions.

Comparing the numbers in Table 3 with the English baseline of Table 2, we can also conclude that distance features and syntactic features lead to about the same level of performance when the other set of features is not used. When the distance features are used, the syntactic features further help to improve the performance of the NOM and PRO mention type, albeit to a less degree because of information overlap between the two sets of features.

4.4.2 Chinese System

Results in Table 2 show that the syntactic features are not so effective for Chinese as for Arabic and English. The first thing we look into is if there is any idiosyncrasy in the Chinese language.

In Table 4, we list the statistics collected over the training sets of the three languages: the second row are the total number of mentions, the third row the number of pronoun mentions, the fourth row the number of events where the c-command feature $ccmd(m_1, m_2)$ is used, and the last row the average number of c-command features per pronoun (i.e., the fourth row divided by the third row). A pronouns event is defined as a tuple of training instance (e, m_1, m_2) where m_1 is a mention in entity e, and the second mention m_2 is a pronoun.

From Table 4, it is clear that Chinese pronoun distribution is very different: pronoun mentions account for about 8.7% of the total mentions in Chinese, while 29.0% of Arabic mentions and 25.1% of English mentions are pronouns (the same disparity can be observed in the devtest set in Table 2). This is because Chinese is a pro-drop language (Huang, 1984): for example, in the Chinese Penn treebank version 4, there are 4933 overt pronouns, but 5750 pro-drops! The ubiquity of pro-drops in Chinese results in signigicantly less pronoun training events. Consequently, the pronoun-related features are not trained as well as in English and Arabic. One way to quantify this is by looking at the average number of c-command features on a per-pronoun basis: as shown in the last row of Table 4, the c-command feature is seen more than twice often in Arabic and English as in Chinese. Since low-count features are filtered out, the sparsity of pronoun events prevent many compound features (e.g., conjunction of syntactic and distance features) from being trained in the Chinese system, which explains why the syntactic features do not help Chinese pronouns.

	Arabic	Chinese	English
#total-mentions	31706	33851	58202
#pron-mentions	9183	2941	14635
#-ccmd-event	10236	1260	13691
#ccmd/pron	1.14	0.428	0.936

Table 4: Distribution of Pronoun Mentions and Frequency of c-command Features

4.4.3 Arabic System

As stated in Table 4, 29.0% of Arabic mentions are pronouns, compared to a slightly lower number (25.1%) for English. This explains the relatively high positive impact of the syntactic features on the Arabic coreference system, compared to English and Chinese systems. To understand how syntactic features work in the Arabic system, we examine two examples extracted from the devtest set: (1) the first example shows the negative impact of syntactic features because of the noisy parsing output, and (2) the second example proves the effectiveness of the syntactic features to find the dependency between two mentions. In both examples, the baseline system and the system with syntactic features give different results.

Let's consider the following sentence:

... وتعتبر إسرِئيل **القدس** عَاصمتها ...

... its-capital ← Jerusalem ← Israel ← consider ← and ...

... فيمَا يريد الفلسطينيون الشطر الشرقي **لِلمدينة** ...

of-the-city ← the-Eastern ← the-half ← the-Palestininan ← want ← while

The English text shown above is a word-to-word translation of the Arabic text (read from right-to-left). In this example, the parser wrongly put the nominal mention القدس (Jerusalem) and the pronominal mention المدينة (the-city) under the same constituent, which activates the *same_parent* feature. The use of the feature *same_parent*(القدس, المدينة) leads to the two mentions being put into different entities. This is because there are many cases in the training data where two mentions under the same parent are indeed in different entities: a similar English example is "*John called his sister*", where "*his*" and "*sister*" belong to two different entities. The *same_parent* feature is a strong indicator of not putting them into the same entity.

كَان + **ال** + **زقَاقيون** + ي + حَاول + ون + نهب + ال + محل + ات + ال + تجَاري + ة ب + **حجة** + أَن + **هم** + ...
kAn + **Al** + **zqAqywn** + y + HAwl + wn + nhb + Al + mHl + At + Al + tjAry + p + b + Hjp + An + **hm** + ...
was + **the** + **zqAqywn** + *present-verb-marker* y + trying + *plural-verb-marker* wn + to-steal + the + office + s + the + commercial + s + with + excuse + that + **they** + ...

Table 5: An example where syntactic features help to link the PRO mention هم (hm) with its antecedent, the NAM mention الزقاقيون (AlzqAqywn): top – Arabic sentence; middle – corresponding romanized sentence; bottom – token-to-token English translation.

Table 5 shows another example in the devtest set. The top part presents the segmented Arabic text, the middle part is the corresponding romanized text, and the bottom part contains the token-to-token English translation. Note that Arabic text reads from right to left and its corresponding romanized text from left to right (i.e., the right-most Arabic token maps to the left-most romanized token). The parser output the correct syntactic structure: Figure 2 shows a portion of the system-generated parse tree. It can be checked that NP1 c-commands NP2 and the group of features inspired by the binding theory are active. These features help to link the PRO(onominal) mention هم (hm) with the NAM(e) mention الزقاقيون (AlzqAqywn). Without syntactic features theses two mentions were split into different entities.

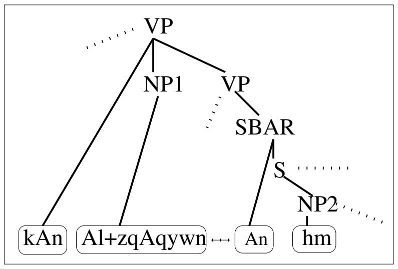

Figure 2: A Portion of the Syntactic Tree.

4.5 ACE 2004 Results

To get a sense of the performance level of our system, we report the results on the ACE 2004 official test set with both the F-measure and the official ACE-Value metric. This data is used as the blind test set which we run our system only once.

Results are summarized in Table 6, where the second row (i.e. "base") contains the baseline numbers, and the third row (i.e., "+synt") contains the numbers from systems with the syntactic features. Columns under "F" are F-measure and those under "AV" are ACE-Value. The last row N_m contains the number of mentions in the three test sets.

	Arabic		Chinese		English	
	F	AV	F	AV	F	AV
base	80.1	88.0	84.7	92.7	80.6	90.9
+synt	81.5	88.9	84.7	92.8	82.0	91.6
N_m	11358		11178		10336	

Table 6: Summary Results on the 2004 ACE Evaluation Data.

The performance of three full ("+synt") systems is remarkably close to that on the devtest set(cf. Table 2): For Arabic, F-measure is 80.1 on the devtest vs. 81.5 here; For Chinese, 84.9 vs. 84.7; And for English, 80.8 vs. 82.0. The syntactic features again help Arabic and English – statistically very significant in F-measure, but have no significant impact on Chinese. The performance consistency across the devtest and blind test set indicates that the systems are well trained.

The F-measures are computed on all types of mentions. Improvement on mention-types targeted by the syntactic features is larger than the lump-sum F-measure. For example, the F-measure for English pronouns on this test set is improved from 69.5% to 73.7% (not shown in Table 6 due to space limit). The main purpose of Table 6 is to get a sense of performance level correspondence between the F-measure and ACE-Value.

Also note that, for Arabic and English, the difference between the "base" and "+synt" systems, when measured by ACE-Value, is much smaller. This is not surprising since ACE-Value heavily discounts pronouns and is insensitive to improvement on pronouns – the very reason we adopt the F-measure in Section 4.3 and 4.4 when reporting the contrastive experiment results.

5 Related Work

Many researchers have used the syntactic information in their coreference system before. For example, Hobbs (1976) uses a set of rules that are applied to parse trees to determine the antecedent of a pronoun. The rule precedence is determined heuristically and no weight is used. Lappin and Leass (1994) extracted rules from the output of the English Slot Grammar (ESG) (McCord, 1993). Rule weights are assigned manually and the system resolves the third person pronouns and reflexive pronouns only. Ge et al. (1998) uses a non-parametrized statistical model to find the antecedent from a list of candidates generated by applying the Hobbs algorithm to the English Penn Treebank. Kehler et al. (2004) experiments making use of predicate-argument structure extracted from a large TDT-corpus. Compared with these work, our work uses machine-generated parse trees from which trainable features are extracted in a maximum-entropy coreference system, while (Ge et al., 1998) assumes that correct parse trees are given. Feature weights are automatically trained in our system while (Lappin and Leass, 1994; Stuckardt, 2001) assign weights manually.

There are a large amount of published work (Morton, 2000; Soon et al., 2001; Ng and Cardie, 2002; Yang et al., 2003; Luo et al., 2004; Kehler et al., 2004) using machine-learning techniques in coreference resolution. But none of these work tried to compute complex linguistic concept such as governing category [3]. Our work demonstrates how relevant linguistic knowledge can be derived automatically from system-generated parse trees and encoded into computable and trainable features in a machine-learning framework.

6 Conclusions

In this paper, linguistic knowledge is used to guide us to design features in maximum-entropy-based coreference resolution systems. In particular, we show how to compute a set of features to approximate the linguistic notions such as governing category and apposition, and how to compute the dependency features using syntactic parse trees. While the features are motivated by examining English data, we see significant improvements on both English and Arabic systems. Due to the language idiosyncrasy (e.g., pro-drops), we do not see the syntactic features change the Chinese system significantly.

[3]Ng and Cardie (2002) used a BINDING feature, but it is not clear from their paper how the feature was computed and what its impact was on their system.

Analyzing models for semantic role assignment using confusability

Katrin Erk and **Sebastian Padó**
Computational Linguistics
Saarland University
Saarbrücken, Germany
{erk,pado}@coli.uni-sb.de

Abstract

We analyze models for semantic role assignment by defining a *meta-model* that abstracts over features and learning paradigms. This meta-model is based on the concept of *role confusability*, is defined in information-theoretic terms, and predicts that roles realized by less specific grammatical functions are more difficult to assign. We find that confusability is strongly correlated with the performance of classifiers based on syntactic features, but not for classifiers including semantic features. This indicates that syntactic features approximate a description of grammatical functions, and that semantic features provide an independent second view on the data.

1 Introduction

Semantic roles have become a focus of research in computational linguistics during the recent years. The driving force behind this interest is the prospect that semantic roles, as a shallow meaning representation, can improve many NLP applications, while still being amenable to automatic analysis. The benefit of semantic roles has already been demonstrated for a number of tasks, among others for machine translation (Boas, 2002), information extraction (Surdeanu et al., 2003), and question answering (Narayanan and Harabagiu, 2004).

Robust and accurate *automatic semantic role assignment*, a prerequisite for the wide-range use of semantic roles in NLP, has been investigated in a number of studies and shared tasks. Typically, role assignment has been modeled as a classification task, with models being estimated from large corpora (Gildea and Jurafsky, 2002; Moschitti, 2004; Xue and Palmer, 2004; Surdeanu et al., 2003; Pradhan et al., 2004; Litkowski, 2004; Carreras and Màrquez, 2005).

Within this framework, there is a number of architectural parameters which lend themselves to optimization: the machine learning framework, the feature set, pre- and postprocessing, each of which has been investigated in the context of semantic role assignment. The current paper concentrates on feature engineering, since the feature set is a pivotal component of any kind of machine learning system, and allows us to incorporate and test linguistic intuitions on the role assignment task.

We approach feature engineering not by directly optimizing system performance. Instead, we proceed by *error analysis*, like Pado and Boleda (2004). Our aim is to form a *global hypothesis* that explains the distribution of errors across classes. Insofar as the model does not contain model-specific information, following this methodology can provide a *meta-model* of a model family which abstracts over concrete features and over the learning paradigm.

The concrete global hypothesis we test is: (1) All features of current models approximate a description of grammatical functions, and the complete systems approximate an assignment based on grammatical functions. (2) System performance for a given role depends on how easily it is confused with other roles. We will give this concept of *role confusability* a formal, information-theoretic definition.

The present study specifically analyzes models for semantic role assignment in the FrameNet paradigm (Fillmore et al., 2003). We are going to show that our hypothesis indeed holds for a variety of models – but only models that comprise exclusively syntactic features. We conclude that syntactic features approximate a description of grammatical functions, but that semantic features model a different aspect of the role assignment mapping. Together with the reasonable performance of a solely semantics-based system, this leads us to suggest a closer investigation of semantic features – and in particular, a co-training approach with syntactic and semantic features as different views on the role assignment data.

Plan of the paper. In Section 2, we give a brief introduction to FrameNet, the semantic role paradigm and corpus we are using in this study. Our first experiment, described in Section 3, establishes that there is a high variance in performance across roles, and that this variance is itself stable across models and learners. In Section 4, we state our hypothesis, namely that this variance can be explained through role confusability, and formalize the concept . In Section 5, we perform detailed correlation tests to verify our hypothesis and discuss our findings. Section 6 concludes the paper.

2 FrameNet

This section presents the semantic role paradigm and the role-annotated corpus on which the present study is based. FrameNet[1] is a lexical resource based on Fillmore's Frame Semantics (Fillmore, 1985). It describes *frames*, representations of prototypical situations. Each frame provides its set of semantic roles, the entities or concepts pertaining to the prototypical situation. Each frame is further associated with a set of *target predicates* (nouns, verbs or adjectives), occurrences of which can introduce the frame.

FrameNet provides manually annotated examples for each predicate, sampled from the British National Corpus (Burnard, 1995). The size of this corpus exceeds 135,000 sentences. The following sentences are examples for verbs in the IMPACT frame, which describes a situation in which typically "an IMPACTOR makes sudden, forcible contact with the IMPACTEE, or two IMPACTORS both ... [make] forcible contact":

[1]`http://www.icsi.berkeley.edu/~framenet/`

(1) [$_{\text{Impactee}}$ His car] was **struck** [$_{\text{Impactor}}$ by a third vehicle].

(2) [$_{\text{Impactor}}$ The door] **slammed** [$_{\text{Result}}$ shut].

(3) [$_{\text{Impactors}}$ Their vehicles] **collided** [$_{\text{Place}}$ at Pond Hill].

FrameNet manual annotation also comprises a layer of grammatical functions: For example, the subject of finite verbs is labeled `Ext`, and `Mod` is a label used for modifiers of heads, e.g. an adjective modifying a noun. The grammatical functions used in FrameNet are listed in Fillmore and Petruck (2003).

Note that the frame-specificity of semantic roles in FrameNet has important consequences for semantic role assignment, since there is no direct way to generalize role assignments across frames, and learning has to proceed frame-wise. This compounds the data sparseness problem, and automatic assignment for frames with no training data is very difficult (Gildea and Jurafsky, 2002).

3 Experiment 1: Variance in role assignment

Several studies have established that there is considerable variance in semantic role assignment performance across different semantic roles within systems (Carreras and Màrquez, 2004; Carreras and Màrquez, 2005; Pado and Boleda Torrent, 2004). However, these studies used either the PropBank semantic role paradigm (Carreras and Màrquez) or a limited of experimental conditions (Pado and Boleda). For this reason, we perform a first experiment to replicate this phenomenon in our setting.

Note that the vast majority of participant systems in recent shared tasks divides semantic role assignment into multiple sequential steps. The maximal decomposition is as follows: *preprocessing*, e.g. removal of unlikely argument candidates; *argument recognition*, the distinction between role-bearing and non-role-bearing instances; *argument labeling*, the actual classification of role-bearing instances; and *postprocessing*, e.g. by inference over probable role sequences.

Following this distinction, we concentrate in this study on the argument labeling step, i.e. distinguishing between roles, rather than distinguishing roles from non-roles. This is justified by earlier empirical results, namely that the argument labeling step requires more training data than argument recognition (Fleischmann and Hovy, 2003), and that it calls for more sophisticated feature construction (Xue and Palmer, 2004). We take this as evidence that the quality of the argument labeling step is central to a good semantic role assignment system.

In order to isolate the effects of argument labeling, we assume perfect argument recognition by using gold standard role boundaries; however, we do not use gold standard parse trees, but rather automatically computed ones, which realistically introduces some noise (see the following paragraph).

Data and preprocessing. As experimental material, we used the same data that was used in the Senseval-3 semantic role assignment task: 40 frames from FrameNet version 1.1, comprising 66,777 instances. The number of roles per frame ranged from 2 to 22, and the number of role instances ranged from 593 to 8,378. The data was randomly split into training (90%) and test instances (10%).

The data was parsed with the Collins model 3 (1996) parser; in addition, all tokens were lemmatized with TreeTagger (Schmid, 1994).

Modeling. We model role assignment as a classification task, with parse tree constituents as instances to be classified. We repeated the classification with two different learners: The first learner, TiMBL (Daelemans et al., 2003) is an implementation of nearest-neighbor classification algorithms in the memory-based learning paradigm[2]. The second learner, Malouf's probabilistic maximum entropy (Maxent) system (Malouf, 2002), uses the LMVM algorithm to estimate log-linear models. We did not perform smoothing.

Table 5 shows the features we use. Here as in the system setup, we keep close to current existing models for semantic role assignment in order to make our results as representative as possible. We investigate different feature sets in order to verify our results. In Exp. 1, we limit ourselves to two feature sets, *Syn* (syntactic features) and *Sem* (lexical features) from the bottom of Table 5. The feature sets were exactly the same for both learners.

[2]TiMBL was set to k-NN classification, using the MVDM distance metric and 5 neighbors.

	Syn/Sem	Syn
MBL	87.1 ± 12.7	82.2 ± 17.8
Maxent	87.5 ± 13.4	$82.4 \pm 18.\ 2$

Table 2: Exp. 1: Role-specific figures of system performance for four example frames.

Results. Table 1 shows the systems' overall F-scores and standard deviation across roles. Table 2 illustrates the differences in performance across roles on four frames: It lists all roles with ≥ 5 occurrences for each frame. PART_ORIENTATIONAL shows very little variance, while the roles of CHANGE_POSITION_ON_A_SCALE and especially TRAVEL differ widely. For KINSHIP, the system shows good performance for both roles, but the F-scores still differ by around 9 points.

Discussion. Table 1 shows that there is considerable variance across roles, with a standard deviation in the range of 18% for the syntax-only model. We note that the deviation decreases to 13% for the combined syntax-semantics model. Table 2 confirms that this is not purely between-frames, but also within-frames variance. This confirms the phenomenon described at the beginning of this section.

4 A meta-model for role assignment: Confusability

The experiment of the previous section has shown a considerable variance in system performance across roles. The aim of this section is to develop a meta-model which can explain this variance.

The models we have explored in Exp. 1 rely mainly on syntactic features: Even in the combined syntax-semantics model, 24 of the 31 features describe syntactic structure. This predominance of syntactic features can be observed in many current models for semantic role assignment. Accordingly, our meta-model focuses on the uniformity of the mapping from syntactic structure to semantic roles. We formalize the variance in this mapping by the *confusability* of a semantic role. It implements the following hypothesis:

(1) The semantic role assignment systems we study approximate role assignment through grammatical functions.

(2) System performance for a given role depends on the role's *confusability*: A role is highly confusable if the grammatical functions that instantiate it often also instantiate other roles.

By using the ideal, manually assigned grammatical functions that are available from the FrameNet data – and which are not passed on to the learner – our meta-model abstracts over concrete feature sets.

Our definition of confusability proceeds in two steps. First we model the informativity of a grammatical function by the entropy of semantic roles that it maps to. Then we compute the confusability of a role as a weighted average of the entropies of the grammatical functions that realize it.

Grammatical function entropy. Viewing a grammatical function as a random variable with semantic roles as values, we define the entropy of a grammatical function *gf* within the frame *fr* as

$$H_{fr}(gf) = \sum_{fe \in fes(fr)} -p(fe|gf) \log p(fe|gf)$$

where $p(fe|gf) = \frac{f(gf,fe)}{f(gf)}$ is the conditional probability of roles *fe* given *gf* (cf. the notation in Table 3).

Role confusability. The confusability of a role is the sum of its grammatical function entropies, weighted by the conditional probabilities $p(gf|fe) = \frac{f(gf,fe)}{f(fe)}$ of grammatical functions *gf* given *fe*.

$$c_{fr}(fe) = \sum_{gf \in gfs(fr)} p(gf|fe) H_{fr}(gf)$$

Grammatical function entropy					
GF	DEG	THM	DEP	LOC	H
`Mod`	69	43	24	0	1.46
`Comp`	18	491	12	41	0.72
`Ext`	0	17	0	561	0.16

Table 4: Grammatical function entropy and role confusability for the frame ABUNDANCE

An example. Table 4 shows the grammatical function entropies and role confusabilities for the frame ABUNDANCE, both computed on the training data. The upper part of Table 4 lists the entropies of the grammatical functions `Mod`, `Comp`, `Ext`, `Head` and `Obj`[3] and the counts $f(gf, fe)$ of occurrences of the grammatical functions together with the roles DEGREE (DEG), THEME (THM), DEPICTIVE (DEP) and LOCATION (LOC). The entropy of `Mod`, with similar numbers of occurrences for three different roles, is relatively high, while `Ext` occurs almost exclusively for one role and has a much lower entropy. The lower part of Table 4 shows the confusability for the same set of roles. The confusability of

[3]See Fillmore and Petruck (2003) for a glossary of FrameNet's grammatical functions.

DEGREE is relatively high even though it is mostly realized by `Mod` because `Mod` has a high entropy, i.e. it indicates multiple roles; LOCATION on the other hand is not very confusable even though it occurs frequently as both `Ext` and `Head`, since both grammatical functions indicate this role.

Related work. Our approach is similar to Pado and Boleda (2004) in that they also use the uniformity of linking as an explanation for performance variations in semantic role assignment. However, their analysis is located at the frame level. We examine individual roles, which allows us to derive a simpler and more intuitive formalization of linking uniformity. Also, our model will ultimately lead us to a different conclusion: the uniformity of linking is a good predictor of the performance of role assignment systems, but only for exclusively syntactic models (see Section 5).

5 Experiment 2: Relating confusability and system performance

In this section, we test the validity of our metamodel. We assess whether confusability, defined in Section 4, can explain the variance in role assignment that we have found in Section 3, by testing the correlation between the two variables.

Experimental setup. We use the same data set (Senseval-3) and the same two classifiers (memory-based and maximum entropy classification) as in Exp. 1. To cover a wider range of models and thus increase the validity of our analysis, we split up the *Syn* feature set from Exp. 1 into the four smaller sets described in the upper part of Table 5. We use these sets individually, combined, and together with the lexical features in the *Sem* set. This results in a total of 20 different models (10 for each classifier), for which we computed role-specific F-scores.

In parallel, we estimated the confusability as described in Section 4, with FrameNet's manually assigned grammatical functions as a basis, using only the training portion of our data. We did not smooth, but omitted roles occurring less than 5 times to avoid sparse and thus unreliable data points. Recall that confusability does not vary with the feature set, since its central asset is to abstract over concrete model parameters and feature sets.

Feature set	F_{MBL}	F_{Maxent}
Path0	70.9	71.3
Path	73.3	72.6
Pt	78.8	79.0
Path/Pt	80.8	79.8
Path/Sibling	76.7	76.6
Pt/Sibling	78.8	79.1
Syn	82.2	82.4
Sem	80.3	80.7
Syn/Sem	87.1	87.5

Table 6: Exp. 2: Results for different feature sets

Results. The F-scores for the subdivided *Syn* feature set are shown in the upper part of Table 6, with the complete *Syn* and *Sem* sets and their combination below. There is a clear relationship between features and F-score: additional features are consistently rewarded with higher performance. Interestingly, phrase type information appears to be a better role predictor than path (compare models *Path* and *Pt*). Also, the semantic feature set alone (*Sem*) performs at over 80% F-Score, slightly better any of the individual syntactic feature groups.

The high F-score variance between individual roles which we have shown for the feature sets *Syn* and *Syn/Sem* in Exp. 1 generalizes to the other feature sets; all individual syntactic feature sets exhibit a higher variance than *Syn*, and *Sem* shows a higher variance than the *Syn/Sem* combination. This does not come as a surprise, since the two models of Exp. 1 use the two richest feature sets, and we would expect less robust behavior for weaker models. Another point to note is that the performance of the two learners is remarkably similar.

The high variance in the F-scores is mirrored in the confusability figures; we obtain an average confusability for our semantic roles of 1.79 with a high standard deviation of 0.84. A scatter plot of F-scores against confusability figures (Fig.1) suggests a linear correlation analysis.

Analysis 1: Correlating confusability and F-score. Since the data does not appear to be normally distributed, we apply Kendall's nonparametric rank test. The results, which are listed in Table 7, show an extremely significant negative correlation between confusability and F-score: higher confus-

Path0	These are features centered around the path from the target lemma to the constituent: the path itself, its length, partial path up to the lowest common ancestor, the grammatical rule that expands the target predicate's parent, relative position of constituent to target
Path	Feature set Path, plus target lemma
Pt	These are features related to phrase type and part of speech: the phrase type of the constituent and its parent, the POS of the constituent first word, last word and head as well as the POS of an informative content word of the constituent (for PP and SBar constituents only: the head of the head's complement), as well as the target lemma
Sibling	Phrase type and POS of the head of the left and right sibling constituent, and the Collins parser's judgment on the argumenthood of the constituent
Syn	This set combines Path, Sibling and Pt. Additional features are: target voice; the constituent's preposition; a feature combining path with target voice and target POS; and two rule-based features judging argumenthood and grammatical function of the constituent
Sem	These are lexical features: Head words of the constituent and of its left and right siblings; leftmost and rightmost word of the constituent; informative content word lemma (see set Pt for details); and the governing verb of the target predicate

Table 7: Exp. 2, Analysis 1: Correlation between F-Score and confusability. z: Kendall's tau coefficient, p: significance level

ability appears to be related to lower F-score.

However, note that the correlation is extremely significant even for the model which only uses semantic features. This is unexpected at best and makes a strong interpretation of this correlation doubtful: it is rather likely that there is a third variable with which both F-score and confusability are correlated. The most obvious candidate for such a *confounding variable* is the size of the training set – clearly, we expect our models to perform better with larger training sets. In order to get a more realistic assessment of the relationship between confusability and F-score, we perform an additional analysis to disconfound confusability and frequency.

Analysis 2: Disconfounding confusability and frequency. One way of factoring out the influence of a confounding variable is to perform a partial correlation analysis, which explicitly removes the effects of a third variable when determining the strength of a correlation between two variables. Like a normal correlation analysis, it yields a *partial correlation coefficient*.

Table 8: Exp. 2, Analysis 2: Partial correlation coefficients. r_c: correlation between F-score and confusability, controlling for training set size. r_f: correlation between F-score and training set size, controlling for confusability. Significance levels: ***: $p<0.001$; **: $p<0.01$; *: $p<0.05$.

We first compute partial correlation coefficients between F-score and confusability, controlling for training set size. The results, which indicate the "true" relationship between performance and confusability, are shown in the r_c columns of Table 8. For both learners, confusability is significantly correlated with F-score for all syntactic feature sets, but not for the semantic feature set and for the combined set *Syn/Sem*.

We also compute the partial correlation coefficients between F-score and training set size, controlling for confusability. These figures are reported in the r_f columns of Table 8 and show the "true" relationship between performance and training set size. There is no significant correlation between training set size and performance for simple syntax based-models, but the correlation is highly significant for complex syntactic models and all semantic models.

Discussion. The partial correlation analysis confirms that confusability is a meta-model that can explain the performance of a range of different models for semantic role assignment, namely those models which rely exclusively on syntactic features. Since we used the gold standard features provided by FrameNet and did not introduce implementation- or feature-specific knowledge, this points to a general limitation of syntax-based models. In contrast, semantic features behave completely differently; their contribution is not limited by a role's confusability. At the very least, it cannot be captured by our current meta-model, but the absolute increase in performance indicates that integrating semantics is the way forward, which is surprising given that the purely lexical features we use the present study are usually extremely sparse.

The analysis of the partial correlation between F-score and training set size also allows interesting conclusions. The correlation is not significant for small syntactic feature sets like *Path*, indicating that models for such features can be learned satisfactorily from relatively small training sets (but which are also limited in expressivity). This is markedly different for richer feature sets. Arguably, these feature sets are sparser and can therefore profit more from an increased amount of training data. Again, the effect is most pronounced for the semantic feature set.

6 Conclusion

In this paper, we have formulated a *meta-model* for semantic role assignment. We have used the *confusability* of roles to predict classification performance independently of the classification framework and feature sets used. We have defined role confusability in two steps: First, we have formalized the certainty with which we can predict a semantic role from a given grammatical function with *grammatical function entropy*. Then, we have defined the *confusability of a role* as a weighted sum of grammatical function entropies.

We have found that role confusability is highly significantly correlated with system performance for models based solely on syntactic features. We conclude that syntactic features approximate a description of grammatical functions, but that semantic features model a different aspect of the world.

Much of current research in semantic role assignment is centered on the refinement of syntactic features. Our study suggests that it may be worthwhile to explore the refinement of semantic features as well. The most obvious choice is to investigate features related to selectional preferences. Possible features include goodness of fit relative to pre-computed preferences (Baldewein et al., 2004), named entities (Pradhan et al., 2004), or broad ontological classes like "animate" or "artifact". Following up on this idea, a natural continuation of the present study would be to create a meta-model that subsumes *semantic* features. Such a model could use optimal selectional restrictions as a predictor. The next step would then be to construct a combined meta-model that describes the behavior of systems with both syntactic and semantic features.

Another interesting research direction that our study suggests is the combination of syntactic and semantic models in co-training. Co-training can be sensibly applied only when conditional independence holds for the two target functions and the distribution (Blum and Mitchell, 1998), i.e. when it uses two independent views on the instance set. By pointing out a highly significant distinction between syntactic and semantic features with respect to role confusability, our study provides empirical evidence that syntactic and semantic features model different aspects of the role assignment mapping, and that co-training may be feasible by using syntactic and semantic features as views.

Abstract

In statistical machine translation, estimating word-to-word alignment probabilities for the translation model can be difficult due to the problem of sparse data: most words in a given corpus occur at most a handful of times. With a highly inflected language such as Czech, this problem can be particularly severe. In addition, much of the morphological variation seen in Czech words is not reflected in either the morphology or syntax of a language like English. In this work, we show that using morphological analysis to modify the Czech input can improve a Czech-English machine translation system. We investigate several different methods of incorporating morphological information, and show that a system that combines these methods yields the best results. Our final system achieves a BLEU score of .333, as compared to .270 for the baseline word-to-word system.

1 Introduction

In a statistical machine translation task, the goal is to find the most probable translation of some foreign language text f into the desired language e. That is, the system seeks to maximize $P(e|f)$. Rather than maximizing $P(e|f)$ directly, the standard noisy channel approach to translation uses Bayes inversion to split the problem into two separate parts:

$$\underset{e}{\operatorname{argmax}} \mathrm{P}(e|f) = \underset{e}{\operatorname{argmax}} \mathrm{P}(e)\mathrm{P}(f|e) \qquad (1)$$

where $P(e)$ is known as the *language model* and $P(f|e)$ is known as the *translation model*. The limiting factor in machine translation is usually the quality of the translation model, since the monolingual resources needed for training the language model are generally more available than the parallel corpora needed for training the translation model.

Due to the difficulty in obtaining large parallel corpora, sparse data is a serious issue when estimating the parameters of the translation model. This problem is compounded when one or both of the languages involved is a highly inflected language. In this paper, we present a series of experiments suggesting that morphological analysis can be used to reduce data sparseness and increase similarity between languages, thus improving the quality of machine translation for highly inflected languages. Our work is on a language pair in which the input language (Czech) is highly inflected, and the output language (English) is not. We discuss in Section 5 how our methods might be generalized to pairs where both languages are highly inflected.

The plan of this paper is as follows: In Section 2, we review previous work on using morphological analysis for statistical machine translation. In Section 3, we describe several methods for utilizing morphological information in a statistical translation model. Section 4 presents the results of our experiments using these methods. Sections 5 and 6 discuss the results of our experiments and conclude the paper.

2 Previous Work

Until recently, most machine translation projects involved translating between languages with relatively little morphological structure. Nevertheless, a few research projects have investigated the use of morphology to improve translation quality. Niessen and Ney (2000; 2004) report work on German-English translation, where they investigate various types of morphosyntactic restructuring, including merging German verbs with their detached prefixes, annotating a handful of frequent ambiguous German words with POS tags, combining idiomatic multi-word expressions into single words, and undoing question inversion and *do*-insertion in both German and English. In addition, Niessen and Ney (2004) decompose German words into a hierarchical representation using lemmas and morphological tags, and use a MaxEnt model to combine the different levels of representation in the translation model. The results from these papers indicate that on corpus sizes up to 60,000 parallel sentences, the restructuring operations yielded a large improvement in translation quality, but the morphological decomposition provided only a slight additional benefit. However, since German is not as morphologically complex as Czech, we might expect a larger benefit from morphological analysis in Czech.

Another project utilizing morphological analysis for statistical machine translation is described by Lee (2004). Lee's system for Arabic-English translation takes as input POS-tagged English and Arabic text, where the Arabic words have been pre-segmented into stems and affixes. The system performs an initial alignment of the Arabic morphemes to the English words. Based on the consistency of the English POS tag that each Arabic morpheme aligns to, the system determines whether to keep that morpheme as a separate item, merge it back onto the stem, or delete it altogether. In addition, multiple occurrences of the determiner *Al* within a single Arabic noun phrase are deleted (i.e. only one occurrence is allowed). Using a phrase-based translation model, Lee found that *Al*-deletion was more helpful than the rest of the morphological analysis. Also, *Al*-deletion helped for training corpora up to 3.3 million sentences, but the other morphological analysis helped only on the smaller corpus sizes (up to 350,000 parallel sentences). This result is consistent with anecdotal evidence suggesting that morphological analysis becomes less helpful as corpus sizes increase. However, since parallel corpora of hundreds of thousands of sentences or more are often difficult to obtain, it would still be worthwhile to develop a method for improving systems trained on smaller corpora.

Previous results on Czech-English machine translation suggest that morphological analysis may be quite productive for this highly inflected language where there is only a small amount of closely translated material. Čmejrek et al. (2003), while not focusing on the use of morphology, give results indicating that lemmatization of the Czech input improves BLEU score relative to baseline. These results support the earlier findings of Al-Onaizan et al. (1999), who used subjective scoring measures. Al-Onaizan et al. measured translation accuracy not only for lemmatized input, but for an input form they refer to as *Czech'*. Czech' is intended to capture many of the morphological distinctions of English, while discarding those distinctions that are Czech-specific. The Czech' input was created by distinguishing the Czech lemmas for singular and plural nouns, different verb tenses, and various inflections on pronouns. Artificial words were also added automatically in cases where syntactic information in the Czech parse trees indicated that articles, pronouns, or prepositions might be expected in English. The transformation to Czech' provided a small additional increase in translation quality over basic lemmatization.

The experiments described here are similar to those performed by Al-Onaizan et al. (1999), but there are several important differences. First, we use no syntactic analysis of the Czech input. Our intent is to determine how much can be gained by a purely morphological approach to translation. Second, we present some experiments in which we modify the translation model itself to take advantage of morphological information, rather than simply transforming the input. Finally, our use of BLEU scores rather than subjective measurements allows us to perform more detailed evaluation. We examine the effects of each type of morphological information separately.

3 Morphology for MT

Morphological variations in Czech are reflected in several different ways in English. In some cases, such as verb past tenses or noun plurals, morphological distinctions found in Czech are also found in English. In other instances, English may use function words to express a meaning that occurs as a morphological variant in Czech. For example, genitive case marking can often be translated as *of* and instrumental case as *by* or *with*. In still other instances, morphological distinctions made in Czech are either completely absent in English (e.g. gender on common nouns) or are reflected in English syntax (e.g. many case markings). Handling these correspondences between morphology and syntax requires analysis above the lexical level and is therefore beyond the scope of this paper. However, morphological analysis of the Czech input can potentially be used to improve the translation model by exploiting the other types of correspondences we have mentioned.

Before we describe how this can be done, it is important to clarify the kind of morphological analysis we assume in our input. Our data comes from the Prague Czech-English Dependency Treebank (PCEDT) (Hajič, 1998; Čmejrek et al., 2004), the Czech portion of which has been fully annotated with morphological information. Each Czech word in the corpus is associated with an analysis containing the word's lemma and a sequence of morphological

Figure 1: A sentence from the PCEDT corpus. Each token is followed by its lemma and a string giving the values of up to 15 morphological tags. Dashes indicates tags that are not applicable for a particular token. This sentence corresponds to the English sentence *It would make sense for somebody to do it.*

tags. These tags provide values along several morphological dimensions, such as part of speech, gender, number, tense, and negation. There are a total of 15 dimensions along which words may be characterized, although most words have a number of dimensions unspecified. An example sentence from the Czech corpus is shown in Figure 1.

In what follows, we describe four different ways that the Czech lemma and tag information can be used to modify the parameters of the translation model. The first three of these are similar to the work of Al-Onaizan et al. (1999) and involve transformations to the input data only. The assumptions underlying the word alignment model $P(f_j|e_i)$ (where f_j and e_i are individual words in an aligned sentence pair) are maintained. The fourth method of incorporating morphological information is novel and changes the alignment model itself.

3.1 Lemmas

A very simple way to modify the input data using morphological information is by replacing each wordform with its associated lemma (see Figure 2). Based on previous results (Al-Onaizan et al., 1999; Čmejrek et al., 2003), we expected that this transformation would lead to an improvement in translation quality due to reduction of data sparseness. However, since lemmatization does remove some useful information from the Czech wordforms, we also tried two alternative lemmatization schemes. First, we tried lemmatizing only certain parts of speech, leaving other parts of speech alone. We reasoned that nouns, verbs, and pronouns all carry inflectional morphology in English, so by lemmatizing only the other parts of speech, we might retain some of the benefits of full lemmatization without losing as much information. We also tried lemmatizing all parts of speech except pronouns, which are very common and therefore should be less affected by sparse data problems.

As a second alternative to full lemmatization, we experimented with lemmatizing only the less frequent wordforms in the corpus. This allows the translation system to use the full wordform information from more frequent forms, where sparse data is less of a problem.

To determine whether knowledge of lemmas was actually necessary, we compared lemmatization with word truncation. We truncated each wordform in the data after a fixed number of characters, as suggested by Och (1995).

3.2 Pseudowords

As discussed earlier, much of the information encoded in Czech morphology is encoded as function words in English. One way to reintroduce some of the information lost during Czech lemmatization is by using some of the morphological tags to add extra "words" to the Czech input. In many cases, these pseudowords will also increase the correspondence of English function words to items in the Czech input. In our system, each pseudoword encodes a single morphological tag (feature/value pair), such as PER_1 ('first person') or TEN_F ('future tense'). Figure 2 shows a Czech input sentence after generating pseudowords for the person feature on verbs.

We expected that the class of tags most likely to be useful as pseudowords would be the person tags, because Czech is a pro-drop language. Using the person tags as pseudowords should simulate the existence of pronouns for the English pronouns to align to. We also expected that negation (which is expressed on verbs in Czech) would be a useful pseudoword, and that case markings might also be helpful since they sometimes correspond to prepositions in English, such as *of*, *with*, or *to*.

3.3 Modified Lemmas

In some cases, such as the past tense, Czech morphology is likely to correspond not to a function word in English, but rather to English inflectional morphology. In order to capture this kind of phenomenon, we experimented with concatenating the Czech morphological tags onto their lemmas instead of inserting them as separate input tokens. See Figure 2 for an example. This concatenation creates distinctions between some lemmas, which will ideally correspond to morphological distinctions made in English. Although this transformation splits the Czech data (relative to pure lemmatization), it still suppresses many of the distinctions made in the full Czech wordforms. We expected that number mark-

Words:	`Pro někoho by její provedení mělo smysl .`
Lemmas:	`pro někdo být jeho provedení mít smysl .`
Lemmas+Pseudowords:	`pro někdo být PER_3 jeho provedení mít PER_X smysl .`
Modified Lemmas:	`pro někdo být+PER_3 jeho provedení mít+PER_X smysl .`

Figure 2: Various transformations of the Czech sentence from Figure 1. The pseudowords and modified lemmas encode the verb person feature, with the values 3 (third person) and X ("any" person).

ing on nouns and tense marking on verbs would be the tags best treated in this way.

3.4 Morphemes

Our final set of experiments used the same input format as the Modified Lemma experiments. However, in this set of experiments, we changed the model used to calculate the word-to-word alignment probabilities. In the standard system, the alignment model parameters $P(f_j|e_i)$ are found using maximum likelihood estimation based on the expected number of times f_j aligns to e_i in the parallel corpus. Our new model assumes a compositional structure for f_j, so that $f_j = f_{j0} \dots f_{jK}$, where f_{j0} is the lemma of f_j, and $f_{j1} \dots f_{jK}$ are morphemes generated from the tags associated with f_j. We assume that every word contains exactly K morphemes, and that the kth morpheme in each word is used to encode the value for the kth class of morphological tag, where the classes (e.g. person or tense) are assigned an ordering beforehand. f_{jk} is assigned a null value if the value of the kth tag class is unspecified for f_j.

Given this decomposition of words into morphemes, and a generative model in which each morpheme in f_j is generated independently conditioned on e_i, we have

$$\mathrm{P}(f_j|e_i) = \prod_{k=0}^{K} \mathrm{P}(f_{jk}|e_i) \tag{2}$$

We can now estimate $\mathrm{P}(f_j|e_i)$ using a slightly modified version of the standard EM algorithm for learning alignment probabilities. During the E step, we calculate the expected alignment counts between Czech morphemes and English words based on the current word alignments, and revise our estimate of $\mathrm{P}(f_j|e_i)$ using Equation 2. The M step of the algorithm remains the same.

The morpheme-based model in Equation 2 is similar to the modified lemma model in that it removes much of the differentiation between Czech wordforms, but leaves the differences that are most likely to appear as inflection on English words. However, it also performs an additional smoothing function. The model assumes that, in the absence of other information, an English word that has aligned mostly to Czech words with a particular morphological tag is more likely to align to another word with this tag than to a Czech word with a different tag. For example, an English word aligned to mostly past tense forms is more likely to align to another past tense form than to a present or future tense form.

4 Experiments

In order to evaluate the effectiveness of the techniques described in the previous section, we ran a number of experiments using data from the PCEDT corpus. The English portion of this corpus (used to train the language model) contains the same material as the Penn WSJ corpus, but with a different division into training, development, and test sets. About 250 sentences each for development and test were translated once into Czech and then back into English by five different translators. These translations are used to calculate BLEU scores. The remainder of the corpus (about 50,000 sentences) is used for training. About 21,000 of the training sentences have been translated into Czech and morphologically annotated for use as a parallel corpus.

Some statistics on the parallel corpus are shown in the graph in Figure 3. This graph illustrates the sparse data problem in Czech that our morphological analysis is intended to address. Although the number of infrequently occurring lemmas is about the same in both English and Czech, the number of infrequently occurring inflected wordforms is approximately twice as high in Czech.[1]

For all of our experiments, we used the same language model, trained with the CMU Statistical Language Modelling Toolkit (Clarkson and Rosenfeld, 1997). Our translation models were trained using GIZA++ (Och and Ney, 2003), which we modi-

[1]Although we did not use it for the experiments in this paper, the PCEDT corpus does contain lemma information for the English data. There is a slight discrepancy between the English and Czech data in the lemma information for pronouns, in that English pronouns (including accusitive, possessive, and other forms) are assigned themselves as lemmas, whereas Czech pronouns are reduced to uninflected forms. Given that pronouns generally have many tokens, this discrepancy should not affect the data in Figure 3.

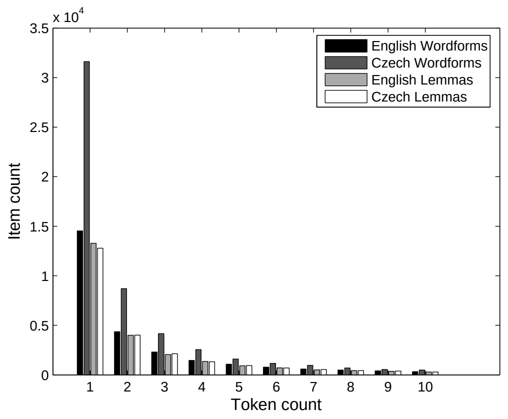

Figure 3: The number of items (full wordforms or lemmas) y appearing in the parallel corpus with a token count of x.

fied as necessary for the morpheme-based experiments. We used the ISI ReWrite Decoder (Marcu and Germann, 2005) for producing translations. Before beginning our experiments, we obtained a baseline BLEU score by training a standard word-to-word translation model. Our baseline results indicate that the test set for this corpus is considerably more difficult than the development set: word-to-word scores were .311 (development) and .270 (test).

4.1 Lemmas

As Figure 3 shows, lemmatization of the Czech corpus cuts the number of unique items by more than half, and the number of items with no more than ten occurrences by nearly half. The lemmatization BLEU scores in Table 1 indicate that this has a large impact on the quality of translation. As expected, full lemmatization performed better than word-to-word translation, with an an improvement of about .04 in the development set BLEU score and .03 in the test set. (In this and the following experiments, BLEU score differences of .009 or more are significant at the .05 level.) Experiments on the development set showed that leaving certain parts of speech unlemmatized did not improve results, but lemmatizing only low-frequency words did. A frequency cutoff of 50 worked best on the development set (i.e. only words with frequency less than 50 were lemmatized). Despite the improvement on the development set, using this cutoff with the test set yielded only a non-significant improvement over full lemmatization.

The results of these lemmatization experiments support the argument that lemmatization improves translation quality by reducing data sparseness, but also removes potentially useful information. Our results suggest that lemmatizing only infrequent words may, in some cases, work better than lemmatizing all words.

	Dev	Test
word-to-word	.311	.270
lemmatize all	.355	.299
except Pro	.350	
except Pro, V, N	.346	
lemmatize $n < 50$	.370	.306
truncate all	.353	.283

Table 1: BLEU scores for the word-to-word baseline, lemmatization, and word truncation experiments.

As Table 1 indicates, it is possible to get some of the benefits of lemmatization without using any morphological knowledge at all. For both dev and test sets, truncating words to 6 characters (the best length on the dev set) provided a significant improvement over word-to-word translation, but was also significantly worse than the best lemmatization scores. Changing the frequency cutoff for truncation did not produce any significant differences in the BLEU score.

4.2 Pseudowords

Results for the pseudoword experiments on the development set are shown in the first column of Table 2. Note that in these (and the following) experiments, we treated all words the same way regardless of their frequency, so the effects of adding morphological information are in comparison to the full lemmatization scheme. In most of our experiments, we added morphological information for only a single class of tags at a time in order to determine the effects of each class individually. The classes we used were verb person (PER), verb tense (TEN), noun number (NUM), noun case (CASE), and negation (NEG).

Most of the results of the pseudoword experiments confirm our expectations. Adding the verb person tags was helpful, and examination of the alignments revealed that they did indeed align to English pronouns with high probability. The noun number tags did not help, since plurality is expressed as an affix in English. Negation tags helped slightly, though the improvement was not significant. This is probably because negation tags are relatively infrequent, as can be seen in Table 3. The addition of pseudowords for case did not yield an improvement, probably because these pseudowords were so frequent. The additional ambiguity caused by so many extra words likely overwhelmed any positive effect.

A somewhat puzzling result is the behavior of the

Tag type	Pseudo	Mod-Lem	Morph
PER	.365	.356	.356
TEN	.365	.361	.364
PER,TEN	.355	.362	.355
NUM	.354	.367	.361
CASE	.353	.340	.337
NEG	.357	.356	.353

Table 2: BLEU scores indicating the results of incorporating the information from different classes of morphological tags in the the experiments using pseudowords (Pseudo), modified lemmas (Mod-Lem), and morphemes (Morph). Scores are from the development set. Differences of .009 are significant ($p < .05$).

Tag class	Count	Avg/sentence
PER	49700	2.35
TEN	47744	2.26
past	22544	1.07
pres	20291	0.96
fut	1707	0.08
'any'	3202	0.15
NUM	151646	7.17
CASE	151646	7.17
NEG	3326	0.16

Table 3: Number of occurrences of each class of tags in the Czech training data.

verb tense tags. With the exception of future tense, English generally does not mark tense with an auxiliary. Yet Table 3 shows that only a very small percentage of sentences have a future tense marker, so it seems unlikely that this explains the positive effects of the tense pseudowords. In fact, we tried adding only future tense pseudowords to the lemmatized Czech data, and found that the results were no better than basic lemmatization.

The other unusual behavior we see with pseudowords is that when verb person and tense tags are combined, they seem to cancel each other out, resulting in a score that is no better than lemmatization alone. Examination of the alignments did not reveal any obvious reason for this effect.

4.3 Modified Lemmas

As shown in the second column of Table 2, the number and tense tags yield an improvement under the modified lemma transformation, while the person tags do not. Again, this confirms our predictions based on the morphology of English.

Our results using the case tags under this model actually decreased performance, but this is not surprising given that differentiating Czech lemmas based on case marking creates as much as a 7-way split of the data (there are seven cases in Czech), without adding much information that would be useful in English.

4.4 Morphemes

BLEU scores for the morpheme-based model are given in the third column of Table 2. None of the differences in scores between this model and the modified lemma model are significant, although the trend for most of the tag classes is for this model to perform slightly worse. This suggests that the type of smoothing induced by the morpheme-based model may not be as helpful as simply attempting to create Czech words that reflect the same morphological distinctions as the English words. In Section 5, we propose a generalized version of the morpheme model that might be an improvement.

4.5 Combined Model

In the experiments described so far, we used only a single method at a time of incorporating morphological information into the translation process. However, it is straightforward to combine the pseudoword method with either the modified-lemma or morpheme-based methods by using pseudowords for certain tags and attaching others to the Czech lemmas. The experiments described above allowed us to confirm our intuitions about how each class of tags should be treated under such a combined model. We then created a model using the pseudoword treatment of the person and negation tags, and the modified lemma treatment of number and tense. We did not use the case tags in this model, since they did not seem to yield an improvement in any of the three basic morphological models.

Our combined model achieved a BLEU score of .390 (development) and .333 (test), outperforming the models in all of our previous experiments.

5 Discussion

The results of our experiments provide additional support for the findings of previous researchers that using morphological analysis can improve the quality of statistical machine translation for highly-inflected languages. While human judgment is probably the best metric for evaluating translation quality, our use of the automatically-derived BLEU score allowed us to easily compare many different translation models and evaluate the effects of each one individually. We found that simple lemmatization, by significantly reducing the sparse data problem, was quite effective despite the loss of information involved. Lemmatizing the less frequent words in the corpus seemed to increase performance slightly, but these results were inconclusive. Word truncation, which requires no morphological information at all, was effective at increasing scores over the word-to-word baseline, but did not perform quite as well as lemmatization. This result conflicts with Och's (Och, 1995), and is likely due to the much smaller size of our corpus. In any case, our results suggest that lemmatization or word truncation could yield a significant improvement in the quality of translation from a highly-inflected to a less-inflected language, even when limited morphological information is available.

Our primary results concern the use of full morphological information. We found that certain tags were more useful when we treated them as discrete input words, while others provided a greater benefit when attached directly to their lemmas. The best choice of which method to use for each class of tags seems to correspond closely with how that class of information is expressed in English (either using function words or inflection). In a sense, the goal of the morphological analysis is to make the Czech input data more English-like by suppressing unnecessary morphological distinctions and expressing necessary distinctions in ways that are similar to English. This sort of procedure could be taken further by incorporating syntactic information as well, but as we stated earlier, our goal was to determine exactly how much benefit we could derive from a strictly morphological approach.

In the work we have presented, the output language (English) is low in inflection. We therefore considered it less important to perform morphological analysis on the English data. However, we expect that the work described here could be generalized to highly inflected output languages by doing morphological analysis on both the input and output languages. The most promising way to do this seems to be by extending the morpheme-based translation model in Equation 2 to incorporate morphemes in both languages, so that

$$\mathrm{P}(f_j|e_i) = \prod_{k=0}^{K} \mathrm{P}(f_{jk}|e_{ik}) \tag{3}$$

where f_{jk} are the morphemes in the input language, and e_{ik} are the corresponding morphemes in the output language. This extended model may also prove a benefit to Czech-English translation; we are currently investigating this possibility.

In this work, we used a word-based translation system due to the availability of source code that could be modified for our morph experiments. An obvious extension to the current work would be to move to a phrase-based translation system. One advantage of phrase-based models is their ability to align phrases in one language to morphologically complex words in the other language. However, this feature still suffers from the same sparse data problems as a word-based system: if a morphologically complex word only appears a handful of times in the training corpus, the system will have difficulty determining its (phrasal or word) alignment. We expect that morphological analysis would still be helpful in this situation, at the very least because it can be used to remove distinctions that appear in only one language.

6 Conclusion

In this paper we used morphological analysis of Czech to improve a Czech-English statistical machine translation system. We have argued that this improvement was primarily due to a reduction of the sparse data problem caused by the highly inflected nature of Czech. An alternative method for reducing sparse data is to use a larger parallel corpus; however, it is often easier to obtain additional monolingual resources, such as a morphological analyzer or tagged corpus, than additional parallel data for a specific language pair. For that reason, we believe that the approach taken here is a promising one.

We have described several different ways of using morphological information for machine translation, and have shown how these can be combined to yield an improved translation model. In general, we would not expect the exact combination of techniques that yielded our best results for Czech-English to be optimal for other language pairs. Rather, we have suggested that these techniques should be combined in a way that makes the input language more similar to the output language. Although this combination will need to be determined for each language pair, the general approach outlined here should provide benefits for any MT system involving a highly inflected language.

A Translation Model for Sentence Retrieval

Vanessa Murdock and **W. Bruce Croft**

Abstract

In this work we propose a translation model for monolingual sentence retrieval. We propose four methods for constructing a parallel corpus. Of the four methods proposed, a lexicon learned from a bilingual Arabic-English corpus aligned at the sentence level performs best, significantly improving results over the query likelihood baseline. Further, we demonstrate that smoothing from the local context of the sentence improves retrieval over the query likelihood baseline.

1 Introduction

Sentence retrieval is the task of retrieving a relevant sentence in response to a user's query. Tasks such as question answering, novelty detection and summarization often incorporate a sentence retrieval module. In previous work we examined sentence retrieval for question answering (Murdock and Croft, 2004). This involves the comparison of two well-formed sentences, one a question, one a statement. In this work we compare well-formed sentences to queries, which can be typical keyword queries of 1 to 3 terms, or a set of sentences or sentence fragments. The TREC Novelty Track provides this type of data in the form of topic titles and descriptions, and sentence-level relevance judgments for a small subset of the collection.

We present a translation model specifically for monolingual data, and show that it significantly improves sentence retrieval over query-likelihood. Translation models train on a parallel corpus and in previous work we used a corpus of question/answer pairs. No such corpus is available for the novelty data, so in this paper we present four ways to construct a parallel corpus, to estimate a translation model.

Many systems treat sentence retrieval as a type of document or passage retrieval. In our data a sentence is an average of 18 words, most of which occur once. A document is an average of 700 words, many of which are multiples of the same term. It is much less likely for a word and its synonym terms to appear in the same sentence than in the same document.

Passages may be any length, either fixed or variable, but are somewhat arbitrarily designated. Many systems that have a passage retrieval module, on closer inspection have defined the passage to be a sentence. What is needed is a sentence retrieval mechanism that retains the benefits of passage retrieval, where a passage is longer than a sentence. We propose that smoothing from the local context of the sentence improves retrieval over the query likelihood baseline, and the larger the context, the greater the improvement.

We describe our translation model in section 2, along with our smoothing approach. In section 3 we discuss previous work in sentence retrieval for the Novelty task, and translation models for information retrieval tasks. Section 4 presents four ways to estimate a translation model, in the absence of a parallel corpus, and presents our experimental results. We discuss the results in section 5, and present our conclusions and future work in section 6.

2 Methodology

Our data was provided by NIST, as part of the TREC Novelty Track[1]. The documents for the TREC Novelty Track in 2002 were taken from the TREC volumes 4 and 5, and consist of news articles from the Financial Times, the Foreign Broadcast Information Service, and the Los Angeles Times from non-overlapping years. In 2003 and 2004, the documents were taken from the Aquaint Corpus, which is distributed by the Linguistic Data Consortium[2] and consists of newswire text in English from the Xinhua News Service, the New York Times, and the Associated Press from overlapping years.

We retrieved the top 1000 documents for each topic from the TREC and Aquaint collections, and sentence segmented the documents using MXTerminator (Reynar and Ratnaparkhi, 1997), which is a freely available sentence boundary detector. Each topic was indexed separately and had an average of 30,000 sentences. It was impractical to do sentence-level relevance assessments for the complete set of 150,000 documents, so we used the relevance assessments provided as part of the Novelty task, recognizing that the results are a lower bound on performance, because the relevance assessments do not cover the collection. The relevance assessments cover 25 known relevant documents for each topic.

We evaluated precision at N documents because many systems using sentence retrieval emphasize the results at the top of the ranked list, and are less concerned with the overall quality of the list.

2.1 Translation Models

We incorporated a machine translation model in two steps: estimation and ranking. In the estimation step, the probability that a term in the sentence "translates" to a term in the query is estimated using the implementation of IBM Model 1 (Brown et al., 1990) in GIZA++ (Al-Onaizan et al., 1999) out-of-the-box without alteration. In the ranking step we incorporate the translation probabilities into the query-likelihood framework.

In Berger and Lafferty (1999), the IBM Model 1 is incorporated thus:

$$P(q_i|S) = \sum_{j=1}^{m} P(q_i|s_j)P(s_j|S) \tag{1}$$

where $P(q_i|s_j)$ is the probability that term s_j in the sentence translates to term q_i in the query. If the translation probabilities are modified such that $P(q_i|s_j) = 1$ if $q_i = s_j$ and 0 otherwise, this is Berger and Lafferty's "Model 0", and it is exactly the query-likelihood model (described in section 2.2).

A major difference between machine translation and sentence retrieval is that machine translation assumes there is little, if any, overlap in the vocabularies of the two languages. In sentence retrieval we depend heavily on the overlap between the two vocabularies. With the Berger and Lafferty formulation in equation 1, the probability of a word translating to itself is estimated as a fraction of the probability of the word translating to all other words. Because the probabilities must sum to one, if there are any other translations for a given word, its self-translation probability will be less than 1.0. To accommodate this monolingual condition, we make the following improvement.

Let $t_i = 1$ if there exists a term in the sentence s_j such that $q_i = s_j$, and 0 otherwise:

$$\sum_{1 \le j \le n} p(q_i|s_j)p(s_j|S) \Longrightarrow$$
$$t_i p(q_i|S) + (1 - t_i) \sum_{1 \le j \le n, s_j \ne q_i} p(q_i|s_j)p(s_j|S) \tag{2}$$

The translation probabilities still sum to one. We determined empirically that this adjustment improved the results over IBM model 1, and over Berger and Lafferty model 0.

[1]http://trec.nist.gov
[2]http://www.ldc.upenn.edu

2.2 Document Smoothing

Query likelihood is a generative model that assumes that the sentence is a sample of a multinomial distribution of terms. Sentences are ranked according to the probability they generate the query. We estimate this probability by interpolating the term distribution in the sentence with the term distribution in the collection:

$$P(Q|S) = P(S)\prod_{i=1}^{|Q|}\Big(\lambda P(q_i|S) + (1-\lambda)P(q_i|C)\Big) \tag{3}$$

where Q is the query, S is the sentence, $P(S)$ is the (uniform) prior probability of the sentence, $P(q_i|S)$ is the probability that term q_i in the query appears in the sentence, and $P(q_i|C)$ is the probability that q_i appears in the collection.

In the experiments with document smoothing, we estimate the probability of a sentence generating the query:

$$P(Q|S) = \\ P(S)\prod_{i=1}^{|Q|}\Big(\alpha P(q_i|S) + \beta P(q_i|D_S) + \gamma P(q_i|C)\Big) \tag{4}$$

where $\alpha+\beta+\gamma = 1.0$ and $P(q_i|D_S)$ is the probability that the term q_i in the query appears in the document the sentence came from. In our case, since the sentences for each topic are indexed separately, the collection statistics are in reference to the documents in the individual topic index.

3 Previous Work

The TREC Novelty Track ran for three years, from 2002 to 2004. Overviews of the track can be found in (Harman, 2002), (Soboroff and Harman, 2003) and (Soboroff, 2004). A number of systems use traditional information retrieval techniques for sentence retrieval, using various techniques to compensate for the sparse term distributions in sentences. The University of Massachusetts (Larkey et al., 2002) and Carnegie Mellon University (Collins-Thompson et al., 2002) both ranked sentences by the cosine similarity of the sentence vector to the query vector of tf.idf-weighted terms. Amsterdam University (Monz et al., 2002) used tfc.nfx term weighting which is a variant of tf.idf term weighting that normalizes the lengths of the document vectors. Meiji University (Ohgaya et al., 2003) expanded the query with concept groups, and then ranked the sentences by the cosine similarity between the expanded topic vector and the sentence vector.

Berger and Lafferty (1999) proposed the use of translation models for (mono-lingual) document retrieval. They used IBM Model 1 (Brown et al., 1990), to rank documents according to their translation probability, given the query. They make no adjustment for the fact that the query and the document are in the same language, and instead rely on the translation model to learn the appropriate weights for word pairs. The models are trained on parallel data artificially constructed from the mutual information distribution of terms in the document. The results presented either were not tested for statistical significance, or they were not statistically significant, because no significance results were given.

Berger et al. (2000) used IBM Model 1 to rank answers to questions in call-center data. In their data, there were no answers that were not in response to at least one of the questions, and all questions had at least one answer. Furthermore, there are multiples of the same question. The task is to match questions and answers, given that every question has at least one match in the data. The translation models performed better for this task than the tf.idf baseline.

4 Experiments and Results

In this section we describe four methods for estimating a translation model in the absence of a parallel corpus. We describe experimental results for each of the translation models, as well as for document smoothing.

4.1 Mutual Information and TREC

As in Berger and Lafferty (1999), a set of documents was selected at random from the TREC collection, and for each document we

	Query Likelihood	MT (MI)	MT (TREC)
Prec@5	0.1176	0.1149	0.1392*
Prec@10	0.1115	0.1047	0.1095

Table 2: Comparing translation-based retrieval for description queries, using the relevance judgments provided by NIST. The translation model was trained from TREC topics.

constructed a distribution according to each term's mutual information with the document, and randomly generated five queries of 8 words according to this distribution. We were retrieving sentences rather than documents, so each sentence in the document was ranked according to its probability of having generated the query, and then the query was aligned with the top 5 sentences. We call this approach "MI".

The second approach uses the TREC topic titles and descriptions aligned with the top 5 retrieved sentences from documents known to be relevant to those topics, excluding topics that were included in the Novelty data. We call this approach "TREC".

Table 1 shows the results of incorporating translations for topic descriptions. Results in the tables with an asterisk are significant at the .05 level using a two-tailed t-test. The results for sentence retrieval are lower than those typically obtained for document retrieval. Manual inspection of the results indicates that the actual precision is much higher, and resembles the results for document retrieval. The lower results are an artifact of the way the relevance assessments were obtained. The sentence-level judgements from the TREC Novelty Track are only for 25 documents per topic.

The Novelty data from 2003-2004 consists of event and opinion queries. We observed that a number of the topic descriptions for event topics had a high degree of vocabulary overlap with the sentences in our data. This was not true of the opinion queries. The results of using a translation-based retrieval on description queries are given in table 2, broken down by the sentiment of the query. The Novelty queries from 2002 were included in the "event" set.

Not all of the sentences judged relevant to opinion topics express opinions. To assess opinion-relevance we evaluated the top 10 sentences, and marked sentences that expressed opinions. In our data approximately 10% of sentences in the top 10 express opinions. Table 3 shows the result of using a translation model trained on TREC data for description queries, broken down by sentiment, with the baselines evaluated for this particular set of relevance judgments. For opinion questions, the column labeled "topical" indicates topical relevance. The column labeled "opinion" indicates topical relevance that also expresses an opinion.

If we consider a sentence relevant to an opinion question only if it expresses an opinion, we see improvement in the results at the top of the ranked list for those queries, using a translation model trained on TREC data. Of the 150 topics, only 50 were opinion topics, so although the magnitude of the improvement in opinion queries is large the results are not statistically

significant with respect to the baseline.

4.2 Lexicons

External lexicons are often useful for translation and query expansion. The most obvious approach was to incorporate a thesaurus into the training process in GIZA as a dictionary, which affects the statistics in the first iteration of EM. This is intended to improve the quality of the alignments over subsequent iterations. We incorporated the thesauri into the training process of the data generated from the artificial mutual information distribution. The dictionaries had almost no effect on the results.

4.2.1 WordNet

We created a parallel corpus of synonym-term pairs from WordNet, and added this data to the artificial mutual information data to train the translation model. The results of using this approach to retrieve sentences using title queries are in figure 1, labeled "MI_WN". Using WordNet alone, without the mutual information data, is labeled "WN_Only". The results are statistically significant using a Wilcoxon sign test at the .05 level for precision at .10, .20 and .60. Query likelihood retrieval is the baseline. The results for description queries are not shown, and were not significantly different from the baseline.

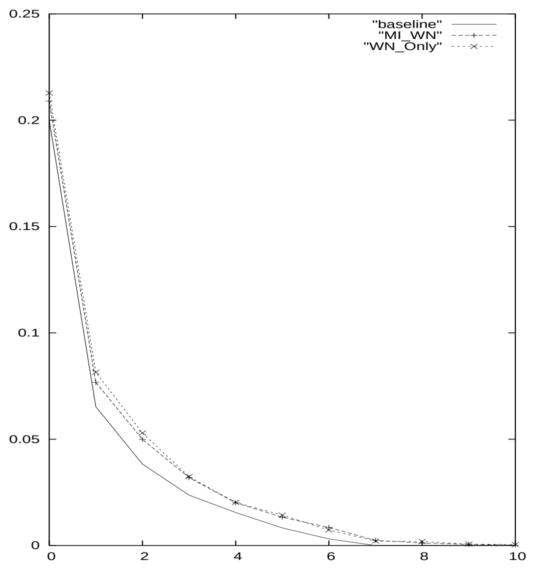

Figure 1: Comparing interpolated recall-precision for title queries using WordNet. The results are statistically significant using a Wilcoxon sign test at the .05 level, for precision at .10, .20 and .60.

4.2.2 Arabic-English corpus

Xu et al. (2002) derive an Arabic thesaurus from a parallel corpus. We derived an English thesaurus using the same approach, from a pair of English-Arabic/Arabic-English lexicons, learned from a parallel corpus. We assumed that if two English terms translate to the same Arabic term, the English terms are synonyms whose probability is given by

$$P(e_2|e_1) = \sum_{a \in A} P(e_2|a)P(a|e_1) \qquad (5)$$

Figure 2 shows the interpolated recall-precision of these results, for description queries. The English terms were not stemmed, and so the baseline query-likelihood results are also not stemmed. The results are statistically significant using a Wilcoxon sign test at the .05 level, for all retrieval levels. Not shown is the average precision, which is also significantly better for the Arabic-English lexicon than for the query-likelihood. The results for title queries are not shown, but are similar to those for descriptions.

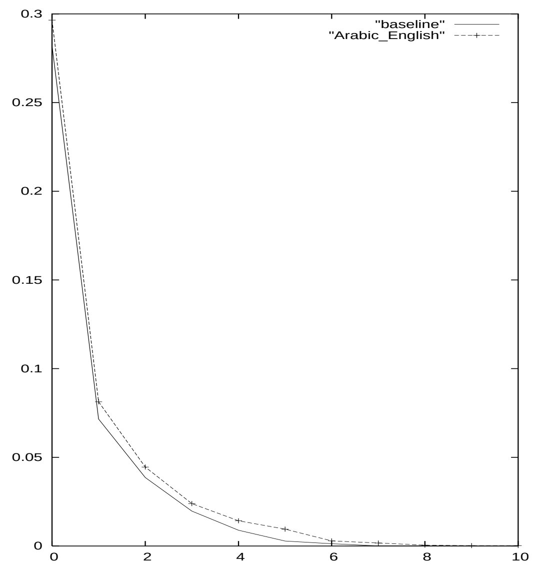

Figure 2: Comparing interpolated recall-precision for description queries using a pair of Arabic-English, English-Arabic lexicons. The results are statistically significant using a Wilcoxon sign test at the .05 level, for precision all recall levels.

4.3 Document Smoothing

Smucker and Allan (2005) demonstrated that under certain conditions, Jelinek-Mercer smoothing is equivalent to Dirichlet smoothing, and that the advantage of Dirichlet smoothing is derived from the fact that it smoothes long documents less than shorter documents. In our data there is much less variance in the length of a sentence than in the length of a document, thus we do not expect to see as great a benefit in performance from Dirichlet smoothing as has been reported in Zhai and Lafferty (2001). In fact we tried Absolute Discounting, Dirichlet, Jelinek-Mercer and Laplace smoothing and found them to produce equivalent results.

The vast majority of sentences in our data are not stand-alone units, and the topic of the sentence is also the topic of surrounding sentences. We took a context of the surrounding 5 sentences, and the surrounding 11 sentences (about 1/3 of the whole document). The sentences were smoothed from the surrounding context, backing-off to the whole document, using Jelinek-Mercer smoothing. Table 4 shows a comparison of the amount of context. Smoothing from the local context is clearly better than the baseline result.

Table 4: Comparison of smoothing context on description queries, retrieving sentences from the top 1000 documents. Results with an asterisk are significant at the .05 level using a two-tailed t-test.

We investigated the effect of smoothing from the entire document. Table 5 shows the results. Both topic titles and descriptions get significantly better results with document smoothing.

4.4 Novelty Relevance Task

In the TREC Novelty Track, participants are given a set of 25 documents most of which are relevant for each topic. If we believe that a document is relevant because it has relevant sentences in it, then a "good" sentence would come from a "good" document. This would suggest that smoothing from the document the sentence came from would improve retrieval. We found that for title queries document smoothing improved precision in the top 5 documents by 12.5%, which is statistically significant using a two-tailed t-test at the .05 level. Precision in the top 10 - 100 documents also improved results by an average of 5%, but the result is not statistically significant. For description queries, smoothing from the document had no effect.

For title queries, translation models improve the average precision, and R-Precision. For both title and description queries, the number of relevant documents that are retrieved is also improved with translation models.

5 Discussion

The results for sentence retrieval are low, in comparison to results we would expect for document retrieval. We might think that although we show improvements, nothing is working well. In reality, the relevance assessments provided by NIST as part of the Novelty Track only cover 25 documents per topic. Evaluating the top 10 sentences by hand shows that the systems give a performance comparable to document retrieval systems, and the low numbers are the result of a lack of coverage in the assessments. Unfortunately, there is no collection of documents of significant size, where the relevance assessments at the sentence level cover the collection. Constructing such a corpus would be a major undertaking, outside of the scope of this paper.

The best performing method of constructing a parallel corpus used a bilingual lexicon derived from a sentence-aligned Arabic-English parallel corpus. This suggests that data in which sentences are actually translations of one another, as opposed to sentences aligned with key terms from the document, yield a higher quality lexicon. The model trained on the parallel corpus of TREC topics and relevant sentences performed better than the MI corpus, but not as well as the Arabic-English corpus. The TREC corpus consisted of approximately 15,000 sentence pairs, whereas the Arabic-English corpus was trained on more than a million sentence pairs. This may account in part for the higher quality results. In addition, the TREC corpus was created by retrieving the top 5 sentences from each relevant document. Even when the document is known to be relevant, the retrieval process is noisy. Furthermore, although there were 15,000 sentence pairs, there were only 450 unique queries, limiting the size of the source vocabulary.

Opinion topics have much less vocabulary overlap with relevant sentences than do event topics. Translation models would be expected to perform better when retrieving sentences that contain synonym or related terms. For sentences that have exact matches in the query, query likelihood will perform better.

We find that smoothing from the local context of the sentence performs significantly better than the baseline retrieval. The sentences are all about the same length, so there is no performance advantage to using Dirichlet smoothing, whose smoothing parameter is a function of the document length. The smoothing parameters gave very little weight to the collection. As sentences have few terms, relative to documents, matching a term in the query is a good indication of relevance.

6 Conclusions and Future Work

We have shown that translation models improve retrieval for title and opinion queries, and that a translation model derived from a high-quality bilingual lexicon significantly improves retrieval for title and description queries. Smoothing from the local context of a sentence dramatically improves retrieval, with smoothing from the document that contains the sentence performing the best.

We evaluated sentences based on lexical similarity, but structural similarity is also an important measure, which we plan to investigate in the future. The translation model we used was the most basic model. We used this model because it had been shown effective in document retrieval, and was easily incorporated in the query-likelihood framework, but we intend to explore more sophisticated translation models, and better alignment mechanisms. Preliminary results suggest that sentence retrieval can be used to improve document retrieval, but we plan a more extensive investigation of evaluating document similarity and relevance based on sentence-level similarity.

Maximum Expected F-Measure Training of Logistic Regression Models

Martin Jansche

jansche@acm.org

Abstract

We consider the problem of training logistic regression models for binary classification in information extraction and information retrieval tasks. Fitting probabilistic models for use with such tasks should take into account the demands of the task-specific utility function, in this case the well-known F-measure, which combines recall and precision into a global measure of utility. We develop a training procedure based on empirical risk minimization / utility maximization and evaluate it on a simple extraction task.

1 Introduction

Log-linear models have been used in many areas of Natural Language Processing (NLP) and Information Retrieval (IR). Scenarios in which log-linear models have been applied often involve simple binary classification decisions or probability assignments, as in the following three examples: Ratnaparkhi et al. (1994) consider a restricted form of the prepositional phrase attachment problem where attachment decisions are binary; Ittycheriah et al. (2003) reduce entity mention tracking to the problem of modeling the probability of two mentions being linked; and Greiff and Ponte (2000) develop models of probabilistic information retrieval that involve binary decisions of relevance. What is common to all three approaches is the application of log-linear models to binary classification tasks.[1] As Ratnaparkhi (1998, p. 27f.) points out, log-linear models of binary response variables are equivalent to, and in fact mere notational variants of, logistic regression models.

In this paper we focus on binary classification tasks, and in particular on the loss or utility associated with classification decisions. The three problems mentioned before – prepositional phrase attachment, entity mention linkage, and relevance of a document to a query – differ in one crucial aspect: The first is evaluated in terms of accuracy or, equivalently, symmetric zero–one loss; but the second and third are treated as information extraction/retrieval problems and evaluated in terms of recall and precision. Recall and precision are combined into a single overall utility function, the well-known F-measure. It may be desirable to estimate the parameters of a logistic regression model by maximizing F-measure during training. This is analogous, and in a certain sense equivalent, to empirical risk minimization, which has been used successfully in related areas, such as speech recognition (Rahim and Lee, 1997), language modeling (Paciorek and Rosenfeld, 2000), and machine translation (Och, 2003).

The novel contribution of this paper is a training procedure for (approximately) maximizing the expected F-measure of a probabilistic classifier based on a logistic regression model. We formulate a vector-valued utility function which has a well-defined expected value; F-measure is then a rational function of this expectation and can be maximized numerically under certain conventional regularizing assumptions.

[1] These kinds of log-linear models are also known among the NLP community as "maximum entropy models" (Berger et al., 1996; Ratnaparkhi, 1998). This is an unfortunate choice of terminology, because the term "maximum entropy" does not uniquely determine a family of models unless the constraints subject to which entropy is being maximized are specified.

We begin with a review of logistic regression (Section 2) and then discuss the use of F-measure for evaluation (Section 3). We reformulate F-measure as a function of an expected utility (Section 4) which is maximized during training (Section 5). We discuss the differences between our parameter estimation technique and maximum likelihood training on a toy example (Section 6) as well as on a real extraction task (Section 7). We conclude with a discussion of further applications and generalizations (Section 8).

2 Review of Logistic Regression

Bernoulli regression models are conditional probability models of a binary response variable Y given a vector $\vec{X}$ of k explanatory variables $(X_1,\ldots,X_k)$. We will use the convention[2] that Y takes on a value $y \in \{-1,+1\}$.

Logistic regression models (Cox, 1958) are perhaps best viewed as instances of generalized linear models (Nelder and Wedderburn, 1972; McCullagh and Nelder, 1989) where the the response variable follows a Bernoulli distribution and the link function is the logit function. Let us summarize this first, before expanding the relevant definitions:

$$\begin{aligned} Y &\sim \text{Bernoulli}(p) \\ \text{logit}(p) &= \theta_0 + x_1\,\theta_1 + x_2\,\theta_2 + \cdots + x_k\,\theta_k \end{aligned}$$

What this means is that there is an unobserved quantity p, the success probability of the Bernoulli distribution, which we interpret as the probability that Y will take on the value $+1$:

$$\Pr(Y = +1 \mid \vec{X} = (x_1, x_2, \ldots, x_k), \vec{\theta}) = p$$

The logit (log odds) function is defined as follows:

$$\text{logit}(p) = \ln\left(\frac{p}{1-p}\right)$$

The logit function is used to transform a probability, constrained to fall within the interval $(0,1)$, into a real number ranging over $(-\infty,+\infty)$. The inverse function of the logit is the cumulative distribution function of the standard logistic distribution (also known as the *sigmoid* or *logistic* function), which we call g:

$$g(z) = \frac{1}{1+\exp(-z)}$$

This allows us to write

$$p = g(\theta_0 + x_1\,\theta_1 + x_2\,\theta_2 + \cdots + x_k\,\theta_k).$$

We also adopt the usual convention that $\vec{x} = (1, x_1, x_2, \ldots, x_k)$, which is a $k+1$-dimensional vector whose first component is always 1 and whose remaining k components are the values of the k explanatory variables. So the Bernoulli probability can be expressed as

$$p = g\left(\sum_{j=0}^{k} x_j\,\theta_j\right) = g\left(\vec{x}\cdot\vec{\theta}\right).$$

The conditional probability model then takes the following abbreviated form, which will be used throughout the rest of this paper:

$$\Pr(+1 \mid \vec{x}, \vec{\theta}) = \frac{1}{1+\exp(-\vec{x}\cdot\vec{\theta})} \qquad (1)$$

A classifier can be constructed from this probability model using the MAP decision rule. This means predicting the label $+1$ if $\Pr(+1 \mid \vec{x}, \vec{\theta})$ exceeds $1/2$, which amounts to the following:

$$y_{\text{map}}(\vec{x}) = \underset{y}{\text{argmax}}\ \Pr(y \mid \vec{x}, \vec{\theta}) = \text{sgn}\left(\vec{x}\cdot\vec{\theta}\right)$$

This illustrates the well-known result that a MAP classifier derived from a logistic regression model is equivalent to a (single-layer) perceptron (Rosenblatt, 1958) or linear threshold unit.

3 F-Measure

Suppose the parameter vector θ of a logistic regression model is known. The performance of the resulting classifier can then be evaluated in terms of the *recall* (or *sensitivity*) and *precision* of the classifier on an evaluation dataset. Recall (R) and precision (P) are defined in terms of the number of true positives (A), misses (B), and false alarms (C) of the classifier (cf. Table 1):

$$R = \frac{A}{A+B} \qquad\qquad P = \frac{A}{A+C}$$

[2]The natural choice may seem to be for Y to range over the set $\{0,1\}$, but the convention adopted here is more common for classification problems and has certain advantages which will become clear soon.

		predicted		total
		$+1$	-1	
true	$+1$	A	B	n_{pos}
	-1	C	D	n_{neg}
total		m_{pos}	m_{neg}	n

Table 1: Schema for a 2×2 contingency table

The F_α measure – familiar from Information Retrieval – combines recall and precision into a single utility criterion by taking their α-weighted harmonic mean:

$$F_\alpha(R,P) = \left(\alpha \frac{1}{R} + (1-\alpha)\frac{1}{P}\right)^{-1}$$

The F_α measure can be expressed in terms of the triple (A,B,C) as follows:

$$F_\alpha(A,B,C) = \frac{A}{A + \alpha B + (1-\alpha) C} \tag{2}$$

In order to define A, B, and C formally, we use the notation $[\![\pi]\!]$ to denote a variant of the Kronecker delta defined like this, where π is a Boolean expression:

$$[\![\pi]\!] = \begin{cases} 1 & \text{if } \pi \\ 0 & \text{if } \neg\pi \end{cases}$$

Given an evaluation dataset $(\vec{x}_1,y_1),\ldots,(\vec{x}_n,y_n)$ the counts of hits (true positives), misses, and false alarms are, respectively:

$$A = \sum_{i=1}^{n} [\![y_{\text{map}}(\vec{x}_i) = +1]\!]\, [\![y_i = +1]\!]$$
$$B = \sum_{i=1}^{n} [\![y_{\text{map}}(\vec{x}_i) = -1]\!]\, [\![y_i = +1]\!]$$
$$C = \sum_{i=1}^{n} [\![y_{\text{map}}(\vec{x}_i) = +1]\!]\, [\![y_i = -1]\!]$$

Note that F-measure is seemingly a global measure of utility that applies to an evaluation dataset as a whole: while the F-measure of a classifier evaluated on a single supervised instance is well defined, the overall F-measure on a larger dataset is not a function of the F-measure evaluated on each instance in the dataset. This is in contrast to ordinary loss/utility, whose grand total (or average) on a dataset can be computed by direct summation.

4 Relation to Expected Utility

We reformulate F-measure as a scalar-valued rational function composed with a vector-valued utility function. This allows us to define notions of expected and average utility, setting up the discussion of parameter estimation in terms of empirical risk minimization (or rather, utility maximization).

Define the following vector-valued utility function u, where $u(\tilde{y} \mid y)$ is the utility of choosing the label $\tilde{y}$ if the true label is y:

$$\begin{aligned} u(+1 \mid +1) &= (1,0,0) \\ u(-1 \mid +1) &= (0,1,0) \\ u(+1 \mid -1) &= (0,0,1) \\ u(-1 \mid -1) &= (0,0,0) \end{aligned}$$

This function indicates whether a classification decision is a hit, miss, or false alarm. Correct rejections are not counted.

Expected values are, of course, well-defined for vector-valued functions. For example, the expected utility is

$$\mathrm{E}[u] = \sum_{(\vec{x},y)} u(y_{\text{map}}(\vec{x}) \mid y)\ \Pr(\vec{x},y).$$

In empirical risk minimization we approximate the expected utility of a classifier by its average utility U_S on a given dataset $S = (\vec{x}_1,y_1),\ldots,(\vec{x}_n,y_n)$:

$$\begin{aligned} \mathrm{E}[u] \approx U_S &= \frac{1}{n}\sum_{i=1}^{n} u(y_{\text{map}}(\vec{x}_i) \mid y_i) \\ &= \frac{1}{n}\sum_{i=1}^{n} u(+1 \mid y_i)\, [\![y_{\text{map}}(\vec{x}_i) = +1]\!] \\ &\qquad + u(-1 \mid y_i)\, [\![y_{\text{map}}(\vec{x}_i) = -1]\!] \end{aligned}$$

Now it is easy to see that U_S is the following vector:

$$U_S = \frac{1}{n}\begin{pmatrix} \sum_{i=1}^{n} [\![y_{\text{map}}(\vec{x}_i) = +1]\!]\, [\![y_i = +1]\!] \\ \sum_{i=1}^{n} [\![y_{\text{map}}(\vec{x}_i) = -1]\!]\, [\![y_i = +1]\!] \\ \sum_{i=1}^{n} [\![y_{\text{map}}(\vec{x}_i) = +1]\!]\, [\![y_i = -1]\!] \end{pmatrix} \tag{3}$$

So $U_S = n^{-1}(A,B,C)$ where A, B, and C are as defined before. This means that we can interpret the

F-measure of a classifier as a simple rational function of its empirical average utility (the scaling factor $1/n$ in (3) can in fact be omitted). This allows us to approach the parameter estimation task as an empirical risk minimization or utility maximization problem.

5 Discriminative Parameter Estimation

In the preceding two sections we assumed that the parameter vector $\vec{\theta}$ was known. Now we turn to the problem of estimating $\vec{\theta}$ by maximizing the F-measure formulated in terms of expected utility. We make the dependence on $\vec{\theta}$ explicit in the formulation of the optimization task:

$$\vec{\theta}^\star = \operatorname*{argmax}_{\vec{\theta}} F_\alpha(A(\vec{\theta}), B(\vec{\theta}), C(\vec{\theta})),$$

where $(A(\vec{\theta}), B(\vec{\theta}), C(\vec{\theta})) = U_S(\vec{\theta})$ as defined in (3). We encounter the usual problem: the basic quantities involved are integers (counts of hits, misses, and false alarms), and the optimization objective is a piecewise-constant functions of the parameter vector $\vec{\theta}$, due to the fact that $\vec{\theta}$ occurs exclusively inside Kronecker deltas. For example:

$$[\![y_{\text{map}}(\vec{x}) = +1]\!] = \left[\!\!\left[\Pr(+1 \mid \vec{x}, \vec{\theta}) > 0.5 \right]\!\!\right]$$

In general, we can set

$$\left[\!\!\left[\Pr(+1 \mid \vec{x}, \vec{\theta}) > 0.5 \right]\!\!\right] \approx \Pr(+1 \mid \vec{x}, \vec{\theta}), \qquad (4)$$

and in the case of logistic regression this arises as a special case of approximating the limit

$$\left[\!\!\left[\Pr(+1 \mid \vec{x}, \vec{\theta}) > 0.5 \right]\!\!\right] = \lim_{\gamma \to \infty} g(\gamma\, \vec{x} \cdot \vec{\theta})$$

with a fixed value of $\gamma = 1$. The choice of γ does not matter much. The important point is that we are now dealing with approximate quantities which depend continuously on $\vec{\theta}$. In particular $A(\vec{\theta}) \approx \tilde{A}(\vec{\theta})$, where

$$\tilde{A}(\vec{\theta}) = \sum_{\substack{i=1 \\ y_i=+1}}^{n} g(\gamma\, \vec{x}_i \cdot \vec{\theta}). \qquad (5)$$

Since the marginal total of positive instances n_{pos} (cf. Table 1) does not depend on $\vec{\theta}$, we use the identities $\tilde{B}(\vec{\theta}) = n_{\text{pos}} - \tilde{A}(\vec{\theta})$ and $\tilde{m}_{\text{pos}}(\vec{\theta}) = \tilde{A}(\vec{\theta}) + \tilde{C}(\vec{\theta})$ to rewrite the optimization objective as $\tilde{F}_\alpha$:

$$\tilde{F}_\alpha(\vec{\theta}) = \frac{\tilde{A}(\vec{\theta})}{\alpha\, n_{\text{pos}} + (1-\alpha)\, \tilde{m}_{\text{pos}}(\vec{\theta})}, \qquad (6)$$

where $\tilde{A}(\vec{\theta})$ is given by (5) and $\tilde{m}_{\text{pos}}(\vec{\theta})$ is

$$\tilde{m}_{\text{pos}}(\vec{\theta}) = \sum_{i=1}^{n} g(\gamma\, \vec{x}_i \cdot \vec{\theta}).$$

Maximization of $\tilde{F}$ as defined in (6) can be carried out numerically using multidimensional optimization techniques like conjugate gradient search (Fletcher and Reeves, 1964) or quasi-Newton methods such as the BFGS algorithm (Broyden, 1967; Fletcher, 1970; Goldfarb, 1970; Shanno, 1970). This requires the evaluation of partial derivatives. The jth partial derivative of $\tilde{F}$ is as follows:

$$\begin{aligned}
\frac{\partial \tilde{F}(\vec{\theta})}{\partial \theta_j} &= h\, \frac{\partial \tilde{A}(\vec{\theta})}{\partial \theta_j} - h^2\, \tilde{A}(\vec{\theta})\, (1-\alpha)\, \frac{\partial \tilde{m}_{\text{pos}}(\vec{\theta})}{\partial \theta_j} \\
h &= \frac{1}{\alpha\, n_{\text{pos}} + (1-\alpha)\, \tilde{m}_{\text{pos}}(\vec{\theta})} \\
\frac{\partial \tilde{A}(\vec{\theta})}{\partial \theta_j} &= \sum_{\substack{i=1 \\ y_i=+1}}^{n} g'(\gamma\, \vec{x}_i \cdot \vec{\theta})\, \gamma x_{ij} \\
\frac{\partial \tilde{m}_{\text{pos}}(\vec{\theta})}{\partial \theta_j} &= \sum_{i=1}^{n} g'(\gamma\, \vec{x}_i \cdot \vec{\theta})\, \gamma x_{ij} \\
g'(z) &= g(z)\, (1 - g(z))
\end{aligned}$$

One can compute the value of $\tilde{F}(\vec{\theta})$ and its gradient $\nabla \tilde{F}(\vec{\theta})$ simultaneously at a given point $\vec{\theta}$ in $\mathrm{O}(nk)$ time and $\mathrm{O}(k)$ space. Pseudo-code for such an algorithm appears in Figure 1. In practice, the inner loops on lines 8–9 and 14–18 can be made more efficient by using a sparse representation of the row vectors $x[i]$. A concrete implementation of this algorithm can then be used as a callback to a multidimensional optimization routine. We use the BFGS minimizer provided by the GNU Scientific Library (Galassi et al., 2003). Important caveat: the function $\tilde{F}$ is generally not concave. We deal with this problem by taking the maximum across several runs of the optimization algorithm starting from random initial values. The next section illustrates this point further.

Table 2: Toy dataset

6 Comparison with Maximum Likelihood

A comparison with the method of maximum likelihood illustrates two important properties of discriminative parameter estimation. Consider the toy dataset in Table 2 consisting of four supervised instances with a single explanatory variable. Thus the logistic regression model has two parameters and takes the following form:

$$\Pr_{\text{toy}}(+1 \mid x, \theta_0, \theta_1) = \frac{1}{1 + \exp(-\theta_0 - x\,\theta_1)}$$

The log-likelihood function L is simply

$$\begin{aligned} L(\theta_0, \theta_1) = &\log \Pr_{\text{toy}}(+1 \mid 0, \theta_0, \theta_1) \\ &+ \log \Pr_{\text{toy}}(-1 \mid 1, \theta_0, \theta_1) \\ &+ \log \Pr_{\text{toy}}(+1 \mid 2, \theta_0, \theta_1) \\ &+ \log \Pr_{\text{toy}}(+1 \mid 3, \theta_0, \theta_1). \end{aligned}$$

A surface plot of L is shown in Figure 2. Observe that L is concave; its global maximum occurs near $(\theta_0, \theta_1) \approx (0.35, 0.57)$, and its value is always strictly negative because the toy dataset is not linearly separable. The classifier resulting from maximum likelihood training predicts the label $+1$ for all training instances and thus achieves a recall of $3/3$ and precision $3/4$ on its training data. The $F_{\alpha=0.5}$ measure is $6/7$.

Contrast the shape of the log-likelihood function L with the function $\tilde{F}_\alpha$. Surface plots of $\tilde{F}_{\alpha=0.5}$ and $\tilde{F}_{\alpha=0.25}$ appear in Figure 3. The figures clearly illustrate the first important (but undesirable) property of $\tilde{F}$, namely the lack of concavity. They also illustrate a desirable property, namely the ability to take into account certain properties of the loss function during training. The $\tilde{F}_{\alpha=0.5}$ surface in the left panel of Figure 3 achieves its maximum in the right corner for $(\theta_0, \theta_1) \rightarrow (+\infty, +\infty)$. If we choose $(\theta_0, \theta_1) = (20, 15)$ the classifier labels every instance of the training data with $+1$.

Figure 1: Algorithm for computing $\tilde{F}$ and $\nabla\tilde{F}$

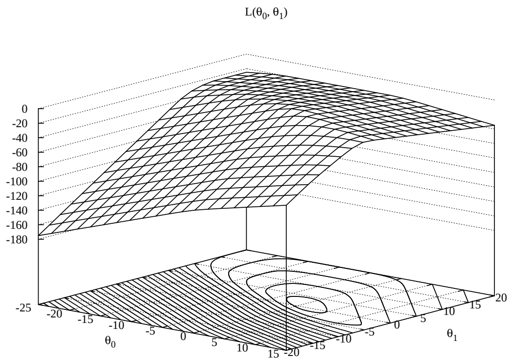

Figure 2: Surface plot of L on the toy dataset

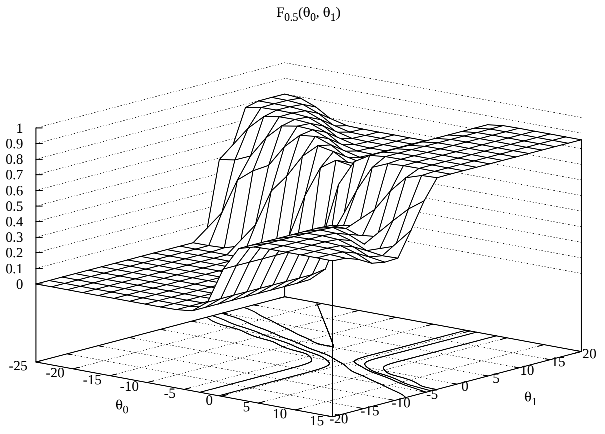
Observe the difference between the $\tilde{F}_{\alpha=0.5}$ surface and the $\tilde{F}_{\alpha=0.25}$ surface in the right hand panel of Figure 3: $\tilde{F}_{\alpha=0.25}$ achieves its maximum in the back corner for $(\theta_0, \theta_1) \rightarrow (-\infty, +\infty)$. If we set $(\theta_0, \theta_1) = (-20, 15)$ the resulting classifier labels the first two



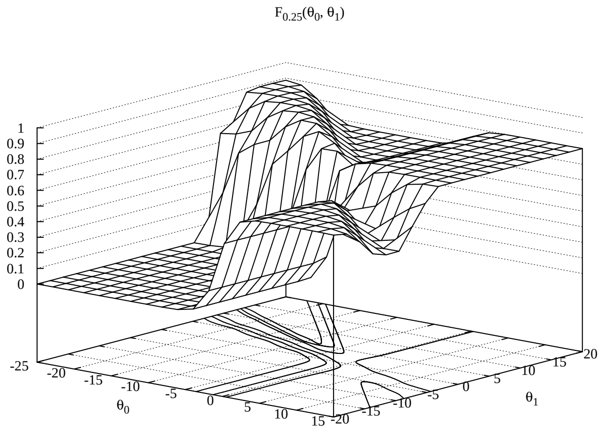


Figure 3: Surface plot of $\tilde{F}_{\alpha=0.5}$ (left) and $\tilde{F}_{\alpha=0.25}$ (right) on the toy dataset

instances ($x = 0$ and $x = 1$) as -1 and the last two instances ($x = 2$ and $x = 3$) as $+1$.

The classifier trained according to the $\tilde{F}_{\alpha=0.5}$ criterion achieves an $F_{\alpha=0.5}$ measure of $6/7 \approx 0.86$, compared with $4/5 = 0.80$ for the classifier trained according to the $\tilde{F}_{\alpha=0.25}$ criterion. Conversely, that classifier achieves an $F_{\alpha=0.25}$ measure of $8/9 \approx 0.89$ compared with $4/5 = 0.80$ for the classifier trained according to the $\tilde{F}_{\alpha=0.5}$ criterion. This demonstrates that the training procedure can effectively take information from the utility function into account, producing a classifier that performs well under a given evaluation criterion. This is the result of optimizing a task-specific utility function during training, not simply a matter of adjusting the decision threshold of a trained classifier.

7 Evaluation on an Extraction Problem

We evaluated our discriminative training procedure on a real extraction problem arising in broadcast news summarization. The overall task is to summarize the stories in an audio news broadcast (or in the audio portion of an A/V broadcast). We assume that story boundaries have been identified and that each story has been broken up into sentence-like units. A simple way of summarizing a story is then to classify each sentence as either belonging into a summary or not, so that a relevant subset of sentences can be extracted to form the basis of a summary. What makes the classification task hard, and therefore interesting, is the fact that reliable features are hard to come by. Existing approaches such as Maskey and Hirschberg 2005 do well only when combining diverse features such as lexical cues, acoustic properties, structural/positional features, etc.

The task has another property which renders it problematic, and which prompted us to develop the discriminative training procedure described in this paper. Summarization, by definition, aims for brevity. This means that in any dataset the number of positive instances will be much smaller than the number of negative instances. Given enough data, balance could be restored by discarding negative instances. This, however, was not an option in our case: a moderate amount of manually labeled data had been produced and about one third would have had to be discarded to achieve a balance in the distribution of class labels. This would have eliminated precious supervised training data, which we were not prepared to do.

The training and test data were prepared by Maskey and Hirschberg (2005), who performed the feature engineering, imputation of missing values, and the training–test split. We used the data unchanged in order to allow for a comparison between approaches. The dataset is made up of 30 features, divided into one binary response variable, and one binary explanatory variable plus 28 integer- and real-valued explanatory variables. The training portion consists of 3 535 instances, the test portion of 408 instances.

We fitted logistic regression models in three different ways: by maximum likelihood ML, by $\tilde{F}_{\alpha=0.5}$ maximization, and by $\tilde{F}_{\alpha=0.75}$ maximization. Each

Method	R	P	$F_{\alpha=0.5}$	$F_{\alpha=0.75}$
ML	24/99	24/33	0.3636	0.2909
ML†	85/99	85/229	0.5183	0.6464
$\tilde{F}_{\alpha=0.5}$	85/99	85/211	0.5484	0.6693
$\tilde{F}_{\alpha=0.75}$	95/99	95/330	0.4429	0.6061

Table 3: Evaluation results

classifier was evaluated on the test dataset and its recall (R), precision (P), $F_{\alpha=0.5}$ measure, and $F_{\alpha=0.75}$ measure recorded. The results appear in Table 3.

The row labeled ML† is special: the classifier used here is the logistic regression model fitted by maximum likelihood; what is different is that the threshold for positive predictions was adjusted *post hoc* to match the number of true positives of the first discriminatively trained classifier. This has the same effect as manually adjusting the threshold parameter θ_0 based on partial knowledge of the test data (via the performance of another classifier) and is thus not permissible. It is interesting to note, however, that the ML trained classifier performs worse than the $\tilde{F}_{\alpha=0.5}$ trained classifier even when one parameter is adjusted by an oracle with knowledge of the test data and the performance of the other classifier.

Fitting a model based on $\tilde{F}_{\alpha=0.75}$, which gives increased weight to recall compared with $\tilde{F}_{\alpha=0.5}$, led to higher recall as expected. However, we also expected that the $F_{\alpha=0.75}$ score of the $\tilde{F}_{\alpha=0.75}$ trained classifier would be higher than the $F_{\alpha=0.75}$ score of the $\tilde{F}_{\alpha=0.5}$ trained classifier. This is not the case, and could be due to the optimization getting stuck in a local maximum, or it may have been an unreasonable expectation to begin with.

8 Conclusions

We have presented a novel estimation procedure for probabilistic classifiers which we call, by a slight abuse of terminology, *maximum expected F-measure* training. We made use of the fact that expected utility computations can be carried out in a vector space, and that an ordering of vectors can be imposed for purposes of maximization which can employ auxiliary functions like the F-measure (2). This technique is quite general and well suited for working with other quantities that can be expressed in terms of hits, misses, false alarms, correct rejections, etc. In particular, it could be used to find a point estimate which provides a certain tradeoff between specificity and sensitivity, or operating point. A more general method would try to optimize several such operating points simultaneously, an issue which we will leave for future research.

The classifiers discussed in this paper are logistic regression models. However, this choice is not crucial. The approximation (4) is reasonable for binary decisions in general, and one can use it in conjunction with any well-behaved conditional Bernoulli model or related classifier. For Support Vector Machines, approximate F-measure maximization was introduced by Musicant et al. (2003).

Maximizing F-measure during training seems especially well suited for dealing with skewed classes. This can happen by accident, because of the nature of the problem as in our summarization example above, or by design: for example, one can expect skewed binary classes as the result of the one-vs-all reduction of multi-class classification to binary classification; and in multi-stage classification one may want to alternate between classifiers with high recall and classifiers with high precision.

Finally, the ability to incorporate non-standard tradeoffs between precision and recall at training time is useful in many information extraction and retrieval applications. Human end-users often create asymmetries between precision and recall, for good reasons: they may prefer to err on the side of caution (e.g., it is less of a problem to let an unwanted spam email reach a user than it is to hold back a legitimate message), or they may be better at some tasks than others (e.g., search engine users are good at filtering out irrelevant documents returned by a query, but are not equipped to crawl the web in order to look for relevant information that was not retrieved). In the absence of methods that work well for a wide range of operating points, we need training procedures that can be made sensitive to rare cases depending on the particular demands of the application.

Acknowledgements

I would like to thank Julia Hirschberg, Sameer Maskey, and the three anonymous reviewers for helpful comments. I am especially grateful to

Sameer Maskey for allowing me to use his speech summarization dataset for the evaluation in Section 7. The usual disclaimers apply.

Abstract

We present *Evita*, an application for recognizing events in natural language texts. Although developed as part of a suite of tools aimed at providing question answering systems with information about both temporal and intensional relations among events, it can be used independently as an event extraction tool. It is unique in that it is not limited to any pre-established list of relation types (events), nor is it restricted to a specific domain. Evita performs the identification and tagging of event expressions based on fairly simple strategies, informed by both linguistic- and statistically-based data. It achieves a performance ratio of 80.12% F-measure.[1]

1 Introduction

Event recognition is, after entity recognition, one of the major tasks within Information Extraction. It is currently being succesfully applied in different areas, like bioinformatics and text classification. Recognizing events in these fields is generally carried out by means of pre-defined sets of relations, possibly structured into an ontology, which makes such tasks domain dependent, but feasible. Event recognition is also at the core of Question Answering, since input questions touch on events and situations in the world (states, actions, properties, etc.), as they are reported in the text. In this field as well, the use of pre-defined sets of relation patterns has proved fairly reliable, particularly in the case of factoid type queries (Brill et al., 2002; Ravichandran and Hovy, 2002; Hovy et al., 2002; Soubbotin and Soubbotin, 2002).

Nonetheless, such an approach is not sensitive to certain contextual elements that may be fundamental for returning the appropriate answer. This is for instance the case in reporting or attempting contexts. Given the passage in (1a), a pattern-generated answer to question (1b) would be (1c). Similarly, disregarding the reporting context in example (2) could erroneously lead to concluding that no one from the White House was involved in the Watergate affair.

(1) a. Of the 14 known ways to reach the summit, only the East Ridge route has never been successfully climbed since George Mallory and Andrew ”Sandy” Irvine first attempted to climb Everest in 1924.
b. When did George Mallory and Andrew Irvine first climb Everest?
c. #In 1924.

(2) a. Nixon claimed that White House counsel John Dean had conducted an investigation into the Watergate matter and found that no-one from the White House was involved.
b. What members of the White House were involved in the Watergate matter?
c. #Nobody.

Intensional contexts like those above are generated by predicates referring to events of attempting, intending, commanding, and reporting, among others. When present in text, they function as modal

[1]This work was supported by a grant from the Advanced Research and Development Activity in Information Technology (ARDA), a U.S. Government entity which sponsors and promotes research of import to the Intelligence Community which includes but is not limited to the CIA, DIA, NSA, NIMA, and NRO.

qualifiers of the truth of a given proposition, as in example (2), or they indicate the factuality nature of the event expressed by the proposition (whether it happened or not), as in (1) (Saurí and Verhagen, 2005).

The need for a more sophisticated approach that sheds some awareness on the specificity of certain linguistic contexts is in line with the results obtained in previous TREC Question Answering competitions (Voorhees, 2002, 2003). There, a system that attempted a minimal understanding of both the question and the answer candidates, by translating them into their logical forms and using an inference engine, achieved a notably higher score than any surface-based system (Moldavan et al., 2002; Harabagiu et al., 2003).

Non-factoid questions introduce an even higher level of difficulty. Unlike factoid questions, there is no simple or unique answer, but more or less satisfactory ones instead. In many cases, they involve dealing with several events, or identifying and reasoning about certain relations among events which are only partially stated in the source documents (such as temporal and causal ones), all of which makes the pattern-based approach less suitable for the task (Small et al., 2003, Soricut and Brill, 2004). Temporal information in particular plays a significant role in the context of question answering systems (Pustejovsky et al., forthcoming). The question in (3), for instance, requires identifying a set of events related to the referred killing of peasants in Mexico, and subsequently ordering them along a temporal axis.

(3) What happened in Chiapas, Mexico, after the killing of 45 peasants in Acteal?

Reasoning about events in intensional contexts, or with event-ordering relations such as temporality and causality, is a requisite for any open-domain QA system aiming at both factoid and non-factoid questions. As a first step, this involves the identification of all relevant events reported in the source documents, so that later processing stages can locate intensional context boundaries and temporal relations among these events.

In this article, we present **Evita**, a tool for recognizing events in natural language texts. It has been developed as part of a suite of tools aimed at providing QA systems with information about both temporal and intensional relations between events; we anticipate, however, that it will be useful for other NLP tasks as well, such as narrative understanding, summarization, and the creation of factual databases from textual sources.

In the next section, we provide the linguistic foundations and technical details of our event recognizer tool. Section 3 gives the results and discusses them in the context of the task. We conclude in section 4, with an overview of Evita's main achievements and a brief discussion of future directions.

2 Evita, An Event Recognition Tool

Evita ('Events In Text Analyzer') is an event recognition system developed under the ARDA-funded TARSQI research framework. TARSQI is devoted to two complementary lines of work: (1) establishing a specification language, TimeML, aimed at capturing the richness of temporal and event related information in language (Pustejovsky et al., 2003a, forthcoming), and (2) the construction of a set of tools that perform tasks of identifying, tagging, and reasoning about eventive and temporal information in natural language texts (Pustejovsky and Gaizauskas, forthcoming, Mani, 2005; Mani and Schiffman, forthcoming; Verhagen, 2004; Verhagen et al., 2005; Verhagen and Knippen, forthcoming). Within TARSQI's framework, Evita's role is locating and tagging all event-referring expressions in the input text that can be temporally ordered.

Evita combines linguistic- and statistically-based techniques to better address all subtasks of event recognition. For example, the module devoted to recognizing temporal information that is expressed through the morphology of certain event expressions (such as tense and aspect) uses grammatical information (see section 2.4), whereas disambiguating nouns that can have both eventive and non-eventive interpretations is carried out by a statistical module (section 2.3).

The functionality of Evita breaks down into two parts: event identification and analysis of the event-based grammatical features that are relevant for temporal reasoning purposes. Both tasks rely on a preprocessing step which performs part-of-speech tagging and chunking, and on a module for clustering together chunks that refer to the same event. In the following subsection we provide the linguistic assumptions informing Evita. Then, subsections 2.2 to 2.5 provide a detailed description of Evita's different subcomponents: preprocessing, clustering of chunks, event identification, and analysis of the grammatical features associated to events.

2.1 Linguistic settings

TimeML identifies as events those event-denoting expressions that participate in the narrative of a given document and which can be temporally ordered. This includes all dynamic situations (punctual or durative) that happen or occur in the text, but also states in which something obtains or holds true, if they are temporally located in the text. As a result, generics and most state-denoting expressions are filtered out (see Saurí et al. (2004) for a more exhaustive definition of the criteria for event candidacy in TimeML).

Event-denoting expressions are found in a wide range of syntactic expressions, such as finite clauses (*that no-one from the White House* **was involved**), nonfinite clauses (*to* **climb** *Everest*), noun phrases headed by nominalizations (*the young industry's rapid* **growth**, *several anti-war* **demonstrations**) or event-referring nouns (*the controversial* **war**), and adjective phrases (*fully* **prepared**).

In addition to identifying the textual extent of events, Evita also analyzes certain grammatical features associated with them. These include:

- The *polarity* (positive or negative) of the expression tells whether the referred event has happened or not;
- *Modality* (as marked by modal auxiliaries *may, can, might, could, should*, etc., or adverbials like *probably, likely*, etc.) qualifies the denoted event with modal information (irrealis, necessity, possibility), and therefore has implications for the suitability of statements as answers to questions, in a parallel way to other intensional contexts exemplified in (1-2);
- *Tense* and *aspect* provide crucial information for the temporal ordering of the events;
- Similarly, the *non-finite morphology* of certain verbal expressions (infinitival, present participle, or past participle) has been shown as useful in predicting temporal relations between events (Lapata and Lascarides, 2004). We also consider as possible values here the categories of noun and adjective.
- Event *class* distinguishes among states (e.g., *be the director of*), general occurrences (*walk*), reporting (*tell*), intensional (*attempt*), and perception (*observe*) events. This classification is relevant for characterizing the nature of the event as irrealis, factual, possible, reported, etc. (recall examples (1-2) above).

Despite the fact that modality, tense, aspect, and non-finite morphology are typically verbal features, some nouns and adjectives can also have this sort of information associated with them; in particular, when they are part of the predicative complement of a copular verb (e.g., *may be* **ready**, *had been a* **collaborator**). A TimeML mark-up of these cases will tag only the complement as an event, disregarding the copular verb. Therefore, the modality, tense, aspect, and non-finite morphology information associated with the verb is incorporated as part of the event identified as the nominal or adjectival complement.

Except for *event class*, the characterization of all the features above relies strictly on surface linguistic cues. Notice that this surface-based approach does not provide for the actual temporal interpretation of the events in the given context. The tense of a verbal phrase, for example, does not always map in a straightforward way with the time being referred to in the world; e.g., simple present is sometimes used to express future time or habituality. We handle the task of mapping event features onto their semantics during a later processing stage, not addressed in this paper, but see Mani and Schiffman (forthcoming).

TimeML does not identify event participants, but the event tag and its attributes have been designed to interface with Named Entity taggers in a straightforward manner. In fact, the issue of argument linking to the events in TimeML is already being addressed in the effort to create a unified annotation with PropBank and NomBank (Pustejovsky et al. 2005). A complete overview of the linguistic foundations of TimeML can be obtained in Pustejovsky et al. (forthcoming).

2.2 Preprocessing

For the task of event recognition, Evita needs access to part of speech tags and to the result of some form of syntactic parsing. Section 2.1 above detailed some of the different syntactic structures that are used to refer to events. However, using a shallow parser is enough to retrieve event referring expressions, since they are generally conveyed by three possible part of speech categories: verbs (*go, see, say*), nouns (*departure, glimpse, war*), and adjectives (*upset, pregnant, dead*).

Part of speech tags and phrase chunks are also valuable for the identification of certain grammatical features such as tense, non-finite morphology, or polarity. Finally, lexical stems are necessary for those tasks involving lexical look-up. We obtain all such grammatical information by first preprocessing the input file using the Alembic Workbench tagger, lemmatizer, and chunker (Day et al., 1997). Evita's input must be XML-compliant, but need not conform to the TimeML DTD.

2.3 Event Recognition

Event identification in Evita is based on the notion of event as defined in the previous section. Only lexical items tagged by the preprocessing stage as either verbs, nouns, or adjectives are considered event candidates.

Different strategies are used for identifying events in these three categories. Event identification in verbal chunks is based on lexical look-up, accompanied by minimal contextual parsing in order to exclude weak stative predicates, such as 'be', and some generics (e.g., verbs with bare plural subjects). For every verbal chunk in the text, Evita first applies a pattern-based selection step that distinguishes among different kinds of information: the chunk head, which is generally the most-right element of verbal nature in the chunk, thus disregarding particles of different sort and punctuation marks; the modal auxiliary sequence, if any (e.g., *may have to*); the sequence of *do, have,* or *be* auxiliaries, marking for aspect, tense and voice; and finally, any item expressing the polarity of the event. The last three pieces of information will be used later, when identifying the event grammatical features (section 2.4).

Based on basic lexical inventories, the chunk may then be rejected if the head belongs to a certain class. For instance, copular verbs are generally disregarded for event tagging, although they enter into a a process of chunk clustering, together with their predicative complement (see section 2.5).

The identification of nominal and adjectival events is also initiated by the step of information selection. For each noun and adjective chunk, their head and polarity markers, if any, are distinguished.

Identifying events expressed by nouns involves two parts: a phase of lexical lookup, and a disambiguation process. The lexical lookup aims at an initial filtering of candidates to nominal events. First, Evita checks whether the head of the noun chunk is an event in WordNet. We identified about 25 subtrees from WordNet where all synsets denote nominal events. One of these, the largest, is the tree underneath the synset that contains the word *event*. Other subtrees were selected by analyzing events in SemCor and TimeBank1.2[2] and mapping them to WordNet synsets. One example is the synset with the noun *phenomenon*. In some cases, exceptions are defined. For example, a noun in a subset subsumed by the *phenomenon* synset is not an event if it is also subsumed by the synset with the noun *cloud* (in other words, many phenomena are events but clouds are not).

If the result of lexical lookup is inconclusive (that is, if a nominal occurs in WN as both and event and a non-event), then a disambiguation step is applied. This process is based on rules learned by a Bayesian classifier trained on SemCor.

Finally, identifying events from adjectives takes a conservative approach of tagging as events only those adjectives that were annotated as such in TimeBank1.2, whenever they appear as the head of a predicative complement. Thus, in addition to the use of corpus-based data, the subtask relies again on a minimal contextual parsing capable of identifying the complements of copular predicates.

[2]TimeBank1.2 is our gold standard corpus of around 200 news report documents from various sources, annotated with TimeML temporal and event information. A previous version, TimeBank1.1, can be downloaded from `http://www.timeml.org/`. For additional information see Pustejovsky et al. (2003b).

2.4 Identification of Grammatical Features

Identifying the grammatical features of events follows different procedures, depending on the part of speech of the event-denoting expression, and whether the feature is explicitely realized by the morphology of such expressions.

In event-denoting expressions that contain a verbal chunk, *tense*, *aspect*, and *non-finite morphology* values are directly derivable from the morphology of this constituent, which in English is quite straightforward. Thus, the identification of these features is done by first extracting the verbal constituents from the verbal chunk (disregarding adverbials, punctuation marks, etc.), and then applying a set of over 140 simple linguistic rules, which define different possible verbal phrases and map them to their corresponding tense, aspect, and non-finite morphology values. Figure 1 illustrates the rule for verbal phrases of future tense, progressive aspect, which bear the modal form *have to* (as in, e.g., *Participants* **will have to be working** *on the same topics*):

```
[form in futureForm],
[form=='have'],
[form=='to', pos=='TO'],
[form=='be'], [pos=='VBG'],
==>
[tense='FUTURE',
aspect='PROGRESSIVE',
nf_morph='NONE']
```

Figure 1: Grammatical Rule

For event-denoting expressions containing no verbal chunk, tense and aspect is established as null (`'NONE'` value), and non-finite morphology is `'noun'` or `'adjective'`, depending on the part-of-speech of their head.

Modality and *polarity* are the two remaining morphology-based features identified here. Evita extracts the values of these two attributes using basic pattern-matching techniques over the approapriate verbal, nominal, or adjectival chunk.

On the other hand, the identification of event *class* cannot rely on linguistic cues such as the morphology of the expression. Instead, it requires a combination of lexical resource-based look-up and word sense disambiguation. At present, this task has been attempted only in a very preliminary way, by tagging events with the class that was most frequently assigned to them in TimeBank1.2. Despite the limitations of such a treatment, the accuracy ratio is fairly good (refer to section 3).

2.5 Clustering of Chunks

In some cases, the chunker applied at the preprocessing stage identifies two independent constituents that contribute information about the same event. This may be due to a chunker error, but it is also systematically the case in verbal phrases containing the *have to* modal form or the *be going to* future form (Figure 2).

```
<VG>
<VX><lex pos="VBD">had</lex></VX>
</VG>
<VG-INF>
<INF><lex pos="TO">to</lex>
<lex pos="VB">say</lex>
</INF>
</VG-INF>
```

Figure 2: *have to* VP

It may be also necessary in verbal phrases with other modal auxiliaries, or with auxiliary forms of the *have*, *do*, or *be* forms, in which the auxiliary part is split off the main verb because of the presence of an adverbial phrase or similar (Figure 3).

```
<VG>
<VX><lex pos="VBZ">has</lex></VX>
</VG>
<lex pos=",">,</lex>
<lex pos="IN">of</lex>
<NG>
<HEAD><lex pos="NN">course</lex></HEAD>
</NG>
<lex pos=",">,</lex>
<VG>
<VX><lex pos="VBD">tried</lex></VX>
</VG>
```

Figure 3: *have V_en* VP

Constructions with copular verbs are another kind of context which requires clustering of chunks, in order to group together the verbal chunk corresponding to the copular predicate and the non-verbal chunk that functions as its predicative complement. In all these cases, additional syntactic parsing is needed for the tasks of event recognition and grammatical feature identification, in order to cluster together the two independent chunks.

The task of clustering chunks into bigger ones is activated by specific triggers (e.g., a chunk headed by an auxiliary form, or a chunk headed by the copular verb *be*) and carried out locally in the context of that trigger. For each trigger, there is a set of grammatical patterns describing the possible structures it can be a constituent of. The form *have*, for instance, may be followed by an infinitival phrase *to V*, constituting part of the modal form *have to* in the bigger verbal group *have to V*, as in Figure 2 above, or it may also be followed by a past participle-headed chunk, with which it forms a bigger verbal phrase *have V-en* expressing perfective aspect (Figure 3).

The grammatical patterns established for each trigger are written using the standard syntax of regular expressions, allowing for a greater expressiveness in the description of sequences of chunks (optionality of elements, inclusion of adverbial phrases and punctuation marks, variability in length, etc.). These patterns are then compiled into finite state automata that work with grammatical objects instead of string characters. Such an approach is based on well-established techniques using finite-state methods (see for instance Koskenniemi, 1992; Appelt et al. 1993; Karttunen et al., 1996; Grefenstette, 1996, among others).

Evita sequentially feeds each of the FSAs for the current trigger with the right-side part of the trigger context (up to the first sentence boundary), which is represented as a sequence of grammatical objects. If one of the FSAs accepts this sequence or a subpart of it, then the clustering operation is applied on the chunks within the accepted (sub)sequence.

3 Results

Evaluation of Evita has been carried out by comparing its performance against TimeBank1.2. The current performance of Evita is at 74.03% precision, 87.31% recall, for a resulting F-measure of 80.12% (with β=0.5). These results are comparable to the interannotation agreement scores for the task of tagging verbal and nominal events, by graduate linguistics students with only basic training (Table 1).[3] By basic training we understand that they had read the guidelines, had been given some additional advice, and subsequently annotated over 10 documents before annotating those used in the interannotation evaluation. They did not, however, have any meetings amongst themselves in order to discuss issues or to agree on a common strategy.

[3]These figures are also in terms of F-measure. See Hripcsak and Rothschild (2005) for the use of such metric in order to quantify interannotator reliability.

Category	F-measure
Nouns	64%
Verbs	80%

Table 1: Interannotation Agreement

On the other hand, the Accuracy ratio (i.e., the percentage of values Evita marked according to the gold standard) on the identification of event grammatical features is as shown:

Feature	Accuracy
polarity	98.26%
aspect	97.87%
modality	97.02%
tense	92.05%
nf_morph	89.95%
class	86.26%

Table 2: Accuracy of Grammatical Features

Accuracy for *polarity, aspect*, and *modality* is optimal: over 97% in all three cases. In fact, we were expecting a lower accuracy for polarity, since Evita relies only on the polarity elements present in the chunk containg the event, but does not take into account non-local forms of expressing polarity in English, such as negative polarity on the subject of a sentence (as in *Nobody saw him* or in *No victims were found*).

The slightly lower ratio for *tense* and *nf_morph* is in most of the cases due to problems from the POS tagger used in the preprocessing step, since tense and non-finite morphology values are mainly based on its result. Some common POS tagging mistakes deriving on tense and nf_morph errors are, for instance, identifying a present form as the base form of the verb, a simple past form as a past participle form, or vice versa. Errors in the nf_morph value are also due to the difficulty in distinguishing sometimes between present participle and noun (for *ing*-forms), or between past participle and adjective.

The lowest score is for event *class*, which nevertheless is in the 80s%. This is the only feature that cannot be obtained based on surface cues. Evita's treatment of this feature is still very basic, and we envision that it can be easily enhanced by exploring standard word sense disambiguation techniques.

4 Discussion and Conclusions

We have presented Evita, a tool for recognizing and tagging events in natural language text. To our knowledge, this is a unique tool within the community, in that it is not based on any pre-established list of event patterns, nor is it restricted to a specific domain. In addition, Evita identifies the grammatical information that is associated with the event-referring expression, such as tense, aspect, polarity, and modality. The characterization of these features is based on explicit linguistic cues. Unlike other work on event recognition, Evita does not attempt to identify event participants, but relies on the use of entity taggers for the linking of arguments to events.

Evita combines linguistic- and statistically-based knowledge to better address each particular subtask of the event recognition problem. Linguistic knowledge has been used for the parsing of very local and controlled contexts, such as verbal phrases, and the extraction of morphologically explicit information. On the other hand, statistical knowledge has contributed to the process of disambiguation of nominal events, following the current trend in the Word Sense Disambiguation field.

Our tool is grounded on simple and well-known technologies; namely, a standard preprocessing stage, finite state techniques, and Bayesian-based techniques for word sense disambiguation. In addition, it is conceived from a highly modular perspective. Thus, an effort has been put on separating linguistic knowledge from the processing thread. In this way we guarantee a low-cost maintainance of the system, and simplify the task of enriching the grammatical knowledge (which can be carried out even by naive programmers such as linguists) when additional data is obtained from corpus exploitation.

Evita is a component within a larger suite of tools. It is one of the steps within a processing sequence which aims at providing basic semantic information (such as temporal relations or intensional context boundaries) to applications like Question Answering or Narrative Understanding, for which text understanding is shown to be fundamental, in addition to shallow-based techniques. Nonetheless, Evita can also be used independently for purposes other than those above.

Additional tools within the TimeML research framework are (a) GUTime, a recognizer of temporal expressions which extends Tempex for TimeML (Mani, 2005), (b) a tool devoted to the temporal ordering and anchoring of events (Mani and Schiffman, forthcoming), and (c) Slinket, an application in charge of identifying subordination contexts that introduce intensional events like those exemplified in (1-2) (Verhagen et al., 2005). Together with these, Evita provides capabilities for a more adequate treatment of temporal and intensional information in textual sources, thereby contributing towards incorporating greater inferential capabilities to applications within QA and related fields, a requisite that has been shown necessary in the Introduction section.

Further work on Evita will be focused on two main areas: (1) improving the sense disambiguation of candidates to event nominals by experimenting with additional learning techniques, and (2) improving event classification. The accuracy ratio for this latter task is already fairly acceptable (86.26%), but it still needs to be enhanced in order to guarantee an optimal detection of subordinating intensional contexts (recall examples 1-2). Both lines of work will involve the exploration and use of word sense disambiguation techniques.

Using Sketches to Estimate Associations

Abstract

We should not have to look at the entire corpus (e.g., the Web) to know if two words are associated or not.[1] A powerful sampling technique called *Sketches* was originally introduced to remove duplicate Web pages. We generalize sketches to estimate contingency tables and associations, using a maximum likelihood estimator to find the most likely contingency table given the sample, the margins (document frequencies) and the size of the collection. Not unsurprisingly, computational work and statistical accuracy (variance or errors) depend on sampling rate, as will be shown both theoretically and empirically. Sampling methods become more and more important with larger and larger collections. At Web scale, sampling rates as low as 10^{-4} may suffice.

1 Introduction

Word associations (co-occurrences) have a wide range of applications including: Speech Recognition, Optical Character Recognition and Information Retrieval (IR) (Church and Hanks, 1991; Dunning, 1993; Manning and Schutze, 1999). It is easy to compute association scores for a small corpus, but more challenging to compute lots of scores for lots of data (e.g. the Web), with billions of web pages (D) and millions of word types (V). For a small corpus, one could compute pair-wise associations by multiplying the (0/1) term-by-document matrix with its transpose (Deerwester et al., 1999). But this is probably infeasible at Web scale.

[1]This work was conducted at Microsoft while the first author was an intern. The authors thank Chris Meek, David Heckerman, Robert Moore, Jonathan Goldstein, Trevor Hastie, David Siegmund, Art Own, Robert Tibshirani and Andrew Ng.

Approximations are often good enough. We should not have to look at every document to determine that two words are strongly associated. A number of sampling-based randomized algorithms have been implemented at Web scale (Broder, 1997; Charikar, 2002; Ravichandran et al., 2005).[2]

A conventional random sample is constructed by selecting D_s documents from a corpus of D documents. The (corpus) sampling rate is $\frac{D_s}{D}$. Of course, word distributions have long tails. There are a few high frequency words and many low frequency words. It would be convenient if the sampling rate could vary from word to word, unlike conventional sampling where the sampling rate is fixed across the vocabulary. In particular, in our experiments, we will impose a floor to make sure that the sample contains at least 20 documents for each term. (When working at Web scale, one might raise the floor somewhat to perhaps 10^4.)

Sampling is obviously helpful at the top of the frequency range, but not necessarily at the bottom (especially if frequencies fall below the floor). The question is: how about "ordinary" words? To answer this question, we randomly picked 15 pages from a Learners' dictionary (Hornby, 1989), and selected the first entry on each page. According to Google, there are 10 million pages/word (median value, aggregated over the 15 words), no where near the floor.

Sampling can make it possible to work in memory, avoiding disk. At Web scale ($D \approx 10$ billion pages), inverted indexes are large (1500 GBs/billion pages)[3], probably too large for memory. But a sample is more manageable; the inverted index for a 10^{-4} sample of the entire web could fit in memory on a single PC (1.5 GB).

[2]*http://labs.google.com/sets* produces fascinating sets, although we don't know how it works. Given the seeds, "America" and "China," *http://labs.google.com/sets* returns: "America, China, Japan, India, Italy, Spain, Brazil, Persia, Europe, Australia, France, Asia, Canada."

[3]This estimate is extrapolated from Brin and Page (1998), who report an inverted index of 37.2 GBs for 24 million pages.

Table 1: The number of intermediate results after the first join can be reduced from 504,000 to 120,000, by starting with "Schwarzenegger & Austria" rather than the baseline ("Schwarzenegger & Terminator"). The standard practice of starting with the two least frequent terms is a good rule of thumb, but one can do better, given (estimates of) joint frequencies.

Query	Hits (Google)
Austria	88,200,000
Governor	37,300,000
Schwarzenegger	4,030,000
Terminator	3,480,000
Governor & Schwarzenegger	1,220,000
Governor & Austria	708,000
Schwarzenegger & Terminator	504,000
Terminator & Austria	171,000
Governor & Terminator	132,000
Schwarzenegger & Austria	120,000

1.1 An Application: The Governator

Google returns the top k hits, plus an estimate of how many hits there are. Table 1 shows the number of hits for four words and their pair-wise combinations. Accurate estimates of associations would have applications in Database query planning (Garcia-Molina et al., 2002). Query optimizers construct a plan to minimize a cost function (e.g., intermediate writes). The optimizer could do better if it could estimate a table like Table 1. But efficiency is important. We certainly don't want to spend more time optimizing the plan than executing it.

Suppose the optimizer wanted to construct a plan for the query: "Governor Schwarzenegger Terminator Austria." The standard solution starts with the two least frequent terms: "Schwarzenegger" and "Terminator." That plan generates 504,000 intermediate writes after the first join. An improvement starts with "Schwarzenegger" with "Austria," reducing the 504,000 down to 120,000.

In addition to counting hits, Table 1 could also help find the top k pages. When joining the first pair of terms, we'd like to know how far down the ranking we should go. Accurate estimates of associations would help the optimizer make such decisions.

It is desirable that estimates be consistent, as well as accurate. Google, for example, reports 6 million hits for "America, China, Britain," and 23 million for "America, China, Britain, Japan." Joint frequencies decrease monotonically: $s \subset S \implies \text{hits}(s) \geq \text{hits}(S)$.

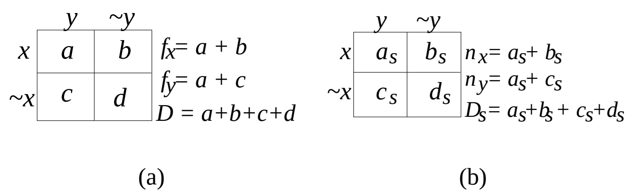

Figure 1: (a): A contingency table for word x and word y. Cell a is the number of documents that contain both x and y, b is the number that contain x but not y, c is the number that contain y but not x, and d is the number that contain neither x nor y. The margins, $f_x = a + b$ and $f_y = a + c$ are known as document frequencies in IR. D is the total number of documents in the collection. (b): A sample contingency table, with "s" indicating the *sample space*.

1.2 Sampling and Estimation

Two-way associations are often represented as two-way contingency tables (Figure 1(a)). Our task is to construct a sample contingency table (Figure 1(b)), and estimate 1(a) from 1(b). We will use a maximum likelihood estimator (MLE) to find the most likely contingency table, given the sample and various other constraints. We will propose a sampling procedure that bridges two popular choices: (A) sampling over documents and (B) sampling over postings. The estimation task is straightforward and well-understood for (A). As we consider more flexible sampling procedures such as (B), the estimation task becomes more challenging.

Flexible sampling procedures are desirable. Many studies focus on rare words (Dunning, 1993; Moore, 2004); butterflies are more interesting than moths. The sampling rate can be adjusted on a word-by-word basis with (B), but not with (A). The sampling rate determines the trade-off between computational work and statistical accuracy.

We assume a standard inverted index. For each word x, there are a set of postings, X. X contains a set of document IDs, one for each document containing x. The size of postings, $f_x = |X|$, corresponds to the margins of the contingency tables in Figure 1(a), also known as document frequencies in IR.

The postings lists are approximated by *sketches*, skX, first introduced by Broder (1997) for removing duplicate web pages. Assuming that document IDs are random (e.g., achieved by a random permutation), we can compute skX, a random sample of

X, by simply selecting the first few elements of X.

In Section 3, we will propose using sketches to construct sample contingency tables. With this novel construction, the contingency table (and summary statistics based on the table) can be estimated using conventional statistical methods such as MLE.

2 Broder's Sketch Algorithm

One could randomly sample two postings and intersect the samples to estimate associations. The sketch technique introduced by Broder (1997) is a significant improvement, as demonstrated in Figure 2.

Assume that each document in the corpus of size D is assigned a unique random ID between 1 and D. The postings for word x is a sorted list of f_x doc IDs. The sketch, skX, is the first (smallest) s_x doc IDs in X. Broder used $\text{MIN}_s(Z)$ to denote the s smallest elements in the set, Z. Thus, $skX = \text{MIN}_{s_x}(X)$. Similarly, Y denotes the postings for word y, and skY denotes its sketch, $\text{MIN}_{s_y}(Y)$. Broder assumed $s_x = s_y = s$.

Broder defined resemblance (R) and sample resemblance (R_s) to be:

$$R = \frac{a}{a+b+c}, \quad R_s = \frac{|\text{MIN}_s(skX \cup skY) \cap skX \cap skY|}{|\text{MIN}_s(skX \cup skY)|}.$$

Broder (1997) proved that R_s is an unbiased estimator of R. One could use R_s to estimate a but he didn't do that, and it is not recommended.[4]

Sketches were designed to improve the coverage of a, as illustrated by Monte Carlo simulation in Figure 2. The figure plots, $\text{E}\left(\frac{a_s}{a}\right)$, percentage of intersections, as a function of (postings) sampling rate, $\frac{s}{f}$, where $f_x = f_y = f$, $s_x = s_y = s$. The solid lines (sketches), $\text{E}\left(\frac{a_s}{a}\right) \approx \frac{s}{f}$, are above the dashed curve (random sampling), $\text{E}\left(\frac{a_s}{a}\right) = \frac{s^2}{f^2}$. The difference is particularly important at low sampling rates.

3 Generalizing Sketches: $R \rightarrow$ Tables

Sketches were first proposed for estimating resemblance (R). This section generalizes the method to construct sample contingency tables, from which we can estimate associations: R, LLR, cosine, etc.

[4]There are at least three problems with estimating a from R_s. First, the estimate is biased. Secondly, this estimate uses just s of the $2 \times s$ samples; larger samples $\rightarrow$ smaller errors. Thirdly, we would rather not impose the restriction: $s_x = s_y$.

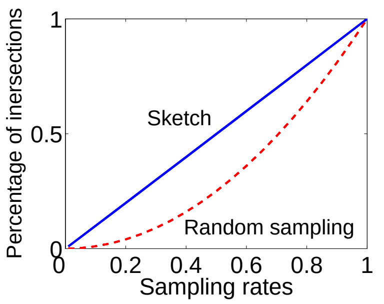

Figure 2: Sketches (solid curves) dominate random sampling (dashed curve). a=0.22, 0.38, 0.65, 0.80, 0.85f, f=0.2D, D=10^5. There is only one dashed curve across all values of a. There are different but indistinguishable solid curves depending on a.

Recall that the doc IDs span the integers from 1 to D with no gaps. When we compare two sketches, skX and skY, we have effectively looked at $D_s = \min\{skX_{(s_x)}, skY_{(s_y)}\}$ documents, where $skX_{(j)}$ is the jth smallest element in skX. The following construction generates the sample contingency table, a_s, b_s, c_s, d_s (as in Figure 1(b)). The example shown in Figure 3 may help explain the procedure.

$$\begin{aligned}
&D_s = \min\{skX_{(s_x)}, skY_{(s_y)}\}, \quad a_s = |skX \cap skY|,\\
&n_x = s_x - |\{j : skX_{(j)} > D_s\}|,\\
&n_y = s_y - |\{j : skY_{(j)} > D_s\}|,\\
&b_s = n_x - a_s, \quad c_s = n_y - a_s, \quad d_s = D_s - a_s - b_s - c_s.
\end{aligned}$$

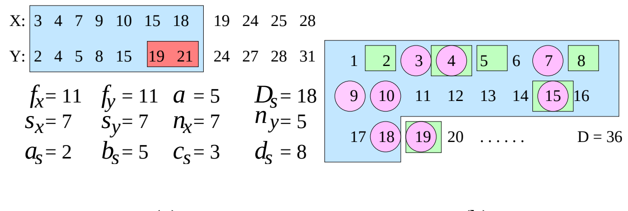
Given the sample contingency table, we are now ready to estimate the contingency table. It is sufficient to estimate a, since the rest of the table can be determined from f_x, f_y and D. For practical applications, we recommend the convenient closed-form approximation (8) in Section 5.1.

4 Margin-Free (MF) Baseline

Before considering the proposed MLE method, we introduce a baseline estimator that will not work as well because it does not take advantage of the margins. The baseline is the *multivariate hypergeometric* model, usually simplified as a *multinomial* by assuming "sample-with-replacement."

The sample expectations are (Siegrist, 1997),

$$\text{E}(a_s) = \frac{D_s}{D}a, \qquad \text{E}(b_s) = \frac{D_s}{D}b,$$
$$\text{E}(c_s) = \frac{D_s}{D}c, \qquad \text{E}(d_s) = \frac{D_s}{D}d. \tag{1}$$



X: 3 4 7 9 10 15 18 19 24 25 28
Y: 2 4 5 8 15 19 21 24 27 28 31
f_x = 11 f_y = 11 a = 5 D_s = 18
s_x = 7 s_y = 7 n_x = 7 n_y = 5
a_s = 2 b_s = 5 c_s = 3 d_s = 8
1 2 3 4 5 6 7 8
9 10 11 12 13 14 15 16
17 18 19 20 ...... D = 36
(a)
(b)

Figure 3: (a): The two sketches, skX and skY (larger shaded box), are used to construct a sample contingency table: a_s, b_s, c_s, d_s. skX consists of the first $s_x = 7$ doc IDs in X, the postings for word x. Similarly, skY consists of the first $s_y = 7$ doc IDs in Y, the postings for word y. There are 11 doc IDs in both X and Y, and $a = 5$ doc IDs in the intersection: {4, 15, 19, 24, 28}. (a) shows that $D_s = \min(18, 21) = 18$. Doc IDs 19 and 21 are excluded because we cannot determine if they are in the intersection or not, without looking outside the box. As it turns out, 19 is in the intersection and 21 is not. (b) enumerates the $D_s = 18$ documents, showing which documents contain x (small circles) and which contain y (small squares). Both procedures, (a) and (b), produce the same sample contingency table: $a_s = 2$, $b_s = 5$, $c_s = 3$ and $d_s = 8$.

The margin-free estimator and its variance are

$$\hat{a}_{MF} = \frac{D}{D_s}a_s, \;\; \text{Var}(\hat{a}_{MF}) = \frac{D}{D_s}\frac{1}{\frac{1}{a}+\frac{1}{D-a}}\frac{D-D_s}{D-1}. \quad (2)$$

For the multinomial simplification, we have

$$\hat{a}_{MF,r} = \frac{D}{D_s}a_s, \quad \text{Var}(\hat{a}_{MF,r}) = \frac{D}{D_s}\frac{1}{\frac{1}{a}+\frac{1}{D-a}}. \quad (3)$$

where "r" indicates "sample-with-replacement."

The term $\frac{D-D_s}{D-1} \approx \frac{D-D_s}{D}$ is often called the "finite-sample correction factor" (Siegrist, 1997).

5 The Proposed MLE Method

The task is to estimate the contingency table from the samples, the margins and D. We would like to use a maximum likelihood estimator for the most probable a, which maximizes the (full) likelihood (probability mass function, PMF) $P(a_s, b_s, c_s, d_s; a)$. Unfortunately, we do not know the exact expression for $P(a_s, b_s, c_s, d_s; a)$, but we do know the conditional probability $P(a_s, b_s, c_s, d_s|D_s; a)$. Since the doc IDs are uniformly random, sampling the first D_s contiguous documents is statistically equivalent to randomly sampling D_s documents from the corpus. Based on this key observation and Figure 3, *conditional* on D_s, $P(a_s, b_s, c_s, d_s|D_s; a)$ is the PMF of a two-way sample contingency table.

We factor the full likelihood into:

$$P(a_s, b_s, c_s, d_s; a) = P(a_s, b_s, c_s, d_s|D_s; a) \times P(D_s; a).$$

$P(D_s; a)$ is difficult. However, since we do not expect a strong dependency of D_s on a, we maximize the partial likelihood instead, and assume that is good enough. An example of partial likelihood is the Cox proportional hazards model in survival analysis (Venables and Ripley, 2002, Section 13.3) .

Our partial likelihood is

$$P(a_s, b_s, c_s, d_s|D_s; a) = \frac{\binom{a}{a_s}\binom{f_x-a}{b_s}\binom{f_y-a}{c_s}\binom{D-f_x-f_y+a}{d_s}}{\binom{D}{D_s}}$$
$$\propto \prod_{i=0}^{a_s-1}(a-i) \times \prod_{i=0}^{b_s-1}(f_x-a-i) \times \prod_{i=0}^{c_s-1}(f_y-a-i)$$
$$\times \prod_{i=0}^{d_s-1}(D-f_x-f_y+a-i), \quad (4)$$

where $\binom{n}{m} = \frac{n!}{m!(n-m)!}$. "$\propto$" is "proportional to."

We now derive an MLE for (4), a result that was not previously known, to the best of our knowledge. Let $\hat{a}_{MLE}$ maximizes $\log P(a_s, b_s, c_s, d_s|D_s; a)$:

$$\sum_{i=0}^{a_s-1}\log(a-i) + \sum_{i=0}^{b_s-1}\log(f_x-a-i)$$
$$+ \sum_{i=0}^{c_s-1}\log(f_y-a-i) + \sum_{i=0}^{d_s-1}\log(D-f_x-f_y+a-i),$$

whose first derivative, $\frac{\partial \log P(a_s,b_s,c_s,d_s|D_s;a)}{\partial a}$, is

$$\sum_{i=0}^{a_s-1}\frac{1}{a-i} - \sum_{i=0}^{b_s-1}\frac{1}{f_x-a-i} - \sum_{i=0}^{c_s-1}\frac{1}{f_y-a-i}$$
$$+ \sum_{i=0}^{d_s-1}\frac{1}{D-f_x-f_y+a-i}. \quad (5)$$

Since the second derivative, $\frac{\partial^2 \log P(a_s,b_s,c_s,d_s|D_s;a)}{\partial a^2}$, is negative, the log likelihood function is concave, hence has a unique maximum. One could numerically solve (5) for $\frac{\partial \log P(a_s,b_s,c_s,d_s|D_s;a)}{\partial a} = 0$. However, we derive the exact solution using the following updating formula from (4):

$$P(a_s,b_s,c_s,d_s|D_s;a) = P(a_s,b_s,c_s,d_s|D_s;a-1)\times \frac{f_x-a+1-b_s}{f_x-a+1}\frac{f_y-a+1-c_s}{f_y-a+1}\frac{D-f_x-f_y+a}{D-f_x-f_y+a-d_s} \frac{a}{a-a_s} = P(a_s,b_s,c_s,d_s|D_s;a-1)\times g(a). \tag{6}$$

Since our MLE is unique, it suffices to find a from $g(a)=1$, which is a cubic function in a.

5.1 A Convenient Practical Approximation

Rather than solving the cubic equation for the exact MLE, the following approximation may be more convenient. Assume we sample $n_x = a_s + b_s$ from X and obtain a_s co-occurrences without knowledge of the samples from Y. Further assuming "sample-with-replacement," a_s is then binomially distributed, $a_s \sim \text{Binom}(n_x, \frac{a}{f_x})$. Similarly, assume $a_s \sim \text{Binom}(n_y, \frac{a}{f_y})$. Under these assumptions, the PMF of a_s is a product of two binomial PMFs:

$$\binom{f_x}{n_x}\left(\frac{a}{f_x}\right)^{a_s}\left(\frac{f_x-a}{f_x}\right)^{b_s}\binom{f_y}{n_y}\left(\frac{a}{f_y}\right)^{a_s}\left(\frac{f_y-a}{f_y}\right)^{c_s} \propto a^{2a_s}(f_x-a)^{b_s}(f_y-a)^{c_s}. \tag{7}$$

Setting the first derivative of the logarithm of (7) to be zero, we obtain $\frac{2a_s}{a} - \frac{b_s}{f_x-a} - \frac{c_s}{f_y-a} = 0$, which is quadratic in a and has a solution:

$$\hat{a}_{MLE,a} = \frac{f_x(2a_s+c_s)+f_y(2a_s+b_s)}{2(2a_s+b_s+c_s)} - \frac{\sqrt{(f_x(2a_s+c_s)-f_y(2a_s+b_s))^2+4f_xf_yb_sc_s}}{2(2a_s+b_s+c_s)}. \tag{8}$$

Section 6 shows that $\hat{a}_{MLE,a}$ is very close to $\hat{a}_{MLE}$.

5.2 Theoretical Evaluation: Bias and Variance

How good are the estimates? A popular metric is mean square error (MSE): $\text{MSE}(\hat{a}) = \text{E}(\hat{a}-a)^2 = \text{Var}(\hat{a}) + \text{Bias}^2(\hat{a})$. If $\hat{a}$ is unbiased, $\text{MSE}(\hat{a}) = \text{Var}(\hat{a}) = \text{SE}^2(\hat{a})$, where SE is the standard error. Here all expectations are conditional on D_s.

Large sample theory (Lehmann and Casella, 1998, Chapter 6) says that, under "sample-with-replacement," $\hat{a}_{MLE}$ is asymptotically unbiased and converges to Normal with mean a and variance $\frac{1}{\text{I}(a)}$, where $\text{I}(a)$, the Fisher Information, is

$$\text{I}(a) = -\text{E}\left(\frac{\partial^2}{\partial a^2}\log P(a_s,b_s,c_s,d_s|D_s;a,r)\right). \tag{9}$$

Under "sample-with-replacement," we have

$$P(a_s,b_s,c_s,d_s|D_s;a,r) \propto \left(\frac{a}{D}\right)^{a_s}\times\left(\frac{f_x-a}{D}\right)^{b_s} \times\left(\frac{f_y-a}{D}\right)^{c_s}\times\left(\frac{D-f_x-f_y+a}{D}\right)^{d_s}, \tag{10}$$

Therefore, the Fisher Information, $\text{I}(a)$, is

$$\frac{\text{E}(a_s)}{a^2}+\frac{\text{E}(b_s)}{(f_x-a)^2}+\frac{\text{E}(c_s)}{(f_y-a)^2}+\frac{\text{E}(d_s)}{(D-f_x-f_y+a)^2}. \tag{11}$$

We plug (1) from the margin-free model into (11) as an approximation, to obtain

$$\text{Var}(\hat{a}_{MLE}) \approx \frac{\frac{D}{D_s}-1}{\frac{1}{a}+\frac{1}{f_x-a}+\frac{1}{f_y-a}+\frac{1}{D-f_x-f_y+a}}, \tag{12}$$

which is $\frac{1}{\text{I}(a)}$ multiplied by $\frac{D-D_s}{D}$, the "finite-sample correction factor," to consider "sample-without-replacement."

We can see that $\text{Var}(\hat{a}_{MLE})$ is less than $\text{Var}(\hat{a}_{MF})$ in (2). In addition, $\hat{a}_{MLE}$ is asymptotically unbiased while $\hat{a}_{MF}$ is no longer unbiased under margin constraints. Therefore, we expect $\hat{a}_{MLE}$ has smaller MSE than $\hat{a}_{MF}$. In other words, the proposed MLE method is more accurate than the MF baseline, in terms of variance, bias and mean square error. If we know the margins, we ought to use them.

5.3 Unconditional Bias and Variance

$\hat{a}_{MLE}$ is also unconditionally unbiased:

$$\text{E}(\hat{a}_{MLE}-a) = \text{E}(\text{E}(\hat{a}_{MLE}-a|D_s)) \approx \text{E}(0) = 0. \tag{13}$$

The unconditional variance is useful because often we would like to estimate the errors before knowing D_s (e.g., for choosing sample sizes).

To compute the unconditional variance of $\hat{a}_{MLE}$, we should replace $\frac{D}{D_s}$ with $\text{E}\left(\frac{D}{D_s}\right)$ in (12). We resort to an approximation for $\text{E}\left(\frac{D}{D_s}\right)$. Note that $skX_{(s_x)}$ is the order statistics of a discrete random variable (Siegrist, 1997) with expectation

$$\text{E}\left(skX_{(s_x)}\right) = \frac{s_x(D+1)}{f_x+1} \approx \frac{s_x}{f_x}D. \tag{14}$$

By Jensen's inequality, we know that

$$\text{E}\left(\frac{D_s}{D}\right) \le \min\left(\frac{\text{E}\left(skX_{(s_x)}\right)}{D}, \frac{\text{E}\left(skY_{(s_y)}\right)}{D}\right) = \min\left(\frac{s_x}{f_x}, \frac{s_y}{f_y}\right) \tag{15}$$

$$\text{E}\left(\frac{D}{D_s}\right) \ge \frac{1}{\text{E}\left(\frac{D_s}{D}\right)} \ge \max\left(\frac{f_x}{s_x}, \frac{f_y}{s_y}\right). \tag{16}$$

Table 2: Gold standard joint frequencies, a. Document frequencies are shown in parentheses. These words are frequent, suitable for evaluating our algorithms at very low sampling rates.

	THIS	HAVE	HELP	PROGRAM
THIS (27633)	—	13517	7221	3682
HAVE (17396)	13517	—	5781	3029
HELP (10791)	7221	5781	—	1949
PROGRAM (5327)	3682	3029	1949	—

Replacing the inequalities with equalities underestimates the variance, but only slightly.

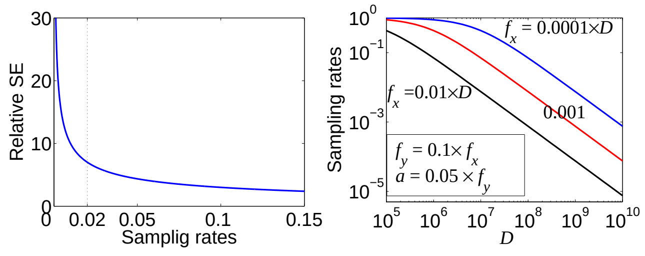
5.4 Smoothing

Although not a major emphasis here, our evaluations will show that $\hat{a}_{MLE+S}$, a smoothed version of the proposed MLE method, is effective, especially at low sampling rates. $\hat{a}_{MLE+S}$ uses "add-one" smoothing. Given that such a simple method is as effective as it is, it would be worth considering more sophisticated methods such as Good-Turing.

5.5 How Many Samples Are Sufficient?

The answer depends on the trade-off between computation and estimation errors. One simple rule is to sample "2%." (12) implies that the standard error is proportional to $\sqrt{D/D_s - 1}$. Figure 4(a) plots $\sqrt{D/D_s - 1}$ as a function of sampling rate, D_s/D, indicating a "elbow" about 2%. However, 2% is too large for high frequency words.

A more reasonable metric is the "coefficient of variation," cv = $\frac{\text{SE}(\hat{a})}{a}$. At Web scale (10 billion pages), we expect that a very small sampling rate such as 10^{-4} or 10^{-5} will suffice to achieve a reasonable cv (e.g., 0.5). See Figure 4(b).



(a) (b)

Figure 4: How large should the sampling rate be? (a): We can sample up to the "elbow point" (2%), but after that there are diminishing returns. (b): An analysis based on cv = $\frac{\text{SE}}{a}$ = 0.5 suggests that we can get away with much lower sampling rates. The three curves plot the critical value for the sampling rate, $\frac{D_s}{D}$, as a function of corpus size, D. At Web scale, $D \approx 10^{10}$, sampling rates above 10^{-3} to 10^{-5} satisfy cv < 0.5, at least for these settings of f_x, f_y and a. The settings were chosen to simulate "ordinary" words. The three curves correspond to three choices of f_x: $D/100$, $D/1000$, and $D/10,000$. $f_y = f_x/10$, $a = f_y/20$. SE is based on (12).

6 Evaluation

Two sets of experiments were run on a collection of $D = 2^{16}$ web pages, provided by MSN. The first experiment considered 4 English words shown in Table 2, and the second experiment considers 968 English words with mean *df* = 2135 and median *df* = 1135. They form 468,028 word pairs, with mean co-occurrences = 188 and median = 74.

6.1 Small Dataset Monte Carlo Experiment

Figure 5 evaluates the various estimate methods by MSE over a wide range of sampling rates. Doc IDs were randomly permuted 10^5 times. For each permutation we constructed sketches from the inverted index at a series of sampling rates. The figure shows that the proposed method, $\hat{a}_{MLE}$, is considerably better (by $20\% - 40\%$) than the margin-free baseline, $\hat{a}_{MF}$. Smoothing is effective at low sampling rates. The recommended approximation, $\hat{a}_{MLE,a}$, is remarkably close to the exact solution.

Figure 6 shows agreement between the theoretical and empirical unconditional variances. Smoothing reduces variances, at low sampling rates. We used the empirical $\text{E}\left(\frac{D}{D_S}\right)$ to compute the theoretical variances. The approximation, $\max\left(\frac{f_x}{s_x}, \frac{f_y}{s_y}\right)$, is $> 0.95\text{E}\left(\frac{D}{D_S}\right)$ at sampling rates > 0.01.

Figure 7 verifies that the proposed MLE is unbiased, unlike the margin-free baselines.

6.2 Large Dataset Experiment

The large experiment considers 968 English words (468,028 pairs) over a range of sampling rates. A floor of 20 was imposed on sample sizes.

As reported in Figure 8, the large experiment confirms once again that proposed method, $\hat{a}_{MLE}$, is considerably better than the margin-free baseline (by

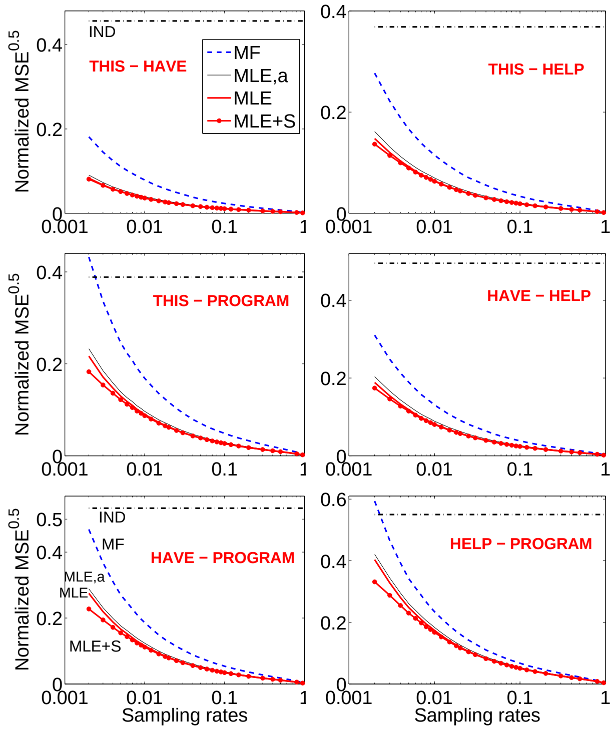


Figure 5: The proposed method, $\hat{a}_{MLE}$ outperforms the margin-free baseline, $\hat{a}_{MF}$, in terms of $\frac{\text{MSE}^{0.5}}{a}$. The recommended approximation, $\hat{a}_{MLE,a}$, is close to $\hat{a}_{MLE}$. Smoothing, $\hat{a}_{MLE+S}$, is effective at low sampling rates. All methods are better than assuming independence (IND).

$15\% - 30\%$). The recommended approximation, $\hat{a}_{MLE,a}$, is close to $\hat{a}_{MLE}$. Smoothing, $\hat{a}_{MLE+S}$ helps at low sampling rates.

6.3 Rank Retrieval: Top k Associated Pairs

We computed a gold standard similarity cosine ranking of the 468,028 pairs using a 100% sample: $\cos = \frac{a}{\sqrt{f_x f_y}}$. We then compared the gold standard to rankings based on smaller samples. Figure 9(a) compares the two lists in terms of agreement in the top k. For $3 \leq k \leq 200$, with a sampling rate of 0.005, the agreement is consistently 70% or higher. Increasing sampling rate, increases agreement.

The same comparisons are evaluated in terms of precision and recall in Figure 9(b), by fixing the top 1% of the gold standard list but varying the top percentages of the sample list. Again, increasing sampling rate, increases agreement.

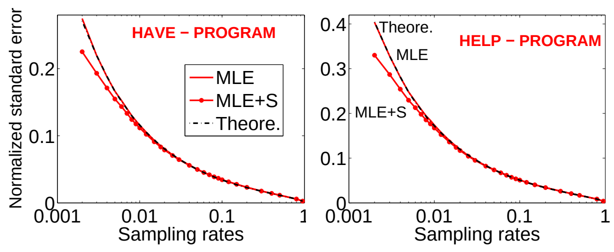

Figure 6: The theoretical and empirical variances show remarkable agreement, in terms of $\frac{\text{SE}(\hat{a})}{a}$. Smoothing reduces variances at low sampling rates.

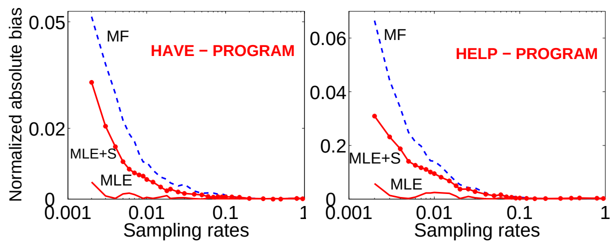

Figure 7: Biases in terms of $\frac{|\text{E}(\hat{a})-a|}{a}$. $\hat{a}_{MLE}$ is practically unbiased, unlike $\hat{a}_{MF}$. Smoothing increases bias slightly.

7 Conclusion

We proposed a novel sketch-based procedure for constructing sample contingency tables. The method bridges two popular choices: (A) sampling over documents and (B) sampling over postings. Well-understood maximum likelihood estimation (MLE) techniques can be applied to sketches (or to traditional samples) to estimate word associations. We derived an exact cubic solution, $\hat{a}_{MLE}$, as well as a quadratic approximation, $\hat{a}_{MLE,a}$. The approximation is recommended because it is close to the exact solution, and easy to compute.

The proposed MLE methods were compared empirically and theoretically to a margin-free (MF) baseline, finding large improvements. When we know the margins, we ought to use them.

Sample-based methods (MLE & MF) are often better than sample-free methods. Associations are often estimated without samples. It is popular to assume independence: (Garcia-Molina et al., 2002, Chapter 16.4), i.e., $\hat{a} \approx \frac{f_x f_y}{D}$. Independence led to large errors in our experiments.

Not unsurprisingly, there is a trade-off between computational work (space and time) and statistical

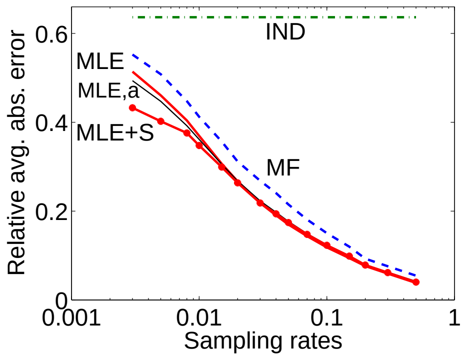

Figure 8: We report the (normalized) mean absolute errors (divided by the mean co-occurrences, 188). All curves are averaged over three permutations. The proposed MLE and the recommended approximation are very close and both are significantly better than the margin-free (MF) baseline. Smoothing, $\hat{a}_{MLE+S}$, helps at low sampling rates. All estimators do better than assuming independence.

accuracy (variance or errors); reducing the sampling rate saves work, but costs accuracy. We derived formulas for variance, showing precisely how accuracy depends on sampling rate. Sampling methods become more and more important with larger and larger collections. At Web scale, sampling rates as low as 10^{-4} may suffice for "ordinary" words.

We have recently generalized the sampling algorithm and estimation method to multi-way associations; see (Li and Church, 2005).

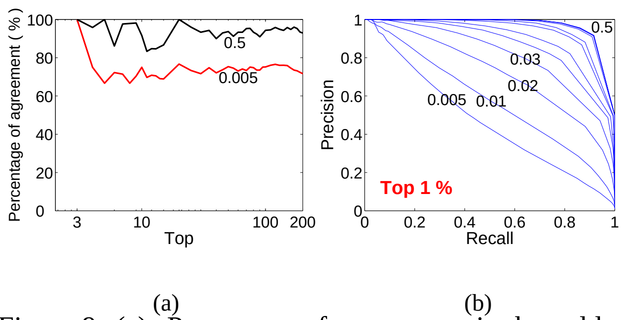

Figure 9: (a): Percentage of agreements in the gold standard and reconstructed (from samples) top 3 to 200 list. (b):Precision-recall curves in retrieving the top 1% gold standard pairs, at different sampling rates. For example, 60% recall and 70% precision is achieved at sampling rate = 0.02.

Context and Learning in Novelty Detection

Barry Schiffman and **Kathleen R. McKeown**

Abstract

We demonstrate the value of using context in a new-information detection system that achieved the highest precision scores at the Text Retrieval Conference's Novelty Track in 2004. In order to determine whether information within a sentence has been seen in material read previously, our system integrates information about the context of the sentence with novel words and named entities within the sentence, and uses a specialized learning algorithm to tune the system parameters.

1 Introduction

New-information detection addresses two important problems in a society awash in more digital information than people can exploit. A novelty detection system could help people who are tracking an event in the news, where numerous sources present similar material. It could also provide a way to organize summaries by focusing on the most recent information, much like an automated bulletin service.

We envision that many types of users would find such a system valuable. Certainly analysts, business people, and anyone interested in current events, would benefit from being able to track news stories automatically, without repetition. Different news organizations report on the same event, often working hard to make their reports look different from one another, whether or not they have new material to report. Our system would help readers to zero in on new information. In addition, a focus on new information provides a way of organizing a general summary.

Our approach is unique in representing and maintaining the focus in discourse. The idea stems from the fact that novelty often comes in bursts, which is not surprising since the articles are composed of some number of smaller, coherent segments. Each segment is started by some kind of introductory passage, and that is where we expect to find the *novel* words. Novel words are identified by comparing the current sentence's words against a table of all words seen in the inputs to that point. They let us know whether the entire segment is likely to contain more novel material. Subsequent passages are likely to continue the novel discussion whether or not they contain novel words. They may contain pronomial references or other anaphoric references to the novel entity. Our long-term goal is to integrate the approach described in this paper into our larger new-information detector, a system that performs a more complicated syntactic analysis of the input texts and employs machine learning to classify passages as new or old.

Meanwhile, we tested our focus-based approach at the Novelty Track at the Text Retrieval Conference (TREC) in 2004. The Novelty Tracks in 2003 and in 2004 were divided into four tasks; Task 1 and Task 3 incorporate retrieval, requiring submissions to locate the relevant sentences before filtering them for novelty. Tasks 2 and 4 are novelty detection alone, using the relevant sentences selected by humans as input. Since our interest is in novelty detection, we chose to concentrate on Task 2[1] Our TREC submission was also designed to test a specialized learning mechanism we implemented to target either high precision or high recall.

In all, the problem of novelty detection is deceptively difficult. We were struck by the difficulty that all groups in the Novelty Track in 2002 and 2003 had in obtaining high precision scores. Submissions that classify a very large proportion of the input sentences as novel reached the highest F-measure scores by getting high recall scores, but failed to achieve any substantial compression of material for users. Given that our goal is to generate an update summary, we focused on improving precision and increasing compression, removing as many false positives as possible.

The next section discusses the Novelty Track and the approaches others have tried; Section 3 details our system, and Section 4 presents the experiments.

2 Novelty Track

Much of the work in new-information detection has been done for the TREC Novelty Track. The task is related to first story detection, which is defined on whole documents rather than on passages within documents. In Task 1 of the Novelty Track, a system is given about 25 documents on a topic and asked to find all sentences relevant to the topic. In Task 2, the inputs are the set of relevant sentences, so that the program does not see the entire documents. The program must scan the sentences in order and output all that contain new information, that is information not seen in the previous input sentences.

2.1 Related Work

At the recent TREC, Dublin City University did well by comparing the words in a sentence against the accumulated words in all previous sentences (Blott et al., 2004). Their runs varied the way in which the words were weighted with frequency and inverse document frequency. Like our system, theirs follows from the intuition that words that are new to a discussion are evidence of novelty. But our system distinguishes between several kinds of words, including common nouns, named persons, named organization, etc. Our system also incorporates a mechanism for looking at the context of the sentence.

Both the Dublin system and ours are preceded by the University of Iowa's approach at TREC 2003. It based novelty decisions on a straightforward count of new named entities and noun phrases in a sentence (Eichmann et al., 2003). In 2004, the Iowa system (Eichmann et al., 2004) tried several embellishments, one using synonyms in addition to the words for novelty comparisons, and one using word-sense disambiguation. These two runs were above average in F-measure and about average in precision.

The University of Massachusetts system (Abdul-Jaleel et al., 2004) mixed a vector-space model with cosine similarity and a count of previously unseen named entities. Their system resembled one of two baseline methods that we submitted without our focus feature. Their submission used a similarity threshold that was tuned experimentally, while ours was learned automatically. In earlier work with the TREC 2002 data, UMass (Allan et al., 2003) compared a number of sentence-based models ranging in complexity from a count of new words and cosine distance, to a variety of sophisticated models based on KL divergence with different smoothing strategies and a "core mixture model" that considered the distribution of the words in the sentence with the distributions in a topic model and a general English model.

A number of groups have experimented with matrix-based methods. In 2003, a group from the University of Maryland and the Center for Computing Sciences (Conroy et al., 2003) used three techniques that used QR decomposition and singular value decomposition. The University of Maryland, Baltimore County, worked with clustering algorithms and singular value decomposition in sentence-sentence similarity matrices (Kallurkar et al., 2003). In 2004, Conroy (Conroy, 2004) tested Maximal Marginal Relevance (Goldstein et al., 2000) as well as QR decomposition.

The information retrieval group at Tsinghua University used a pooling technique, grouping similar sentences into clusters in order to capture sentences that partially match two or more other sentences(Ru et al., 2004). They said they had found difficulties

[1]Task 4 was similar to Task 2, in that both have the human annotations as input. For Task 2, participants only get the annotations, but in Task 4, they also receive the novel sentences from the fi rst fi ve documents as input. We felt that we would learn as much from the one task as from both.

with sentence-by-sentence comparisons.

2.2 Precision

At all three Novelty Track evaluations, from 2002 to 2004, it is clear that high precision is much harder to obtain than high recall. Trivial baselines – such as accept all sentences as novel – have proved to be difficult to beat by very much. This one-line algorithm automatically obtains 100% recall and precision equal to the proportion of novel sentences in the input. In 2003, when 66% of the relevant sentences were novel, the mean precision score was 0.635[2] and the median was 0.7. In 2004, 41% of the relevant sentences were novel, and the average precision dropped to 0.46. The median precision was also 0.46. Meanwhile, average recall scores across all submissions actually rose to 0.861 in 2004, compared with 0.795 in 2003. In terms of a real world system, this means that as the number of target sentences shrank, the number of sentences in the average program output rose. Likewise, a trivial system could guarantee no errors by returning nothing, but this would have no value.

2.3 Sentences

Normally, in Information Retrieval tasks, stricter thresholds result in higher precision, and looser thresholds, higher recall. In that way, a system can target its results to a user's needs. But in new-information detection, this rule of thumb fails at some point as thresholds become stricter. Recall does fall, but precision does not rise. In other words, there seems to be a ceiling for precision.

Several participants noted that their simpler strategies produced the best results. For example, in 2003, the Chinese Academy of Sciences (Sun et al., 2003), noted that word overlap was surprisingly strong as a similarity measure. As we have seen above, the Iowa approach of counting nouns was incorporated by a few others for 2004, including us. This strategy compares words in a sentence against all previous seen words and thus, avoids computing pairwise similarity between all sentences. Almost all participants performed such pairwise comparisons of systems.

A sentence-by-sentence comparison is clearly not the optimal operation for establishing novelty. Sentences with a large amount of overlap can express very different thoughts. In the extreme, a single word change can reverse the meaning of two sentences: *accept* and *reject*. This phenomenon led the Tsinghua University group to remark, "many sentences with an overlap of nearly 1 are real novel ones." (Ru et al., 2004).

On the other hand, it's not hard to find cases where realizations of equivalent statements take many different surface forms – with different choices of words and different syntactic structures. The data in the Novelty Task is drawn from three news services and clustered into fairly cohesive sets. The news writers consciously try to avoid echoing each other, and over time, echoing themselves. Sentences such as these have low word overlap, but are not novel. For this reason, we turned to a strategy of classifying each sentence S_i against the cumulative background of all the words in all preceding sentences $S_{1 \ldots i-1}$.

3 System

The system described in this paper was built with the Novelty Track in mind. The goal was to look at ways to consider longer spans of text than a sentence, and to avoid sentence by sentence comparisons.

In the Novelty track, the relevant sentences are presented in natural order, i.e. by the date of the document they came from, and then by their location in the document. The key characteristics of our program include:

- For each relevant sentence, our program calculates a sum of novel terms, which are terms that have not been previously seen. The terms are weighted according to their category, like person, location, common noun or verb. The weights are learned automatically.

- For the entire set, the program maintains a focus variable, which indicates whether the previous sentence is novel or old. Thresholds determine whether to continue or shift the focus. These are also learned automatically.

[2]One group appeared to have submitted a large number of irrelevant sentences in its submission, since it obtained relatively high recall scores, but very low precision scores, causing the average to drop below 0.66. The average precision of all other groups is about 0.7.

All input documents are fed in parallel into a named-entity recognizer, which marks persons, organizations, locations, part-of-speech tags for common nouns, and into a finite-state parser, which is used only to identify sentences beginning with subject pronouns. The output from the two preprocessing modules are merged and sent to the classifier.

The classifier reads a configuration file that contains a set of weights that were learned on the 2003 Novelty Track data to apply to different classes of words that have not been previously seen.

For each sentence, the system adds up the amount of novelty from the weighted terms in a sentence and compares that to a learned threshold; it classifies the sentence as novel if it exceeds the threshold. It also stores the classification in a focus variable. If the novelty threshold is not met, the system performs a series of tests described below, and possibly classifies some sentences with few content words as novel, depending on the status of the focus variable. Our algorithm enumerates all cases of changes in focus, and tests these in the order that allows the system to make the decision it can be most confident about first. Thus, when we find a named entity new to the discussion, we can be pretty sure that we have found a novel sentence. We can classify that sentence as new without regard to what preceded it. But, when we find a sentence devoid of high-content words, like "She said the idea sounded good," the system uses the classification of the previous sentence. If the antecedents to *she* or *idea* are novel, then this sentence must also be novel. The series of learned thresholds are imposed in a cascade to maximize the number of correct decisions over the training cases, in hopes the values will also cover unseen cases.

Thus, the classifier puts each sentence through the tests below, using the learned thresholds and weights described in Section 3.1. If any test succeeds, the system goes on to the next sentence.

1. *If there is a sufficient concentration of novel words, classify the sentence as novel* A sufficient concentration occurs when the sum of the weights of the novel content words (including named entities) exceeds a threshold, T_{novel}. If the previous focus was old, this indicates the focus has shifted to a novel segment.

2. *If there is a lack of novel words, classify the sentence as old* This is computed by comparing the sum of the weights of the already-seen content words to a separate threshold, T_{old}. If the previous focus was novel, this means the focus has shifted to an old segment.

3. For any remaining sentences, the classification is based on context:

   (a) *If the sentence does not have a sufficient number of content words, use the classification in the focus variable.* This adds the sums of both new and old content words and compares that to a threshold, T_{keep}.

   (b) *If the first noun phrase is a third person personal pronoun, use the classification in the focus variable.* Pronouns are known to signal that the same focus continues (Grosz and Sidner, 1986).

   (c) *If the sentence has not met any of the above tests but has a minimum number of content words, shift the focus.* If all tests above fail and there are a minimum number of content words, with a sum of T_{shift} shift the focus.

4. *Default* This rarely occurs but the default is to continue the focus, whether novel or old.

We examined the 2003 Novelty Track data and found that more than half the novel sentences appear in sequences of consecutive sentences (See Table 1). This circumstance creates an opportunity to make principled classifications on some sentences that have few, if any, clearly novel words, but continue a new segment. The use of a focus variable handles these cases.

3.1 Learning

In all, the system uses 11 real-valued parameters, weights and thresholds, and we wanted to learn optimal values for these. In particular, we wanted to be able to target either high recall or high precision, As we noted above, precision was much more difficult, and for a summarization task, much more important.

To learn the optimal values for the parameters, we opted to use an ad hoc algorithm. The main advantage in doing so was when considering instance i, the program can reference the classifications made

Length of Run	Count
1	1338
2	421
3	132
4	72
5	43
6	22
7	11
8	2
9	3
10	3
11	2
12	2
15	2
17	1

Table 1: Novelty often comes in bursts. This table shows that 1,338 of the novel sentences in the 2003 evaluation were singletons, and not a part of a run of novel sentences. Meanwhile, 1,526 of the sentences were part of runs of 2, 3 or 4 sentences.

for instance $i-1$, $i-2$, and possibly all the way back to instance 1, because the classification for instance i partly depends on the classification of previous instances. Not only do many standard supervised learning methods assume conditional independence, but they also do not provide access to the online classifications during learning. We constructed a randomized hill-climbing. The learner is structured like a neural net, but the weight adjustments are chosen at random as they are in genetic algorithms (See Figure 1). The evaluation, or fitness function, is the Novelty Track score itself, and the training data was the 2003 Novelty Track data.

Changes to the hypothesis are selected at random and evaluated. If the change does not hurt results, it is accepted. Otherwise the program backtracks and chooses another weight to update. We required the new configuration to produce a score greater than or equal to the previous one before we accepted it. The choice of which weight to update is made at random, in an effort to avoid local minima in the search space, but with an important restriction: the previous n choices are kept in a history list, which is checked to avoid re-use. This list is updated at each iteration. The configurations usually converge well within 100 iterations.

```
1. Initialize weights, history
       Weights take random values
2. Run the system using current weight set
3. If current score $>=$ previous best
       Update previous best
4. Otherwise
       Undo move
5. Update history
6. Choose next weight to change
7. Go to step 2
```

Figure 1: The learning algorithm uses a randomized hill climbing approach with backtracking

3.2 Bias Adjustment

In training on the 2003 data, the biggest problem was to find a way to deal with the large percentage of novel sentences. About 65% of the instances are positive, so that a random system achieves a relatively high F-measure by increasing the number of sentences it calls novel – until recall reaches 1.0. Another strategy would be to choose only the sentences in the first document, achieving a high precision – more than 90% of the relevant sentences in the first document for each topic were called novel.

In the Novelty Track the F-measure was set to give equal weight to precision and recall, but we wanted to be able to coax the learner to give greater weight to either precision or by adjusting the F-measure computation:

$$F = \frac{1}{\frac{\beta}{prec} + \frac{(1-\beta)}{recall}}$$

β is a number between 0 and 1. The closer it gets to 1, the more the formula favors precision.

We chose whether to emphasize precision or recall by altering the value of β. At the most extreme, we set β at 0.9 for the largest emphasis on precision. When emphasizing recall, we left β at 0.5.

The design was motivated by the need to explore the problem more fully and inform the algorithm for deciding novelty as much as to find optimal parameters for the values. Thus, we wanted to be able to record all the steps the learner made through the search space, and to save the intermediate states. At times, the learner would settle into a configuration that produced a trivial solution, and we could choose one of the intermediate configurations that produced a more reasonable score.

3.3 Vector-Space Module

In addition to the system which integrates novel word features with focus tracking, we also implemented a vector-space approach as a baseline – the *Cosine* run. We tested the vector-space system alone to contrast it with the focus system, but we also tested a version which integrated the vector-space system with the focus system.

Our vector-space module assigns all non-stop-words a value of 1, and uses the cosine distance metric to compute similarity.

$$Cos(u,v) = \frac{u \cdot v}{\|u\| \cdot \|v\|}$$

and

$$Novel(s_i) \begin{cases} True & \text{if} \quad Cos(s_i, s_j) < T, \\ & \text{for} \quad j = 1 \ldots i-1 \\ False & \text{otherwise} \end{cases}$$

As each sentence is scanned, its similarity is computed with all previous sentences and the maximum similarity is compared to a threshold T. If that maximum exceeds T, it is considered novel. We chose the value of T after trials on the 2003 Novelty Track data. It was set at 0.385, resulting in a balanced system that matched the results of one of the strongest performers at the TREC evaluations that year.

On the 2003 data, when we set T at .9, we found that we had a precision of .71 and a recall of 0.98, indicating that about 6% of the sentences were quite similar to some preceding sentence (See Figure 2). After that, each point of precision was very costly in terms of recall. Our experience was mirrored by the participants at TREC 2003 and again at TREC 2004.

We considered this vector-space model to be our baseline. We also tried it in combination with the *Recall* run explained above. Because both the *Recall* and *Cosine* runs produced a relatively large output and because they used different methods, we thought the intersection would result in higher precision, though with some loss of recall.

In practice, the range of recall was much greater than precision. Judging from the experiences of the participants at TREC and our own exploratory experiments, it was difficult to push precision above 0.80 with the TREC 2003 data, and above 0.50 with the TREC 2004 data.

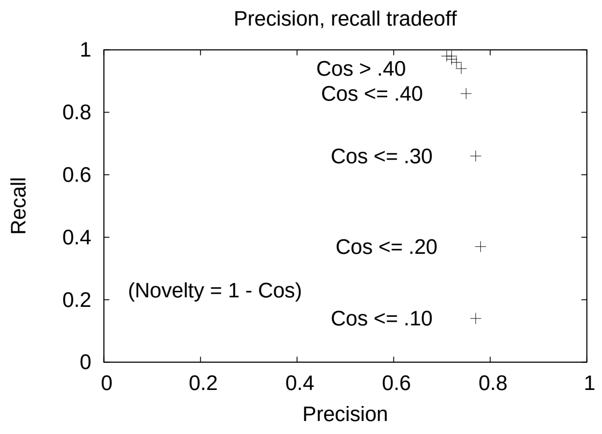

Figure 2: The precision and recall scores of a vector-space model with cosine similarity at different thresholds, on the TREC 2003 data. Making the test for novelty stricter fails to improve precision but has a drastic effect on recall.

4 Experiments

4.1 Results from TREC 2004

Our results are encouraging, especially since the configurations that were oriented toward higher precision, indeed, achieved the best precision scores in the evaluation, with our best precision run about 20% higher in precision than the best of all the runs by other groups (See Figure 3.) Meanwhile, our recall-oriented run was one of eight runs that were in a virtual tie for achieving the top f-measure. These eight runs were within 0.01 of one another in the measure.

Our five submitted runs were:

Prec1 aimed at moderately high precision, with reasonable recall.

Prec2 aimed at high precision, with little attention to recall.

Recall weighted precision and recall equally.

Cosine a baseline of a standard vector-space model with a cosine similarity metric.

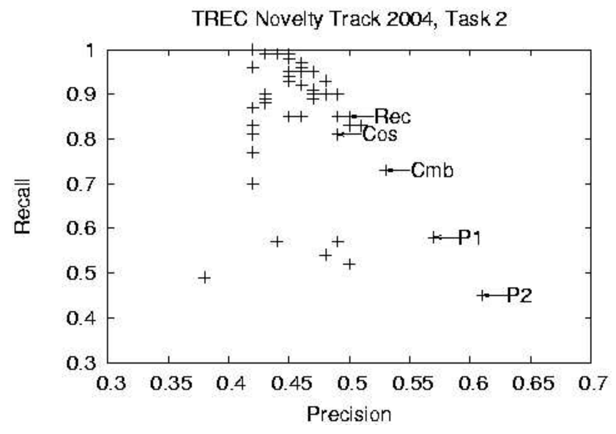

Figure 3: The graph shows all 54 submission in Task 2 for the Novelty Track, with our five submissions labeled. Our precision-oriented runs were well ahead of all others in precision, while our recall-oriented run was in a large group that reached about 0.5 precision with relatively high recall.

Combo a composite submission using the intersection of Recall and Cosine.

Table 2 shows the numbers of our performance of our five submissions. *Prec1* had an F-score close to the average of 0.577 for all systems, while *Prec2* was 50% ahead of random selection in accuracy. Both our *Combo* system and our baseline *Cosine* were above average in F-measure. Our emphasis on precision is justified in a number of ways, although the official yardstick was the F-measure.

An analysis of the system's behavior under the different parameters showed that the precision-oriented runs, in particular *Prec1*, valued verbs and common nouns more than named entities in deciding novelty. The precision-oriented runs also benefited more from the focus variable, with their scores about 5% higher in terms of F-measure than they were without it. The pronoun test, however, was rarely used, firing less than 1% of the time.

We note that we are developing novelty detection for summarization, where compression of the report is valuable. Table 2 shows the lengths of our returns. It is impossible to compare these precisely with other systems, because the averages given by NIST are averages of the scores for each of the 50 sets, and we do not have the breakdown of the numbers by set for any submissions but our own. However, we can estimate the size of the other output by considering average precision and recall as if they were computed over the total number of sentences in all 50 sets. This computation shows an average output for all participants of about 6,500 sentences and a median of 6,981 – out of a total of 8,343 sentences. However, this total includes some amount of header material, not only the headline, but the document ID and other identifiers, the date and some shorthand messages from the wire services to its clients. In addition, a number of the sets had near perfect duplicate articles. This is in sharp contrast with typical summaries. At the 2004 Document Understanding Conference, the typical input cluster contained more than 4,000 words, and the task required that this be reduced to 100 words. We contend there is little value in a system that does no more than weed out very few sentences, even though they might have achieved high F-measures.

Second, our experience, and the results of other groups, shows that high precision is harder than high recall. In all three years of the Novelty Track, precision scores tended to hover in a narrow band just above what one would get by mechanically labeling all sentences as *novel*.

5 Conclusion

The success of our use of context in the TREC Novelty Track led us to incorporate the idea into a larger system. This system identifies *clauses* within sentences that express new information and tries to identify semantic equivalents. It is being developed as part of a multi-document summarizer that produces topical updates for users.

In addition, the work here suggests three directions for future work:

- Adapt the features used here to some of the newer probabilistic formalisms, like conditional random fields.
- Try full segmentation of the input documents rather than treat the sentences as a sequence.
- Try to identify all nominal references to canonical forms.

With this experimental system, we obtained the the top precision scores in the Novelty Track, and

Run-Id	Precision	Recall	F-meas	Output length
Prec1	0.57	0.58	0.562	3276
Prec2	0.61	0.45	0.506	2372
Recall	0.51	0.82	0.611	5603
Cosine	0.49	0.81	0.599	5537
Combo	0.53	0.73	0.598	4578
Choose All	0.41	1.000	0.581	8343
Average All Runs	0.46	0.86	0.577	6500

Table 2: Comparison of results of our five runs, compared to a random selection of sentences, and the overall average F-scores by all 55 submissions.

we obtained the program settings to do this automatically. High precision is very difficult to obtain, and every point in precision costs too much in recall. Further exploration is needed to determine whether linguistic knowledge will help, and whether state-of-the-art tools are powerful enough to improve performance.

Beyond new-information detection, the idea of tracking context with a surface means like the focus variable is worth exploring in other tasks, including summarization and question-answering.

A Shortest Path Dependency Kernel for Relation Extraction

Razvan C. Bunescu and **Raymond J. Mooney**

Abstract

We present a novel approach to relation extraction, based on the observation that the information required to assert a relationship between two named entities in the same sentence is typically captured by the shortest path between the two entities in the dependency graph. Experiments on extracting top-level relations from the ACE (Automated Content Extraction) newspaper corpus show that the new shortest path dependency kernel outperforms a recent approach based on dependency tree kernels.

1 Introduction

One of the key tasks in natural language processing is that of Information Extraction (IE), which is traditionally divided into three subproblems: coreference resolution, named entity recognition, and relation extraction. Consequently, IE corpora are typically annotated with information corresponding to these subtasks (MUC (Grishman, 1995), ACE (NIST, 2000)), facilitating the development of systems that target only one or a subset of the three problems. In this paper we focus exclusively on extracting relations between predefined types of entities in the ACE corpus. Reliably extracting relations between entities in natural-language documents is still a difficult, unsolved problem, whose inherent difficulty is compounded by the emergence of new application domains, with new types of narrative that challenge systems developed for previous well-studied domains. The accuracy level of current syntactic and semantic parsers on natural language text from different domains limit the extent to which syntactic and semantic information can be used in real IE systems. Nevertheless, various lines of work on relation extraction have shown experimentally that the use of automatically derived syntactic information can lead to significant improvements in extraction accuracy. The amount of syntactic knowledge used in IE systems varies from part-of-speech only (Ray and Craven, 2001) to chunking (Ray and Craven, 2001) to shallow parse trees (Zelenko et al., 2003) to dependency trees derived from full parse trees (Culotta and Sorensen, 2004). Even though exhaustive experiments comparing the performance of a relation extraction system based on these four levels of syntactic information are yet to be conducted, a reasonable assumption is that the extraction accuracy increases with the amount of syntactic information used. The performance however depends not only on the amount of syntactic information, but also on the details of the exact models using this information. Training a machine learning system in a setting where the information used for representing the examples is only partially relevant to the actual task often leads to overfitting. It is therefore important to design the IE system so that the input data is stripped of unnecessary features as much as possible. In the case of the tree kernels from (Zelenko et al., 2003; Culotta and Sorensen, 2004), the authors reduce each relation example to the smallest subtree in the parse or dependency tree that includes both entities. We will show in this paper that increased extraction performance can be

Proceedings of Human Language Technology Conference and Conference on Empirical Methods in Natural Language Processing (HLT/EMNLP), pages 724–731, Vancouver, October 2005. ©2005 Association for Computational Linguistics

obtained by designing a kernel method that uses an even smaller part of the dependency structure – the shortest path between the two entities in the undirected version of the dependency graph.

2 Dependency Graphs

Let e_1 and e_2 be two entities mentioned in the same sentence such that they are observed to be in a relationship R, i.e $R(e_1, e_2) = 1$. For example, R can specify that entity e_1 is LOCATED (AT) entity e_2. Figure 1 shows two sample sentences from ACE, with entity mentions in bold. Correspondingly, the first column in Table 1 lists the four relations of type LOCATED that need to be extracted by the IE system. We assume that a relation is to be extracted only between entities mentioned in the same sentence, and that the presence or absence of a relation is independent of the text preceding or following the sentence. This means that only information derived from the sentence including the two entities will be relevant for relation extraction. Furthermore, with each sentence we associate its dependency graph, with words figured as nodes and word-word dependencies figured as directed edges, as shown in Figure 1. A subset of these word-word dependencies capture the predicate-argument relations present in the sentence. Arguments are connected to their target predicates either directly through an arc pointing to the predicate ('troops $\rightarrow$ raided'), or indirectly through a preposition or infinitive particle ('warning $\leftarrow$ to $\leftarrow$ stop'). Other types of word-word dependencies account for modifier-head relationships present in adjective-noun compounds ('several $\rightarrow$ stations'), noun-noun compounds ('pumping $\rightarrow$ stations'), or adverb-verb constructions ('recently $\rightarrow$ raided'). In Figure 1 we show the full dependency graphs for two sentences from the ACE newspaper corpus.

Word-word dependencies are typically categorized in two classes as follows:

- **[Local Dependencies]** These correspond to local predicate-argument (or head-modifier) constructions such as 'troops $\rightarrow$ raided', or 'pumping $\rightarrow$ stations' in Figure 1.

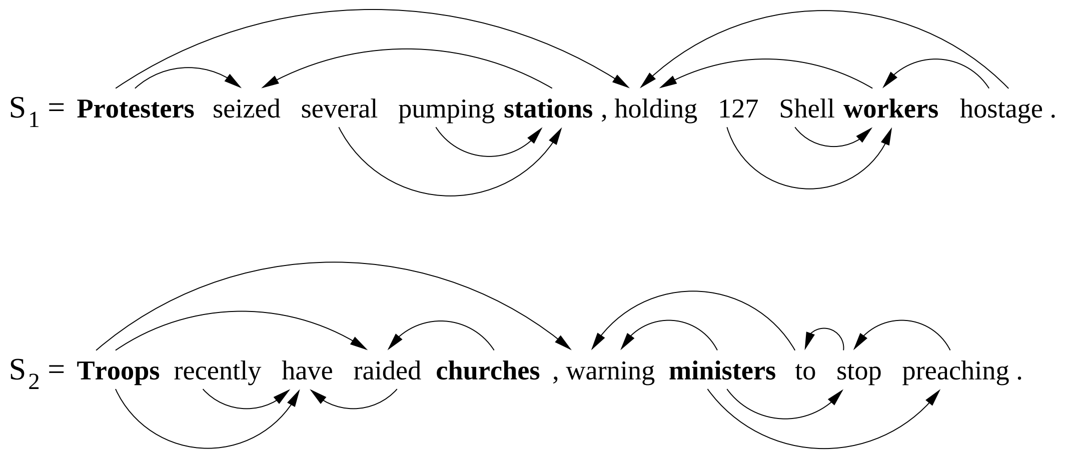
- **[Non-local Dependencies]** Long-distance dependencies arise due to various linguistic constructions such as coordination, extraction, raising and control. In Figure 1, among non-local dependencies are 'troops $\rightarrow$ warning', or 'ministers $\rightarrow$ preaching'.

A Context Free Grammar (CFG) parser can be used to extract local dependencies, which for each sentence form a dependency tree. Mildly context sensitive formalisms such as Combinatory Categorial Grammar (CCG) (Steedman, 2000) model word-word dependencies more directly and can be used to extract both local and long-distance dependencies, giving rise to a directed acyclic graph, as illustrated in Figure 1.

3 The Shortest Path Hypothesis

If e_1 and e_2 are two entities mentioned in the same sentence such that they are observed to be in a relationship R, our hypothesis stipulates that the contribution of the sentence dependency graph to establishing the relationship $R(e_1, e_2)$ is almost exclusively concentrated in the shortest path between e_1 and e_2 in the undirected version of the dependency graph.

If entities e_1 and e_2 are arguments of the same predicate, then the shortest path between them will pass through the predicate, which may be connected directly to the two entities, or indirectly through prepositions. If e_1 and e_2 belong to different predicate-argument structures that share a common argument, then the shortest path will pass through this argument. This is the case with the shortest path between 'stations' and 'workers' in Figure 1, passing through 'protesters', which is an argument common to both predicates 'holding' and 'seized'. In Table 1 we show the paths corresponding to the four relation instances encoded in the ACE corpus for the two sentences from Figure 1. All these paths support the LOCATED relationship. For the first path, it is reasonable to infer that if a PERSON entity (e.g. 'protesters') is doing some action (e.g. 'seized') to a FACILITY entity (e.g. 'station'), then the PERSON entity is LOCATED at that FACILITY entity. The second path captures the fact that the same PERSON entity (e.g. 'protesters') is doing two actions (e.g. 'holding' and 'seized') , one action to a PERSON entity (e.g. 'workers'), and the other action to a FACILITY entity (e.g. 'station'). A reasonable inference in this case is that the 'workers' are LOCATED at the



S 1 = Protesters seized several pumping stations , holding 127 Shell workers hostage .
S 2 = Troops recently have raided churches , warning ministers to stop preaching .

Figure 1: Sentences as dependency graphs.

Relation Instance	Shortest Path in Undirected Dependency Graph
S_1: protesters AT stations	**protesters** $\longrightarrow$ seized $\longleftarrow$ **stations**
S_1: workers AT stations	**workers** $\longrightarrow$ holding $\longleftarrow$ protesters $\longrightarrow$ seized $\longleftarrow$ **stations**
S_2: troops AT churches	**troops** $\longrightarrow$ raided $\longleftarrow$ **churches**
S_2: ministers AT churches	**ministers** $\longrightarrow$ warning $\longleftarrow$ troops $\longrightarrow$ raided $\longleftarrow$ **churches**

Table 1: Shortest Path representation of relations.

’station’.

In Figure 2 we show three more examples of the LOCATED (AT) relationship as dependency paths created from one or two predicate-argument structures. The second example is an interesting case, as it illustrates how annotation decisions are accommodated in our approach. Using a reasoning similar with that from the previous paragraph, it is reasonable to infer that ’troops’ are LOCATED in ’vans’, and that ’vans’ are LOCATED in ’city’. However, because ’vans’ is not an ACE markable, it cannot participate in an annotated relationship. Therefore, ’troops’ is annotated as being LOCATED in ’city’, which makes sense due to the transitivity of the relation LOCATED. In our approach, this leads to shortest paths that pass through two or more predicate-argument structures.

The last relation example is a case where there exist multiple shortest paths in the dependency graph between the same two entities – there are actually two different paths, with each path replicated into three similar paths due to coordination. Our current approach considers only one of the shortest paths, nevertheless it seems reasonable to investigate using all of them as multiple sources of evidence for relation extraction.

There may be cases where e_1 and e_2 belong to predicate-argument structures that have no argument in common. However, because the dependency graph is always connected, we are guaranteed to find a shortest path between the two entities. In general, we shall find a shortest sequence of predicate-argument structures with target predicates $P_1, P_2, ..., P_n$ such that e_1 is an argument of P_1, e_2 is an argument of P_n, and any two consecutive predicates P_i and P_{i+1} share a common argument (where by “argument” we mean both arguments and complements).

4 Learning with Dependency Paths

The shortest path between two entities in a dependency graph offers a very condensed representation of the information needed to assess their relationship. A dependency path is represented as a sequence of words interspersed with arrows that in-

(1) He had no regrets for **his** actions in **Brcko**.

his → actions ← in ← **Brcko**

(2) U.S. **troops** today acted for the first time to capture an alleged Bosnian war criminal, rushing from unmarked vans parked in the northern Serb-dominated **city** of Bijeljina.

troops → rushing ← from ← vans → parked ← in ← **city**

(3) Jelisic created an atmosphere of terror at the **camp** by killing, abusing and threatening the **detainees**.

detainees → killing ← Jelisic → created ← at ← **camp**

detainees → abusing ← Jelisic → created ← at ← **camp**

detainees → threatning ← Jelisic → created ← at ← **camp**

detainees → killing → by → created ← at ← **camp**

detainees → abusing → by → created ← at ← **camp**

detainees → threatening → by → created ← at ← **camp**

Figure 2: Relation examples.

dicate the orientation of each dependency, as illustrated in Table 1. These paths however are completely lexicalized and consequently their performance will be limited by data sparsity. We can alleviate this by categorizing words into classes with varying degrees of generality, and then allowing paths to use both words and their classes. Examples of word classes are part-of-speech (POS) tags and generalizations over POS tags such as Noun, Active Verb or Passive Verb. The entity type is also used for the two ends of the dependency path. Other potentially useful classes might be created by associating with each noun or verb a set of hypernyms corresponding to their synsets in WordNet.

The set of features can then be defined as a Cartesian product over these word classes, as illustrated in Figure 3 for the dependency path between ’protesters’ and ’station’ in sentence S_1. In this representation, sparse or contiguous subsequences of nodes along the lexicalized dependency path (i.e. path fragments) are included as features simply by replacing the rest of the nodes with their corresponding generalizations.

The total number of features generated by this dependency path is $4 \times 1 \times 3 \times 1 \times 4$, and some of them are listed in Table 2.

$$\begin{bmatrix} \text{protesters} \\ \text{NNS} \\ \text{Noun} \\ \text{PERSON} \end{bmatrix} \times [\rightarrow] \times \begin{bmatrix} \text{seized} \\ \text{VBD} \\ \text{Verb} \end{bmatrix} \times [\leftarrow] \times \begin{bmatrix} \text{stations} \\ \text{NNS} \\ \text{Noun} \\ \text{FACILITY} \end{bmatrix}$$

Figure 3: Feature generation from dependency path.

protesters	→	seized	←	stations
Noun	→	Verb	←	Noun
PERSON	→	seized	←	FACILITY
PERSON	→	Verb	←	FACILITY
... (48 features)				

Table 2: Sample Features.

For verbs and nouns (and their respective word classes) occurring along a dependency path we also use an additional suffix ’(-)’ to indicate a negative polarity item. In the case of verbs, this suffix is used when the verb (or an attached auxiliary) is modified by a negative polarity adverb such as ’not’ or ’never’. Nouns get the negative suffix whenever they are modified by negative determiners such as ’no’, ’neither’ or ’nor’. For example, the phrase “**He** never went to **Paris**” is associated with the dependency path ’**He** → went(-) ← to ← **Paris**’.

Explicitly creating for each relation example a vector with a position for each dependency path feature is infeasible, due to the high dimensionality of the feature space. Here we can exploit *dual* learning algorithms that process examples only via computing their dot-products, such as the Support Vector Machines (SVMs) (Vapnik, 1998; Cristianini and Shawe-Taylor, 2000). These dot-products between feature vectors can be efficiently computed through a *kernel* function, without iterating over all the corresponding features. Given the kernel function, the SVM learner tries to find a hyperplane that separates positive from negative examples and at the same time maximizes the separation (margin) between them. This type of max-margin separator has been shown both theoretically and empirically to resist overfitting and to provide good generalization performance on unseen examples.

Computing the dot-product (i.e. kernel) between two relation examples amounts to calculating the number of common features of the type illustrated in Table 2. If $\boldsymbol{x} = x_1 x_2 ... x_m$ and $\boldsymbol{y} = y_1 y_2 ... y_n$ are two relation examples, where x_i denotes the set of word classes corresponding to position i (as in Figure 3), then the number of common features between $\boldsymbol{x}$ and $\boldsymbol{y}$ is computed as in Equation 1.

$$K(\boldsymbol{x},\boldsymbol{y}) = \begin{cases} 0, & m \neq n \\ \prod_{i=1}^{n} c(x_i, y_i), & m = n \end{cases} \tag{1}$$

where $c(x_i, y_i) = |x_i \cap y_i|$ is the number of common word classes between x_i and y_i.

This is a simple kernel, whose computation takes $O(n)$ time. If the two paths have different lengths, they correspond to different ways of expressing a relationship – for instance, they may pass through a different number of predicate argument structures. Consequently, the kernel is defined to be 0 in this case. Otherwise, it is the product of the number of common word classes at each position in the two paths. As an example, let us consider two instances of the LOCATED relationship:

1. '**his** actions in **Brcko**', and
2. '**his** arrival in **Beijing**'.

Their corresponding dependency paths are:

1. '**his** $\rightarrow$ actions $\leftarrow$ in $\leftarrow$ **Brcko**', and
2. '**his** $\rightarrow$ arrival $\leftarrow$ in $\leftarrow$ **Beijing**'.

Their representation as a sequence of sets of word classes is given by:

1. $\boldsymbol{x} = [x_1\ x_2\ x_3\ x_4\ x_5\ x_6\ x_7]$, where x_1 = {his, PRP, PERSON}, x_2 = {$\rightarrow$}, x_3 = {actions, NNS, Noun}, x_4 = {$\leftarrow$}, x_5 = {in, IN}, x_6 = {$\leftarrow$}, x_7 = {Brcko, NNP, Noun, LOCATION}
2. $\boldsymbol{y} = [y_1\ y_2\ y_3\ y_4\ y_5\ y_6\ y_7]$, where y_1 = {his, PRP, PERSON}, y_2 = {$\rightarrow$}, y_3 = {arrival, NN, Noun}, y_4 = {$\leftarrow$}, y_5 = {in, IN}, y_6 = {$\leftarrow$}, y_7 = {Beijing, NNP, Noun, LOCATION}

Based on the formula from Equation 1, the kernel is computed as $K(\boldsymbol{x},\boldsymbol{y}) = 3 \times 1 \times 1 \times 1 \times 2 \times 1 \times 3 = 18$.

We use this relation kernel in conjunction with SVMs in order to find decision hyperplanes that best separate positive examples from negative examples. We modified the LibSVM[1] package for SVM learning by plugging in the kernel described above, and used its default one-against-one implementation for multiclass classification.

5 Experimental Evaluation

We applied the shortest path dependency kernel to the problem of extracting top-level relations from the ACE corpus (NIST, 2000), the version used for the September 2002 evaluation. The training part of this dataset consists of 422 documents, with a separate set of 97 documents allocated for testing. This version of the ACE corpus contains three types of annotations: coreference, named entities and relations. Entities can be of the type PERSON, ORGANIZATION, FACILITY, LOCATION, and GEO-POLITICAL ENTITY. There are 5 general, top-level relations: ROLE, PART, LOCATED, NEAR, and SOCIAL. The ROLE relation links people to an organization to which they belong, own, founded, or provide some service. The PART relation indicates subset relationships, such as a state to a nation, or a subsidiary to its parent company. The AT relation indicates the location of a person or organization at some location. The NEAR relation indicates the proximity of one location to another. The SOCIAL relation links two people in personal, familial or professional relationships. Each top-level relation type is further subdivided into more fine-grained subtypes, resulting in a total of 24 relation types. For example, the LOCATED relation includes subtypes such as LOCATED-AT, BASED-IN, and RESIDENCE. In total, there are 7,646 intra-sentential relations, of which 6,156 are in the training data and 1,490 in the test data.

We assume that the entities and their labels are known. All preprocessing steps – sentence segmentation, tokenization, and POS tagging – were performed using the OpenNLP[2] package.

5.1 Extracting dependencies using a CCG parser

CCG (Steedman, 2000) is a type-driven theory of grammar where most language-specific aspects of the grammar are specified into lexicon. To each lex-

[1]URL:http://www.csie.ntu.edu.tw/˜cjlin/libsvm/
[2]URL: http://opennlp.sourceforge.net

ical item corresponds a set of syntactic categories specifying its valency and the directionality of its arguments. For example, the words from the sentence “protesters seized several stations” are mapped in the lexicon to the following categories:

protesters	:	NP
seized	:	$(S\backslash NP)/NP$
several	:	NP/NP
stations	:	NP

The transitive verb ’seized’ expects two arguments: a noun phrase to the right (the object) and another noun phrase to the left (the subject). Similarly, the adjective ’several’ expects a noun phrase to its right. Depending on whether its valency is greater than zero or not, a syntactic category is called a *functor* or an *argument*. In the example above, ’seized’ and ’several’ are functors, while ’protesters’ and ’stations’ are arguments.

Syntactic categories are combined using a small set of typed combinatory rules such as functional application, composition and type raising. In Table 3 we show a sample derivation based on three functional applications.

protesters	seized	several	stations
NP	$(S\backslash NP)/NP$	NP/NP	NP
NP	$(S\backslash NP)/NP$	NP	
NP	$S\backslash NP$		
S			

Table 3: Sample derivation.

In order to obtain CCG derivations for all sentences in the ACE corpus, we used the CCG parser introduced in (Hockenmaier and Steedman, 2002)[3]. This parser also outputs a list of dependencies, with each dependency represented as a 4-tuple $\langle f, a, w_f, w_a\rangle$, where f is the syntactic category of the functor, a is the argument number, w_f is the head word of the functor, and w_a is the head word of the argument. For example, the three functional applications from Table 3 result in the functor-argument dependencies enumerated below in Table 4.

[3]URL:http://www.ircs.upenn.edu/˜juliahr/Parser/

f	a	w_f	w_a
NP/NP	1	’several’	’stations’
$(S\backslash NP)/NP$	2	’seized’	’stations’
$(S\backslash NP)/NP$	1	’seized’	’protesters’

Table 4: Sample dependencies.

Because predicates (e.g. ’seized’) and adjuncts (e.g. ’several’) are always represented as functors, while complements (e.g. ’protesters’ and ’stations’) are always represented as arguments, it is straightforward to transform a functor-argument dependency into a head-modifier dependency. The head-modifier dependencies corresponding to the three functor-argument dependencies in Table 4 are: ’protesters $\rightarrow$ seized’, ’stations $\rightarrow$ seized’, and ’several $\rightarrow$ stations’.

Special syntactic categories are assigned in CCG to lexical items that project unbounded dependencies, such as the relative pronouns ’who’, ’which’ and ’that’. Coupled with a head-passing mechanism, these categories allow the extraction of long-range dependencies. Together with the local word-word dependencies, they create a directed acyclic dependency graph for each parsed sentence, as shown in Figure 1.

5.2 Extracting dependencies using a CFG parser

Local dependencies can be extracted from a CFG parse tree using simple heuristic rules for finding the head child for each type of constituent. Alternatively, head-modifier dependencies can be directly output by a parser whose model is based on lexical dependencies. In our experiments, we used the full parse output from Collins’ parser (Collins, 1997), in which every non-terminal node is already annotated with head information. Because local dependencies assemble into a tree for each sentence, there is only one (shortest) path between any two entities in a dependency tree.

5.3 Experimental Results

A recent approach to extracting relations is described in (Culotta and Sorensen, 2004). The authors use a generalized version of the tree kernel from (Zelenko et al., 2003) to compute a kernel over relation examples, where a relation example consists of the smallest dependency tree containing the two entities of the relation. Precision and recall values are reported for the task of extracting the 5 top-level relations in the ACE corpus under two different scenarios:

– **[S1]** This is the classic setting: one multi-class SVM is learned to discriminate among the 5 top-level classes, plus one more class for the no-relation cases.

– **[S2]** Because of the highly skewed data distribution, the recall of the SVM approach in the first scenario is very low. In (Culotta and Sorensen, 2004) the authors propose doing relation extraction in two steps: first, one binary SVM is trained for *relation detection*, which means that all positive relation instances are combined into one class. Then the thresholded output of this binary classifier is used as training data for a second multi-class SVM, which is trained for *relation classification*. The same kernel is used in both stages.

We present in Table 5 the performance of our shortest path (SP) dependency kernel on the task of relation extraction from ACE, where the dependencies are extracted using either a CCG parser (SP-CCG), or a CFG parser (SP-CFG). We also show the results presented in (Culotta and Sorensen, 2004) for their best performing kernel K4 (a sum between a bag-of-words kernel and their dependency kernel) under both scenarios.

Method	Precision	Recall	F-measure
(S1) SP-CCG	67.5	37.2	48.0
(S1) SP-CFG	**71.1**	**39.2**	**50.5**
(S1) K4	70.3	26.3	38.0
(S2) SP-CCG	63.7	41.4	50.2
(S2) SP-CFG	**65.5**	**43.8**	**52.5**
(S2) K4	67.1	35.0	45.8

Table 5: Extraction Performance on ACE.

The shortest-path dependency kernels outperform the dependency kernel from (Culotta and Sorensen, 2004) in both scenarios, with a more significant difference for SP-CFG. An error analysis revealed that Collins' parser was better at capturing local dependencies, hence the increased accuracy of SP-CFG. Another advantage of our shortest-path dependency kernels is that their training and testing are very fast – this is due to representing the sentence as a chain of dependencies on which a fast kernel can be computed. All the four SP kernels from Table 5 take between 2 and 3 hours to train and test on a 2.6GHz Pentium IV machine.

To avoid numerical problems, we constrained the dependency paths to pass through at most 10 words (as observed in the training data) by setting the kernel to 0 for longer paths. We also tried the alternative solution of normalizing the kernel, however this led to a slight decrease in accuracy. Having longer paths give larger kernel scores in the unnormalized version does not pose a problem because, by definition, paths of different lengths correspond to disjoint sets of features. Consequently, the SVM algorithm will induce lower weights for features occurring in longer paths, resulting in a linear separator that works irrespective of the size of the dependency paths.

6 Related Work

In (Zelenko et al., 2003), the authors do relation extraction using a tree kernel defined over shallow parse tree representations of sentences. The same tree kernel is slightly generalized in (Culotta and Sorensen, 2004) and used in conjunction with dependency trees. In both approaches, a relation instance is defined to be the smallest subtree in the parse or dependency tree that includes both entities. In this paper we argued that the information relevant to relation extraction is almost entirely concentrated in the shortest path in the dependency tree, leading to an even smaller representation. Another difference between the tree kernels above and our new kernel is that the tree kernels used for relation extraction are *opaque* i.e. the semantics of the dimensions in the corresponding Hilbert space is not obvious. For the shortest-path kernels, the semantics is known by definition: each path feature corresponds to a dimension in the Hilbert space. This transparency allows us to easily restrict the types of patterns counted by the kernel to types that we deem relevant for relation extraction. The tree kernels are also more time consuming, especially in the sparse setting, where they count sparse subsequences of children common to nodes in the two trees. In (Zelenko et al., 2003), the tree kernel is computed in $O(mn)$ time, where m and n are the number of nodes in the two trees. This changes to $O(mn^3)$ in the sparse setting.

Our shortest-path intuition bears some similarity with the underlying assumption of the relational pathfinding algorithm from (Richards and Mooney, 1992) : "in most relational domains, important concepts will be represented by a small number of fixed paths among the constants defining a positive instance – for example, the grandparent relation is defined by a single fixed path consisting of two parent relations." We can see this happening also in the task of relation extraction from ACE, where "important concepts" are the 5 types of relations, and the "constants" defining a positive instance are the 5 types of entities.

7 Future Work

Local and non-local (deep) dependencies are equally important for finding relations. In this paper we tried extracting both types of dependencies using a CCG parser, however another approach is to recover deep dependencies from syntactic parses, as in (Campbell, 2004; Levy and Manning, 2004). This may have the advantage of preserving the quality of local dependencies while completing the representation with non-local dependencies.

Currently, the method assumes that the named entities are known. A natural extension is to automatically extract both the entities and their relationships. Recent research (Roth and Yih, 2004) indicates that integrating entity recognition with relation extraction in a global model that captures the mutual influences between the two tasks can lead to significant improvements in accuracy.

8 Conclusion

We have presented a new kernel for relation extraction based on the shortest-path between the two relation entities in the dependency graph. Comparative experiments on extracting top-level relations from the ACE corpus show significant improvements over a recent dependency tree kernel.

Abstract

We address the problem of multi-way relation classification, applied to identification of the interactions between proteins in bioscience text. A major impediment to such work is the acquisition of appropriately labeled training data; for our experiments we have identified a database that serves as a proxy for training data. We use two graphical models and a neural net for the classification of the interactions, achieving an accuracy of 64% for a 10-way distinction between relation types. We also provide evidence that the exploitation of the sentences surrounding a citation to a paper can yield higher accuracy than other sentences.

1 Introduction

Identifying the interactions between proteins is one of the most important challenges in modern genomics, with applications throughout cell biology, including expression analysis, signaling, and rational drug design. Most biomedical research and new discoveries are available electronically but only in free text format, so automatic mechanisms are needed to convert text into more structured forms. The goal of this paper is to address this difficult and important task, the extraction of the interactions between proteins from free text. We use graphical models and a neural net that were found to achieve high accuracy in the related task of extracting the relation types might hold between the entities "treatment" and "disease" (Rosario and Hearst, 2004).

Labeling training and test data is time-consuming and subjective. Here we report on results using an existing curated database, the HIV-1 Human Protein Interaction Database[1], to train and test the classification system. The accuracies obtained by the classification models proposed are quite high, confirming the validity of the approach. We also find support for the hypothesis that the sentences surrounding citations are useful for extraction of key information from technical articles (Nakov et al., 2004).

In the remainder of this paper we discuss related work, describe the dataset, and show the results of the algorithm on documents and sentences.

2 Related work

There has been little work in general NLP on trying to identify different relations between entities. Many papers that claim to be doing relationship recognition in actuality address the task of role extraction: (usually two) entities are identified and the relationship is *implied* by the co-occurrence of these entities or by some linguistic expression (Agichtein and Gravano, 2000; Zelenko et al., 2002).

The ACE competition[2] has a relation recognition subtask, but assumes a particular type of relation holds between particular entity types (e.g., if the two entities in question are an EMP and an ORG, then an employment relation holds between them; which type of employment relation depends on the type of entity, e.g., staff person vs partner).

[1] www.ncbi.nlm.nih.gov/RefSeq/HIVInteractions/index.html
[2] http://www.itl.nist.gov/iaui/894.01/tests/ace/

In the BioNLP literature there have recently been a number of attempts to automatically extract protein-protein interactions from PubMed abstracts. Some approaches simply report that a relation exists between two proteins but do not determine which relation holds (Bunescu et al., 2005; Marcotte et al., 2001; Ramani et al., 2005), while most others start with a list of interaction verbs and label only those sentences that contain these trigger words (Blaschke and Valencia, 2002; Blaschke et al., 1999; Rindflesch et al., 1999; Thomas et al., 2000; Sekimizu et al., 1998; Ahmed et al., 2005; Phuong et al., 2003; Pustejovsky et al., 2002). However, as Marcotte et al. (2001) note, "... searches for abstracts containing relevant keywords, such as interact*, poorly discriminate true hits from abstracts using the words in alternate senses and miss abstracts using different language to describe the interactions."

Most of the existing methods also suffer from low recall because they use hand-built specialized templates or patterns (Ono et al., 2001; Corney et al., 2004). Some systems use link grammars in conjunction with trigger verbs instead of templates (Ahmed et al., 2005; Phuong et al., 2003). Every paper evaluates on a different test set, and so it is quite difficult to compare systems.

In this paper, we use state-of-the-art machine learning methods to determine the interaction *types* and to extract the proteins involved. We do not use trigger words, templates, or dictionaries.

3 Data

We use the information from a domain-specific database to gather labeled data for the task of classifying the interactions between proteins in text. The manually-curated HIV-1 Human Protein Interaction Database provides a summary of documented interactions between HIV-1 proteins and host cell proteins, other HIV-1 proteins, or proteins from disease organisms associated with HIV or AIDS. We use this database also because it contains information about the *type* of interactions, as opposed to other protein interaction databases (BIND, MINT, DIP, for example[3]) that list the protein pairs interacting, without specifying the type of interactions.

Interaction	**#Triples**	**Interaction**	**#Triples**
Interacts with	1115	*Complexes with*	45

Induces	52	*Requires*	22
Inactivates	51		

Table 1: Number of triples for the most common interactions of the HIV-1 database, after removing the distinction in directionality and the triples with more than one interaction.

In this database, the definitions of the interactions depend on the proteins involved and the articles describing the interactions; thus there are several definitions for each interaction type. For the interaction *bind* and the proteins *ANT* and *Vpr*, we find (among others) the definition "*Interaction of HIV-1 Vpr with human adenine nucleotide translocator (ANT) is presumed based on a specific binding interaction between Vpr and rat ANT.*"

The database contains 65 types of interactions and 809 proteins for which there is interaction information, for a total of 2224 pairs of interacting proteins. For each documented protein-protein interaction the database includes information about:

- A pair of proteins (PP),
- The interaction type(s) between them (I), and
- PubMed identification numbers of the journal article(s) describing the interaction(s) (A).

A protein pair PP can have multiple interactions (for example, AIP1 *binds* to HIV-1 p6 and also *is incorporated* into it) for an average of 1.9 interactions per PP and a maximum of 23 interactions for the pair CDK9 and tat p14.

We refer to the combination of a protein pair PP and an article A as a "triple." Our goal is to automatically associate to each triple an interaction

[3]DIP lists only the protein pairs, BIND has only some information about the method used to provide evidence for the interaction, and MIND does have interaction type information but the vast majority of the entries (99.9% of the 47,000 pairs) have been assigned the same type of interaction (*aggregation*). These databases are all manually curated.

type. For the example above, the triple “AIP1 HIV-1-p6 14519844” is assigned the interaction *binds* (14519844 being the PubMed number of the paper providing evidence for this interaction)[4].

Journal articles can contain evidence for multiple interactions: there are 984 journal articles in the database and on average each article is reported to contain evidence for 5.9 triples (with a maximum number of 90 triples).

In some cases the database reports multiple different interactions for a given triple. There are 5369 unique triples in the database and of these 414 (7.7%) have multiple interactions. We exclude these triples from our analysis; however, we do include articles and PPs with multiple interactions. In other words, we tackle cases such as the example above of the pair AIP1, HIV-1-p6 (that can both *bind* and *incorporate*) as long as the evidence for the different interactions is given by two different articles.

Some of the interactions differ only in the directionality (e.g., *regulates* and *regulated by*, *inhibits* and *inhibited by*, etc.); we collapsed these pairs of related interactions into one[5]. Table 1 shows the list of the 25 interactions of the HIV-1 database for which there are more than 10 triples.

For these interactions and for a random subset of the protein pairs PP (around 45% of the total pairs in the database), we downloaded the corresponding full-text papers. From these, we extracted all and only those sentences that contain both proteins from the indicated protein pair. We assigned each of these sentences the corresponding interaction I from the database (“papers”).

Nakov et al. (2004) argue that the sentences surrounding citations to related work, or *citances*, are a useful resource for bioNLP. Building on that work, we use citances as an additional form of evidence to determine protein-protein interaction types. For a given database entry containing PubMed article A, protein pair PP, and interaction type I, we downloaded a subset of the papers that cite A. From these citing papers, we extracted all and only those sentences that mention A explicitly; we further filtered these to include all and only the sentences that contain PP. We labeled each of these sentences with interaction type I (“citances”).

There are often many different names for the same protein. We use LocusLink[6] protein identification numbers and synonym names for each protein, and extract the sentences that contain an exact match for (some synonym of) each protein. By being conservative with protein name matching, and by not doing co-reference analysis, we miss many candidate sentences; however this method is very precise.

On average, for “papers,” we extracted 0.5 sentences per triple (maximum of 79) and 50.6 sentences per interaction (maximum of 119); for “citances” we extracted 0.4 sentences per triple (with a maximum of 105) and 49.2 sentences per interaction (162 maximum). We required a minimum number (40) of sentences for each interaction type for both “papers” and “citances”; the 10 interactions of Table 2 met this requirement. We used these sentences to train and test the models described below[7].

Since all the sentences extracted from one triple are assigned the same interaction, we ensured that sentences from the same triple did not appear in both the testing and the training sets. Roughly 75% of the data were used for training and the rest for testing.

As mentioned above the goal is to automatically associate to each triple an interaction type. The task tackled here is actually slightly more difficult: given some sentences extracted from article A, assign to A an interaction type I and extract the proteins PP involved. In other words, for the purpose of classification, we act as if we do not have information about the proteins that interact. However, given the way the sentence extraction was done, all the sentences extracted from A contain the PP.

[4]To be precise, there are for this PP (as there are often) multiple articles (three in this case) describing the interaction *binds*, thus we have the following three triples to which we associate *binds*: “AIP1 HIV-1-p6 14519844,” “AIP1 HIV-1-p6 14505570” and “AIP1 HIV-1-p6 14505569.”

[5]We collapsed these pairs because the directionality of the interactions was not always reliable in the database. This implies that for some interactions, we are not able to infer the *different* roles of the two proteins; we considered only the pair “prot1 prot2” or “prot2 prot1,” not both. However, our algorithm can detect *which* proteins are involved in the interactions.

[6]LocusLink was recently integrated into Entrez Gene, a unified query environment for genes (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=gene).

[7]We also looked at larger chunks of text, in particular, we extracted the sentence containing the PP along with the previous and the following sentences, and the three consecutive sentences that contained the PP (the proteins could appear in any of the sentences). However, the results obtained by using these larger chunks were consistently worse.

Table 2: Number of interaction sentences extracted.

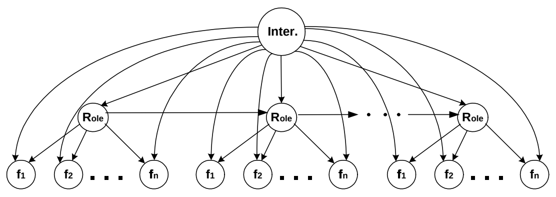

Figure 1: Dynamic graphical model (DM) for protein interaction classification (and role extraction).

A hand-assessment of the individual sentences shows that not every sentence that mentions the target proteins PP actually describes the interaction I (see Section 5.4). Thus the evaluation on the test set is done at the document level (to determine if the algorithm can predict the interaction that a curator would assign to a document as a whole given the protein pair).

Note that we assume here that the papers that provide the evidence for the interactions are given – an assumption not usually true in practice.

4 Models

For assigning interactions, we used two generative graphical models and a discriminative model. Figure 1 shows the generative dynamic model, based on previous work on role and relation extraction (Rosario and Hearst, 2004) where the task was to extract the entities TREATMENT and DISEASE and the relationships between them. The nodes labeled "Role" represent the entities (in this case the choices are PROTEIN and NULL); the children of the role nodes are the words (which act as features), thus there are as many role states as there are words in the sentence; this model consists of a Markov sequence of states where each state generates one or multiple observations. This model makes the additional assumption that there is an interaction present in the sentence (represented by the node "Inter.") that generates the role sequence and the observations. (We assume here that there is a single interaction for each sentence.) The "Role" nodes can be observed or hidden. The results reported here were obtained using only the words as features (i.e., in the dynamic model of Figure 1 there is only one feature node per role) and with the "Role" nodes hidden (i.e., we had no information regarding which proteins were involved). Inference is performed with the junction tree algorithm[8].

We used a second type of graphical model, a simple Naive Bayes, in which the node representing the interaction generates the observable features (all the words in the sentence). We did not include role information in this model.

We defined joint probability distributions over these models, estimated using maximum likelihood on the training set with a simple absolute discounting smoothing method. We performed 10-fold cross validation on the training set and we chose the smoothing parameters for which we obtained the best classification accuracies (averaged over the ten runs) on the training data; the results reported here were obtained using these parameters on the held-out test sets[9].

In addition to these two generative models, we also used a discriminative model, a neural network. We used the Matlab package to train a feed-forward network with conjugate gradient descent. The network has one hidden layer, with a hyperbolic tangent function, and an output layer representing the relationships. A logistic sigmoid function is used in the output layer. The network was trained for several choices of numbers of hidden units; we chose the best-performing networks based on training set error. We then tested these networks on held-out testing data. The features were words, the same as those used for the graphical models.

[8]Using Kevin Murphy's BNT package: http://www.cs.ubc.ca/˜murphyk/Software/BNT/bnt.html.

[9]We did not have enough data to require that the sentences in the training and test sets *of the cross validation procedure* originate from disjoint triples (they do originate from disjoint triple in the final held out data). This may result in a less than optimal choice of the parameters for the aggregate measures described below.

	All		Papers		Citances	
	Mj	**Cf**	**Mj**	**Cf**	**Mj**	**Cf**
DM	60.5	59.7	**57.8**	55.6	53.4	54.5

NN	**63.7**	–	44.4	–	**55.8**	–
Key	20.1	–	24.4	–	20.4	–
KeyB	25.8	–	40.0	–	26.1	–
Base.	21.8		11.1		26.1	

Table 3: Accuracies for classification of the 10 protein-protein interactions of Table 2. DM: dynamic model, NB: Naive Bayes, NN: neural network. Baselines: Key: trigger word approach, KeyB: trigger word with backoff, Base: the accuracy of choosing the most frequent interaction.

The task is the following: given a triple consisting of a PP and an article, extract the sentences from the article that contain both proteins. Then, predict for the entire document one of the interactions of Table 2 given the sentences extracted for that triple. This is a 10-way classification problem, which is significantly more complex than much of the related work in which the task is to make the binary prediction (see Section 2).

5 Results

The evaluation was done on a document-by-document basis. During testing, we choose the interaction using the following aggregate measures that use the constraint that all sentences coming from the same triple are assigned the same interaction.

- **Mj**: For each triple, for each sentence of the triple, find the interaction that maximizes the posterior probability of the interaction given the features; then assign to *all* sentences of this triple the most frequent interaction among those predicted for the individual sentences.

- **Cf**: Retain all the conditional probabilities (do not choose an interaction per sentence), then, for each triple, choose the interaction that maximizes the sum over all the triple's sentences.

Table 3 reports the results in terms of classification accuracies averaged across all interactions, for the cases "all" (sentences from "papers" and "citances" together), only "papers" and only "citances". The accuracies are quite high; the dynamic model achieves around 60% for "all," 58% for "papers" and 54% for "citances." The neural net achieves the best results for "all" with around 64% accuracy. From these results we can make the following observations: all models greatly outperform the baselines; the performances of the dynamic model DM, the Naive Bayes NB and the NN are very similar; for "papers" the best results were obtained with the graphical models; for "all" and "citances" the neural net did best. The use of "citances" allowed the gathering of additional data (and therefore a larger training set) that lead to higher accuracies (see "papers" versus "all").

In the confusion matrix in Table 5 we can see the accuracies for the individual interactions for the dynamic model DM, using "all" and "Mj." For three interactions this model achieves perfect accuracy.

5.1 Hiding the protein names

In order to ensure that the algorithm was not overfitting on the protein names, we ran an experiment in which we replaced the protein names in all sentences with the token "PROT_NAME." For example, the sentence: *"Selective CXCR4 antagonism by Tat"* became: *"Selective PROT_NAME2 antagonism by PROT_NAME1."*

Table 5.1 shows the results of running the models on this data. For "papers" and "citances" there is always a decrease in the classification accuracy when we remove the protein names, showing that the protein names do help the classification. The differences in accuracy in the two cases using "citances" are much smaller than the differences using "papers" at least for the graphical models. This suggests that citation sentences may be more robust for some language processing tasks and that the models that use "citances" learn better the linguistic context of the interactions. Note how in this case the graphical models always outperform the neural network.

5.2 Using a "trigger word" approach

As mentioned above, much of the related work in this field makes use of "trigger words" or "interaction words" (see Section 2). In order to (roughly) compare our work and to build a more realistic baseline, we created a list of 70 keywords that are repre-

sentative of the 10 interactions. For example, for the interaction *degrade* some of the keywords are "degradation," "degrade," for *inhibit* we have "inhibited," "inhibitor," "inhibitory" and others. We then checked whether a sentence contained such keywords. If it did, we assigned to the sentence the corresponding interaction. If it contained more than one keyword corresponding to multiple interactions consisting of the generic *interact with* plus a more specific one, we assigned the more specific interaction; if the two predicted interactions did not include *interact with* but two more specific interactions, we did not assign an interaction, since we wouldn't know how to choose between them. Similarly, we assigned no interaction if there were more than two predicted interactions or no keywords present in the sentence. The results are shown in the rows labeled "Key" and "KeyB" in Table 3. Case "KeyB" is the "Key" method with back-off: when no interaction was predicted, we assigned to the sentence the most frequent interaction in the training data. As before, we calculated the accuracy when we force all the sentences from one triple to be assign to the most frequent interaction among those predicted for the individual sentences.

KeyB is more accurate than Key and although the KeyB accuracies are higher than the other baselines, they are significantly lower than those obtained with the trained models. The low accuracies of the trigger-word based methods show that the relation classification task is nontrivial, in the sense that not all the sentences contain the most obvious word for the interactions, and suggests that the trigger word approach is insufficient.

5.3 Protein extraction

The dynamic model of Figure 1 has the appealing property of simultaneously performing interaction recognition and protein name tagging (also known as role extraction): the task consists of identifying all the proteins present in the sentence, given a sequence of words. We assessed a slightly different task: the identification of all (and only) the proteins present in the sentence *that are involved in the interaction*.

The F-measure[10] achieved by this model for this task is 0.79 for "all," 0.67 for "papers" and 0.79 for "citances"; again, the model parameters were chosen with cross validation on the training set, and "ci-

[10]The F-measure is a weighted combination of precision and recall. Here, precision and recall are given equal weight, that is, F-measure = $(2 * PRE * REC)/(PRE + REC)$.

tances" had superior performance. Note that we did not use a dictionary: the system learned to recognize the protein names using only the training data. Moreover, our role evaluation is quite strict: every token is assessed and we do not assign partial credit for constituents for which only some of the words are correctly labeled. We also did not use the information that all the sentences extracted from one triple contain the same proteins.

Given these strong results (both F-measure and classification accuracies), we believe that the dynamic model of Figure 1 is a good model for performing both name tagging and interaction classification simultaneously, or either of these task alone.

5.4 Sentence-level evaluation

In addition to assigning interactions to protein pairs, we are interested in sentence-level semantics, that is, in determining the interactions that are actually expressed in the sentence. To test whether the information assigned to the entire document by the HIV-1 database record can be used to infer information at the sentence level, an annotator with biological expertise hand-annotated the sentences from the experiments. The annotator was instructed to assign to each sentence one of the interactions of Table 2, "not interacting," or "other" (if the interaction between the two proteins was not one of Table 2).

Of the 2114 sentences that were hand-labeled, 68.3% of them disagreed with the HIV-1 database label, 28.4% agreed with the database label, and 3.3% were found to contain multiple interactions between the proteins. Among the 68.3% of the sentences for which the labels did not agree, 17.4% had the vague *interact with* relation, 7.4% did not contain any interaction and 43.5% had an interaction different from that specified by the triple[11]. In Table 6 we report the mismatch between the two sets of labels. The total accuracy of 38.9%[12] provides a useful baseline for using a database for the labeling at the sentence level. It may be the case that certain interactions tend to be biologically related and thus tend to co-occur (*upregulate* and *stimulate* or *inactivate* and *inhibit*, for example).

[11]For 28% of the triples, none of the sentences extracted from the target paper were found by the annotator to contain the interaction given by the database. We read four of these papers and found sentences containing that interaction, but our system had failed to extract them.

[12]The accuracy without the vague *interact with* is 49.4%.

	All	**Papers**	**Citan.**
DM	48.9	28.9	47.9
NB	47.1	33.3	53.4
NN	**52.9**	**36.7**	**63.2**
Key	30.5	18.9	38.3
KeyB	46.2	36.3	52.6
Base	36.3	34.4	37.6

Table 7: Classification accuracies when the models are trained and tested on the hand labeled sentences.

We investigated a few of the cases in which the labels were "suspiciously" different, for example a case in which the database interaction was *stimulate* but the annotator found the same proteins to be related by *inhibit* as well. It turned out that the authors of the article assigned *stimulate* found little evidence for this interaction (in favor of *inhibit*), suggesting an error in the database. In another case the database interaction was *require* but the authors of the article, while supporting this, found that under certain conditions (when a protein is too abundant) the interaction changes to one of *inhibit*. Thus we were able to find controversial facts about protein interactions just by looking at the confusion matrix of Table 6.

We trained the models using these hand-labeled sentences in order to determine the interaction expressed *for each sentence* (as opposed to for each document). This is a difficult task; for some sentences it took the annotator several minutes to understand them and decide which interaction applied. Table 7 shows the results on running the classification models on the six interactions for which there were more than 40 examples in the training sets. Again, the sentences from "papers" are especially difficult to classify; the best result for "papers" is 36.7% accuracy versus 63.2% accuracy for "citances." In this case the difference in performance of "papers" and "citances" is larger than for the previous task of document-level relation classification.

6 Conclusions

We tackled an important and difficult task, the classification of different interaction types between proteins in text. A solution to this problem would have an impact on a variety of important challenges in modern biology. We used a protein-interaction

database to automatically gather labeled data for this task, and implemented graphical models that can simultaneously perform protein name tagging and relation identification, achieving high accuracy on both problems. We also found evidence supporting the hypothesis that citation sentences are a good source of training data, most likely because they provide a concise and precise way of summarizing facts in the bioscience literature.

BLANC[1]: Learning Evaluation Metrics for MT

Lucian Vlad Lita and **Monica Rogati** and **Alon Lavie**
Carnegie Mellon University
{llita,mrogati,alavie}@cs.cmu.edu

Abstract

We introduce BLANC, a family of dynamic, trainable evaluation metrics for machine translation. Flexible, parametrized models can be learned from past data and automatically optimized to correlate well with human judgments for different criteria (e.g. adequacy, fluency) using different correlation measures. Towards this end, we discuss ACS (all common skip-ngrams), a practical algorithm with trainable parameters that estimates reference-candidate translation overlap by computing a weighted sum of all common skip-ngrams in polynomial time. We show that the BLEU and ROUGE metric families are special cases of BLANC, and we compare correlations with human judgments across these three metric families. We analyze the algorithmic complexity of ACS and argue that it is more powerful in modeling both local meaning and sentence-level structure, while offering the same practicality as the established algorithms it generalizes.

1 Introduction

Although recent MT evaluation methods show promising correlations to human judgments in terms of adequacy and fluency, there is still considerable room for improvement (Culy and Riehemann, 2003). Most of these studies have been performed at a system level and have not investigated metric robustness at a lower granularity. Moreover, even though the emphasis on adequacy vs. fluency is application-dependent, automatic evaluation metrics do not distinguish between the need to optimize correlation with regard to one or the other.

Machine translation automatic evaluation metrics face two important challenges: the lack of powerful features to capture both sentence level structure and local meaning, and the difficulty of designing good functions for combining these features into meaningful quality estimation algorithms.

In this paper, we introduce BLANC[1], an automatic MT evaluation metric family that is a generalization of popular and successful metric families currently used in the MT community (BLEU, ROUGE, F-measure etc.). We describe an efficient, polynomial-time algorithm for BLANC, and show how it can be optimized to target adequacy, fluency or any other criterion. We compare our metric's performance with traditional and recent automatic evaluation metrics. We also describe the parameter conditions under which BLANC can emulate them.

Throughout the remainder of this paper, we distinguish between two components of automatic MT evaluation: the *statistics* computed on candidate and reference translations and the *function* used in defining evaluation metrics and generating translation scores. Commonly used statistics include bag-of-words overlap, edit distance, longest common subsequence, ngram overlap, and skip-bigram overlap. Preferred functions are various combinations of precision and recall (Soricut and Brill, 2004), including

[1]Since existing evaluation metrics (e.g. BLEU, ROUGE) are special cases of our metric family, it is only natural to name it Broad Learning and Adaptation for Numeric Criteria (BLANC) – white light contains light of all frequencies

weighted precision and F-measures (Van-Rijsbergen, 1979).

BLANC implements a practical algorithm with learnable parameters for automatic MT evaluation which estimates the reference-candidate translation overlap by computing a weighted sum of common subsequences (also known as skip-ngrams). Common skip-ngrams are sequences of words in their sentence order that are found both in the reference and candidate translations. By generalizing and separating the overlap statistics from the function used to combine them, and by identifying the latter as a learnable component, BLANC subsumes the ngram based evaluation metrics as special cases and can better reflect the need of end applications for adequacy/fluency tradeoffs .

1.1 Related Work

Initial work in evaluating translation quality focused on edit distance-based metrics (Su et al., 1992; Akiba et al., 2001). In the MT context, edit distance (Levenshtein, 1965) represents the amount of word insertions, deletions and substitutions necessary to transform a candidate translation into a reference translation. Another evaluation metric based on edit distance is the *Word Error Rate* (Niessen et al., 2000) which computes the normalized edit distance. BLEU is a weighted precision evaluation metric introduced by IBM (Papineni et al., 2001). BLEU and its extensions/variants (e.g. NIST (Doddington, 2002)) have become de-facto standards in the MT community and are consistently being used for system optimization and tuning. These methods rely on local features and do not explicitly capture sentence-level features, although implicitly longer n-gram matches are rewarded in BLEU. The General Text Matcher (GTM) (Turian et al., 2003) is another MT evaluation method that rewards longer ngrams instead of assigning them equal weight.

(Lin and Och, 2004) recently proposed a set of metrics (ROUGE) for MT evaluation. ROUGE-L is a longest common subsequence (LCS) based automatic evaluation metric for MT. The intuition behind it is that long common subsequences reflect a large overlap between a candidate translation and a reference translation. ROUGE-W is also based on LCS, but assigns higher weights to sequences that have fewer gaps. However, these metrics still do not distinguish among translations with the same LCS but different number of shorter sized subsequences, also indicative of overlap. ROUGE-S attempts to correct this problem by combining the precision/recall of skip-*bigrams* of the reference and candidate translations. However, by using skip-ngrams with n¿=2, we might be able to capture more information encoded in the higher level sentence structure. With BLANC, we propose a way to exploit local contiguity in a manner similar to BLEU and also higher level structure similar to ROUGE type metrics.

2 Approach

We have designed an algorithm that can perform a full overlap search over variable-size, non-contiguous word sequences (skip-ngrams) efficiently. At first glance, in order to perform this search, one has to first exhaustively generate all skip-ngrams in the candidate and reference segments and then assess the overlap. This approach is highly prohibitive since the number of possible sequences is exponential in the number of words in the sentence. Our algorithm – ACS (all common skip-ngrams) – directly constructs the set of overlapping skip-ngrams through incremental composition of word-level matches. With ACS, we can reduce computation complexity to a fifth degree polynomial in the number of words.

Through the ACS algorithm, BLANC is not limited only to counting skip-ngram overlap: the contribution of different skip-ngrams to the overall score is based on a set of features. ACS computes the overlap between two segments of text and also allows local and global features to be computed during the overlap search. These local and global features are subsequently used to train evaluation models within the BLANC family. We introduce below several simple skip-ngram-based features and show that special-case parameter settings for these features emulate the computation of existing ngram-based metrics. In order to define the relative significance of a particular skip-ngram found by the ACS algorithm, we employ an exponential model for feature integration.

2.1 Weighted Skip-Ngrams

We define *skip-ngrams* as sequences of n words taken in sentence order allowing for arbitrary gaps. In algorithms literature skip-ngrams are equivalent to *subsequences*. As special cases, skip-ngrams with n=2 are referred to as skip-bigrams and skip-ngrams with no gaps between the words are simply $ngrams$. A sentence S of size $|S|$ has $C(|S|, n) = \frac{|S|!}{(|S|-n)!n!}$ skip-ngrams.

For example, the sentence "*To be or not to be*" has $C(6, 2) = 15$ corresponding skip-bigrams including "*be or*", "*to to*", and three occurrences of "*to be*". It also has $C(6, 4) = 15$ corresponding skip-4grams ($n = 4$) including "to be to be" and "to or not to".

Consider the following sample reference and candidate translations:

R_0:	machine translated text is evaluated automatically
K_1:	machine translated stories are chosen automatically
K_2:	machine and human together can forge a friendship that cannot be translated into words automatically
K_3:	machine code is being translated automatically

The skip-ngram "*machine translated automatically*" appears in both the reference R_0 and all candidate translations. Arguably, a skip-bigram that contains few gaps is likely to capture local structure or meaning. At the same time, skip-ngrams spread across a sentence are also very useful since they may capture part of the high level sentence structure.

We define a **weighting** feature function for skip-ngrams that estimates how likely they are to capture local meaning and sentence structure. The weighting function φ for a skip-ngram w_1 ..w_n is defined as:

$$\varphi(w_1..w_n) = e^{-\alpha \cdot G(w_1..w_n)} \tag{1}$$

where $\alpha \geq 0$ is a decay parameter and G($w_1..w_n$) measures the overall gap of the skip-ngram $w_1..w_n$ in a specific sentence. This overall skip-ngram weight can be decomposed into the weights of its constituent skip-bigrams:

$$\begin{aligned} \varphi(w_1..w_n) &= e^{-\alpha \cdot G(w_1,..,w_n)} && (2) \\ &= e^{-\alpha \cdot \sum_{i=1}^{n-1} G(w_i, w_{i+1})} \\ &= \prod_{i=1}^{n-1} \varphi(w_i\ w_{i+1}) && (3) \end{aligned}$$

In equation 3, $\varphi(w_i\ w_{i+1})$ is the number of words between w_i and w_{i+1} in the sentence. In the example above, the skip-ngram "machine translated automatically" has weight $e^{-3\alpha}$ for sentence K_1 and weight $e^{-12\alpha} = 1$ for sentence K_2.

In our initial experiments the gap G has been expressed as a linear function, but different families of functions can be explored and their corresponding parameters learned. The parameter α dictates the behavior of the weighting function. When $\alpha = 0$ φ equals $e^0 = 1$, rendering gap sizes irrelevant. In this case, skip-ngrams are given the same weight as contiguous ngrams. When α is very large, φ approaches 0 if there are any gaps in the skip-ngram and is 1 if there are no gaps. This setting has the effect of considering only contiguous ngrams and discarding all skip-ngrams with gaps.

In the above example, although the skip-ngram "machine translated automatically" has the same cumulative gap in both in K_1 and K_3, the occurrence in K_1 has is a gap distribution that more closely reflects that of the reference skip-ngram in R_0. To model gap distribution differences between two occurrences of a skip-ngram, we define a piece-wise distance function δ_{XY} between two sentences x and y. For two successive words in the skip-ngram, the distance function is defined as:

$$\delta_{XY}(w_1 w_2) = e^{-\beta \cdot |G_X(w_1,w_2) - G_Y(w_1,w_2)|} \tag{4}$$

where $\beta \geq 0$ is a decay parameter. Intuitively, the β parameter is used to reward better aligned skip-ngrams. Similar to the φ function, the overall δ_{XY} distance between two occurrences of a skip-ngram with $n > 1$ is:

$$\delta_{XY}(w_1..w_n) = \prod_{i=1}^{n-1} \delta_{XY}(w_i w_{i+1}) \tag{5}$$

Note that equation 5 takes into account pairs of skip-ngrams skip in different places by summing over piecewise differences. Finally, using an exponential model, we assign an overall score to the matched skip-ngram. The skip-ngram scoring function S_{xy} allows independent features to be incorporated into the overall score:

$$\begin{aligned} S_{xy}(w_i..w_k) &= \varphi(w_i..w_k) \cdot \delta_{xy}(w_i..w_k) \\ &\cdot e^{\lambda_1 f_1(w_i..w_k)} \cdot ... \cdot e^{\lambda_h f_h(w_i..w_k)} \end{aligned} \tag{6}$$

where features $f_1..f_h$ can be functions based on the syntax, semantics, lexical or morphological aspects of the skip-ngram. Note that different models for combining skip-ngram features can be used in conjunction with ACS.

2.2 Multiple References

In BLANC we incorporate multiple references in a manner similar to the ROUGE metric family. We compute the precision and recall of each size skip-ngrams for individual references. Based on these we combine the maximum precision and maximum recall of the candidate translation obtained using all reference translations and use them to compute an aggregate F-measure.

The F-measure parameter β_F is modeled by BLANC. In our experiments we optimized β_F individually for fluency and adequacy.

2.3 The ACS Algorithm

We present a practical algorithm for extracting *All Common Skip-ngrams* (ACS) of any size that appear in the candidate and reference translations. For clarity purposes, we present the ACS algorithm as it relates to the MT problem: find all common skip-ngrams (ACS) of any size in two sentences X and Y:

$$wSKIP \leftarrow Acs(\delta, \varphi, X, Y) \quad (7)$$

$$= \{wSKIP_1..wSKIP_{min(|X|,|Y|)}\} \quad (8)$$

where $wSkip_n$ is the set of all skip-ngrams of size n and is defined as:

$$wSKIP_n = \{\text{“}w_1..w_n\text{”} \mid w_i \in X, w_i \in Y, \forall i \in [1..n] \text{ and } w_i \prec w_j, \forall i < j \in [1..n]\}$$

Given two sentences X and Y we observe a *match* (w, x, y) if word w is found in sentence X at index x and in sentence Y at index y:

$$(w, x, y) \equiv \{0 \leq x \leq |X|, 0 \leq y \leq |Y|, w \in V, \textit{and } X[x] = Y[y] = w\} \quad (9)$$

where V is the vocabulary with a finite set of words.

In the following subsections, we present the following steps in the ACS algorithm:

1. *identify all matches* – find matches and generate corresponding nodes in the dependency graph
2. *generate dependencies* – construct edges according to pairwise match dependencies
3. *propagate common subsequences* – count all common skip-ngrams using corresponding weights and distances

In the following sections we use the following example to illustrate the intermediate steps of ACS.

X. “to be or not to be”
Y. “to exist or not be”

2.3.1 Step 1: Identify All Matches

In this step we identify all word matches (w, x, y) in sentences X and Y. Using the example above, the intermediate inputs and outputs of this step are:

Input:	X.	“to be or not to be”
	Y.	“to exist or not be”
Output:	(*to*,1,1); (*to*,5,1); (*or*,3,3); (*be*,2,5); …	

For each match we create a corresponding node N in a dependency graph. With each node we associate the actual word matched and its corresponding index positions in both sentences.

2.3.2 Step 2: Generate Dependencies

A dependency $N_1 \rightarrow N_2$ occurs when the two corresponding matches (w_1, x_1, y_1) and (w_2, x_2, y_2) can form a valid common skip-bigram: i.e. when $x_1 < x_2$ and $y_1 < y_2$. Note that the matches can cover identical words, but their indices cannot be the same ($x_1 \neq x_2$ and $y_1 \neq y_2$) since a skip-bigram requires two different word matches.

In order to facilitate the generation of all common subsequences, the graph is populated with the appropriate dependency edges:

```
for each node N in DAG
  for each node M$\neq$N in DAG
    if N(x)$\leq$M(x) and N(y)$\leq$M(y)
      create edge E: N$\rightarrow$M
        compute $\delta_{XY}$(E)
        compute $\varphi$(E)
```

This step incorporates the concepts of skip-ngram weight and distance into the graph. With each edge $E : N_1 \rightarrow N_2$ we associate step-wise weight and distance information for the corresponding skip-bigram formed by matches (w_1, x_1, y_1) and (w_2, x_2, y_2).

Note that rather than counting all skip-ngrams, which would be exponential in the worst case scenario, we only construct a structure of match dependencies (i.e. skip-bigrams). As in dynamic programming, in order to avoid exponential complexity, we compute individual skip-ngram scores only once.

2.3.3 Step 3: Propagate Common Subsequences

In this last step, the ACS algorithm *counts* all common skip-ngrams using corresponding weights and distances. In the general case, this step is equivalent measuring the overlap of the two sentences X and Y. As a special case, if no features are used, the

ACS algorithm is equivalent to counting the number of common skip-ngrams regardless of gap sizes.

```
// depth first search (DFS)
for each node N in DAG
    compute node N's depth

// initialize skip-ngram counts
for each node N in DAG
    v_N[1] ← 1
    for i=2 to LCS(X,Y)
        v_N[i] = 0

// compute ngram counts
for d=1 to MAXDEPTH
    for each node N of depth d in DAG
        for each edge E: N→M
            for i=2 to d
                v_M[i] += $S_{xy}$($\delta$(E), $\varphi$(E), v_N[i-1])
```

After algorithm ACS is run, the number of skip-ngrams (weighted skip-ngram score) of size k is simply the sum of the number of skip-ngrams of size k ending in each node N's corresponding match:

$$wSKIP_k = \sum_{N_i \in DAG} v_{N_i}[k] \tag{10}$$

2.3.4 ACS Complexity and Feasibility

In the worst case scenario, both sentences X and Y are composed of exactly the same repeated word: X = "*w w w w* .. " and Y = "*w w w w* ..". We let $m = |X|$ and $n = |Y|$. In this case, the number of matches is $M = n \cdot m$. Therefore, Step 1 has worst case time and space complexity of $O(m \cdot n)$. However, empirical data suggest that there are far fewer matches than in the worst-case scenario and the actual space requirements are drastically reduced. Even in the worst-case scenario, if we assume the average sentences is fewer than 100 words, the number of nodes in the DAG would only be $10,000$. Step 2 of the algorithm consists of creating edges in the dependency graph. In the worst case scenario, the number of directed edges is $O(M^2)$ and furthermore if the sentences are uniformly composed of the same repeated word as seen above, the worst-case time and space complexity is $m(m+1)/2 \cdot n(n+1)/2 = O(m^2n^2)$. In Step 3 of the algorithm, the DFS complexity for computing of node depths is $O(M)$ and the complexity of $LCS(X, Y)$ is $O(m \cdot n)$. The dominant step is the propagation of common subsequences (skip-ngram counts). Let l be the size of the LCS. The upper bound on the size of the longest common subsequence is $min(|X|, |Y|) = min(m, n)$. In the worst case scenario, for each node we propagate l count values (the size of vector v) to all other nodes in the DAG. Therefore, the time complexity for Step 3 is $O(M^2 \cdot l) = O(m^2n^2l)$ (fifth degree polynomial).

3 BLANC as a Generalization of BLEU and ROUGE

Due to its parametric nature, the All Common Subsequences algorithm can emulate the ngram computation of several popular MT evaluation metrics. The weighting function φ allows skip-ngrams with different gap sizes to be assigned different weights. Parameter α controls the shape of the weighting function.

In one extreme scenario, if we allow α to take very large values, the net effect is that all contiguous ngrams of any size will have corresponding weights of $e^0 = 1$ while all other skip-ngrams will have weights that are zero. In this case, the distance function will only apply to contiguous ngrams which have the same size and no gaps. Therefore, the distance function will also be 1. The overall result is that the ACS algorithm collects contiguous common ngram counts for all ngram sizes. This is equivalent to computing the ngram overlap between two sentences, which is equivalent to the ngram computation performed BLEU metric. In addition to computing ngram overlap, BLEU incorporates a thresholding (clipping) on ngram counts based on reference translations, as well as a brevity penalty which makes sure the machine-produced translations are not too short. In BLANC, this is replaced by standard F-measure, which research (Turian et al., 2003) has shown it can be used successfully in MT evaluation.

Another scenario consists of setting the α and β parameters to 0. In this case, all skip-ngrams are assigned the same weight value of 1 and skip-ngram matches are also assigned the same distance value of 1 regardless of gap sizes and differences in gap sizes. This renders all skip-ngrams equivalent and the ACS algorithm is reduced to counting the *skip-ngram overlap* between two sentences. Using these counts, precision and recall-based metrics such as the F-measure can be computed. If we let the α and β parameters to be zero, disregard redundant matches, and compute

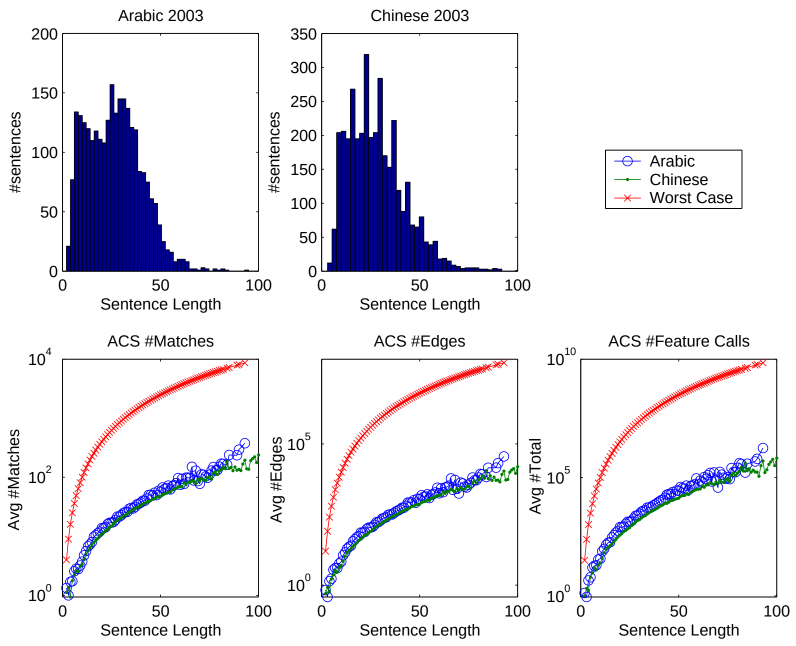

Figure 1: Empirical and theoretical behavior of ACS on 2003 machine translation evaluation data (semilog scale).

the ACS only for skip-ngrams of size 2, the ACS algorithm is equivalent to the ROUGE-S metric (Lin and Och, 2004). This case represents a specific parameter setting in the ACS skip-ngram computation.

The longest common subsequence statistic has also been successfully used for automatic machine translation evaluation in the ROUGE-L (Lin and Och, 2004) algorithm. In BLANC, if we set both α and β parameters to zero, the net result is a set of skip-bigram (common subsequence) overlap counts for all skip-bigram sizes. Although dynamic programming or suffix trees can be used to compute the LCS much faster, under this parameter setting the ACS algorithm can also produce the longest common subsequence:

$$LCS(X,Y) \leftarrow \underset{k}{\text{argmax}}\ ACS(wSKIP_k) > 0$$

where $Acs(wSKIP_k)$ is the number of common skip-ngrams (common subsequences) produced by the ACS algorithm.

ROUGE-W (Lin and Och, 2004) relies on a weighted version of the longest common subsequence, under which longer contiguous subsequences are assigned a higher weight than subsequences that incorporate gaps. ROUGE-W uses the polynomial function x^a in the weighted LCS computation. This setting can also be simulated by BLANC by adjusting the parameters α to reward tighter skip-ngrams and β to assign a very high score to similar size gaps. Intuitively, α is used to reward skip-ngrams that have smaller gaps, while β is used to reward better aligned skip-ngram overlap.

4 Scalability & Data Exploration

In Figure 1 we show theoretical and empirical practical behavior for the ACS algorithm on the 2003 TIDES machine translation evaluation data for Arabic and Chinese. Sentence length distribution is somewhat similar for the two languages – only a very small amount of text segments have more than 50 tokens. We show the ACS graph size in the worst case scenario, and the empirical average number of matches for both languages as a function of sentence length. We also show (on a log scale) the upper bound on time/space complexity in terms of total number of feature computations. Even though the worst-case scenario is tractable (polynomial), the empirical amount of computation is considerably smaller in the form of polynomials of lower degree. In Figure 1, sentence length is the average between reference and candidate lengths.

Finally, we also show the total number of feature computations involved in performing a full overlap search and computing a numeric score for the reference-candidate translation pair. We have experimented with the ACS algorithm using a worst-case scenario where all words are exactly the same for a fifty words reference translation and candidate translation. In practice when considering real sentences the number of matches is very small. In this setting, the algorithm takes less than two seconds on a low-end desktop system when working on the worst case scenario, and less then a second for all candidate-reference pairs in the TIDES 2003 dataset. This result renders the ACS algorithm very practical for automatic MT evaluation.

5 Experiments & Results

In the dynamic metric BLANC, we have implemented the ACS algorithm using several parameters including the aggregate gap size α, the displacement feature β, a parameter for regulating skip-ngram size contribution, and the F-measure β_F parameter.

Until recently, most experiments that evaluate automatic metrics correlation to human judgments have been performed at a system level. In such experiments, human judgments are aggregated across sentences for each MT system and compared to aggregate scores for automatic metrics. While high scoring metrics in this setting are useful for understanding relative system performance, not all of them are robust enough for evaluating the quality of machine translation output at a lower granularity. Sentence-level translation quality estimation is very useful when MT is used as a component in a pipeline of text-processing applications (e.g. question answering). The fact that current automatic MT evaluation metrics including BLANC do not correlate well with human judgments at the sentence level, does not mean we should ignore this need and focus only on system level evaluation. On the contrary, further research is required to improve these metrics. Due to its trainable nature, and by allowing additional features to be incorporated into its model, BLANC has the potential to address this issue.

For comparison purposes with previous literature, we have also performed experiments at system level for Arabic. The datasets used consist of the MT translation outputs from all systems available through the Tides 2003 evaluation (663 sentences) for training and Tides 2004 evaluation (1353 sentences) for testing.

We compare (Table 1) the performance of BLANC on Arabic translation output with the performance of more established evaluation metrics: BLEU and NIST, and also with more recent metrics: ROUGE-L and ROUGE-S (using an unlimited size skip window), which have been shown to correlate well with human judgments at system level – as confirmed by our results. We have performed experiments in which case information is preserved as well as experiments that ignore case information. Since the results are very similar, we only show here experiments under the former condition. In order to maintain consistency, when using any metric we apply the same preprocessing provided by the MTEval script. When computing the correlation between metrics and human judgments, we only keep strictly positive scores. While this is not fully equivalent to BLEU smoothing, it partially mitigates the same problem of zero count ngrams for short sentences. In future work we plan to implement smoothing for all metrics, including BLANC.

We train BLANC separately for adequacy and fluency, as well as for system level and segment level correlation with human judgments. The BLANC parameters are currently trained using a simple hill-climbing procedure and using several starting points in order to decrease the chance of reaching a local maximum.

BLANC proves to be robust across criteria and granularity levels. As expected, different parameter values of BLANC optimize different criteria (e.g. adequacy and fluency). We have observed that training BLANC for adequacy results in more bias towards recall (β_F=3) compared to training it for fluency (β_F=2). This confirms our intuition that a dynamic, parametric metric is justified for automatic evaluation.

6 Conclusions & Future Work

In previous sections we have defined simple distance functions. More complex functions can also be incorporated in ACS. Skip-ngrams in the candidate sentence might be rewarded if they contain fewer gaps in the candidate sentence and penalized if they contain more. Different distance functions could also be used in ACS, including functions based on surface-form features and part-of-speech features.

Table 1: Pearson correlation of several metrics with human judgments at system level and segment level for fluency and adequacy.

static functions according to which automatic evaluation scores are computed. In this paper, we have laid the foundation for a more flexible, parametric approach that can be trained using existing MT data and that can be optimized for highest agreement with human assessors, for different criteria.

We have introduced ACS, a practical algorithm with learnable parameters for automatic MT evaluation and showed that ngram computation of popular evaluation methods can be emulated through different parameters by ACS. We have computed time and space bounds for the ACS algorithm and argued that while it is more powerful in modeling local and sentence structure, it offers the same practicality as established algorithms.

In our experiments, we trained and tested BLANC on data from consecutive years, and therefore tailored the metric for two different operating points in MT system performance. In this paper we show that BLANC correlates well with human performance when trained on previous year data for both sentence and system level.

In the future, we plan to investigate the stability and performance of BLANC and also apply it to automatic summarization evaluation. We plan to optimize the BLANC parameters for different criteria in addition to incorporating syntactic and semantic features (e.g. ngrams, word classes, part-of-speech).

In previous sections we have defined simple distance functions. More complex functions can also be incorporated in ACS. Skip-ngrams in the candidate sentence might be rewarded if they contain fewer gaps in the candidate sentence and penalized if they contain more. Different distance functions could also be used in ACS, including functions based on surface-form features and part-of-speech features.

Looking beyond the BLANC metric, this paper makes the case for the need to shift to trained, dynamic evaluation metrics which can adapt to individual optimization criteria and correlation functions.

We plan to make available an implementation of BLANC at *http://www.cs.cmu.edu/ llita/blanc*.

Composition of Conditional Random Fields for Transfer Learning

Charles Sutton and Andrew McCallum

{sutton,mccallum}@cs.umass.edu

Abstract

Many learning tasks have subtasks for which much training data exists. Therefore, we want to *transfer* learning from the old, general-purpose subtask to a more specific new task, for which there is often less data. While work in transfer learning often considers how the old task should affect learning on the new task, in this paper we show that it helps to take into account how the new task affects the old. Specifically, we perform joint decoding of separately-trained sequence models, preserving uncertainty between the tasks and allowing information from the new task to affect predictions on the old task. On two standard text data sets, we show that joint decoding outperforms cascaded decoding.

1 Introduction

Many tasks in natural language processing are solved by chaining errorful subtasks. Within information extraction, for example, part-of-speech tagging and shallow parsing are often performed before the main extraction task. Commonly these subtasks have their own standard sets of labeled training data: for example, many large data sets exist for learning to extract person names from newswire text; whereas the available training data for new applications, such as extracting appointment information from email, tends to be much smaller. Thus, we need to transfer regularities learned from a well-studied subtask, such as finding person names in newswire text, to a new, related task, such as finding names of speakers in email seminar announcements.

In previous NLP systems, transfer is often accomplished by training a model for the subtask, and using its prediction as a feature for the new task. For example, recent CoNLL shared tasks (Tjong Kim Sang & De Meulder, 2003; Carreras & Marquez, 2004), which are standard data sets for such common NLP tasks as clause identification and named-entity recognition, include predictions from a part-of-phrase tagger and a shallow parser as features. But including only the single most likely subtask prediction fails to exploit useful dependencies between the tasks. First, if the subtask prediction is wrong, the model for the new task may not be able to recover. Often, errors propagate upward through the chain of tasks, causing errors in the final output. This problem can be ameliorated by preserving uncertainty in the subtask predictions, because even if the best subtask prediction is wrong, the distribution over predictions can still be somewhat accurate.

Second, information from the main task can inform the subtask. This is especially important for learning transfer, because the new domain often has different characteristics than the old domain, which is often a standard benchmark data set. For example, named-entity recognizers are usually trained on newswire text, which is more structured and grammatical than email, so we expect an off-the-shelf named-entity recognizer to perform somewhat worse on email. An email task, however, often has domain-specific features, such as PREVIOUS WORD IS *Speaker:*), which were unavailable or uninformative to the subtask on the old training set, but are very informative to the subtask in the new domain. While previous work in transfer learning has considered how the old task can help the new task, in this paper we show how the new task can help itself by improving predictions on the old.

In this paper we address the issue of transfer by training a cascade of models independently on the various training sets, but at test time combining them into a single model in which decoding is performed jointly. For the individual models, we use linear-chain conditional random fields (CRFs), because the great freedom that they allow in feature engineering facilitates the learning of richer interactions between the subtasks. We train a linear chain CRF on each subtask, using the prediction of the previous subtask as a feature. At test time, we combine the learned weights from the original CRFs into a single grid-shaped factorial CRF, which makes predictions for all the tasks at once. Viterbi decoding in this combined model implicitly considers all possible predictions for the subtask when making decisions in the main task.

We evaluate joint decoding for learning transfer on a standard email data set and a standard entity recognition task. On the email data set, we show a significant gain in performance, including new state-of-the-art results. Of particular interest for transfer learning, we also show that using joint decoding, we achieve equivalent results to cascaded decoding with 25% less training data.

2 Linear-chain CRFs

Conditional random fields (CRFs) (Lafferty et al., 2001) are undirected graphical models that are conditionally trained. In this section, we describe CRFs for the linear-chain case. Linear-chain CRFs can be roughly understood as conditionally-trained finite state machines. A linear-chain CRF defines a distribution over state sequences $\mathbf{s} = \{s_1, s_2, \ldots, s_T\}$ given an input sequence $\mathbf{x} = \{x_1, x_2, \ldots, x_T\}$ by making a first-order Markov assumption on states. These Markov assumptions imply that the distribution over sequences factorizes in terms of pairwise functions $\Phi_t(s_{t-1}, s_t, \mathbf{x})$ as:

$$p(\mathbf{s}|\mathbf{x}) = \frac{\prod_t \Phi_t(s_{t-1}, s_t, \mathbf{x})}{Z(\mathbf{x})}, \tag{1}$$

The partition function $Z(\mathbf{x})$ is defined to ensure that the distribution is normalized:

$$Z(\mathbf{x}) = \sum_{\mathbf{s}'} \prod_t \Phi_t(s'_{t-1}, s'_t, \mathbf{x}). \tag{2}$$

The *potential functions* $\Phi_t(s_{t-1}, s_t, \mathbf{x})$ can be interpreted as the cost of making a transition from state s_{t-1} to state s_t at time t, similar to a transition probability in an HMM.

Computing the partition function $Z(\mathbf{x})$ requires summing over all of the exponentially many possible state sequences $\mathbf{s}'$. By exploiting Markov assumptions, however, $Z(\mathbf{x})$ (as well as the node marginals $p(s_t|\mathbf{x})$ and the Viterbi labeling) can be calculated efficiently by variants of the standard dynamic programming algorithms used for HMMs.

We assume the potentials factorize according to a set of features $\{f_k\}$, which are given and fixed, so that

$$\Phi(s_{t-1}, s_t, \mathbf{x}) = \exp\left(\sum_k \lambda_k f_k(s_{t-1}, s_t, \mathbf{x}, t)\right). \tag{3}$$

The model parameters are a set of real weights $\Lambda = \{\lambda_k\}$, one for each feature.

Feature functions can be arbitrary. For example, one feature function could be a binary test $f_k(s_{t-1}, s_t, \mathbf{x}, t)$ that has value 1 if and only if s_{t-1} has the label SPEAKERNAME, s_t has the label OTHER, and the word x_t begins with a capital letter. The chief practical advantage of conditional models, in fact, is that we can include arbitrary highly-dependent features without needing to estimate their distribution, as would be required to learn a generative model.

Given fully-labeled training instances $\{(\mathbf{s}_j, \mathbf{x}_j)\}_{j=1}^{M}$, CRF training is usually performed by maximizing the penalized log likelihood

$$\ell(\Lambda) = \sum_j \sum_t \sum_k \lambda_k f_k(s_{j,t-1}, s_{j,t}, \mathbf{x}, t) - \sum_j \log Z(\mathbf{x}_j) - \sum_k \frac{\lambda_k^2}{2\sigma^2} \tag{4}$$

where the final term is a zero-mean Gaussian prior placed on parameters to avoid overfitting. Although this maximization cannot be done in closed form, it can be optimized numerically. Particularly effective are gradient-based methods that use approximate second-order information, such as conjugate gradient and limited-memory BFGS (Byrd et al., 1994). For more information on current training methods for CRFs, see Sha and Pereira (2003).

3 Dynamic CRFs

Dynamic conditional random fields (Sutton et al., 2004) extend linear-chain CRFs in the same way that dynamic Bayes nets (Dean & Kanazawa, 1989) extend HMMs. Rather than having a single monolithic state variable, DCRFs factorize the state at each time step by an undirected model.

Formally, DCRFs are the class of conditionally-trained undirected models that repeat structure and parameters over a sequence. If we denote by $\Phi_c(\mathbf{y}_{c,t}, \mathbf{x}_t)$ the repetition of clique c at time step t, then a DCRF defines the probability of a label sequence $\mathbf{s}$ given the input $\mathbf{x}$ as:

$$p(\mathbf{s}|\mathbf{x}) = \frac{\prod_t \Phi_c(\mathbf{y}_{c,t}, \mathbf{x}_t)}{Z(\mathbf{x})}, \tag{5}$$

where as before, the clique templates are parameterized in terms of input features as

$$\Phi_c(\mathbf{y}_{c,t}, \mathbf{x}_t) = \exp\left\{\sum_k \lambda_k f_k(\mathbf{y}_{c,t}, \mathbf{x}_t)\right\}. \tag{6}$$

Exact inference in DCRFs can be performed by forward-backward in the cross product state space, if the cross-product space is not so large as to be infeasible. Otherwise, approximate methods must be used; in our experience, loopy belief propagation is often effective in grid-shaped DCRFs. Even if inference is performed monolithically, however, a factorized state representation is still useful because it requires much fewer parameters than a fully-parameterized linear chain in the cross-product state space.

Sutton et al. (2004) introduced the *factorial CRF* (FCRF), in which the factorized state structure is a grid (Figure 1). FCRFs were originally applied to jointly performing interdependent language processing tasks, in particular part-of-speech tagging and noun-phrase chunking. The previous work on FCRFs used joint training, which requires a single training set that is jointly labeled for all tasks in the cascade. For many tasks such data is not readily available, for example, labeling syntactic parse trees for every new Web extraction task would be prohibitively expensive. In this paper, we train the subtasks separately, which allows us the freedom to use large, standard data sets for well-studied subtasks such as named-entity recognition.

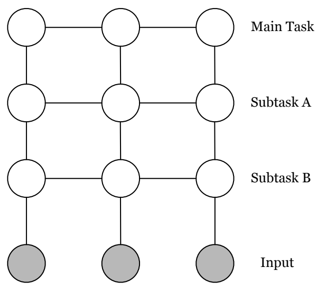

Figure 1: Graphical model for the jointly-decoded CRF. All of the pairwise cliques also have links to the observed input, although we omit these edges in the diagram for clarity.

4 Alternatives for Learning Transfer

In this section, we enumerate several classes of methods for learning transfer, based on the amount and type of interaction they allow between the tasks. The principal differences between methods are whether the individual tasks are performed separately in a cascade or jointly; whether a single prediction from the lower task is used, or several; and what kind of confidence information is shared between the subtasks.

The main types of transfer learning methods are:

1. *Cascaded training and testing.* This is the traditional approach in NLP, in which the single best prediction from the old task is used in the new task at training and test time. In this paper, we show that allowing richer interactions between the subtasks can benefit performance.

2. *Joint training and testing.* In this family of approaches, a single model is trained to perform all the subtasks at once. For example, in Caruana's work on multitask learning (Caruana, 1997), a neural network is trained to jointly perform multiple classification tasks, with hidden nodes that form a shared representation among the tasks. Jointly trained methods allow potentially the richest interaction between tasks, but can be expensive in both computation time required for training and in human effort required to label the joint training data.

   Exact inference in a jointly-trained model, such as forward-backward in an FCRF, implicitly considers all possible subtask predictions with confidence given by the model's probability of the prediction. However, for computational efficiency, we can use inference methods such as particle filtering and sparse message-passing (Pal et al., 2005), which communicate only a limited number of predictions between sections of the model.

3. *Joint testing with cascaded training.* Although a joint model over all the subtasks can have better performance, it is often much more expensive to train. One approach for reducing training time is cascaded training, which provides both computational efficiency and the ability to reuse large, standard training sets for the subtasks. At test time, though, the separately-trained models are combined into a single model, so that joint decoding can propagate information between the tasks.

   Even with cascaded training, it is possible to preserve some uncertainty in the subtask's predictions. Instead of using only a single subtask prediction for training the main task, the subtask can pass upwards a lattice of likely predictions, each of which is weighted by the model's confidence. This has the advantage of making the training procedure more similar to the joint testing procedure, in which all possible subtask predictions are considered.

In the next two sections, we describe and evaluate joint testing with cascaded training for transfer learning in linear-chain CRFs. At training time, only the best subtask prediction is used, without any confidence information. Even though this is perhaps the simplest joint-testing/cascaded-training method, we show that it still leads to a significant gain in accuracy.

5 Composition of CRFs

In this section we briefly describe how we combine individually-trained linear-chain CRFs using composition. For a series of N cascaded tasks, we train individual CRFs separately on each task, using the prediction of the previous CRF as a feature. We index the CRFs by i, so that the state of CRF i at time t is denoted s^i_t. Thus, the feature functions for CRF i are of the form $f^i_k(s^i_{t-1}, s^i_t, s^{i-1}_t, \mathbf{x}, t)$—that is, they depend not only on the observed input $\mathbf{x}$ and the transition $(s^i_{t-1} \to s^i_t)$ but

$w_t = w$
w_t matches `[A-Z][a-z]+`
w_t matches `[A-Z][A-Z]+`
w_t matches `[A-Z]`
w_t matches `[A-Z]+`
w_t matches `[A-Z]+[a-z]+[A-Z]+[a-z]`
w_t appears in list of first names, last names, honorifics, etc.
w_t appears to be part of a time followed by a dash
w_t appears to be part of a time preceded by a dash
w_t appears to be part of a date
$T_t = T$
$q_k(\mathbf{x}, t+\delta)$ for all k and $\delta \in [-4, 4]$

Table 1: Input features $q_k(\mathbf{x}, t)$ for the seminars data. In the above w_t is the word at position t, T_t is the POS tag at position t, w ranges over all words in the training data, and T ranges over all Penn Treebank part-of-speech tags. The "appears to be" features are based on hand-designed regular expressions that can span several tokens.

also on the state s_t^{i-1} of the previous transducer.

We also add all conjunctions of the input features and the previous transducer's state, for example, a feature that is 1 if the current state is SPEAKERNAME, the previous transducer predicted PERSONNAME, and the previous word is `Host:`.

To perform joint decoding at test time, we form the composition of the individual CRFs, viewed as finite-state transducers. That is, we define a new linear-chain CRF whose state space is the cross product of the states of the individual CRFs, and whose transition costs are the sum of the transition costs of the individual CRFs.

Formally, let $S^1, S^2, \ldots S^N$ be the state sets and $\Lambda^1, \Lambda^2, \ldots \Lambda^N$ the weights of the individual CRFs. Then the state set of the combined CRF is $\mathbf{S} = S^1 \times S^2 \times \ldots \times S^N$. We will denote weight k in an individual CRF i by λ_k^i and a single feature by $f_k^i(s_{t-1}^i, s_t^i, s_t^{i-1}, \mathbf{x}, t)$. Then for $\mathbf{s} \in \mathbf{S}$, the combined model is given by:

$$p(\mathbf{s}|\mathbf{x}) = \frac{\prod_t \exp\left\{\sum_{i=1}^N \sum_k \lambda_k^i f_k^i(s_{t-1}^i, s_t^i, s_t^{i-1}, \mathbf{x}, t)\right\}}{Z(\mathbf{x})}. \tag{7}$$

The graphical model for the combined model is the factorial CRF in Figure 1.

6 Experiments

6.1 Email Seminar Announcements

We evaluate joint decoding on a collection of 485 e-mail messages announcing seminars at Carnegie Mellon University, gathered by Freitag (1998). The messages are annotated with the seminar's starting time, ending time, location, and speaker. This data set has been the subject of much previous work using a wide variety of learning methods. Despite all this work, however, the best

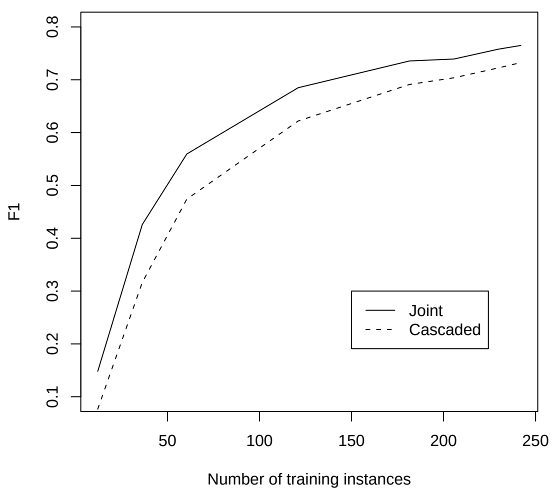

Figure 2: Learning curves for the seminars data set on the speaker field, averaged over 10-fold cross validation. Joint training performs equivalently to cascaded decoding with 25% more data.

reported systems have precision and recall on speaker names of only about 70%—too low to use in a practical system. This task is so challenging because the messages are written by many different people, who each have different ways of presenting the announcement information.

Because the task includes finding locations and person names, the output of a named-entity tagger is a useful feature. It is not a perfectly indicative feature, however, because many other kinds of person names appear in seminar announcements—for example, names of faculty hosts, departmental secretaries, and sponsors of lecture series. For example, the token *Host:* indicates strongly both that what follows is a person name, but that person is not the seminars' speaker.

Even so, named-entity predictions do improve performance on this task. We use the predictions from a CRF named-entity tagger that we trained on the standard CoNLL 2003 English data set. The CoNLL 2003 data set consists of newswire articles from Reuters labeled as either people, locations, organizations, or miscellaneous entities. It is much larger than the seminar announcements data set. While the named-entity data contains 203,621 tokens for training, the seminar announcements data set contains only slightly over 60,000 training tokens.

Previous work on the seminars data has used a one-field-per-document evaluation. That is, for each field, the CRF selects a single field value from its Viterbi path, and this extraction is counted as correct if it exactly matches any of the true field mentions in the document. We compute precision and recall following this convention, and report their harmonic mean F_1. As in the previous work,

System		stime	etime	location	speaker	overall
WHISK	(Soderland, 1999)	92.6	86.1	66.6	18.3	65.9
SRV	(Freitag, 1998)	98.5	77.9	72.7	56.3	76.4
HMM	(Frietag & McCallum, 1999)	98.5	62.1	78.6	76.6	78.9
RAPIER	(Califf & Mooney, 1999)	95.9	94.6	73.4	53.1	79.3
SNOW-IE	(Roth & Wen-tau Yih, 2001)	**99.6**	**96.3**	75.2	73.8	86.2
$(LP)^2$	(Ciravegna, 2001)	99.0	95.5	75.0	**77.6**	86.8
CRF (no transfer)	This paper	99.1	97.3	81.0	73.7	87.8
CRF (cascaded)	This paper	99.2	96.0	84.3	74.2	88.4
CRF (joint)	This paper	99.1	96.0	**85.3**	76.3	**89.2**

Table 2: Comparison of F_1 performance on the seminars data. Joint decoding performs significantly better than cascaded decoding. The overall column is the mean of the other four. (This table was adapted from Peshkin and Pfeffer (2003).)

we use 10-fold cross validation with a 50/50 training/test split. We use a spherical Gaussian prior on parameters with variance $\sigma^2 = 0.5$.

We evaluate whether joint decoding with cascaded training performs better than cascaded training and decoding. Table 2 compares cascaded and joint decoding for CRFs with other previous results from the literature.[1] The features we use are listed in Table 1. Although previous work has used very different feature sets, we include a no-transfer CRF baseline to assess the impact of transfer from the CoNLL data set. All the CRF runs used exactly the same features.

On the most challenging fields, location and speaker, cascaded transfer is more accurate than no transfer at all, and joint decoding is more accurate than cascaded decoding. In particular, for speaker, we see an error reduction of 8% by using joint decoding over cascaded. The difference in F1 between cascaded and joint decoding is statistically significant for speaker (paired t-test; $p = 0.017$) but only marginally significant for location ($p = 0.067$). Our results are competitive with previous work; for example, on location, the CRF is more accurate than any of the existing systems.

Examining the trained models, we can observe both errors made by the general-purpose named entity tagger, and how they can be corrected by considering the seminars labels. In newswire text, long runs of capitalized words are rare, often indicating the name of an entity. In email announcements, runs of capitalized words are common in formatted text blocks like:

```
Location:  Baker Hall
    Host:  Michael Erdmann
```

In this type of situation, the named entity tagger often mistakes *Host:* for the name of an entity, especially because the word preceding *Host* is also capitalized. On one of the cross-validated testing sets, of 80 occurrences of the word *Host:*, the named-entity tagger labels 52 as some kind of entity. When joint decoding is used, however, only 20 occurrences are labeled as entities. Recall that the joint model uses exactly the same weights as the cascaded model; the only difference is that the joint model takes into account information about the seminar labels when choosing named-entity labels. This is an example of how domain-specific information from the main task can improve performance on a more standard, general-purpose subtask.

[1]We omit one relevant paper (Peshkin & Pfeffer, 2003) because its evaluation method differs from all the other previous work.

$w_t = w$
w_t matches `[A-Z][a-z]+`
w_t matches `[A-Z][A-Z]+`
w_t matches `[A-Z]`
w_t matches `[A-Z]+`
w_t matches `[A-Z]+[a-z]+[A-Z]+[a-z]`
w_t is punctuation
w_t appears in list of first names, last names, honorifics, etc.
$q_k(\mathbf{x}, t + \delta)$ for all k and $\delta \in [-2, 2]$
Conjunction $q_k(\mathbf{x}, t)$ and $q_{k'}(\mathbf{x}, t)$ for all features k, k'
Conjunction $q_k(\mathbf{x}, t)$ and $q_{k'}(\mathbf{x}, t + 1)$ for all features k, k'

Table 3: Input features $q_k(\mathbf{x}, t)$ for the ACE named-entity data. In the above w_t is the word at position t, and w ranges over all words in the training data.

Figure 2 shows the difference in performance between joint and cascaded decoding as a function of training set size. Cascaded decoding with the full training set of 242 emails performs equivalently to joint decoding on only 181 training instances, a 25% reduction in the training set.

In summary, even with a simple cascaded training method on a well-studied data set, joint decoding performs better for transfer than cascaded decoding.

6.2 Entity Recognition

In this section we give results on joint decoding for transfer between two newswire data sets with similar but overlapping label sets. The Automatic Content Extraction (ACE) data set is another standard entity recognition data

	Transfer Type		
	none	cascaded	joint
Person name	81.0	86.9	87.3
Person nominal	34.9	36.1	42.4
Organization name	53.9	62.6	61.1
Organization nominal	33.7	35.3	40.8
GPE name	78.5	84.0	84.0
GPE nominal	51.2	54.1	59.2

Table 4: Comparison of F_1 performance between joint and cascaded training on the ACE entity recognition task. GPE means geopolitical entities, such as countries. Joint decoding helps most on the harder nominal (common noun) references. These results were obtained using a small subset of the training set.

set, containing 422 stories from newspaper, newswire, and broadcast news. Unlike the CoNLL entity recognition data set, in which only proper names of entities are annotated, the ACE data includes annotation both for named entities like *United States*, and also nominal mentions of entities like *the nation*. Thus, although the input text has similar distribution in the CoNLL NER and ACE data set, the label distributions are very different.

Current state-of-the-art systems for the ACE task (Florian et al., 2004) use the predictions of other named-entity recognizers as features, that is, they use cascaded transfer. In this experiment, we test whether the transfer between these datasets can be further improved using joint decoding. We train a CRF entity recognizer on the ACE dataset, with the output of a named-entity entity recognizer trained on the CoNLL 2003 English data set. The CoNLL recognizer is the same CRF as was used in the previous experiment. In these results, we use a subset of 10% of the ACE training data. Table 3 lists the features we use. Table 4 compares the results on some representative entity types. Again, cascaded decoding for transfer is better than no transfer at al, and joint decoding is better than cascaded decoding. Interestingly, joint decoding has most impact on the harder nominal references, showing marked improvement over the cascaded approach.

7 Related Work

Researchers have begun to accumulate experimental evidence that joint training and decoding yields better performance than the cascaded approach. As mentioned earlier, the original work on dynamic CRFs (Sutton et al., 2004) demonstrated improvement due to joint training in the domains of part-of-speech tagging and noun-phrase chunking. Also, Carreras and Marquez (Carreras & Màrquez, 2004) have obtained increased performance in clause finding by training a cascade of perceptrons to minimize a single global error function. Finally, Miller et al. (Miller et al., 2000) have combined entity recognition, parsing, and relation extraction into a jointly-trained single statistical parsing model that achieves improved performance on all the subtasks.

Part of the contribution of the current work is to suggest that joint decoding can be effective even when joint training is not possible because jointly-labeled data is unavailable. For example, Miller et al. report that they originally attempted to annotate newswire articles for all of parsing, relations, and named entities, but they stopped because the annotation was simply too expensive. Instead they hand-labeled relations only, assigning parse trees to the training set using a standard statistical parser, which is potentially less flexible than the cascaded training, because the model for main task is trained explicitly to match the noisy subtask predictions, rather than being free to correct them.

In the speech community, it is common to compose separately trained weighted finite-state transducers (Mohri et al., 2002) for joint decoding. Our method extends this work to conditional models. Ordinarily, higher-level transducers depend only on the output of the previous transducer: a transducer for the lexicon, for example, consumes only phonemes, not the original speech signal. In text, however, such an approach is not sensible, because there is simply not enough information in the named-entity labels, for example, to do extraction if the original words are discarded. In a conditional model, weights in higher-level transducers are free to depend on arbitrary features of the original input without any additional complexity in the finite-state structure.

Finally, stacked sequential learning (Cohen & Carvalho, 2005) is another potential method for combining the results of the subtask transducers. In this general meta-learning method for sequential classification, first a base classifier predicts the label at each time step, and then a higher-level classifier makes the final prediction, including as features a window of predictions from the base classifier. For transfer learning, this would correspond to having an independent base model for each subtask (e.g., independent CRFs for named-entity and seminars), and then having a higher-level CRF that includes as a feature the predictions from the base models.

8 Conclusion

In this paper we have shown that joint decoding improves transfer between interdependent NLP tasks, even when the old task is named-entity recognition, for which highly accurate systems exist. The rich features afforded by a conditional model allow the new task to influence the predictions of the old task, an effect that is only possible with joint decoding.

It is now common for researchers to publicly release trained models for standard tasks such as part-of-speech tagging, named-entity recognition, and parsing. This paper has implications for how such standard tools are packaged. Our results suggest that off-the-shelf NLP tools will need not only to provide a single-best prediction, but also to be engineered so that they can easily communicate distributions over predictions to models for higher-level tasks.

Abstract

This paper presents a phrase-based statistical machine translation method, based on non-contiguous phrases, i.e. phrases with *gaps*. A method for producing such phrases from a word-aligned corpora is proposed. A statistical translation model is also presented that deals such phrases, as well as a training method based on the maximization of translation accuracy, as measured with the NIST evaluation metric. Translations are produced by means of a beam-search decoder. Experimental results are presented, that demonstrate how the proposed method allows to better generalize from the training data.

1 Introduction

Possibly the most remarkable evolution of recent years in statistical machine translation is the step from word-based models to phrase-based models (Och et al., 1999; Marcu and Wong, 2002; Yamada and Knight, 2002; Tillmann and Xia, 2003). While in traditional word-based statistical models (Brown et al., 1993) the atomic unit that translation operates on is the word, phrase-based methods acknowledge the significant role played in language by multi-word expressions, thus incorporating in a statistical framework the insight behind Example-Based Machine Translation (Somers, 1999).

However, Phrase-based models proposed so far only deal with multi-word units that are sequences of contiguous words on both the source and the target side. We propose here a model designed to deal with multi-word expressions that need not be contiguous in either or both the source and the target side.

The rest of this paper is organised as follows. Section 2 provides motivations, definition and extraction procedure for non-contiguous phrases. The log-linear conditional translation model we adopted is the object of Section 3; the method used to train its parameters is described in Section 4. Section 5 briefly describes the decoder. The experiments we conducted to asses the effectiveness of using non-contiguous phrases are presented in Section 6.

2 Non-contiguous phrases

Why should it be a good thing to use phrases composed of possibly non-contiguous sequences of words? In doing so we expect to improve translation quality by better accounting for additional linguistic phenomena as well as by extending the effect of contextual semantic disambiguation and example-based translation inherent in phrase-based MT. An example of a phenomenon best described using non-contiguous units is provided by English phrasal verbs. Consider the sentence “Mary *switches* her table lamp *off*”. Word-based statistical models would be at odds when selecting the appropriate translation of the verb. If French were the target language, for instance, corpus evidence would come from both examples in which “switch” is translated as “allumer” (to switch on) and as “éteindre” (to switch off). If many-to-one word alignments are not allowed from English to French, as it is usually the

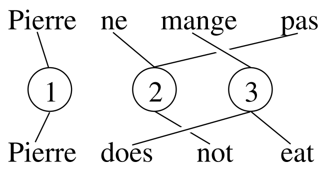

Figure 1: An example of a complex alignment associated with different syntax for negation in English and French.

case, then the best thing a word-based model could do in this case would be to align "off" to the empty word and hope to select the correct translation from "switch" only, basically a 50-50 bet. While handling inseparable phrasal verbs such as "to run out" correctly, previously proposed phrase-based models would be helpless in this case. A comparable behavior is displayed by German separable verbs. Moreover, non-contiguous linguistic units are not limited to verbs. Negation is formed, in French, by inserting the words "ne" and "pas" before and after a verb respectively. So, the sentence "Pierre ne mange pas" and its English translation display a complex word-level alignment (Figure 1) current models cannot account for.

Flexible idioms, allowing for the insertion of linguistic material, are other phenomena best modeled with non-contiguous units.

2.1 Definition and library construction

We define a *bi-phrase* as a pair comprising a *source phrase* and a *target phrase*: $b = \langle \tilde{s}, \tilde{t} \rangle$. Each of the source and target phrases is a sequence of words and gaps (indicated by the symbol $\diamond$); each gap acts as a placeholder for exactly one unspecified word. For example, $\tilde{w} = w_1 w_2 \diamond w_3 \diamond\diamond\, w_4$ is a phrase of length 7, made up of two contiguous words w_1 and w_2, a first gap, a third word w_3, two consecutive gaps and a final word w_4. To avoid redundancy, phrases may not begin or end with a gap. If a phrase does not contain any gaps, we say it is *contiguous*; otherwise it is *non-contiguous*. Likewise, a bi-phrase is said to be *contiguous* if both its phrases are contiguous.

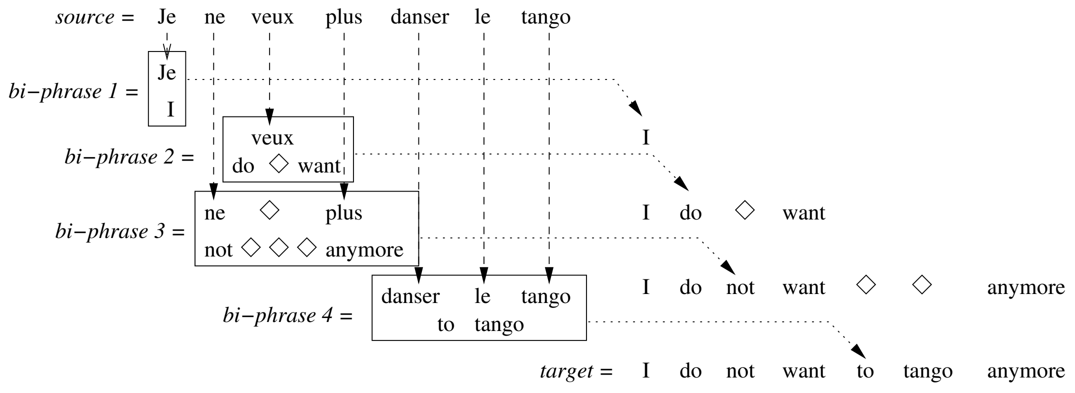
The translation of a source sentence s is produced by combining together bi-phrases so as to cover the source sentence, and produce a well-formed target-language sentence (i.e. without gaps). A complete translation for s can be described as an ordered sequence of bi-phrases $b_1 ... b_K$. When piecing together the final translation, the target-language portion $\tilde{t}_1$ of the first bi-phrase b_1 is first layed down, then each subsequent $\tilde{t}_k$ is positioned on the first "free" position in the target language sentence, i.e. either the leftmost gap, or the right end of the sequence. Figure 2 illustrates this process with an example.

To produce translations, our approach therefore relies on a collection of bi-phrases, what we call a *bi-phrase library*. Such a library is constructed from a corpus of existing translations, aligned at the word level.

Two strategies come to mind to produce non-contiguous bi-phrases for these libraries. The first is to align the words using a "standard" word alignement technique, such as the *Refined Method* described in (Och and Ney, 2003) (the intersection of two IBM Viterbi alignments, forward and reverse, enriched with alignments from the union) and then generate bi-phrases by combining together individual alignments that co-occur in the same pair of sentences. This is the strategy that is usually adopted in other phrase-based MT approaches (Zens and Ney, 2003; Och and Ney, 2004). Here, the difference is that we are not restricted to combinations that produce strictly contiguous bi-phrases.

The second strategy is to rely on a word-alignment method that naturally produces many-to-many alignments between non-contiguous words, such as the method described in (Goutte et al., 2004). By means of a matrix factorization, this method produces a parallel partition of the two texts, seen as sets of word tokens. Each token therefore belongs to one, and only one, subset within this partition, and corresponding subsets in the source and target make up what are called *cepts*. For example, in Figure 1, these cepts are represented by the circles numbered 1, 2 and 3; each cept thus connects word tokens in the source and the target, regardless of position or contiguity. These cepts naturally constitute bi-phrases, and can be used directly to produce a bi-phrase library.

Obviously, the two strategies can be combined, and it is always possible to produce increasingly large and complex bi-phrases by combining together co-occurring bi-phrases, contiguous or not. One problem with this approach, however, is that the resulting libraries can become very large. With con-



source = Je ne veux plus danser le tango
bi−phrase 1 = Je / I
bi−phrase 2 = veux / do ◇ want
bi−phrase 3 = ne ◇ plus / not ◇ ◇ ◇ anymore
bi−phrase 4 = danser le tango / to tango
I
I do ◇ want
I do not want ◇ ◇ anymore
target = I do not want to tango anymore

Figure 2: Combining bi-phrases to produce a translation.

tiguous phrases, the number of bi-phrases that can be extracted from a single pair of sentences typically grows quadratically with the size of the sentences; with non-contiguous phrases, however, this growth is exponential. As it turns out, the number of available bi-phrases for the translation of a sentence has a direct impact on the time required to compute the translation; we will therefore typically rely on various filtering techniques, aimed at keeping only those bi-phrases that are more likely to be useful. For example, we may retain only the most frequently observed bi-phrases, or impose limits on the number of cepts, the size of gaps, etc.

3 The Model

In statistical machine translation, we are given a source language input $s_1^J = s_1 ... s_J$, and seek the target-language sentence $t_1^I = t_1 ... t_I$ that is its most likely translation:

$$\hat{t}_1^I = \text{argmax}_{t_1^I} Pr(t_1^I | s_1^J) \tag{1}$$

Our approach is based on a direct approximation of the posterior probability $Pr(t_1^I | s_1^J)$, using a log-linear model:

$$Pr(t_1^I | s_1^J) = \frac{1}{Z_{s_1^J}} \exp\left(\sum_{m=1}^{M} \lambda_m h_m(t_1^I, s_1^J)\right)$$

In such a model, the contribution of each *feature function* h_m is determined by the corresponding model parameter λ_m; $Z_{s_1^J}$ denotes a normalization constant. This type of model is now quite widely used for machine translation (Tillmann and Xia, 2003; Zens and Ney, 2003)[1].

Additional variables can be introduced in such a model, so as to account for hidden characteristics, and the feature functions can be extended accordingly. For example, our model must take into account the actual set of bi-phrases that was used to produce this translation:

$$Pr(t_1^I, b_1^K | s_1^J) = \frac{1}{Z_{s_1^J}} \exp\left(\sum_{m=1}^{M} \lambda_m h_m(t_1^I, s_1^J, b_1^K)\right)$$

Our model currently relies on seven feature functions, which we describe here.

- The *bi-phrase* feature function h_{bp}: it represents the probability of producing t_1^I using some set of bi-phrases, under the assumption that each source phrase produces a target phrase independently of the others:

$$h_{bp}(t_1^I, s_1^J, b_1^K) = \sum_{k=1}^{K} \log Pr(\tilde{t}_k | \tilde{s}_k) \tag{2}$$

  Individual bi-phrase probabilities $Pr(\tilde{t}_k | \tilde{s}_k)$ are estimated based on occurrence counts in the word-aligned training corpus.

- The *compositional bi-phrase* feature function h_{comp}: this is introduced to compensate for

[1]Recent work from Chiang (Chiang, 2005) addresses similar concerns to those motivating our work by introducing a Synchronous CFG for bi-phrases. If on one hand SCFGs allow to better control the order of the material inserted in the gaps, on the other gap size does not seem to be taken into account, and phrase dovetailing such as the one involving "do ◇want" and "not ◇◇◇anymore" in Fig. 2 is disallowed.

h_{bp}'s strong tendency to overestimate the probability of rare bi-phrases; it is computed as in equation (2), except that bi-phrase probabilities are computed based on individual word translation probabilities, somewhat as in IBM model 1 (Brown et al., 1993):

$$Pr(\tilde{t}|\tilde{s}) = \frac{1}{|\tilde{s}|^{|\tilde{t}|}} \prod_{t \in \tilde{t}} \sum_{s \in \tilde{s}} Pr(t|s)$$

- The *target language* feature function h_{tl}: this is based on a N-gram language model of the target language. As such, it ignores the source language sentence and the decomposition of the target into bi-phrases, to focus on the actual sequence of target-language words produced by the combination of bi-phrases:

$$h_{tl}(t_1^I, s_1^J, b_1^K) = \sum_{i=1}^{I} \log Pr(t_i | t_{i-N+1}^{i-1})$$

- The *word-count* and *bi-phrase count* feature functions h_{wc} and h_{bc}: these control the length of the translation and the number of bi-phrases used to produce it:

$$h_{wc}(t_1^I, s_1^J, b_1^K) = I \quad h_{bc}(t_1^I, s_1^J, b_1^K) = K$$

- The *reordering* feature function $h_{reord}(t_1^I, s_1^J, b_1^K)$: it measures the amount of reordering between bi-phrases of the source and target sentences.

- the *gap count* feature function h_{gc}: It takes as value the total number of gaps (source and target) within the bi-phrases of b_1^K, thus allowing the model some control over the nature of the bi-phrases it uses, in terms of the discontiguities they contain.

4 Parameter Estimation

The values of the λ parameters of the log-linear model can be set so as to optimize a given criterion. For instance, one can maximize the likelyhood of some set of training sentences. Instead, and as suggested by Och (2003), we chose to maximize directly the quality of the translations produced by the system, as measured with a machine translation evaluation metric.

Say we have a set of source-language sentences S. For a given value of λ, we can compute the set of corresponding target-language translations T. Given a set of *reference* ("gold-standard") translations R for S and a function $E(T, R)$ which measures the "error" in T relative to R, then we can formulate the parameter estimation problem as[2]:

$$\hat{\lambda} = \text{argmin}_{\lambda} E(T, R)$$

As pointed out by Och, one notable difficulty with this approach is that, because the computation of T is based on an argmax operation (see eq. 1), it is not continuous with regard to λ, and standard gradient-descent methods cannot be used to solve the optimization. Och proposes two workarounds to this problem: the first one relies on a direct optimization method derived from Powell's algorithm; the second introduces a smoothed (continuous) version of the error function $E(T, R)$ and then relies on a gradient-based optimization method.

We have opted for this last approach. Och shows how to implement it when the error function can be computed as the sum of errors on individual sentences. Unfortunately, this is not the case for such widely used MT evaluation metrics as BLEU (Papineni et al., 2002) and NIST (Doddington, 2002). We show here how it can be done for NIST; a similar derivation is possible for BLEU.

The NIST evaluation metric computes a weighted n-gram precision between T and R, multiplied by a factor $B(S, T, R)$ that penalizes short translations. It can be formulated as:

$$B(S, T, R) \times \sum_{n=1}^{N} \frac{\sum_{s \in S} I_n(t_s, r_s)}{\sum_{s \in S} C_n(t_s)} \tag{3}$$

where N is the largest n-gram considered (usually $N = 4$), $I_n(t_s, r_s)$ is a weighted count of common n-grams between the target (t_s) and reference (r_s) translations of sentence s, and $C_n(t_s)$ is the total number of n-grams in t_s.

To derive a version of this formula that is a continuous function of λ, we will need multiple translations $t_{s,1}, ..., t_{s,K}$ for each source sentence s. The general idea is to weight each of these translations

[2]For the sake of simplicity, we consider a single reference translation per source sentence, but the argument can easily be extended to multiple references.

by a factor $w(\lambda, s, k)$, proportional to the score $m_\lambda(t_{s,k}|s)$ that $t_{s,k}$ is assigned by the log-linear model for a given λ:

$$w(\lambda, s, k) = \left[\frac{m_\lambda(t_{s,k}|s)}{\sum_{k'} m_\lambda(t_{s,k'}|s)} \right]^\alpha$$

where α is the *smoothing factor*. Thus, in the smoothed version of the NIST function, the term $I_n(t_s, r_s)$ in equation (3) is replaced by $\sum_k w(\lambda, s, k) I_n(t_{s,k}, r_s)$, and the term $C_n(t_s)$ is replaced by $\sum_k w(\lambda, s, k) C_n(t_{s,k})$. As for the brevity penalty factor $B(S, T, R)$, it depends on the total length of translation T, i.e. $\sum_s |t_s|$. In the smoothed version, this term is replaced by $\sum_s \sum_k w(\lambda, s, k)|t_{s,k}|$. Note that, when $\alpha \to \infty$, then $w(\lambda, s, k) \to 0$ for all translations of s, except the one for which the model gives the highest score, and so the smooth and normal NIST functions produce the same value. In practice, we determine some "good" value for α by trial and error (5 works fine).

We thus obtain a scoring function for which we can compute a derivative relative to λ, and which can be optimized using gradient-based methods. In practice, we use the *OPT++* implementation of a quasi-Newton optimization (Meza, 1994). As observed by Och, the smoothed error function is not convex, and therefore this sort of minimum-error rate training is quite sensitive to the initialization values for the λ parameters. Our approach is to use a random set of initializations for the parameters, perform the optimization for each initialization, and select the model which gives the overall best performance.

Globally, parameter estimation proceeds along these steps:

1. Initialize the training set: using random parameter values λ_0, for each source sentence of some given set of sentences S, we compute multiple translations. (In practice, we use the M-best translations produced by our decoder; see Section 5).

2. Optimize the parameters: using the method described above, we find λ that produces the best smoothed NIST score on the training set.

3. Iterate: we then re-translate the sentences of S with this new λ, combine the resulting multiple translations with those already in the training set, and go back to step 2.

Steps 2 and 3 can be repeated until the smooothed NIST score does not increase anymore[3].

5 Decoder

We implemented a version of the beam-search stack decoder described in (Koehn, 2003), extended to cope with non-contiguous phrases. Each translation is the result of a sequence of *decisions*, each of which involves the selection of a bi-phrase and of a target position. The final result is obtained by combining decisions, as in Figure 2. *Hypotheses*, corresponding to partial translations, are organised in a sequence of priority stacks, one for each number of source words covered. Hypotheses are extended by filling the first available uncovered position in the target sentence; each extended hypotheses is then inserted in the stack corresponding to the updated number of covered source words. Each hypothesis is assigned a score which is obtained as a combination of the actual feature function values and of admissible heuristics, adapted to deal with gaps in phrases, estimating the future cost for completing a translation. Each stack undergoes both threshold and histogram pruning. Whenever two hypotheses are indistinguishable as far as the potential for further extension is concerned, they are merged and only the highest-scoring is further extended. Complete translations are eventually recovered in the "last" priority stack, i.e. the one corresponding to the total number of source words: the best translation is the one with the highest score, and that does not have any remaining gaps in the target.

6 Evaluation

We have conducted a number of experiments to evaluate the potential of our approach. We were particularly interested in assessing the impact of non-contiguous bi-phrases on translation quality, as well as comparing the different bi-phrase library contruction strategies evoked in Section 2.1.

[3]It can be seen that, as the set of possible translations for S stabilizes, we eventually reach a point where the procedure converges to a maximum. In practice, however, we can usually stop much earlier.

6.1 Experimental Setting

All our experiments focused exclusively on French to English translation, and were conducted using the Aligned Hansards of the 36th Parliament of Canada, provided by the Natural Language Group of the USC Information Sciences Institute, and edited by Ulrich Germann. From this data, we extracted three distinct subcorpora, which we refer to as the *bi-phrase-building set*, the *training set* and the *test set*. These were extracted from the so-called *training*, *test-1* and *test-2* portions of the Aligned Hansard, respectively. Because of efficiency issues, we limited ourselves to source-language sentences of 30 words or less. More details on the evaluation data is presented in Table 1[4].

6.2 Bi-phrase Libraries

From the bi-phrase-building set, we built a number of libraries. A first family of libraries was based on a word alignment "A", produced using the *Refined method* described in (Och and Ney, 2003) (combination of two IBM-Viterbi alignments): we call these the A libraries. A second family of libraries was built using alignments "B" produced with the method in (Goutte et al., 2004): these are the B libraries. The most notable difference between these two alignments is that B contains "native" non-contiguous bi-phrases, while A doesn't.

Some libraries were built by simply extracting the cepts from the alignments of the bi-phrase-building corpus: these are the A^1 and B^1 libraries, and variants. Other libraries were obtained by combining cepts that co-occur within the same pair of sentences, to produce "composite" bi-phrases. For instance, the A^2 libraries contain combinations of 1 or 2 cepts from alignment A; B^3 contains combinations of 1, 2 or 3 cepts, etc.

Some libraries were built using a "gap-size" filter. For instance library A^2-g3 contains those bi-phrases obtained by combining 1 or 2 cepts from alignment A, and in which neither the source nor the target phrase contains more than 3 gaps. In particular, library B^1-g0 does not contain any non-contiguous bi-phrases.

[4]Preliminary experiments on different data sets allowed us to establish that 800 sentences constituted an acceptable size for estimating model parameters. With such a corpus, the estimation procedure converges after just 2 or 3 iterations.

Finally, all libraries were subjected to the same two filtering procedures: the first excludes all bi-phrases that occur only once in the training corpus; the second, for any given source-language phrase, retains only the 20 most frequent target-language equivalents. While the first of these filters typically eliminates a large number of entries, the second only affects the most frequent source phrases, as most phrases have less than 20 translations.

6.3 Experiments

The parameters of the model were optimized independantly for each bi-phrase library. In all cases, we performed only 2 iterations of the training procedure, then measured the performance of the system on the test set in terms of the NIST and BLEU scores against one reference translation. As a point of comparison, we also trained an IBM-4 translation model with the *GIZA++* toolkit (Och and Ney, 2000), using the combined *bi-phrase building* and *training* sets, and translated the test set using the *ReWrite* decoder (Germann et al., 2001)[5].

Table 2 describes the various libraries that were used for our experiments, and the results obtained for each.

System/library	bi-phrases	NIST	BLEU
ReWrite		6.6838	0.3324
A^1	238 K	6.6695	0.3310
A^2-g0	642 K	6.7675	0.3363
A^2-g3	4.1 M	6.7068	0.3283
B^1-g0	193 K	6.7898	0.3369
B^1	267 K	6.9172	0.3407
B^2-g0	499 K	6.7290	0.3391
B^2-g3	3.3 M	6.9707	0.3552
B^1-g1	206 K	6.8979	0.3441
B^1-g2	213 K	6.9406	0.3454
B^1-g3	218 K	6.9546	0.3518
B^1-g4	222 K	6.9527	0.3423

Table 2: Bi-phrase libraries and results

The top part of the table presents the results for the A libraries. As can be seen, library A^1 achieves approximately the same score as the baseline system; this is expected, since this library is essentially

[5]Both the *ReWrite* and our own system relied on a trigram language model trained on the English half of the bi-phrase building set.

Subset	sentences	source words	target words
bi-phrase-building set	931,000	17.2M	15.2M
training set	800	11,667	10,601
test set	500	6726	6041

Table 1: Data sets.

made up of one-to-one alignments computed using IBM-4 translation models. Adding contiguous bi-phrases obtained by combining pairs of alignments does gain us some mileage (+0.1 NIST)[6]. Again, this is consistent with results observed with other systems (Tillmann and Xia, 2003). However, the addition of non-contiguous bi-phrases (A^2-g3) does not seem to help.

The middle part of Table 2 presents analogous results for the corresponding B libraries, plus the B^1-g0 library, which contains only those cepts from the B alignment that are contiguous. Interestingly, in the experiments reported in (Goutte et al., 2004), alignment method B did not compare favorably to A under the widely used *Alignment Error Rate* (AER) metric. Yet, the B^1-g0 library performs better than the analogous A^1 library on the translation task. This suggests that AER may not be an appropriate metric to measure the potential of an alignment for phrase-based translation.

Adding non-contiguous bi-phrases allows another small gain. Again, this is interesting, as it suggests that "native" non-contiguous bi-phrases are indeed useful for the translation task, i.e. those non-contiguous bi-phrases obtained directly as cepts in the B alignment.

Surprisingly, however, combining cepts from the B alignment to produce contiguous bi-phrases (B^2-G0) does not turn out to be fruitful. Why this is so is not obvious and, certainly, more experiments would be required to establish whether this tendency continues with larger combinations (B^3-g0, B^4-g0...). Composite non-contiguous bi-phrases produced with the B alignments (B^2-g3) seem to bring improvements with regard to "basic" bi-phrases (B_1), but it is not clear whether these are significant.

[6]While the differences in scores in these and other experiments are relatively small, we believe them to be significant, as they have been confirmed systematically in other experiments and, in our experience, by visual inspection of the translations.

Visual examination of the B^1 library reveals that many non-contiguous bi-phrases contain long-spanning phrases (i.e. phrases containing long sequences of gaps). To verify whether or not these were really useful, we tested a series of B^1 libraries with different gap-size filters. It must be noted that, because of the final histogram filtering we apply on libraries (retain only the 20 most frequent translations of any source phrase), library B^1-g1 is not a strict subset of B^1-g2. Therefore, filtering on gap-size usually represents a tradeoff between more frequent long-spanning bi-phrases and less frequent short-spanning ones.

The results of these experiments appear in the lower part of Table 2. While the differences in score are small, it seems that concentrating on bi-phrases with 3 gaps or less affords the best compromise. For small libraries such as those under consideration here, this sort of filtering may not be very important. However, for higher-order libraries (B^2, B^3, etc.) it becomes crucial, because it allows to control the exponential growth of the libraries.

7 Conclusions

In this paper, we have proposed a phrase-based statistical machine translation method based on non-contiguous phrases. We have also presented a estimation procedure for the parameters of a log-linear translation model, that maximizes a smooth version of the NIST scoring function, and therefore lends itself to standard gradient-based optimization techniques.

From our experiments with these new methods, we essentially draw two conclusions. The first and most obvious is that non-contiguous bi-phrases can indeed be fruitful in phrase-based statistical machine translation. While we are not yet able to characterize which bi-phrases are most helpful, some of those that we are currently capable of extracting are well suited to cover some short-distance phenomena.

The second conclusion is that alignment quality is crucial in producing good translations with phrase-based methods. While this may sound obvious, our experiments shed some light on two specific aspects of this question. The first is that the alignment method that produces the most useful bi-phrases need not be the one with the best *alignment error rate* (AER). The second is that, depending on the alignments one starts with, constructing increasingly large bi-phrases does not necessarily lead to better translations. Some of our best results were obtained with relatively small libraries (just over 200,000 entries) of short bi-phrases. In other words, it's not how many bi-phrases you have, it's how good they are. This is the line of research that we intend to pursue in the near future.

Abstract

Confidence measures for machine translation is a method for labeling each word in an automatically generated translation as correct or incorrect. In this paper, we will present a new approach to confidence estimation which has the advantage that it does not rely on system output such as N-best lists or word graphs as many other confidence measures do. It is, thus, applicable to any kind of machine translation system.

Experimental evaluation has been performed on translation of technical manuals in three different language pairs. Results will be presented for different machine translation systems to show that the new approach is independent of the underlying machine translation system which generated the translations. To the best of our knowledge, the performance of the new confidence measure is better than that of any existing confidence measure.

1 Introduction

The work presented in this paper deals with confidence estimation for machine translation (MT). Since sentences produced by a machine translation system are often incorrect but may contain correct parts, a method for identifying those correct parts and finding possible errors is desirable. For this purpose, each word in the generated target sentence is assigned a value expressing the confidence that it is correct.

Confidence measures have been extensively studied for speech recognition, but are not well known in other areas. Only recently have researchers started to investigate confidence measures for machine translation (Blatz et al., 2004; Gandrabur and Foster, 2003; Quirk, 2004; Ueffing et al., 2003).

We apply word confidence measures in MT as follows: For a given translation generated by a machine translation system, we determine a confidence value for each word and compare it to a threshold. All words whose confidence is above this threshold are tagged as correct and all others are tagged as incorrect translations. The threshold is optimized on a distinct development set beforehand.

Possible applications for confidence measures include

- post-editing, where words with low confidence could be marked as potential errors,
- improving translation prediction accuracy in trans-type-style interactive machine translation (Gandrabur and Foster, 2003; Ueffing and Ney, 2005),
- combining output from different machine translation systems: hypotheses with low confidence can be discarded before selecting one of the system translations (Akiba et al., 2004), or the word confidence scores can be used for generating new hypotheses from the output of different systems (Jayaraman and Lavie, 2005), or the sentence confidence value can be employed for re-ranking (Blatz et al., 2003).

In this paper, we will present several approaches to word-level confidence estimation and develop a new phrase-based confidence measure which is independent of the machine translation system which generated the translation. The paper is organized as follows: In section 2, we will briefly review the statistical approach to machine translation. The phrase-based translation system, which serves as basis for the new confidence measure, will be presented in section 2.2. Section 3 will give an overview of related work on confidence estimation for statistical machine translation (SMT). In section 4, we will describe methods for confidence estimation which make use of SMT system output such as word graphs and N-best lists. In section 5, we will present the new phrase-based confidence measure. Section 6 contains a short description of an IBM-1 based confidence measure to which we will compare the other measures. Experimental evaluation and comparison of the different confidence measures will be shown in section 7, and section 8 will conclude the paper.

2 Statistical machine translation

2.1 General

In statistical machine translation, the translation is modeled as a decision process: Given a source string $f_1^J = f_1 \ldots f_j \ldots f_J$, we seek the target string $e_1^I = e_1 \ldots e_i \ldots e_I$ with maximal posterior probability:

$$\begin{aligned} \hat{e}_1^{\hat{I}} &= \operatorname*{argmax}_{I,e_1^I} \left\{ Pr(e_1^I \mid f_1^J) \right\} \qquad (1) \\ &= \operatorname*{argmax}_{I,e_1^I} \left\{ Pr(f_1^J \mid e_1^I) \cdot Pr(e_1^I) \right\} \end{aligned}$$

Through this decomposition of the probability, we obtain two knowledge sources: the translation model $Pr(f_1^J \mid e_1^I)$ and the language model $Pr(e_1^I)$. Both of them can be modeled independently of each other. The translation model is responsible for linking the source string f_1^J and the target string e_1^I, i.e. it captures the semantics of the sentence. The target language model captures the well-formedness or the syntax in the target language. Nowadays, most of the state-of-the-art SMT systems are based on bilingual phrases (Bertoldi et al., 2004; Koehn et al., 2003; Och and Ney, 2004; Tillmann, 2003; Vogel et al., 2004; Zens and Ney, 2004). Note that those phrases are sequences of words in the two languages and not necessarily phrases in the linguistic sense. A more detailed description of a phrase-based approach to statistical machine translation will be given in section 2.2.

2.2 Review of phrase-based translation system

For the confidence measures which will be introduced in section 5, we use a state-of-the-art phrase-based approach as described in (Zens and Ney, 2004). The key elements of this translation approach are bilingual phrases, i.e. pairs of source and target language phrases where a phrase is simply a contiguous sequence of words. These bilingual phrases are extracted from a word-aligned bilingual training corpus.

We will present the equations for a monotone search here in order to keep the equations simple. Let (j_0^K, i_0^K) be a segmentation of the source sentence into phrases, with the corresponding (bilingual) phrase pairs $(\tilde{f}_k, \tilde{e}_k) = (f_{j_{k-1}+1}^{j_k}, e_{i_{k-1}+1}^{i_k}), k = 1, \ldots, K$. The phrase-based approach to SMT is then expressed by the following equation:

$$\begin{aligned} \hat{e}_1^{\hat{I}} = \operatorname*{argmax}_{j_0^K, i_0^K, I, e_1^I} & \left\{ \prod_{i=1}^{I} \left[c_1 \cdot p(e_i \mid e_{i-2}^{i-1})^{\lambda_1} \right] \right. \qquad (2) \\ & \cdot \prod_{k=1}^{K} \left[c_2 \cdot \; p(\tilde{f}_k \mid \tilde{e}_k)^{\lambda_2} \cdot p(\tilde{e}_k \mid \tilde{f}_k)^{\lambda_3} \right. \\ & \left. \left. \cdot \prod_{j=j_{k-1}+1}^{j_k} p(f_j \mid \tilde{e}_k)^{\lambda_4} \cdot \prod_{i=i_{k-1}+1}^{i_k} p(e_i \mid \tilde{f}_k)^{\lambda_5} \right] \right\}, \end{aligned}$$

where $p(\tilde{f}_k \mid \tilde{e}_k)$ and $p(\tilde{e}_k \mid \tilde{f}_k)$ are the phrase lexicon models in both translation directions. The phrase translation probabilities are computed as a log-linear interpolation of the relative frequencies and the IBM-1 probability. The single word based lexicon models are denoted as $p(f_j \mid \tilde{e}_k)$ and $p(e_i \mid \tilde{f}_k)$, respectively. $p(f_j \mid \tilde{e}_k)$ is defined as the IBM-1 model probability of f_j over the whole phrase $\tilde{e}_k$, and $p(e_i \mid \tilde{f}_k)$ is the inverse model, respectively.

c_1 is the so-called word penalty, and c_2 is the phrase penalty, assigning constant costs to each target language word/phrase. The language model is a trigram model with modified Kneser-Ney discounting and interpolation (Stolcke, 2002). The search determines the target sentence and segmentation which maximize the objective function.

As equation 2 shows, the sub-models are combined via weighted log-linear interpolation. The model scaling factors $\lambda_1, \ldots, \lambda_5$ and the word and phrase penalties are optimized with respect to some evaluation criterion (Och, 2003), e.g. BLEU score.

3 Confidence measures for SMT

3.1 Related work

In this paper, we will present a new approach to word-level confidence estimation which makes explicit use of a phrase-based translation model. Most of the word-level confidence measures which have been presented in the literature so far are either based on relatively simple translation models such as IBM-1 (Blatz et al., 2003) or make use of information provided by the SMT system such as N-best lists or word graphs (Blatz et al., 2003; Gandrabur and Foster, 2003; Ueffing et al., 2003). In contrast to this, our method is based on a state-of-the-art statistical machine translation model, but nevertheless is independent of the machine translation system which generates the translation hypotheses.

The word-level confidence measures which showed the best performance in comparative experiments (Blatz et al., 2003) are word posterior probabilities and the IBM-1 based measure. Our new confidence measure will be compared to those approaches in section 7.3.

3.2 Word posterior probabilities

The confidence of a target word can be expressed by its posterior probability, i.e. the probability of the word to occur in the target sentence, given the source sentence. Consider a target word e occurring in the sentence in position i[1]. The posterior probability of this event can be determined by summing over all possible target sentences e_1^I containing the word e in position i:

$$p_i(e, f_1^J) \quad = \sum_{I, e_1^I:\, e_i = e} p(e_1^I, f_1^J) \qquad (3)$$

This value has to be normalized in order to obtain a probability distribution over all possible target words:

$$p_i(e \,|\, f_1^J) \quad = \quad \frac{p_i(e, f_1^J)}{\sum\limits_{e'} p_i(e', f_1^J)} \qquad (4)$$

[1]This is a rather strict assumption, because the position of a word in the target sentence can differ largely due to reorderings in the translation process. We present this variant here to keep the notation simple. Improved methods will be shown in the following sections.

4 System based confidence measures

In this section, we will present confidence measures which are based on N-best lists or word graphs generated by the SMT system. Those are representations of the space of the most likely translations of the source sentence.

The summation given in equation 3 is performed over all sentences which are contained in the N-best list or word graph. For a more detailed description, see (Ueffing et al., 2003).

4.1 Word graph based approach

The word posterior probability $p_i(e \,|\, f_1^J)$ can be calculated over a word graph using the forward-backward algorithm.

Let n', n be nodes in a word graph, and (n', n) the directed edge connecting them. The edge is annotated with a target word which we denote by $e(n', n)$ and the probability which this word contributes to the overall sentence probability, denoted by $p(n', n)$.

The forward probability $\Phi_i(n', n)$ of an edge is the probability of reaching this edge from the source of the graph, where the word $e(n', n)$ is the i-th word on the path. It can be obtained by summing the probabilities of all incoming paths of length $i-1$, which allows for recursive calculation. This leads to the following formula:

$$\Phi_i(n', n) \quad = \quad p(n', n) \cdot \sum_{n''} \Phi_{i-1}(n'', n') \; .$$

The backward probability expresses the probability of completing a sentence from the current edge, i.e. of reaching the sink of the graph. It can be determined recursively in descending order of i as follows:

$$\Psi_i(n', n) \quad = \quad p(n', n) \cdot \sum_{n^*} \Psi_{i+1}(n, n^*) \; .$$

Using the forward-backward algorithm, the word posterior probability of word e in position i is determined by combining the forward and backward probabilities of all edges which are annotated with e. This yields

$$p_i(e, f_1^J) = \sum_{(n', n):\, e(n', n) = e} \frac{\Phi_i(n', n) \cdot \Psi_i(n', n)}{p(n', n)} \; . \quad (5)$$

Note that (for computational reasons) the term $p(n', n)$ is included both in the forward and in the backward probability so that we have to divide the product by this term.

To obtain a posterior probability, a normalization, as shown in equation 4, has to be performed. The normalization term $\alpha := \sum\limits_{e'} p_i(e', f_1^J)$ corresponds to the probability mass contained in the word graph and can be calculated by summing the backward probabilities of all outgoing edges leaving the source s of the graph:

$$\alpha = \sum_{(s,n)} \Psi_1(s,n) \; .$$

As stated above, the position of word e in the target sentence can vary due to reorderings in the translation process. Therefore, we would like to relax the condition that e has to occur exactly in position i. This can be achieved by introducing a window of size t over the neighboring target positions and computing the sum of the word posterior probabilities over all positions $i-t, \ldots, i, \ldots, i+t$. In our experiments we found that a window over ± 3 positions yields the best performance.

4.2 N-best list based approach

N-best lists are an alternative representation of the space of translation hypotheses. They have the advantage that the Levenshtein alignment between a hypothesis and all sentences contained in the list can be performed easily. This makes it possible to consider not only target sentences, which contain the word e exactly in a position i (as given in equation 3), but to allow for some variation.

Let $\mathcal{L}(e_1^I, \tilde{e}_1^{\tilde{I}})$ be the Levenshtein alignment between sentences e_1^I and $\tilde{e}_1^{\tilde{I}}$. Then, $\mathcal{L}_i(e_1^I, \tilde{e}_1^{\tilde{I}})$ denotes the Levenshtein alignment of word e_i, i.e. the word in sentence $\tilde{e}_1^{\tilde{I}}$ which e_i is Levenshtein-aligned to.

The word posterior probability is then calculated by summing over all target sentences containing word e in a position which is Levenshtein-aligned to i:

$$p_i(e|f_1^J, I, e_1^I) = \frac{p_i(e, f_1^J, I, e_1^I)}{\sum\limits_{e'} p_i(e', f_1^J, I, e_1^I)} \; ,$$

where

$$p_i(e, f_1^J, I, e_1^I) = \sum_{\tilde{I}, \tilde{e}_1^{\tilde{I}}:\, \mathcal{L}_i(e_1^I, \tilde{e}_1^{\tilde{I}})=e} p(\tilde{e}_1^{\tilde{I}}, f_1^J) \; . \quad (6)$$

The confidence of word e then depends on the source sentence f_1^J as well as the target sentence e_1^I, because the whole target sentence is relevant for the Levenshtein alignment.

5 Phrase-based confidence measures

In contrast to the approaches presented in section 4, the phrase-based confidence measures do not not use the context information at the sentence level, but only at the phrase level. We want to determine a sort of marginal probability $Q(e, f_1^J)$. Therefore, we extract all source phrases f_j^{j+s} which occur in the given source sentence. For such source phrases, we find the possible translations e_i^{i+t} in the bilingual phrase lexicon. The confidence of target word e is then calculated by summing over all phrase pairs (f_j^{j+s}, e_i^{i+t}) where the target part e_i^{i+t} contains the word e.

Let $p(e_i^{i+t})$ be the language model score of the target phrase together with the word penalty c_1, i.e.

$$p(e_i^{i+t}) = \prod_{i'=i}^{i+t} c_1 \cdot p(e_{i'} \mid e_{i'-2}^{i'-1})^{\lambda_1} \; .$$

Analogously, define $p(f_j^{j+s}, e_i^{i+t})$ as the score of the phrase pair which consists of the phrase penalty and the phrase and word lexicon model scores (cf. section 2.2). Following equation 2, the (unnormalized) confidence is then determined as:

$$Q(e, f_1^J) = \sum_{j=1}^{J} \sum_{s=0}^{\min\{s_{\max}, J-j\}} \sum_{e_i^{i+t}:\, e \in e_i^{i+t}} p(e_i^{i+t}) \cdot p(f_j^{j+s}, e_i^{i+t}) \; , \quad (7)$$

where $s \leq s_{\max}$ and t are source and target phrase lengths, $s_{\max}$ being the maximal source phrase length.

In equation 7, the language model only determines the probability of the words within the target part of the phrase, and not across the phrase boundaries, because we consider only the single target phrases without context. Therefore, we assumed that the language model would not have much influence on the confidence estimation and also investigated a model without a language model. The same holds for word and phrase penalty: In the translation process they are useful for adjusting the length of the generated target hypothesis and for assigning more weight to longer phrases. Since this does not make much sense in our setting, we also investigated confidence estimation without word and phrase penalty.

Note that the value calculated in equation 7 is not normalized. In order to obtain a word posterior probability, we divide this value by the sum over the (unnormalized) confidence of all target words:

$$p_{phr}(e \mid f_1^J) = \frac{Q(e, f_1^J)}{\sum\limits_{e'} Q(e', f_1^J)} \; . \tag{8}$$

Unlike the word posterior probabilities presented in the previous section, this value is completely independent of the target sentence position in which the word e occurs.

As stated in section 2.2, the scaling factors of the different sub-models and the penalties in the translation system are optimized with respect to some evaluation criterion. But since the values which are optimal for translation are not necessarily optimal for confidence estimation, we perform optimization here as well: We train the probability models on the training corpus, estimate the word confidences on the development corpus, and optimize the scaling factors with respect to the classification error rate described in section 7.2. The optimization is performed with the Downhill Simplex algorithm (Press et al., 2002).

6 IBM-1 based approach

Another type of confidence measure which does not rely on system output and is thus applicable to any kind of machine translation system is the IBM-1 model based confidence measure which was introduced in (Blatz et al., 2003). We modified this confidence measure because we found that the average lexicon probability used there is dominated by the maximum. Therefore, we determine the *maximal* translation probability of the target word e over the source sentence words:

$$p_{\text{IBM}-1}(e|f_1^J) = \max_{j=0,\dots,J} p(e|f_j) \; , \tag{9}$$

where f_0 is the "empty" source word (Brown et al., 1993). The probabilities $p(e|f_j)$ are word-based lexicon probabilities.

Investigations on the use of the IBM-1 model for word confidence measures showed promising results (Blatz et al., 2003; Blatz et al., 2004). Thus, we apply this method here in order to compare it to the other types of confidence measures.

7 Experiments

7.1 Experimental setting

The experiments were performed on three different language pairs. All corpora were compiled in the EU project TransType2; they consist of technical manuals. The corpus statistics are given in table 1. The SMT systems that the confidence estimation was performed for were trained on these corpora. The same holds for the probability models that were used to estimate the word confidences.

We used several (S)MT systems for testing the confidence measures. A detailed analysis will be given for two of them; the so-called alignment template system (Och and Ney, 2004), (denoted as AT in the tables) and the phrase-based translation system described in section 2.2 (denoted as PBT in the tables). They are both state-of-the-art SMT systems. We produced single best translations, word graphs and N-best lists on all three language pairs using these systems. The translation quality in terms of WER, PER (position independent word error rate), BLEU and NIST score is given in tables 2 and 3. We see that the best results are obtained on Spanish to English translation, followed by French to English and German to English.

Two more translation systems were used for comparative experiments: One is a statistical MT system which is based on a finite state architecture (FSA). For a description of this system, see (Kanthak et al., 2005). Additionally, we used translations generated by Systran[2]. Table 3 presents the translation error rates and scores for all systems on the German $\rightarrow$ English test corpus. These hypotheses were used to investigate whether the phrase-based confidence measures perform well independently of the translation system.

All three SMT systems (AT, PBT and FSA) show very similar performance on the German $\rightarrow$ English test corpus. The fact that Systran generates translations of much lower quality is due to the fact that the technical manuals are very specific in terminology, and the SMT systems have been trained on similar corpora.

BLEU[%]	26.6	25.7	26.5	12.0
NIST	5.92	5.72	5.79	4.09

To determine the true class of each word in a generated translation hypothesis, we use the word error rate (WER). That is, a target word is considered correct if it is aligned to itself in the Levenshtein alignment between hypothesis and reference translation(s). We also investigated PER based classification, but since the tendencies of the results were similar, we omit them here.

7.2 Evaluation metrics

After computing the confidence measure, each generated word is tagged as either *correct* or *false*, depending on whether its confidence exceeds the tagging threshold that has been optimized on the development set beforehand. The performance of the confidence measure is evaluated using the **C**lassification **E**rror **R**ate (CER). This is defined as the number of incorrect tags divided by the total number of generated words in the translated sentence. The baseline CER is determined by assigning the most frequent class to all translations. In the case that the most frequent class is "correct" (meaning at least half of the words in the generated translation are correct w.r.t. to WER), this is the number of substitutions and insertions, divided by the number of generated words. The CER strongly depends on the tagging threshold. Therefore, the tagging threshold is adjusted beforehand (to minimize CER) on a development corpus *distinct* to the test set.

7.3 Experimental results

Table 4 shows the performance of all different confidence measures on the hypotheses generated by the alignment template system and the phrase-based system. For the baseline CER, we determined the 90%- and 99%-confidence intervals using the bootstrap estimation method described in (Bisani and Ney, 2004)[3]. We see that, in all settings but one, the word graph and the N-best list based method outperform the IBM-1 based confidence measure. On French → English, the improvement over the baseline is significant at the 1%-level for these methods, whereas on Spanish → English this is only the case at 10%. The performance of the N-best list based approach is better than that of the word graph based

[3]The tool is freely available from http://www-i6.informatik.rwth-aachen.de/web/Software/index.html

confidence measures for the alignment template system. This is probably due to the fact that the former can take the Levenshtein alignment into account and thus estimate the word confidence more reliably.

The phrase-based confidence measures show a performance which is clearly better than that of the other methods. We obtain a relative improvement of up to 7.8% over the best existing method on these language pairs. The improvement over the baseline is significant even at the 1%-level in all cases.

When analyzing the impact of the different submodels in the phrase-based approach, we found that the language model does not have much impact on the confidence estimation. There are only slight variations in the CER if the model is omitted. The word and phrase penalty on the other hand seem to be important (with one exception in the first setting).

The evaluation of the system-independent confidence measures (i.e. those based on IBM-1 and the new phrase-based method we presented) for four different translation systems is shown in table 5. We see that, for all of them, the phrase-based approach outperforms the IBM-1 based method significantly. The largest gain in terms of CER is achieved for the Systran translations: 23.8% relative over the IBM-1 based measure.

8 Conclusion and outlook

We presented a new approach to word-level confidence estimation for machine translation which makes use of bilingual phrases. By using models from a state-of-the-art phrase-based statistical machine translation system, the word confidences are estimated only on the basis of single best system output. Unlike other confidence measures, this does not rely on information from the machine translation system which generated the translation.

Experimental evaluation on three different language pairs and on output from structurally different translation systems showed that the new confidence measures perform better than existing confidence measures in all cases. The application on output from different MT systems yielded a significant reduction of the error rate over the existing measures. This proves that the method is well-suited for word confidence estimation on statistical as well as non-statistical MT systems.

The task investigated in this work was a text translation task in the domain of technical manuals. We are currently investigating the use of word-level confidence measures on data from the European parliament. It will be interesting to see whether a similar performance can be achieved on this large vocabulary speech translation task.

Abstract

In word sense disambiguation, a system attempts to determine the sense of a word from contextual features. Major barriers to building a high-performing word sense disambiguation system include the difficulty of labeling data for this task and of predicting fine-grained sense distinctions. These issues stem partly from the fact that the task is being treated in isolation from possible uses of automatically disambiguated data. In this paper, we consider the related task of word translation, where we wish to determine the correct translation of a word from context. We can use parallel language corpora as a large supply of partially labeled data for this task. We present algorithms for solving the word translation problem and demonstrate a significant improvement over a baseline system. We then show that the word-translation system can be used to improve performance on a simplified machine-translation task and can effectively and accurately prune the set of candidate translations for a word.

1 Introduction

The problem of distinguishing between multiple possible senses of a word is an important subtask in many NLP applications. However, despite its conceptual simplicity, and its obvious formulation as a standard classification problem, achieving high levels of performance on this task has been a remarkably elusive goal.

In its standard formulation, the disambiguation task is specified via an ontology defining the different senses of ambiguous words. In the Senseval competition, for example, WordNet (Fellbaum, 1998) is used to define this ontology. However, ontologies such as WordNet are not ideally suited to the task of word-sense disambiguation. In many cases, WordNet is overly "specific", defining senses which are very similar and hard to distinguish. For example, there are seven definitions of "respect" *as a noun* (including closely related senses such as "an attitude of admiration or esteem" and "a feeling of friendship and esteem"); there are even more when the verb definitions are included as well. Such closely related senses pose a challenge both for automatic disambiguation and hand labeling. Moreover, the use of a very fine-grained set of senses, most of which are quite rare in practice, makes it very difficult to obtain sufficient amounts of training data.

These issues are clearly reflected in the performance of current word-sense disambiguation systems. When given a large amount of training data for a particular word with reasonably clear sense distinctions, existing systems perform fairly well. However, for the "all-words" task, where all ambiguous words from a test corpus must be disambiguated, it has so far proved difficult to perform significantly better than the baseline heuristic of choosing the most common sense for each word.[1]

In this paper, we address a different formulation of the word-sense disambiguation task. Rather than considering this task on its own, we consider a task of disambiguating words for the purpose of some larger goal. Perhaps the most direct and compelling application of a word-sense disambiguator is to machine translation. If we knew the correct semantic meaning of each word in the source language, we could more accurately determine the appropriate words in the target language. Importantly, for this application, subtle shades of meaning will often be irrelevant in choosing the most appropriate words in the target language, as closely related senses of a single word in one language are often encoded by a single word in another. In the context of this larger goal, we can focus only on sense distinctions that a human would consider when choosing the translation of a word in the source language.

We therefore consider the task of word-sense disambiguation for the purpose of machine translation. Rather than predicting the sense of a particular word a, we predict the possible translations of a into the

[1]See, for example, results of Senseval-3, available at http://www.senseval.org/senseval3

target language. We both train and evaluate the system on this task. This formulation of the word-sense disambiguation task, which we refer to as *word translation*, has multiple advantages. First, a very large amount of "partially-labeled" data is available for this task in the form of bilingual corpora (which exist for a wide range of languages). Second, the "labeling" of these corpora (that is, translation from one language to another), is a task at which humans are quite proficient and which does not generally require the labeler (translator) to make difficult distinctions between fine shades of meaning.

In the remainder of this paper, we first discuss how training data for this task can be acquired automatically from bilingual corpora. We apply a standard learning algorithm for word-sense disambiguation to the word translation task, with several modifications which proved useful for this task.We present the results of our algorithm on word translation, showing that it significantly improves performance on this task. We also consider two simple methods for incorporating word translation into machine translation. First, we can use the output of our model to help a translation model choose better words; since general translation is a very noisy process, we present results on a simplified translation task. Second, we show that the output of our model can be used to prune candidate word sets for translation; this could be used to significantly speed up current translation systems.

2 Machine Translation

In machine translation, we wish to translate a sentence $\mathbf{s}$ in our source language into $\mathbf{t}$ in our target language. The standard approach to statistical machine translation uses the *source-channel model* ,

$$\text{argmax}_{\mathbf{t}} P(\mathbf{t}|\mathbf{s}) = \text{argmax}_{\mathbf{t}} P(\mathbf{t})P(\mathbf{s}|\mathbf{t}),$$

where $P(\mathbf{t})$ is the *language model* for the target language, and $P(\mathbf{s}|\mathbf{t})$ is an *alignment model* from the target language to the source language. Together they define a generative model for the source/target pair $(\mathbf{s}, \mathbf{t})$: first $\mathbf{t}$ is generated according to the language model $P(\mathbf{t})$; then $\mathbf{s}$ is generated from $\mathbf{t}$ according to $P(\mathbf{s}|\mathbf{t})$.[2]

Typically, strong independence assumptions are then made about the distribution $P(\mathbf{s}|\mathbf{t})$. For example, in the IBM Models (Brown et al., 1993), each word t_i independently generates 0, 1, or more words in the source language. Thus, the words generated by t_i are independent of the words generated by t_j for each $j \neq i$. This means that correlations between words in the source sentence are not captured by $P(\mathbf{s}|\mathbf{t})$, and so the context we will use in our word translation models to predict t_i given s_i is not available to a system making these independence assumptions. In this type of system, semantic and syntactic relationships between words are only modeled in the target language; most or all of the semantic and syntactic information contained in the source sentence is ignored. The language model $P(\mathbf{t})$ does introduce some context-dependencies, but the standard n-gram model used in machine translation is too weak to provide a reasonable solution to the strong independence assumptions made by the alignment model.

3 Task Formulation

We define the word translation task as finding, for an individual word a in the source language $\mathcal{S}$, the correct translation, either a word or phrase, in the target language $\mathcal{T}$. Clearly, there are cases where a is part of a multi-word phrase that needs to be translated as a unit. Our approach could be extended by preprocessing the data in $\mathcal{S}$ to find phrases, and then executing the entire algorithm treating phrases as atomic units. We do not explore this extension in this paper, instead focusing on the word-to-phrase translation problem.

As we discussed, a key advantage of the word translation vs. word sense disambiguation is the availability of large amounts of training data. This data is in the form of bilingual corpora, such as the European Parliament proceedings[3]. Such documents provide many training instances, where a word in one language is translated into another. However, the data is only partially labeled in that we are not given a word-to-word alignment between the two languages, and thus we do not know what every word in the source language $\mathcal{S}$ translates to in the target language $\mathcal{T}$. While sentence-to-sentence alignment is a fairly easy task, word-to-word alignment is considerably more difficult. To obtain word-to-word alignments, we used GIZA++[4], an implementation of the IBM Models (specifically, we used the output of IBM Model 4). We did not perform stemming on either language, so as to preserve suffix information for our word translation system and the machine translation language model.

Let $D_{\mathcal{S}}$ be the set of sentences in the source lan-

[2]Note that we refer to $\mathbf{t}$ as the target sentence, even though in the source-channel model, $\mathbf{t}$ is the source sentence which goes through the channel model $P(\mathbf{s}|\mathbf{t})$ to produce the observed sentence $\mathbf{s}$.

guage and $D_{\mathcal{T}}$ the set of target language sentences.

The alignment algorithm can be run in either direction. When run in the $\mathcal{S} \rightarrow \mathcal{T}$ direction, the algorithm aligns each word in $\mathbf{t}$ to at most one word in $\mathbf{s}$. Consider some source sentence $\mathbf{s}$ that contains the word a, and let $U_{a,\mathbf{s}\rightarrow\mathbf{t}} = b_1, \ldots, b_k$ be the set of words that align to a in the aligned sentence $\mathbf{t}$. In general, we can consider $U_a = \{U_{a,\mathbf{s}\rightarrow\mathbf{t}}\}_{\mathbf{s}\in D_a}$ to be the candidate set of translations for a in $\mathcal{T}$, where D_a is the set of source language sentences containing a. However, this definition is quite noisy: a word b_i might have been aligned with a arbitrarily; or, b_i might be a word that itself corresponds to a multi-word translation in $\mathcal{S}$. Thus, we also align the sentences in the $\mathcal{T} \rightarrow \mathcal{S}$ direction, and require that each b_i in the phrase aligns either with a or with nothing. As this process is still fairly noisy, we only consider a word or phrase $b \in U_a$ to be a candidate translation for a if it occurs some minimum number of times in the data.

For example, Table 1 shows a possible candidate set for the English word "rise", with French as the target language. Note that this set can contain not only target words corresponding to different meanings of "rise" (the rows in the table) but also words which correspond to different grammatical forms in the target language corresponding to different parts of speech, verb tenses, etc. So, disambiguation in this case is both over senses and grammatical forms.

The final result of our processing of the corpus is, for each source word a, a set of target words/phrases U_a; and a set of sentences D_a where, in each sentence, a is aligned to some $b \in U_a$. For any sentence $\mathbf{s} \in D_a$, aligned to some target sentence $\mathbf{t}$, let $u_{a,\mathbf{s}} \in U_a$ be the word or phrase in $\mathbf{t}$ aligned with a. We can now treat this set of sentences as a fully-labeled corpus, which can be split into a set used for learning the word-translation model and a test set used for evaluating its performance.

We note, however, that there is a limitation to using accuracy on the test set for evaluating the performance of the algorithm. A source word a in a given context may have two equally good, interchangeable translations into the target language. Our evaluation metric only rewards the algorithm for selecting the target word/phrase that happened to be used in the actual translation. Thus, accuracies measured using this metric may be artificially low. This is a common problem with evaluating machine translation systems.

Another issue is that we take as ground truth the alignments produced by GIZA++. This has two implications: first, our training data may be noisy since some alignments may be incorrect; and second, our test data may not be completely accurate. As mentioned above, we only consider possible translations which occur some minimum number of times; this removes many of the mistakes made by GIZA++. Even if the test set is not 100% reliable, though, improvement over baseline performance is indicative of the potential of a method.

4 Word Translation Algorithms

The word translation task and the word-sense disambiguation task have the same form: each word a is associated with a set of possible labels U_a; given a sentence $\mathbf{s}$ containing word a, we must determine which of the possible labels in U_a to assign to a in the context $\mathbf{s}$. The only difference in the two tasks is the set U_a: for word translation it is the set of possible translations of a, while for word sense disambiguation it is the set of possible senses of a in some ontology. Thus, we may use any word sense disambiguation algorithm as a word translation algorithm by appropriately defining the senses (assuming that the WSD algorithm does not assume that a particular ontology is used to choose the senses).

Our main focus in this paper is to show that machine learning techniques are effective for the word translation task, and to demonstrate that we can use the output of our word translation system to improve performance on two machine-translation related tasks. We will therefore restrict our attention to a relatively simple model, logistic regression (Minka, 2000). There are several motivations for using this discriminative, probabilistic model. First, it is known both theoretically and empirically (e.g., (Ng and Jordan, 2002)) that discriminative models achieve higher accuracies than generative models if enough data is available. For the traditional word-sense disambiguation task, data must be hand-labeled, and is therefore often too scarce to allow for discriminative training. In our setting, however, training data is acquired automatically from bilingual corpora, which are widely available and quite large. Thus, discriminative training is a viable option for the word translation problem. A second consideration is that, to effectively incorporate our system into a statistical machine translation system, we would like to produce not just a single prediction, but a list of confidence-rated possibilities. The optimization procedure of logistic regression attempts to produce a distribution over possible translations which accurately represents the confidence of the model for each translation. By contrast, a classical Naive Bayes model often assigns very low probabilities to all but the most likely translation. Other word-sense disambiguation models may not produce confidence measures at all.

Features. Our word translation model for a word a in a sentence $\mathbf{s} = w_1, \ldots, w_k$ is based on features constructed from the word and its context within the sentence. Our basic logistic regression model uses the following features, which correspond to the feature space for a standard Naive Bayes model:

- the part of speech of a (generated using the Brill tagger)[5];
- a binary "occurs" variable for each word which is 1 if that word is in a fixed context centered at a (c_r words to the right and c_l words to the left), and 0 otherwise.

We also consider an extension to this model, where instead of the fixed context features above, we use:

- for each direction $d \in \{l, r\}$ and each possible context size $c_d \in \{1, ..., C_d\}$, an "occurs" variable for each word.

This is a true generalization of the previous context features, since it contains features for all possible context sizes, not just one particular fixed size. This feature set is equivalent to having one feature for each word in each context position, except that it will have a different prior over parameters under standard L_2 regularization. This feature set allows our model to distinguish between very local (often syntactic) features and somewhat longer range features whose exact position is not as important.

Let $\phi^{a,\mathbf{s}}$ be the set of features for word a to be translated, with sentence context $\mathbf{s}$ (the description of the model does not depend on the particular feature set selected).

Model. The logistic regression model encodes the conditional distribution $(P(u_{a,\mathbf{s}} = b \mid a, \mathbf{s}) : b \in U_a)$. Such a model is parameterized by a set of vectors $\boldsymbol{\theta}^a_b$, one for each word a and each possible target $b \in U_a$, where each vector contains a weight $\theta^a_{b,j}$ for each feature $\phi^{a,\mathbf{s}}_j$. We can now define our conditional distribution:

$$P_{\boldsymbol{\theta}^a}(b \mid a, \mathbf{s}) = \frac{1}{Z_{a,\mathbf{s}}} e^{\boldsymbol{\theta}^a_b \phi^{a,\mathbf{s}}}$$

with partition function $Z_{a,\mathbf{s}} = \sum_{b' \in U_a} \exp(\boldsymbol{\theta}^a_{b'} \phi^{a,\mathbf{s}})$.

Training. We train the logistic regression model to maximize the conditional likelihood of the observed labels given the features in our training set. Thus, our goal in training the model for a is to maximize

$$\prod_{\mathbf{s} \in D_a} P_{\boldsymbol{\theta}^a}(u_{a,\mathbf{s}} \mid a, \mathbf{s}).$$

We maximize this objective by maximizing its logarithm (the log-conditional-likelihood) using conjugate gradient ascent (Shewchuk, 1994).

One important consideration when training using maximum likelihood is regularization of the parameters. In the case of logistic regression, the most common type of regularization is L_2 regularization; we then maximize

$$\prod_{b,j} \exp\left(-\frac{(\theta^a_{b,j})^2}{2\sigma^2}\right) \prod_{\mathbf{s} \in D_a} P_{\boldsymbol{\theta}^a}(u_{a,\mathbf{s}} \mid a, \mathbf{s}).$$

This penalizes the likelihood for the distance of each parameter $\theta^a_{b,j}$ from 0; it corresponds to a Gaussian prior on each parameter with variance σ^2.

5 Word Translation Results

For our word translation experiments we used the European Parliament proceedings corpus, which contains approximately 27 million words in each of English and French (as well as a number of other languages). We tested on a set of 1859 ambiguous words — specifically, all ambiguous words contained in the first document of the corpus. For each of these words, we found all instances of the word in the corpus and split these instances into training and test sets.

We tested four different models. The first, Baseline, always chooses the most common translation for the word; the second, Baseline with Part of Speech, uses tagger-generated parts of speech to choose the most common translation for the observed word/part-of-speech pair. The third model, Simple Logistic, is the logistic regression model with the simpler feature set, a context window of a fixed size. We selected the window size by evaluating accuracy for a variety of window sizes on 20 of the 1859 ambiguous words using a random train-test split. The window size which performed best on average extended one word to the left and

[5] Available at http://www.cs.jhu.edu/ brill/

Model	Macro	Micro
Baseline	0.511	0.526
Baseline with Part of Speech	0.519	0.532
Simple Logistic	0.581	0.605
Logistic	0.596	0.620

Table 2: Average Word Translation Accuracy

two words to the right (larger windows generally resulted in overfitting). The fourth model, Logistic, is the logistic regression model with overlapping context windows; the maximum window size for this model was four words to the left and four words to the right. We selected the standard deviation σ^2 for the logistic models by trying different values on the same small subset of the ambiguous words. For the Simple Logistic model, the best value was $\sigma^2 = 1$; for the Logistic model, it was 0.35.

Table 2 shows results of these four models. The first column is macro-averaged over the 1859 words, that is, the accuracy for each word counts equally towards the average. The second column shows the micro-averaged accuracy, where each test example counts equally. We will focus on the micro-averaged results, since they correspond to overall accuracy.

The less accurate of our two models, Simple Logistic, improves around 8% over the simple baseline and 7% over the part-of-speech baseline on average. Our more complex logistic model, which is able to handle larger context sizes without significantly overfitting, improves accuracy by another 1.5%.

There was a great deal of variance from word to word in the performance of our models relative to baseline. For a few words, we achieved very large increases in accuracy. For instance, the noun "agenda" showed a 31.2% increase over both baselines. Similarly, the word "rise" (either a noun or a verb) had part-of-speech baseline accuracy of 27.9%. Our model increased the accuracy to 57.0%.

It is worth repeating that accuracies on this task are artificially low since in many cases a single word can be translated to many different words with the same meaning. At the same time, accuracies are artificially inflated by the fact that we only consider examples where we can find an aligned word in the French corpus, so translations where a word is dropped or translated as part of a compound word are not counted.

One disadvantage of the EuroParl corpus is that it is not "balanced" in terms of semantic content. It is not clear how this affects our results.

6 Blank-Filling Task

One of the most difficult parts of machine translation is decoding — finding the most likely translation according to some probability model. The difficulty arises from the enormous number of possible translated sentences. Existing decoders generally use either highly pruned search or greedy heuristic search. In either case, the quality of a translation can vary greatly from sentence to sentence. This variation is much higher than the improvement in "semantic" accuracy our model is attempting to achieve. Moreover, currently available decoders do not provide a natural way to incorporate the results of a word translation system. For example, Carpuat and Wu (2005) obtain negative results for two methods of incorporating the output of a word-sense disambiguation system into a machine translation system.

Thus, we instead used our word translation model for a simplified translation problem. We prepared a dataset as follows: for each occurrence of an ambiguous words in an English sentence in the first document of the Europarl corpus, we tried to determine what the correct translation for that word was in the corresponding French sentence. If we found one and exactly one possible translation for that word in the French sentence, we replaced that word with a "blank", and linked the English word to that blank. The final result was a set of 655 sentences with a total of 3018 blanks.

For example, the following English-French sentence pair contains the two ambiguous words *address* and *issue* and one possible translation for each, *examiner* and *question*:

- Therefore, the commission should *address* the *issue* once and for all.
- Par conséquent, la commission devra enfin *examiner* cette *question* particulière.

We replace the translations of the ambiguous words with blanks; we would like a decoder to replace the blanks with the correct translations:

- Par conséquent, la commission devra enfin [*address*] cette [*issue*] particulière.

An advantage of this task is that, for a given distribution $P(\mathbf{t}|\mathbf{s})$, we can easily write a decoder which exhaustively searches the entire solution space for the best answer (provided that there are not too many blanks and that $P(\mathbf{t}|\mathbf{s})$ is sufficiently "local" with respect to $\mathbf{t}$). Thus, we can be sure that it is the probability model, and not the decoder, which is determining the quality of the output. Also, we have removed most or all syntactic variability from the task,

Model	λ_{lm}	λ_{ga}	λ_{da}	λ_{wt}	Acc
Language Model only	1	0	0	0	0.749
Source-Channel	1	1	0	0	0.821
LM + GA + DA	1	0.6^*	0.6^*	0	0.833
LM + GA + DA + WT	1	0.6^*	0^*	1.2^*	0.846

Table 3: Blank-filling results. Weights marked with * have been optimized.

allowing us to better gauge whether we are choosing *semantically* correct translations.

Let (a_i, b_i) be the pairs of words corresponding to the blanks in sentence $\mathbf{t}$. Then the alignment model decomposes as a product of terms over these pairs, e.g. $P(\mathbf{s}|\mathbf{t}) \propto \prod_{(a_i,b_i)} P(a_i|b_i)$. Analogously, we extend the word translation model as $P_{wt}(\mathbf{t}|\mathbf{s}) \propto \prod_{(a_i,b_i)} P_{wt}(b_i|\mathbf{s}, a_i)$.

The source-channel model can be used directly to solve the blank filling task; the language model makes use of the French words surrounding each blank, while the alignment model guesses the appropriate translation based on the aligned English word. As we have mentioned, this model does not take full advantage of the context in the English sentence. Thus, we hope that incorporating the word translation model into the decoder will improve performance on this task.

Conversely, simply using the word translation model alone for the blank-filling task would not take advantage of the available French context. There are four probability distributions we might consider using: the language model $P_{lm}(\mathbf{t})$; the "generative" alignment model $P_{ga}(\mathbf{s}|\mathbf{t})$, which we calculate using the training samples from the previous section; the analogous "discriminative" alignment model $P_{da}(\mathbf{t}|\mathbf{s})$, which corresponds to the Baseline system we compared to on the word translation task; and our overlapping context logistic model, $P_{wt}(\mathbf{t}|\mathbf{s})$, which also goes in the "discriminative" direction, but uses the context features in the source language for determining the distribution over each word's possible translations.

We combine these models by simply taking a log-linear combination:

$$\log P(\mathbf{t}|\mathbf{s}) \propto \lambda_{lm} \log P_{lm}(\mathbf{t}) + \lambda_{ga} \log P_{ga}(\mathbf{s}|\mathbf{t}) + \lambda_{da} \log P_{da}(\mathbf{t}|\mathbf{s}) + \lambda_{wt} \log P_{wt}(\mathbf{t}|\mathbf{s}).$$

The case of $\lambda_{lm} = \lambda_{ga} = 1$ and $\lambda_{da} = \lambda_{wt} = 0$ reduces to the source-channel model; other settings incorporate discriminative models to varying degrees.

We evaluated this combined translation model on the blank-filling task for various settings of the mixture coefficients λ. For our language model we used the CMU-Cambridge toolkit.[6] The word translation model for each ambiguous word was trained on all documents except the first.

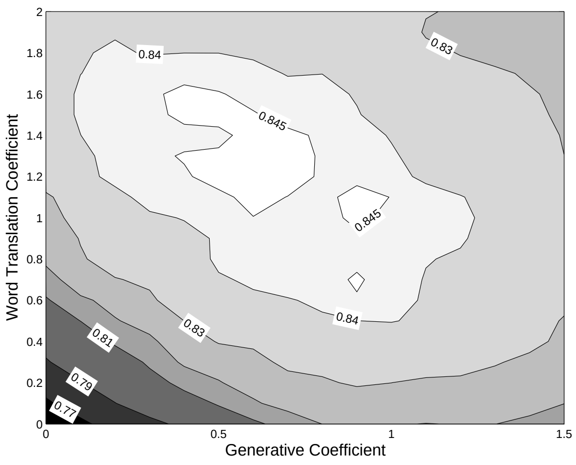

Figure 1: Accuracy on blank-filling task with $\lambda_{lm} = 1$ and $\lambda_{disc} = 0$ as a function of λ_{gen} and λ_{wt}.

Table 3 shows results for several sets of weights. A * denotes entries which we optimized (see below); other entries were fixed. For example, the third model was obtained by fixing the coefficient of the language model to 1 and the word-translation to 0, and optimizing the weights for the generative and discriminative alignment models.

The language model alone is able to achieve reasonable results; adding the alignment models improves performance further. By adding the word-translation model, we are able to improve performance by approximately 2.5% over the source-channel model, a relative error reduction of 14%, and 1.3% over the optimized model using the language model and generative and discriminative alignment models, a relative error reduction of 7.8%.

We chose optimal coefficients for the combined probability models by exhaustively trying all possible settings of the weights, at a resolution of 0.1, evaluating accuracy for each one on the test set. Figure 1 shows the performance on the blank-filling task as a function of the weights of the generative alignment model and the word-translation model (the optimum value of the discriminative alignment model $P(\mathbf{t}|\mathbf{s})$ is always 0 when we include the word-translation model). As we can see, the performance of this model is robust with respect to the exact value of the coefficients. The "obvious" setting of 1.0 for the generative model and 1.0 for the word translation model performs nearly as well

[6]Available at http://mi.eng.cam.ac.uk/ prc14/toolkit.html.

as the optimized setting. In the optimal region, the word-translation model receives twice as much weight as the generative alignment model, indicating that word-translation model is more informative than the generative alignment model. Incorporating the discriminative alignment model into the source-channel model also improves performance, but not nearly as much as using the word-translation model.

An alternate way to optimize weights over translation features is described in Och and Ney (2002). They consider a number of translation features, including the language model and generative and discriminative alignment models.

7 Search Space Pruning

As we have mentioned, one of the main difficulties in translation is that there are an enormous number of possible translations to consider. Decoding algorithms must therefore use some kind of search-space pruning in order to be efficient. A key part of pruning the search space is deciding on the set of words to consider in possible translations (Germann et al., 2001). One standard method is to consider only target words which have high probability according to the discriminative alignment model. But we have already shown that the word translation model achieves much better performance on word translation than this baseline model; thus, we would expect the word translation model to improve accuracy when used to pick sets of candidate translations.

Given a probability distribution over possible translations of a word, $P(b|a, \mathbf{s})$, there are several ways to choose a reduced set of possible translations. Two commonly used methods are to only consider the top n scoring words from this distribution (*best-n*); and to only consider words b such that $P(b|a, \mathbf{s})$ is above some fixed threshold (*cut-off*).

We use the same data set as for the blank-filling task. We evaluate the accuracy of a pruning strategy by evaluating whether the correct translation is in the candidate set selected by the pruning strategy. To compare results for different pruning strategies, we plot performance as a function of average size of the candidate translation set. Figure 2 shows the accuracy vs. average candidate set size for the word-translation model, discriminative alignment model, and generative alignment model.

The generative alignment model has the worst performance of the three. This is not surprising as it does not take into account the prior probability of the target word $P(b)$. More interestingly, we see that the word-translation model outperforms the discriminative translation model by a significant amount. For

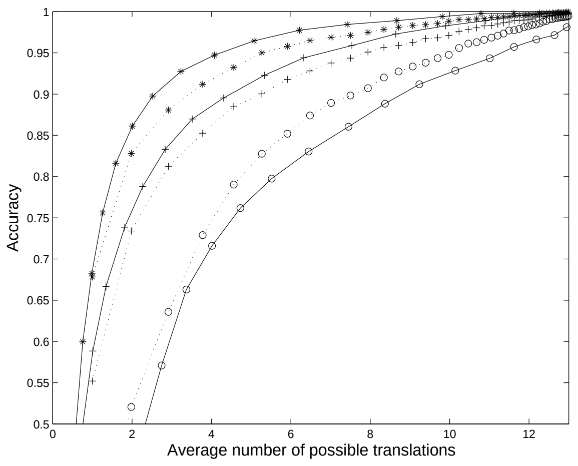

Figure 2: Accuracy of *best-n* strategy (dotted lines) and *cut-off* strategy (solid lines). o = generative alignment, + = discriminative alignment, * = word translation.

instance, to achieve 95% recall (that is, for 95% of the ambiguous words, we retain the correct translation), we only need candidate sets of average size 4.2 for the *cut-off* strategy using the word-translation model, whereas for the same strategy on the discriminative alignment model we require an average set size of 6.7 words.

As the size of the solution space grows exponentially with the size of the candidate sets, the word-translation model could potentially greatly reduce the search space while maintaining good accuracy.

It would be interesting to use similar techniques to learn null fertility (i.e., when a word a has no translation in the target sentence $\mathbf{t}$).

8 Related Work

Berger et al. (1996) apply maximum entropy methods (equivalent to logistic regression) to, among other tasks, the word-translation task. However, no quantitative results are presented. In this paper we demonstrate that the method can improve performance on a large data set and show how it might be used to improve machine translation.

Diab and Resnik (2002) suggest using large bilingual corpora to improve performance on word sense disambiguation. The main idea is that knowing a French word may help determine the meaning of the corresponding English word. They apply this intuition to the Senseval word disambiguation task by running off-the-shelf translators to produce translations which they then use for disambiguation.

Ng et al. (2003) address word sense disambiguation by manually annotating WordNet senses with their translation in the target language (Chinese), and then automatically extracting labeled examples for word sense disambiguation by applying the IBM

Models to a bilingual corpus. They achieve comparable results to training on hand-labeled examples.

Koehn and Knight (2003) focus on the task of noun-phrase translation. They improve performance on the noun-phrase translation task, and show that they can use this to improve full translations. A key difference is that, in predicting noun-phrase translations, they do not consider the context of nouns. They present results which indicate that humans can accurately translate noun phrases without looking at the surrounding context. However, as we have demonstrated in this paper, context can be very useful for a (sub-human-level) machine translator.

A similar argument applies to phrase-based translation methods (e.g., Koehn et al. (2003)). While phrase-based systems do take into account context within phrases, they are not able to use context across phrase boundaries. This is especially important when ambiguous words do not occur as part of a phrase — verbs in particular often appear alone.

9 Conclusions

In this paper, we focus on the word-translation problem. By viewing word-sense disambiguation in the context of a larger task, we were able to obtain large amounts of training data and directly evaluate the usefulness of our system for a real-world task. Our results improve over a baseline which is difficult to outperform in the word sense disambiguation task.

The word translation model could be improved in a variety of ways, drawing upon the large body of work on word-sense disambiguation. In particular, there are many types of context features which could be used to improve word translation performance, but which are not available to standard machine-translation systems. Also, the model could be extended to handle phrases.

To evaluate word translation in the context of a machine translation task, we introduce the novel blank-filling task, which decouples the impact of word translation from a variety of other factors, such as syntactic correctness. For this task, increased word-translation accuracy leads to improved machine translation. We also show that the word translation model is effective at choosing sets of candidate translations, suggesting that a word translation component would be immediately useful to current machine translations systems.

There are several ways in which the results of word translation could be integrated into a full translation system. Most naturally, the word translation model can be used directly to modify the score of different translations. Alternatively, a decoder can produce several candidate translations, which can be reranked using the word translation model. Unfortunately, we were unable to try these approaches, due to the lack of an appropriate publicly available decoder. Carpuat and Wu (2005) recently observed that simpler integration approaches, such as forcing the machine translation system to use the word translation model's first choice, do not improve translation results. Together, these results suggest that one should incorporate the results of word translation in a "soft" way, allowing the word translation, alignment, and language models to work together to produce coherent translations. Given an appropriate decoder, trying such a unified approach is straightforward, and would provide insight about the value of word translation.

Abstract

Hierarchical organization is a well known property of language, and yet the notion of hierarchical structure has been largely absent from the best performing machine translation systems in recent community-wide evaluations. In this paper, we discuss a new hierarchical phrase-based statistical machine translation system (Chiang, 2005), presenting recent extensions to the original proposal, new evaluation results in a community-wide evaluation, and a novel technique for fine-grained comparative analysis of MT systems.

1 Introduction

Hierarchical organization is a well known property of language, and yet the notion of hierarchical structure has, for the last several years, been absent from the best performing machine translation systems in community-wide evaluations. Statistical phrase-based models (e.g. (Och and Ney, 2004; Koehn et al., 2003; Marcu and Wong, 2002)) characterize a source sentence f as a flat partition of non-overlapping subsequences, or "phrases", $\bar{f}_1 \cdots \bar{f}_J$, and the process of translation involves selecting target phrases $\bar{e}_i$ corresponding to the $\bar{f}_j$ and modifying their sequential order. The need for some way to model aspects of syntactic behavior, such as the tendency of constituents to move together as a unit, is widely recognized—the role of syntactic units is well attested in recent systematic studies of translation (Fox, 2002; Hwa et al., 2002; Koehn and Knight, 2003), and their absence in phrase-based models is quite evident when looking at MT system output. Nonetheless, attempts to incorporate richer linguistic features have generally met with little success (Och et al., 2004a).

Chiang (2005) introduces Hiero, a hierarchical phrase-based model for statistical machine translation. Hiero extends the standard, non-hierarchical notion of "phrases" to include nonterminal symbols, which permits it to capture both word-level and phrase-level reorderings within the same framework. The model has the formal structure of a synchronous CFG, but it does not make any commitment to a linguistically relevant analysis, and it does not require syntactically annotated training data. Chiang (2005) reported significant performance improvements in Chinese-English translation as compared with Pharaoh, a state-of-the-art phrase-based system (Koehn, 2004).

In Section 2, we review the essential elements of Hiero. In Section 3 we describe extensions to this system, including new features involving named entities and numbers and support for a fourfold scale-up in training set size. Section 4 presents new evaluation results for Chinese-English as well as Arabic-English translation, obtained in the context of the 2005 NIST MT Eval exercise. In Section 5, we introduce a novel technique for fine-grained comparative analysis of MT systems, which we employ in analyzing differences between Hiero's and Pharaoh's translations.

2 Hiero

Hiero is a stochastic synchronous CFG, whose productions are extracted automatically from unannotated parallel texts, and whose rule probabilities form a log-linear model learned by minimum-error-rate training; together with a modified CKY beam-search decoder (similar to that of Wu (1996)). We describe these components in brief below.

$$
\begin{aligned}
&\mathrm{S} \rightarrow \langle \mathrm{S}_{\boxed{1}}\mathrm{X}_{\boxed{2}}, \mathrm{S}_{\boxed{1}}\mathrm{X}_{\boxed{2}} \rangle \\
&\mathrm{S} \rightarrow \langle \mathrm{X}_{\boxed{1}}, \mathrm{X}_{\boxed{1}} \rangle \\
&\mathrm{X} \rightarrow \langle \text{yu } \mathrm{X}_{\boxed{1}} \text{ you } \mathrm{X}_{\boxed{2}}, \text{have } \mathrm{X}_{\boxed{2}} \text{ with } \mathrm{X}_{\boxed{1}} \rangle \\
&\mathrm{X} \rightarrow \langle \mathrm{X}_{\boxed{1}} \text{ de } \mathrm{X}_{\boxed{2}}, \text{the } \mathrm{X}_{\boxed{2}} \text{ that } \mathrm{X}_{\boxed{1}} \rangle \\
&\mathrm{X} \rightarrow \langle \mathrm{X}_{\boxed{1}} \text{ zhiyi}, \text{one of } \mathrm{X}_{\boxed{1}} \rangle \\
&\mathrm{X} \rightarrow \langle \text{Aozhou}, \text{Australia} \rangle \\
&\mathrm{X} \rightarrow \langle \text{shi}, \text{is} \rangle \\
&\mathrm{X} \rightarrow \langle \text{shaoshu guojia}, \text{few countries} \rangle \\
&\mathrm{X} \rightarrow \langle \text{bangjiao}, \text{diplomatic relations} \rangle \\
&\mathrm{X} \rightarrow \langle \text{Bei Han}, \text{North Korea} \rangle
\end{aligned}
$$

Figure 1: Example synchronous CFG

2.1 Grammar

A *synchronous CFG* or *syntax-directed transduction grammar* (Lewis and Stearns, 1968) consists of pairs of CFG rules with aligned nonterminal symbols. We denote this alignment by coindexation with boxed numbers (Figure 1). A derivation starts with a pair of aligned start symbols, and proceeds by rewriting pairs of aligned nonterminal symbols using the paired rules (Figure 2).

Training begins with phrase pairs, obtained as by Och, Koehn, and others: GIZA++ (Och and Ney, 2000) is used to obtain one-to-many word alignments in both directions, which are combined into a single set of refined alignments using the "final-and" method of Koehn et al. (2003); then those pairs of substrings that are exclusively aligned to each other are extracted as phrase pairs.

Then, synchronous CFG rules are constructed out of the initial phrase pairs by subtraction: every phrase pair $\langle \bar{f}, \bar{e} \rangle$ becomes a rule $\mathrm{X} \rightarrow \langle \bar{f}, \bar{e} \rangle$, and a phrase pair $\langle \bar{f}, \bar{e} \rangle$ can be subtracted from a rule $\mathrm{X} \rightarrow \langle \gamma_1 \bar{f} \gamma_2, \alpha_1 \bar{e} \alpha_2 \rangle$ to form a new rule $\mathrm{X} \rightarrow \langle \gamma_1 \mathrm{X}_{\boxed{i}} \gamma_2, \alpha_1 \mathrm{X}_{\boxed{i}} \alpha_2 \rangle$, where i is an index not already used. Various filters are also applied to reduce the number of extracted rules. Since one of these filters restricts the number of nonterminal symbols to two, our extracted grammar is equivalent to an inversion transduction grammar (Wu, 1997).

2.2 Model

The model is a log-linear model (Och and Ney, 2002) over synchronous CFG derivations. The weight of a derivation is $P_{LM}(e)^{\lambda_{LM}}$, the weighted language model probability, multiplied by the product of the weights of the rules used in the derivation. The weight of each rule is, in turn:

$$(1) \qquad w(X \rightarrow \langle \gamma, \alpha \rangle) = \prod_i \phi_i(X \rightarrow \langle \gamma, \alpha \rangle)^{\lambda_i}$$

where the ϕ_i are features defined on rules. The basic model uses the following features, analogous to Pharaoh's default feature set:

- $P(\gamma \mid \alpha)$ and $P(\alpha \mid \gamma)$
- the lexical weights $P_w(\gamma \mid \alpha)$ and $P_w(\alpha \mid \gamma)$ (Koehn et al., 2003);[1]
- a phrase penalty $\exp(1)$;
- a word penalty $\exp(l)$, where l is the number of terminals in α.

The exceptions to the above are the two "glue" rules, which are the rules with left-hand side S in Figure 1. The second has weight one, and the first has weight $w(\mathrm{S} \rightarrow \langle \mathrm{S}_{\boxed{1}}\mathrm{X}_{\boxed{2}}, \mathrm{S}_{\boxed{1}}\mathrm{X}_{\boxed{2}} \rangle) = \exp(-\lambda_g)$, the idea being that parameter λ_g controls the model's preference for hierarchical phrases over serial combination of phrases.

Phrase translation probabilities are estimated by relative-frequency estimation. Since the extraction process does not generate a unique derivation for each training sentence pair, a distribution over possible derivations is hypothesized, which gives uniform weight to all initial phrases extracted from a sentence pair and uniform weight to all rules formed out of an initial phrase. This distribution is then used to estimate the phrase translation probabilities.

The lexical-weighting features are estimated using a method similar to that of Koehn et al. (2003). The language model is a trigram model with modified Kneser-Ney smoothing (Chen and Goodman, 1998), trained using the SRI-LM toolkit (Stolcke, 2002).

[1]This feature uses word alignment information, which is discarded in the final grammar. If a rule occurs in training with more than one possible word alignment, Koehn et al. take the maximum lexical weight; Hiero uses a weighted average.

$$\begin{aligned}
\langle \mathrm{S}_{\boxed{1}}, \mathrm{S}_{\boxed{1}} \rangle &\Rightarrow \langle \mathrm{S}_{\boxed{2}} \mathrm{X}_{\boxed{3}}, \mathrm{S}_{\boxed{2}} \mathrm{X}_{\boxed{3}} \rangle \\
&\Rightarrow \langle \mathrm{S}_{\boxed{4}} \mathrm{X}_{\boxed{5}} \mathrm{X}_{\boxed{3}}, \mathrm{S}_{\boxed{4}} \mathrm{X}_{\boxed{5}} \mathrm{X}_{\boxed{3}} \rangle \\
&\Rightarrow \langle \mathrm{X}_{\boxed{6}} \mathrm{X}_{\boxed{5}} \mathrm{X}_{\boxed{3}}, \mathrm{X}_{\boxed{6}} \mathrm{X}_{\boxed{5}} \mathrm{X}_{\boxed{3}} \rangle \\
&\Rightarrow \langle \text{Aozhou } \mathrm{X}_{\boxed{5}} \mathrm{X}_{\boxed{3}}, \text{Australia } \mathrm{X}_{\boxed{5}} \mathrm{X}_{\boxed{3}} \rangle \\
&\Rightarrow \langle \text{Aozhou shi } \mathrm{X}_{\boxed{3}}, \text{Australia is } \mathrm{X}_{\boxed{3}} \rangle \\
&\Rightarrow \langle \text{Aozhou shi } \mathrm{X}_{\boxed{7}} \text{ zhiyi, Australia is one of } \mathrm{X}_{\boxed{7}} \rangle \\
&\Rightarrow \langle \text{Aozhou shi } \mathrm{X}_{\boxed{8}} \text{ de } \mathrm{X}_{\boxed{9}} \text{ zhiyi, Australia is one of the } \mathrm{X}_{\boxed{9}} \text{ that } \mathrm{X}_{\boxed{8}} \rangle \\
&\Rightarrow \langle \text{Aozhou shi yu } \mathrm{X}_{\boxed{1}} \text{ you } \mathrm{X}_{\boxed{2}} \text{ de } \mathrm{X}_{\boxed{9}} \text{ zhiyi, Australia is one of the } \mathrm{X}_{\boxed{9}} \text{ that have } \mathrm{X}_{\boxed{2}} \text{ with } \mathrm{X}_{\boxed{1}} \rangle
\end{aligned}$$

Figure 2: Example partial derivation of a synchronous CFG.

The feature weights are learned by maximizing the BLEU score (Papineni et al., 2002) on held-out data, using minimum-error-rate training (Och, 2003) as implemented by Koehn. The implementation was slightly modified to ensure that the BLEU scoring matches NIST's definition and that hypotheses in the *n*-best lists are merged when they have the same translation and the same feature vector.

3 Extensions

In this section we describe our extensions to the base Hiero system that improve its performance significantly. First, we describe the addition of two new features to the Chinese model, in a manner similar to that of Och et al. (2004b); then we describe how we scaled the system up to a much larger training set.

3.1 New features

The LDC Chinese-English named entity lists (900k entries) are a potentially valuable resource, but previous experiments have suggested that simply adding them to the training data does not help (Vogel et al., 2003). Instead, we placed them in a supplementary phrase-translation table, giving greater weight to phrases that occurred less frequently in the primary training data. For each entry $\langle f, \{e_1, \ldots, e_n\}\rangle$, we counted the number of times $c(f)$ that f appeared in the primary training data, and assigned the entry the weight $\frac{1}{c(f)+1}$, which was then distributed evenly among the supplementary phrase pairs $\{\langle f, e_i\rangle\}$. We then created a new model feature for named entities. When one of these supplementary phrase pairs was used in translation, its feature value for the named-entity feature was the weight defined above, and its value in the other phrase-translation and lexical-weighting features was zero. Since these scores belonged to a separate feature from the primary translation probabilities, they could be reweighted independently during minimum-error-rate training.

Similarly, to process Chinese numbers and dates, we wrote a rule-based Chinese number/date translator, and created a new model feature for it. Again, the weight given to this module was optimized during minimum-error-rate training. In some cases we wrote the rules to provide multiple uniformly-weighted English translations for a Chinese phrase (for example, 八日 (*bari*) could become "the 8th" or "on the 8th"), allowing the language model to decide between the options.

3.2 Scaling up training

Chiang (2005) reports on experiments in Chinese-English translation using a model trained on 7.2M+9.2M words of parallel data.[2] For the NIST MT Eval 2005 large training condition, considerably more data than this is allowable. We chose to use only newswire data, plus data from Sinorama, a Taiwanese news magazine.[3] This amounts to almost 30M+30M words. Scaling to this set required reducing the initial limit on phrase lengths, previously fixed at 10, to avoid explosive growth of

[2]Here and below, the notation "X + Y words" denotes X words of foreign text and Y words of English text.

[3]From Sinorama, only data from 1991 and later were used, as articles prior to that were translated quite loosely.

the extracted grammar. However, since longer initial phrases can be beneficial for translation accuracy, we adopted a variable length limit: 10 for the FBIS corpus and other mainland newswire sources, and 7 for the HK News corpus and Sinorama. (During decoding, limits of up to 15 were sometimes used; in principle these limits should all be the same, but in practice it is preferable to tune them separately.)

For Arabic-English translation, we used the basic Hiero model, without special features for named entities or numbers/dates. We again used only the newswire portions of the allowable training data; we also excluded the Ummah data, as the translations were found to be quite loose. Since this amounted to only about 1.5M+1.5M words, we used a higher initial phrase limit of 15 during both training and decoding.

4 Evaluation

Figure 1 shows the performance of several systems on NIST MT Eval 2003 Chinese test data: Pharaoh (2004 version), trained only on the FBIS data; Hiero, with various combinations of the new features and the larger training data.[4] This table also shows Hiero's performance on the NIST 2005 MT evaluation task.[5] The metric here is case-sensitive BLEU.[6]

Figure 2 shows the performance of two systems on Arabic in the NIST 2005 MT Evaluation task: DC, a phrase-based decoder for a model trained by Pharaoh, and Hiero.

5 Analysis

Over the last few years, several automatic metrics for machine translation evaluation have been introduced, largely to reduce the human cost of iterative system evaluation during the development cycle (Lin and Och, 2004; Melamed et al., 2003; Papineni et al., 2002). All are predicated on the concept of *n*-gram matching between the sentence hypothesized by the translation system and one or more *reference translations*—that is, human translations for the test sentence. Although the motivations and formulae underlying these metrics are all different, ultimately they all produce a single number representing the "goodness" of the MT system output over a set of reference documents. This facility is valuable in determining whether a given system modification has a positive impact on overall translation performance. However, the metrics are all holistic. They provide no insight into the specific competencies or weaknesses of one system relative to another.

System	Features	Train	MT03	MT05
Pharaoh	standard	FBIS	0.268	
Hiero	standard	FBIS	0.288	
Hiero	standard	full	0.329	
Hiero	+nums, names	full	0.339	0.300

Table 1: Chinese results. (BLEU-4; MT03 case-insensitive, MT05 case-sensitive)

System	Train	MT05
DC	full	0.399
Hiero	full	0.450

Table 2: Arabic results. (BLEU-4; MT03 case-insensitive, MT05 scores case-sensitive.

Ideally, we would like to use automatic methods to provide immediate diagnostic information about the translation output—*what* the system does well, and what it does poorly. At the most general level, we want to know how our system performs on the two most basic problems in translation—word translation and reordering. Unigram precision and recall statistics tell us something about the performance of an MT system's internal translation dictionaries, but nothing about reordering. It is thought that higher order *n*-grams correlate with the reordering accuracy of MT systems, but this is again a holistic metric.

What we would really like to know is how well the system is able to capture systematic reordering patterns in the input, which ones it is successful with, and which ones it has difficulty with. Word *n*-grams are little help here: they are too many, too sparse, and it is difficult to discern general patterns from them.

[4]The third line, corresponding to the model without new features trained on the larger data, may be slightly depressed because the feature weights from the fourth line were used instead of doing minimum-error-rate training specially for this model.

[5]Full results are available at `http://www.nist.gov/speech/tests/summaries/2005/mt05.htm`. For this test, a phrase length limit of 15 was used during decoding.

[6]For this task, the translation output was uppercased using the SRI-LM toolkit: essentially, it was decoded again using an HMM whose states and transitions are a trigram language model of cased English, and whose emission probabilities are reversed, i.e., probability of cased word given lowercased word.

5.1 A New Analysis Method

In developing a new analysis method, we are motivated in part by recent studies suggesting that word reorderings follow general patterns with respect to syntax, although there remains a high degree of flexibility (Fox, 2002; Hwa et al., 2002). This suggests that in a comparative analysis of two MT systems, it may be useful to look for syntactic patterns that one system captures well in the target language and the other does not, using a syntax based metric.

We propose to summarize reordering patterns using part-of-speech sequences. Unfortunately, recent work has shown that applying statistical parsers to ungrammatical MT output is unreliable at best, with the parser often assigning unreasonable probabilities and incongruent structure (Yamada and Knight, 2002; Och et al., 2004a). Anticipating that this would be equally problematic for part-of-speech tagging, we make the conservative choice to apply annotation only to the reference corpus. Word *n*-gram correspondences with a reference translation are used to infer the part-of-speech tags for words in the system output.

First, we tagged the reference corpus with parts of speech. We used MXPOST (Ratnaparkhi, 1996), and in order to discover more general patterns, we map the tag set down after tagging, e.g. NN, NNP, NNPS and NNS all map to NN. Second, we computed the frequency $\mathit{freq}(t_i \ldots t_j)$ of every possible tag sequence $t_i \ldots t_j$ in the reference corpus. Third, we computed the correspondence between each hypothesis sentence and *each* of its corresponding reference sentences using an approximation to maximum matching (Melamed et al., 2003). This algorithm provides a list of *runs* or contiguous sequences of words $e_i \ldots e_j$ in the reference that are also present in the hypothesis. (Note that runs are order-sensitive.) Fourth, for each recalled *n*-gram $e_i \ldots e_j$, we looked up the associated tag sequence $t_i \ldots t_j$ and incremented a counter $\mathit{recalled}(t_i \ldots t_j)$. Finally, we computed the recall of tag patterns, $R(t_i \ldots t_j) = \mathit{recalled}(t_i \ldots t_j)/\mathit{freq}(t_i \ldots t_j)$, for all patterns in the corpus.

By examining examples of these tag sequences in the reference corpus and their hypothesized translations, we expect to gain some insight into the comparative strengths and weaknesses of the MT systems' reordering models. (An interactive platform for this analysis is demonstrated by Lopez and Resnik (2005).)

5.2 Chinese

We performed tag sequence analysis on the Hiero and Pharaoh systems trained on the FBIS data only. Table 3 shows those *n*-grams for which Hiero and Pharaoh's recall differed significantly ($p < 0.01$). The numbers shown are the ratio of Hiero's recall to Pharaoh's. Note that the *n*-grams on which Hiero had better recall are dominated by fragments of prepositional phrases (in the Penn Treebank tagset, prepositions are tagged IN or TO).

Our hypothesis is that Hiero produces English PPs better because many of them are translated from Chinese phrases which have an NP modifying an NP to its right, often connected with the particle 的 (*de*). These are often translated into English as PPs, which modify the NP to the left. A correct translation, then, would have to reorder the two NPs. Notice in the table that Hiero recalls proportionally more *n*-grams as *n* increases, corroborating the intuition that Hiero should be better at longer-distance reorderings.

Investigating this hypothesis qualitatively, we inspected the first five occurrences of the *n*-grams of the first type on the list (JJ NN IN DT NN). Of these, we omit one example because both systems recalled the *n*-gram correctly, and one because they differed only in lexical choice (Hiero matched the 5-gram with one reference sentence, Pharaoh with zero). The other three examples are shown below (H = Hiero, P = Pharaoh):

P. the first half of

All three of these examples involve an NP modifying an NP to its right; two with the particle 的 (*de*) and one without. In all three cases Hiero reorders the NPs correctly; Pharaoh preserves the Chinese word order in two cases, but in the third, for reasons not understood, drops the modifying NP.

The *n*-grams on which Hiero did worse than Pharaoh mostly involved numbers; here a pattern is not as easily discernible, but there are several cases where Hiero makes errors in translating numbers (neither system in this comparison used the dedicated number translator). For the *n*-gram TO VB PR, it seems Hiero has a tendency to delete possessive pronouns (PR, abbreviated from PRP$).

5.3 Arabic

Initial inspection of the *n*-grams on which Hiero showed significantly higher recall in the Arabic-English task suggested that here, too, better translation of nominal phrases may be at play. We investigated this conjecture further by examining several *n*-gram sets with the highest recall ratios. Some of them on closer inspection turned out to conflate different structural patterns, and provided little interpretable information. However, the 8 sentences in the *n*-gram list IN DT JJ JJ showed a degree of structural consistency. The list contained 6 instances where Hiero performed better in translating a complex NP or PP, one instance in which DC performed better in translating a complex PP, and one case in which they both performed equally poorly. Below we show two examples of phrases on which Hiero performed better, and the one example on which its hierarchical approach produced undesirable results (H = Hiero, D = DC).

6 Conclusions

The work reported in this paper extends the original treatment of Hiero (Chiang, 2005) by evaluating an improved version in a community-wide exercise for Chinese-English and Arabic-English translation, and by introducing a novel analysis technique for comparing MT systems' output. The evaluation results provide strong evidence that the approach gains performance from its hierarchical extensions to phrase-based translation. The analysis of part-of-speech tag sequences provides a way to perform finer-grained comparison of system output, pinpointing phenomena for which the systems differ significantly.

Abstract

In this paper, we look at comparing high-accuracy context-free parsers with high-accuracy finite-state (shallow) parsers on several shallow parsing tasks. We show that previously reported comparisons greatly under-estimated the performance of context-free parsers for these tasks. We also demonstrate that context-free parsers can train effectively on relatively little training data, and are more robust to domain shift for shallow parsing tasks than has been previously reported. Finally, we establish that combining the output of context-free and finite-state parsers gives much higher results than the previous-best published results, on several common tasks. While the efficiency benefit of finite-state models is inarguable, the results presented here show that the corresponding cost in accuracy is higher than previously thought.

1 Introduction

Finite-state parsing (also called chunking or shallow parsing) has typically been motivated as a fast first-pass for – or approximation to – more expensive context-free parsing (Abney, 1991; Ramshaw and Marcus, 1995; Abney, 1996). For many very-large-scale natural language processing tasks (e.g. open-domain question answering from the web), context-free parsing may be too expensive, whereas finite-state parsing is many orders of magnitude faster and can also provide very useful syntactic annotations for large amounts of text. For this reason, finite-state parsing (hereafter referred to as shallow parsing) has received increasing attention in recent years.

In addition to the clear efficiency benefit of shallow parsing, Li and Roth (2001) have further claimed both an accuracy and a robustness benefit versus context-free parsing. The output of a context-free parser, such as that of Collins (1997) or Charniak (2000), can be transformed into a sequence of shallow constituents for comparison with the output of a shallow parser. Li and Roth demonstrated that their shallow parser, trained to label shallow constituents along the lines of the well-known CoNLL-2000 task (Sang and Buchholz, 2000), outperformed the Collins parser in correctly identifying these constituents in the Penn Wall Street Journal (WSJ) Treebank (Marcus et al., 1993). They argued that their superior performance was due to optimizing directly for the local sequence labeling objective, rather than for obtaining a hierarchical analysis over the entire string. They further showed that their shallow parser trained on the Penn WSJ Treebank did a far better job of annotating out-of-domain sentences (e.g. conversational speech) than the Collins parser.

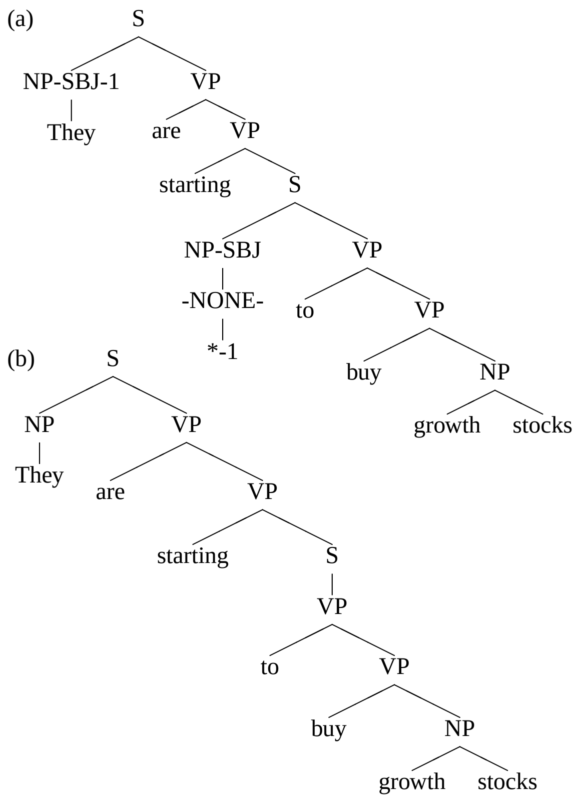
This paper re-examines the comparison of shallow parsers with context-free parsers, beginning with a critical examination of how their outputs are compared. We demonstrate that changes to the conversion routine, which take into account differences between the original treebank trees and the trees output by context-free parsers, eliminate the previously-reported accuracy differences. Second, we show that a convention that is widely accepted for evaluation of context-free parses – ignoring punctuation when setting the span of a constituent – results in improved shallow parsing performance by certain context-free parsers across a variety of shallow parsing tasks. We also demonstrate that context-free parsers perform competitively when applied to out-of-domain data. Finally, we show that large improvements can be obtained in several shallow parsing tasks by using simple strategies to incorporate context-free parser output into shallow parsing models. Our results demonstrate that a rich context-free parsing model is, time permitting, worth applying, even if only shallow parsing output is needed. In addition, our best results, which greatly improve on the previous-best published results on several tasks, shed light on how much accuracy is sacrificed in shallow parsing to get finite-state efficiency.

2 Evaluating Heterogeneous Parser Output

Two commonly reported shallow parsing tasks are Noun-Phrase (NP) Chunking (Ramshaw and Marcus, 1995) and the CoNLL-2000 Chunking task (Sang and Buchholz, 2000), which extends the NP-Chunking task to recognition of 11 phrase types[1] annotated in the Penn Treebank. Reference shallow parses for this latter task were derived from treebank trees via a conversion script known as `chunklink`[2]. We follow Li and Roth (2001) in using `chunklink` to also convert trees output by a context-free parser into a flat representation of shallow constituents. Figure 1(a) shows a Penn Treebank tree and Figure 1(c) its corresponding shallow parse constituents, according to the CoNLL-2000 guidelines. Note that consecutive verb phrase (VP) nodes result in a single VP shallow constituent.

Just as the original treebank trees are converted for training shallow parsers, they are also typically modified for training context-free parsers. This modification includes removal of empty nodes (nodes tagged with "-NONE-" in the treebank), and removal of function tags on non-terminals; e.g., NP-SBJ (subject NP) and NP-TMP (temporal NP) are both mapped to NP. The output of the context-free parser is, of course, in the same format as the training input, so empty nodes and function tags are not present. This type of modified tree is what is shown in Figure 1(b); note that the original treebank tree, shown in Figure 1(a), had an empty subject NP in the embedded clause which has been removed for the modified tree.

To compare the output of their shallow parser with the output of the well-known Collins (1997) parser, Li and Roth applied the `chunklink` conversion script to extract the shallow constituents from the output of the Collins parser on WSJ section 00. Un-



(c) [NP They] [VP are starting to buy] [NP growth stocks]

Figure 1: (a) Penn WSJ treebank tree, (b) modified treebank tree, and (c) CoNLL-2000 style shallow bracketing, all of the same string.

fortunately, the script was built to be applied to the original treebank trees, complete with empty nodes, which are not present in the output of the Collins parser, or any well-known context-free parser. The `chunklink` script searches for empty nodes in the parse tree to perform some of its operations. In particular, any S node that contains an empty subject NP and a VP is reduced to just a VP node, and then combined with any immediately-preceding VP nodes to create a single VP constituent. If the S node does not contain an empty subject NP, as in Figure 1(b), the `chunklink` script creates two VP constituents: [VP are starting] [VP to buy], which in this case results in a bracketing error. However, it is a simple matter to insert an empty subject NP into unary S$\rightarrow$VP productions so that these nodes are processed correctly by the script.

Various conventions have become standard in evaluating parser output over the past decade. Perhaps the most widely accepted convention is that of ignoring punctuation for the purposes of assigning constituent span, under the perspective that, fun-

[1]These include: ADJP, ADVP, CONJP, INTJ, LST, NP, PP, PRT, SBAR, UCP and VP. Anything not in one of these base phrases is designated as "outside".

	VP	88.15	94.31	94.42
Charniak (2000)	All	93.88	95.15	95.32
	VP	88.92	95.11	95.19

Table 1: F-measure shallow bracketing accuracy under three different evaluation scenarios: (a) baseline, used in Li and Roth (2001), with original `chunklink` script converting treebank trees and context-free parser output; (b) same as (a), except that empty subject NPs are inserted into every unary S→VP production; and (c) same as (b), except that punctuation is ignored for setting constituent span. Results for Li and Roth are reported from their paper. The Collins parser is provided with part-of-speech tags output by the Brill tagger (Brill, 1995).

damentally, constituents are groupings of words. Interestingly, this convention was not followed in the CoNLL-2000 task (Sang and Buchholz, 2000), which as we will see has a variable effect on context-free parsers, presumably depending on the degree to which punctuation is moved in training.

2.1 Evaluation Analysis

To determine the effects of the conversion routine and different evaluation conventions, we compare the performance of several different models on one of the tasks presented in Li and Roth (2001). For this task, which we label the *Li & Roth task*, sections 2-21 of the Penn WSJ Treebank are used as training data, section 24 is held out, and section 00 is for evaluation.

For all trials in this paper, we report F-measure labeled bracketing accuracy, which is the harmonic mean of the labeled precision (P) and labeled recall (R), as they are defined in the widely used PARSEVAL metrics; i.e. the F-measure accuracy is $\frac{2PR}{P+R}$.

Table 1 shows baseline results for the Li and Roth[3] shallow parser, two well-known, high-accuracy context-free parsers, and the reference (true) parses after being modified as described above (by removing empty nodes and function tags). Evaluation scenario (a) in Table 1 corresponds to what was used in Li and Roth (2001) following CoNLL-2000 guidelines, with the original `chunklink` script used to transform the context-free parser output into shallow constituents. We can see from the performance of the modified truth in this scenario that there are serious problems with this conversion, due to the way in which it handles unary S→VP productions. If we deterministically insert empty subject NP nodes for all such unary productions prior to the use of the `chunklink` script, which we do in evaluation scenario (b) of Table 1, this repairs the bulk of the errors. Some small number of errors remain, due largely to the fact that if the S node has been annotated with a function tag (e.g. S-PRP, S-PRD, S-CLR), then `chunklink` will not perform its reduction operation on that node. However, for our purposes, this insertion repair sufficiently corrects the error to perform meaningful comparisons. Finally, evaluation scenario (c) follows the context-free parsing evaluation convention of ignoring punctuation when assigning constituent span. This affects some parsers more than others, depending on how the parser treats punctuation internally; for example, Bikel (2004) documents that the Collins parser raises punctuation nodes within the parse tree. Since ignoring punctuation cannot hurt performance, only improve it, even the smallest of these differences are statistically significant.

Note that after inserting empty nodes and ignoring punctuation, the accuracy advantage of Li and Roth over Collins is reduced to a dead heat. Of the two parsers we evaluated, the Charniak (2000) parser gave the best performance, which is consistent with its higher reported performance on the context-free parsing task versus other context-free parsers. Collins (2000) reported a reranking model that improved his parser output to roughly the same level of accuracy as Charniak (2000), and Charniak and Johnson (2005) report an improvement using reranking over Charniak (2000). For the purposes of this paper, we needed an available parser that was (a) trainable on different subsets of the data to be applied to various tasks; and (b) capable of producing n-best candidates, for potential combination with a shallow parser. Both the Bikel (2004) imple-

[3]We were unable to obtain the exact model used in Li and Roth (2001), and so we use their reported results here. Note that they used reference part-of-speech (POS) tags for their results on this task. All other results reported in this paper, unless otherwise noted, were obtained using Brill-tagger POS tags.

Li and Roth (2001)		-	93.02	94.64

Table 2: Baseline results on three shallow parsing tasks: the NP-Chunking task (Ramshaw and Marcus, 1995); the CoNLL-2000 Chunking task (Sang and Buchholz, 2000); and the Li & Roth task (Li and Roth, 2001), which is the same as CoNLL-2000 but with more training data and a different test section. The results reported in this table include the best published results on each of these tasks.

mentation of the Collins parser and the n-best version of the Charniak (2000) parser, documented in Charniak and Johnson (2005), fit the requirements. Since we observed higher accuracy from the Charniak parser, from this point forward we report just Charniak parser results[4].

2.2 Shallow Parser

In addition to the trainable n-best context-free parser from Charniak (2000), we needed a trainable shallow parser to apply to the variety of tasks we were interested in investigating. To this end, we replicated the NP-chunker described in Sha and Pereira (2003) and trained it as either an NP-chunker or with the tagset extended to classify all 11 phrase types included in the CoNLL-2000 task (Sang and Buchholz, 2000). Our shallow parser uses exactly the feature set delineated by Sha and Pereira, and performs the decoding process using a Viterbi search with a second-order Markov assumption as they described. These features include unigram and bigram words up to two positions to either side of the current word; unigram, bigram, and trigram part-of-speech (POS) tags up to two positions to either side of the current word; and unigram, bigram, and trigram shallow constituent tags. We use the averaged perceptron algorithm, as presented in Collins (2002), to train the parser. See (Sha and Pereira, 2003) for more details on this approach.

To demonstrate the competitiveness of our baseline shallow parser, which we label the *SPRep averaged perceptron*, Table 2 shows results on three different shallow parsing tasks. The NP-Chunking task, originally introduced in Ramshaw and Marcus (1995) and also described in (Collins, 2002; Sha and Pereira, 2003), brackets just base NP constituents[5]. The CoNLL-2000 task, introduced as a shared task at the CoNLL workshop in 2000 (Sang and Buchholz, 2000), extends the NP-Chunking task to label 11 different base phrase constituents. For both of these tasks, the training set was sections 15-18 of the Penn WSJ Treebank and the test set was section 20. We follow Collins (2002) and Sha and Pereira (2003) in using section 21 as a heldout set. The third task, introduced by Li and Roth (2001), performs the same labeling as in the CoNLL-2000 task, but with more training data and different testing sets: training was WSJ sections 2-21 and test was section 00. We used section 24 as a heldout set; this section is often used as heldout for training context-free parsers.

Training and testing data for the CoNLL-2000 task is available online[6]. For the heldout sets for each of these tasks, as well as for all data sets needed for the Li & Roth task, reference shallow parses were generated using the `chunklink` script on the original treebank trees. All data was tagged with the Brill POS tagger (Brill, 1995) after the `chunklink` conversion. We verified that using this method on the original treebank trees in sections 15-18 and 20 generated data that is identical to the CoNLL-2000 data sets online. Replacing the POS tags in the input text with Brill POS tags before the

[4]The parser is available for research purposes at ftp://ftp.cs.brown.edu/pub/nlparser/ and can be run in n-best mode. The one-best performance of the parser is the same as what was presented in Charniak (2000).

[5]We follow Sha and Pereira (2003) in deriving the NP constituents from the CoNLL-2000 data sets, by replacing all non-NP shallow tags with the "outside" ("O") tag. They mention that the resulting shallow parse tags are somewhat different than those used by Ramshaw and Marcus (1995), but that they found no significant accuracy differences in training on either set.

[6]Downloaded from the CoNLL-2000 Shared Task website http://www.cnts.ua.ac.be/conll2000/chunking/.

`chunklink` conversion results in slightly different shallow parses.

From Table 2 we can see that our shallow parser is competitive on all three tasks[7]. Sha and Pereira (2003) noted that the difference between their perceptron and CRF results was not significant, and our performance falls between the two, thus replicating their result within noise. Our performance falls 0.6 percentage points below the best published result on the CoNLL-2000 task, and 0.5 percentage points above the performance by Li and Roth (2001) on their task. Overall, ours is a competitive approach for shallow parsing.

3 Experimental Results

3.1 Comparing Finite-State and Context-Free Parsers

The first two rows of Table 3 present a comparison between the SPRep shallow parser and the Charniak (2000) context-free parser detailed in Charniak and Johnson (2005). We can see that the performance of the two models is virtually indistinguishable for all three of these tasks, with or without ignoring of punctuation. As mentioned earlier, we used the version of this parser with improved n-best extraction, as documented in Charniak and Johnson (2005), although without the reranking of the candidates that they also report in that paper. For these trials, we used just the one-best output of that model, which is the same as in Charniak (2000).

Note that the standard training set for context-free parsing (sections 2-21) is only used for the Li & Roth task; for the other two tasks, both the SPRep and the Charniak parsers were trained on sections 15-18, with section 21 as heldout. This demonstrates that the context-free parser, even when trained on a small fraction of the total treebank, is able to learn a competitive model for this task.

3.2 Combining Finite-State and Context-Free Parsers

It is likely true that a context-free parser which has been optimized for global parse accuracy will, on occasion, lose some shallow parse accuracy to satisfy global structure constraints that do not constrain a shallow parser. However, it is also likely true that these longer distance constraints will on occasion enable the context-free parser to better identify the shallow constituent structure. In other words, despite having very similar performance, our shallow parser and the Charniak context-free parser are likely making complementary predictions about the shallow structure that can be exploited for further improvements. In this section, we explore two simple methods for combining the system outputs.

The first combination of the system outputs, which we call *unweighted intersection*, is the simplest kind of 'rovered' system, which restricts the set of shallow parse candidates to the intersection of the sets output by each system, but does not combine the scores. Since the Viterbi search of the SPRep model provides a score for all possible shallow parses, the intersection of the two sets is simply the set of shallow-parse sequences in the 50-best candidates output by the Charniak parser. We then use the SPRep perceptron-model scores to choose from among just these candidates. We converted the 50-best lists returned by the Charniak parser into k-best lists of shallow parses by using `chunklink` to convert each candidate context-free parse into a shallow parse. Many of the context-free parses map to the same shallow parse, so the size of this list is typically much less than 50, with an average of around 7. Each of the unique shallow-parse candidates is given a score by the SPRep perceptron, and the best-scoring candidate is selected. Effectively, we used the Charniak parser's k-best shallow parses to limit the search space for our shallow parser.

The second combination of the system outputs, which we call *weighted intersection*, extends the unweighted intersection by including the scores from the Charniak parser, which are log probabilities. The score for a shallow parse output by the Charniak parser is the log of the sum of the probabilities of all context-free parses mapping to that shallow parse. We normalize across all candidates for a given string, hence these are conditional log probabilities. We multiply these conditional log probabilities by a scaling factor α before adding them to the SPRep perceptron score for a particular candidate. Again, the best-scoring candidate using this composite score is selected from among the shallow

[7]Sha and Pereira (2003) reported the Kudo and Matsumoto (2001) performance on the NP-Chunking task to be 94.39 and to be the best reported result on this task. In the cited paper, however, the result is as reported in our table.

	NP-Chunking		CoNLL-2000		Li & Roth task

Unweighted intersection	95.13	95.16	94.52	94.64	95.77	95.92
Weighted intersection	95.57	95.58	95.03	95.16	96.20	96.33

Table 3: F-measure shallow bracketing accuracy on three shallow parsing tasks, for the SPRep perceptron shallow parser, the Charniak (2000) context-free parser, and for systems combining the SPRep and Charniak system outputs.

parse candidates output by the Charniak parser. We used the heldout data to empirically estimate an optimal scaling factor for the Charniak scores, which is 15 for all trials reported here. This factor compensates for differences in the dynamic range of the scores of the two parsers.

Both of these intersections are done at test-time, i.e. the models are trained independently. To remain consistent with task-specific training and testing section conventions, the individual models were always trained on the appropriate sections for the given task, i.e. WSJ sections 15-18 for NP-Chunking and the CoNLL-2000 tasks, and sections 2-21 for the Li & Roth task.

Results from these methods of combination are shown in the bottom two rows of Table 3. Even the simple unweighted intersection gives quite large improvements over each of the independent systems for all three tasks. All of these improvements are significant at $p < 0.001$ using the Matched Pair Sentence Segment test (Gillick and Cox, 1989). The weighted intersection gives further improvements over the unweighted intersection for all tasks, and this improvement is also significant at $p < 0.001$, using the same test.

3.3 Robustness to Domain Shift

Our final shallow parsing task was also proposed in Li and Roth (2001). The purpose of this task was to examine the degradation in performance when parsers, trained on one relatively clean domain such as WSJ, are tested on another, mismatched domain such as Switchboard. The systems that are reported in this section are trained on sections 2-21 of the WSJ Treebank, with section 24 as heldout, and tested on section 4 of the Switchboard Treebank. Note that the systems used here are exactly the ones presented for the original Li & Roth task, in Sections 3.1 and 3.2; only the test set has changed, training and heldout sets remain exactly the same, as do the mixing parameters for the weighted intersection. In the trials reported in Li and Roth (2001), both of the evaluated systems were provided with reference POS tags from the Switchboard Treebank. In the current results, we show our SPRep averaged perceptron system provided both with reference POS tags for comparison with the Li and Roth results, and provided with Brill-tagger POS tags for comparison with other systems. Table 4 shows our results for this task. Whereas Li and Roth reported a more marked degradation in performance when using a context-free parser as compared to a shallow parser, we again show virtually indistinguishable performance between our SPRep shallow parser and the Charniak context-free parser. Again, using a weighted combined model gave us large improvements over each independent model, even in this mismatched domain.

	Punctuation	
System	Leave	Ignore
Li & Roth (reference tags)	88.47	-
SPRep avg perceptron		
Reference tags	91.37	91.86
Brill tags	87.94	88.42
Charniak (2000)	87.94	88.44
Unweighted intersection	88.66	89.16
Weighted intersection	89.22	89.69

Table 4: Shallow bracketing accuracy of several different systems, trained on sections 2-21 of WSJ Treebank and applied to section 4 of the Switchboard Treebank. Li and Roth (2001) results are as reported in their paper, with reference POS tags rather than Brill-tagger POS tags.

3.4 Reranked n-best List

Just prior to the publication of this paper, we were able to obtain the trained reranker from Charniak

System		WSJ Sect. 00		SWBD Sect. 4	
		Punctuation		Punctuation	
		Leave	Ignore	Leave	Ignore
SPRep		95.12	95.27	87.94	88.43
C & J	one-best	95.15	95.32	87.94	88.44
(2005)	reranked	95.81	96.04	88.64	89.17
Weighted intersection		96.32	96.47	89.32	89.80

Table 5: F-measure shallow bracketing accuracy when trained on WSJ sections 2-21 and applied to either WSJ section 00 or SWBD section 4. Systems include our shallow parser (SPRep); the Charniak and Johnson (2005) system (C & J), both initial one-best and reranked-best; and the weighted intersection between the reranked 50-best list and the SPRep system.

and Johnson (2005), which allows a comparison of the shallow parsing gains that they obtain from that system with those documented here. The reranker is a discriminatively trained Maximum Entropy model with an F-measure parsing accuracy objective. It uses a large number of features, and is applied to the 50-best output from the generative Charniak parsing model. The reranking model was trained on sections 2-21, with section 24 used as heldout. This allows us to compare its shallow parsing accuracy with other systems on the tasks that use this training setup: the Li & Roth task (testing on WSJ section 00) and the domain shift task (testing on Switchboard section 4). Table 5 shows two new trials making use of this reranking model.

The Charniak and Johnson (2005) system output (denoted *C & J* in the table) before reranking (denoted *one-best*) is identical to the Charniak (2000) results that have been reported in the other tables. After reranking (denoted *reranked*), the performance improves by roughly 0.7 percentage points for both tasks, nearly reaching the performance that we obtained with weighted intersection of the SPRep model and the n-best list before reranking. Weighted intersection between the reranked list and the shallow parser as described earlier, with a newly estimated scaling factor (α=30), provides a roughly 0.5 percentage point increase over the result obtained by the reranker. The difference between the Charniak output before and after reranking is statistically significant at $p < 0.001$, as is the difference between the reranked output and the weighted intersection, using the same test reported earlier.

3.5 Discussion

While it may be seen to be overkill to apply a context-free parser for these shallow parsing tasks, we feel that these results are very interesting for a couple of reasons. First, they go some way toward correcting the misperception that context-free parsers are less applicable in real-world scenarios than finite-state sequence models. Finite-state models are undeniably more efficient; however, it is important to have a clear idea of how much accuracy is being sacrificed to reach that efficiency. Any given application will need to examine the efficiency/accuracy trade-off with different objectives for optimality. For those willing to trade efficiency for accuracy, it is worthwhile knowing that it is possible to do much better on these tasks than what has been reported in the past.

4 Conclusion and Future Work

In summary, we have demonstrated in this paper that there is no accuracy or robustness benefit to shallow parsing with finite-state models over using high-accuracy context-free models. Even more, there is a large benefit to be had in combining the output of high-accuracy context-free parsers with the output of shallow parsers. We have demonstrated a large improvement over the previous-best reported results on several tasks, including the well-known NP-Chunking and CoNLL-2000 shallow parsing tasks.

Part of the misperception of the relative benefits of finite-state and context-free models is due to difficulty evaluating across these differing annotation styles. Mapping from context-free parser output to the shallow constituents defined in the CoNLL-2000 task depends on many construction-specific operations that have unfairly penalized context-free parsers in previous comparisons.

While the results of combining system outputs show one benefit of combining systems, as presented in this paper, they hardly exhaust the possibilities of exploiting the differences between these models. Making use of the scores for the shallow parses output by the Charniak parser is a demonstrably effective way to improve performance. Yet there are other possible features explicit in the context-free parse candidates, such as head-to-head dependencies, which might be exploited to further improve performance. We intend to explore including features from the context-free parser output in our perceptron model to improve shallow parsing accuracy.

Another possibility is to look at improving context-free parsing accuracy. Within a multi-pass parsing strategy, the high-accuracy shallow parses that result from system combination could be used to restrict the search within yet another pass of a context-free parser. That parser could then search for the best global analysis from within just the space of parses consistent with the provided shallow parse. Also, features of the sort used in our shallow parser could be included in a reranker, such as that in Charniak and Johnson (2005), with a context-free parsing accuracy objective.

A third possibility is to optimize the definition of the shallow-parse phrase types themselves, for use in other applications. The composition of the set of phrase types put forth by Sang and Buchholz (2000) may not be optimal for certain applications. One such application is discourse parsing, which relies on accurate detection of clausal boundaries. Shallow parsing could provide reliable information on the location of these boundaries, but the current set of phrase types may be too general for such use. For example, consider infinitival verb phrases, which often indicate the start of a clause whereas other types of verb phrases do not. Unfortunately, with only one VP category in the CoNLL-2000 set of phrase types, this distinction is lost. Expanding the defined set of phrase types could benefit many applications.

Future work will also include continued exploration of possible features that can be of use for either shallow parsing models or context-free parsing models. In addition, we intend to investigate ways in which to encode approximations to context-free parser derived features that can be used within finite-state models, thus perhaps preserving finite-state efficiency while capturing at least some of the accuracy gain that was observed in this paper.

Acknowledgments

We would like to thank Eugene Charniak and Mark Johnson for help with the parser and reranker documented in their paper. The first author of this paper was supported under an NSF Graduate Research Fellowship. In addition, this research was supported in part by NSF Grant #IIS-0447214. Any opinions, findings, conclusions or recommendations expressed in this publication are those of the authors and do not necessarily reflect the views of the NSF.

Morphology and Reranking for the Statistical Parsing of Spanish

Abstract

We present two methods for incorporating detailed features in a Spanish parser, building on a baseline model that is a lexicalized PCFG. The first method exploits Spanish morphology, and achieves an F1 constituency score of 83.6%. This is an improvement over 81.2% accuracy for the baseline, which makes little or no use of morphological information. The second model uses a reranking approach to add arbitrary global features of parse trees to the morphological model. The reranking model reaches 85.1% F1 accuracy on the Spanish parsing task. The resulting model for Spanish parsing combines an approach that specifically targets morphological information with an approach that makes use of general structural features.

1 Introduction

Initial methods for statistical parsing were mainly developed through experimentation on English data sets. Subsequent research has focused on applying these methods to other languages. There has been widespread evidence that new languages exhibit linguistic phenomena that pose considerable challenges to techniques originally developed for English; because of this, an important area of current research concerns how to model these phenomena more accurately within statistical approaches. In this paper, we investigate this question within the context of parsing Spanish. We describe two methods for incorporating detailed features in a Spanish parser, building on a baseline model that is a lexicalized PCFG originally developed for English.

Our first model uses morphology to improve the performance of the baseline model. English is a morphologically-impoverished language, while most of the world's languages exhibit far richer morphologies. Spanish is one of these languages. For instance, the forms of Spanish nouns, determiners, and adjectives reflect both number and gender; pronouns reflect gender, number, person, and case. Furthermore, morphological constraints may be manifested at the syntactic level: certain constituents of a noun phrase are constrained to agree in number and gender, and a verb is constrained to agree in number and person with its subject. Hence, morphology gives us important structural cues about how the words in a Spanish sentence relate to one another. The mechanism we employ for incorporating morphology into the PCFG model (the Model 1 parser in (Collins, 1999)) is the modification of its part-of-speech (POS) tagset; in this paper, we explain how this mechanism allows the parser to better capture morphological constraints.

All of the experiments in this paper are carried out using a freely-available Spanish treebank produced by the 3LB project (Navarro et al., 2003). This resource contains around 3,500 hand-annotated trees encoding ample morphological information. We could not use all of this information and adequately train the resulting parameters due to limited training data. Hence, we used development data to test the performance of several models, each incorporating a subset of morphological information. The highest-accuracy model on the development set uses the mode and number of verbs, as well as the number of adjectives, determiners, nouns, and pronouns. On test data, it reaches F1 accuracy of 83.6%/83.9%/79.4% for labeled constituents, unlabeled dependencies, and labeled dependencies, respectively. The baseline model, which makes almost no use of morphology, achieves 81.2%/82.5%/77.0% in these same measures.

We use the morphological model from the aforementioned experiments as a base parser in a second set of experiments. Here we investigate the efficacy of a reranking approach for parsing Spanish by using

Proceedings of Human Language Technology Conference and Conference on Empirical Methods in Natural Language Processing (HLT/EMNLP), pages 795–802, Vancouver, October 2005. ©2005 Association for Computational Linguistics

arbitrary structural features. Previous work in statistical parsing (Collins and Koo, 2005) has shown that applying reranking techniques to the n-best output of a base parser can improve parsing performance. Applying an exponentiated gradient reranking algorithm (Bartlett et al., 2004) to the n-best output of our morphologically-informed Spanish parsing model gives us similar improvements. Using the reranking model combined with the morphological model raises performance to 85.1%/84.7%/80.2% F1 accuracy for labeled constituents, unlabeled dependencies, and labeled dependencies.

2 Related Work

The statistical parsing of English has surpassed 90% accuracy in the precision and recall of labeled constituents (e.g., (Collins, 1999; Charniak and Johnson, 2005)). A recent proliferation of treebanks in various languages has fueled research in the parsing of other languages. For instance, work has been done in Chinese using the Penn Chinese Treebank (Levy and Manning, 2003; Chiang and Bikel, 2002), in Czech using the Prague Dependency Treebank (Collins et al., 1999), in French using the French Treebank (Arun and Keller, 2005), in German using the Negra Treebank (Dubey, 2005; Dubey and Keller, 2003), and in Spanish using the UAM Spanish Treebank (Moreno et al., 2000). The best-reported F1 constituency scores from this work for each language are 79.9% (Chinese (Chiang and Bikel, 2002)), 81.0% (French (Arun and Keller, 2005), 76.2% (German (Dubey, 2005)), and 73.8% (Spanish (Moreno et al., 2000)). The authors in (Collins et al., 1999) describe an approach that gives 80% accuracy in recovering unlabeled dependencies in Czech.[1]

The project that is arguably most akin to the work presented in this paper is that on Spanish parsing (Moreno et al., 2000). However, a direct comparison of scores is complicated by the fact that we have used a different corpus as well as larger training and test sets (2,800- vs. 1,500-sentence training sets, and 700- vs. 40-sentence test sets).

[1]Note that cross-linguistic comparison of results is complicated: in addition to differences in corpus annotation schemes and sizes, there may be significant differences in linguistic characteristics.

Category	**Attributes**
Adjective	gender, number, participle
Determiner	gender, number, person, possessor
Noun	gender, number
Verb	gender, number, person, mode, tense
Preposition	gender, number, form
Pronoun	gender, number, person, case, possessor

Table 1: A list of the morphological features from which we created our models. For brevity, we only list attributes with at least two values. See (Civit, 2000) for a comprehensive list of the morphological attributes included in the Spanish treebank.

3 Models

This section details our two approaches for adding features to a baseline parsing model. First, we describe how morphological information can be added to a parsing model by modifying the POS tagset. Second, we describe an approach that reranks the n-best output of the morphologically-rich parser, using arbitrary, general features of the parse trees as additional information.

3.1 Adding Morphological Information

The mechanism we employ for incorporating morphological information is the modification of the POS tagset of a lexicalized PCFG[2] — the Model 1 parser described in (Collins, 1999) (hereafter Model 1). Each POS tagset can be thought of as a particular morphological model or a subset of morphological attributes. Table 1 shows the complete set of morphological features we considered for Spanish. There are 22 morphological features in total in this table; different POS sets can be created by deciding whether or not to include each of these 22 features; hence, there are 2^{22} different morphological models we could have created. For instance, one particular model might capture the modal information of verbs. In this model, there would be six POS tags for verbs (one for each of indicative, subjunctive, imperative, infinitive, gerund, and participle) instead of just one. A model that captured both the number and mode of verbs would have 18 verbal POS tags, assuming three values (singular, plural, and neutral) for the number feature.

The Effect of the Tagset on Model 1 Modifying the POS tagset allows Model 1 to better distinguish

[2]Hand-crafted head rules are used to lexicalize the trees.

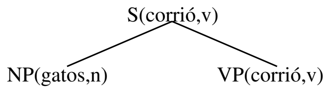

Figure 1: An ungrammatical dependency: the plural noun *gatos* is unlikely to modify the singular verb *corrió*.

events that are unlikely from those that are likely, on the basis of morphological evidence. An example will help to illustrate this point.

Model 1 relies on statistics conditioned on lexical headwords for practically all parameters in the model. This sensitivity to headwords is achieved by propagating lexical heads and POS tags to the nonterminals in the parse tree. Thus, any statistic based on headwords may also be sensitive to the associated POS tag. For instance, consider the subtree in Figure 1. Note that this structure is ungrammatical because the subject, *gatos* (*cats*), is plural, but the verb, *corrió* (*ran*), is singular. In Model 1, the probability of generating the noun phrase (NP) with headword *gatos* and headtag noun (n) is defined as follows:[3]

$$P(\text{gatos}, \mathsf{n}, \mathsf{NP} \mid \text{corrió}, \mathsf{v}, \mathsf{S}, \mathsf{VP}) = P_1(\mathsf{n}, \mathsf{NP} \mid \text{corrió}, \mathsf{v}, \mathsf{S}, \mathsf{VP}) \times P_2(\text{gatos} \mid \mathsf{n}, \mathsf{NP}, \text{corrió}, \mathsf{v}, \mathsf{S}, \mathsf{VP})$$

The parser smooths parameter values using backed-off statistics, and in particular smooths statistics based on headwords with coarser statistics based on POS tags alone. This allows the parser to effectively use POS tags as a way of separating different lexical items into subsets or classes depending on their syntactic behavior. In our example, each term is estimated as follows:

$$\begin{aligned} &P_1(\mathsf{n}, \mathsf{NP} \mid \text{corrió}, \mathsf{v}, \mathsf{S}, \mathsf{VP}) = \\ &\lambda_{1,1}\hat{P}_{1,1}(\mathsf{n}, \mathsf{NP} \mid \text{corrió}, \mathsf{v}, \mathsf{S}, \mathsf{VP}) + \\ &\lambda_{1,2}\hat{P}_{1,2}(\mathsf{n}, \mathsf{NP} \mid \mathsf{v}, \mathsf{S}, \mathsf{VP}) + \\ &\lambda_{1,3}\hat{P}_{1,3}(\mathsf{n}, \mathsf{NP} \mid \mathsf{S}, \mathsf{VP}) \end{aligned}$$

and

$$\begin{aligned} &P_2(\text{gatos} \mid \mathsf{n}, \mathsf{NP}, \text{corrió}, \mathsf{v}, \mathsf{S}, \mathsf{VP}) = \\ &\lambda_{2,1}\hat{P}_{2,1}(\text{gatos} \mid \mathsf{n}, \mathsf{NP}, \text{corrió}, \mathsf{v}, \mathsf{S}, \mathsf{VP}) + \\ &\lambda_{2,2}\hat{P}_{2,2}(\text{gatos} \mid \mathsf{n}, \mathsf{NP}, \mathsf{v}, \mathsf{S}, \mathsf{VP}) + \\ &\lambda_{2,3}\hat{P}_{2,3}(\text{gatos} \mid \mathsf{n}) \end{aligned}$$

[3]Note that the parsing model includes other features such as distance which we omit from the parameter definition for the sake of brevity.

Here the $\hat{P}_{i,j}$ terms are maximum likelihood estimates derived directly from counts in the training data. The $\lambda_{i,j}$ parameters are defined so that $\lambda_{1,1}+\lambda_{1,2}+\lambda_{1,3} = \lambda_{2,1}+\lambda_{2,2}+\lambda_{2,3} = 1$. They control the relative contribution of each level of back-off to the final estimate.

Note that thus far our example has not included any morphological information in the POS tags. Because of this, we will see that there is a danger of the estimates P_1 and P_2 both being high, in spite of the dependency being ungrammatical. P_1 will be high because all three estimates $\hat{P}_{1,1}, \hat{P}_{1,2}$ and $\hat{P}_{1,3}$ will most likely be high. Next, consider P_2. Of the three estimates $\hat{P}_{2,1}, \hat{P}_{2,2}$, and $\hat{P}_{2,3}$, only $\hat{P}_{2,1}$ retains the information that the noun is plural and the verb is singular. Thus P_2 will be sensitive to the morphological clash between *gatos* and *corrió* only if $\lambda_{2,1}$ is high, reflecting a high level of confidence in the estimate of $\hat{P}_{2,3}$. This will only happen if the context $\langle$corrió, v, S, VP$\rangle$ is seen frequently enough for $\lambda_{2,1}$ to take a high value. This is unlikely, given that this context is quite specific. In summary, the impoverished model can only capture morphological restrictions through lexically-specific estimates based on extremely sparse statistics.

Now consider a model that incorporates morphological information — in particular, number information — in the noun and verb POS tags. *gatos* will have the POS pn, signifying a plural noun; *corrió* will have the POS sv, signifying a singular verb. All estimates in the previous equations will reflect these POS changes. For example, P_1 will now be estimated as follows:

$$\begin{aligned} &P_1(\mathsf{pn}, \mathsf{NP} \mid \text{corrió}, \mathsf{sv}, \mathsf{S}, \mathsf{VP}) = \\ &\lambda_{1,1}\hat{P}_{1,1}(\mathsf{pn}, \mathsf{NP} \mid \text{corrió}, \mathsf{sv}, \mathsf{S}, \mathsf{VP}) + \\ &\lambda_{1,2}\hat{P}_{1,2}(\mathsf{pn}, \mathsf{NP} \mid \mathsf{sv}, \mathsf{S}, \mathsf{VP}) + \\ &\lambda_{1,3}\hat{P}_{1,3}(\mathsf{pn}, \mathsf{NP} \mid \mathsf{S}, \mathsf{VP}) \end{aligned}$$

Note that the two estimates $\hat{P}_{1,1}$ and $\hat{P}_{1,2}$ include an (unlikely) dependency between the POS tags pn and sv. Both of these estimates will be 0, assuming that a plural noun is never seen as the subject of a singular verb. At the very least, the context $\langle$sv, S, VP$\rangle$ will be frequent enough for $\hat{P}_{1,2}$ to be a reliable estimate. The value for $\lambda_{1,2}$ will therefore be high, leading to a low estimate for P_1, thus correctly assigning low probability to the ungrammatical dependency. In summary, the morphologically-rich model can make use of non-lexical statistics such as $\hat{P}_{1,2}(\mathsf{pn}, \mathsf{NP} \mid \mathsf{sv}, \mathsf{S}, \mathsf{VP})$ which contain dependencies between POS tags and which will most likely be estimated reliably by the model.

3.2 The Reranking Model

In the reranking model, we use an n-best version of the morphologically-rich parser to generate a number of candidate parse trees for each sentence in training and test data. These parse trees are then represented through a combination of the log probability under the initial model, together with a large number of global features. A reranking model uses the information from these features to derive a new ranking of the n-best parses, with the hope of improving upon the baseline model. Previous approaches (e.g., (Collins and Koo, 2005)) have used a linear model to combine the log probability under a base parser with arbitrary features derived from parse trees. There are a variety of methods for training the parameters of the model. In this work, we use the algorithm described in (Bartlett et al., 2004), which applies the large-margin training criterion of support vector machines (Cortes and Vapnik, 1995) to the reranking problem.

The motivation for the reranking model is that a wide variety of features, which can essentially be sensitive to arbitrary context in the parse trees, can be incorporated into the model. In our work, we included all features described in (Collins and Koo, 2005). As far as we are aware, this is the first time that a reranking model has been applied to parsing a language other than English. One goal was to investigate whether the improvements seen on English parsing can be carried across to another language. We have found that features in (Collins and Koo, 2005), initially developed for English parsing, also give appreciable gains in accuracy when applied to Spanish.

4 Data

The Spanish 3LB treebank is a freely-available resource with about 3,500 sentence/tree pairs that we have used to train our models. The average sentence length is 28 tokens. The data is taken from 38 complete articles and short texts. Roughly 27% of the texts are news articles, 27% scientific articles, 14% narrative, 11% commentary, 11% sports articles, 6% essays, and 5% articles from weekly magazines. The trees contain information about both constituency structure and syntactic functions.

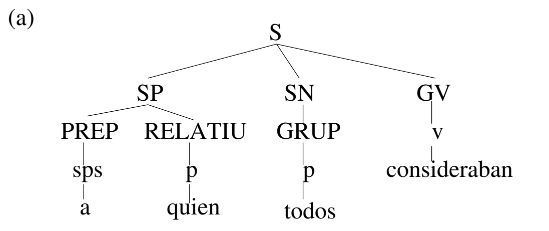
Non-Terminal	Significance
aq	*adjective*
cc	*conjunction*
COORD	*coordinated phrase*
ESPEC	*determiner*
GRUP	*base noun phrase*
GV	*verb phrase*
MORF	*impersonal pronoun*
p	*pronoun*
PREP	*base prepositional phrase*
RELATIU	*relative pronoun phrase*
s	*adjectival phrase*
SN	*noun phrase*
SP	*prepositional phrase*
SADV	*adverbial phrase*
S	*sentence*
sps	*preposition*
v	*verb*

Table 2: The non-terminals and preterminals from the Spanish 3LB corpus used in this paper.

4.1 Preprocessing

It is well-known that tree representation influences parsing performance (Johnson, 1998). Prior to training our models, we made some systematic modifications to the corpus trees in an effort to make it easier for Model 1 to represent the linguistic phenomena present in the trees. For the convenience of the reader, Table 2 gives a key to the non-terminal labels in the 3LB treebank that are used in this section and the remainder of the paper.

Relative and Subordinate Clauses Cases of relative and subordinate clauses appearing in the corpus trees have the basic structure of the example in Figure 2a. Figure 2b shows the modifications we impose on such structures. The modified structure has the advantage that the SBAR selects the CP node as its head, making the relative pronoun *que* the headword for the root of the subtree. This change allows, for example, better modeling of verbs that select for particular complementizers. In addition, the new subtree rooted at the S node now looks like a top-level sentence, making sentence types more uniform in structure and easier to model statistically. Additionally, the new structure differentiates phrases em-



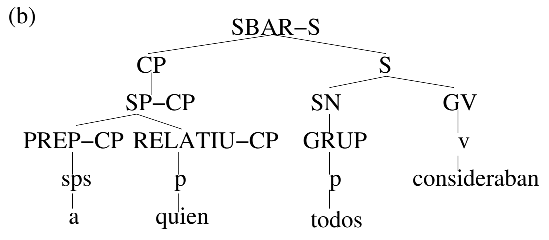


Figure 2: Figure (a) is the original structure from the 3LB treebank for the phrase *a quien todos consideraban* or *whom everyone considered*. We transform structures like (a) into (b) by inserting SBAR and CP nodes, and by marking all non-terminals below the CP with a -CP tag.

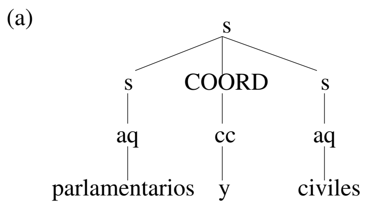

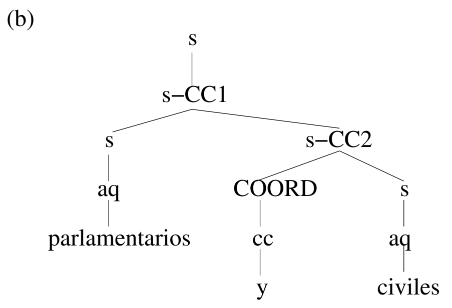

Figure 3: In the 3LB corpus, phrases involving coordination, are represented with a flat structure as in (a). For coordination involving a non-terminal X ($X = \texttt{s}$ in the example), we insert new nodes X-CC1 and X-CC2 to form the structure in (b).

bedded in the complementizers of SBARs from those used in other contexts, allowing relative pronouns like *quien* in Figure 2 to surface as lexical headwords when embedded in larger phrases beneath the CP node.[4]

Coordination In the treebank, coordinated constituents and their coordinating conjunction are placed as sister nodes in a flat structure. We enhance the structure of such subtrees, as in Figure 3. Our structure helps to rule out unlikely phrases such as *cats and dogs and*; the model trained with the original treebank structures will assign non-zero probability to ill-formed structures such as these.

5 Experiments

Our models were trained using a training set consisting of 80% of the data (2,801 sentence/tree pairs, 75,372 words) available to us in the 3LB treebank. We reserved the remaining 20% (692 sentences, 19,343 words) to use as unseen data in a test set. We selected these subsets with two criteria in mind: first, respecting the boundaries of the texts by placing articles in their entirety into either one subset or the other; and second, maintaining, in each subset, the same proportion of genres found in the original set of trees. During development, we used a cross-validation approach on the training set to test different models. We divided the 2,800 training data trees into 14 different development data sets, where each of these data sets consisted of 2,600 training sentences and 200 development sentences. We took the average over the results of the 14 splits to gauge the effectiveness of the model being tested.

To evaluate our models, we considered the recovery of labeled and unlabeled dependencies as well as labeled constituents. Unlabeled dependencies capture how the words in a sentence depend on one another. Formally, they are tuples $\{$*headchild index*, *modifier index*$\}$, where the indices indicate position in the sentence. Labeled dependencies include the labels of the modifier, headchild, and parent non-terminals as well. The root of the tree has a special dependency: $\{$*head index*$\}$ in the unlabeled case and $\{$*TOP*, *headchild index*, *root non-terminal*$\}$ in the labeled case. The labeled constituents in a tree are all of the non-terminals and, for each, the positions of the words it spans. We use the standard definitions of precision, recall, and F-measure.[5]

[4]This is achieved through our head rules.

[5]When extracting dependencies, we replaced all non-punctuation POS labels with a generic label *TAG* to avoid conflating tagging errors with dependency errors. We also included the structural changes that we imposed during preprocessing. Results for constituent precision and recall were computed after we restored the trees to the original treebank structure.

Table 4: Results after running the morphological and reranking models on test data. Row 1 is our baseline model. Row 2 is the morphological model that scored highest during development. Row 3 gives the accuracy of the reranking approach, when applied to n-best output from the model in Row 2.

5.1 The Effects of Morphology

In our first experiments, we trained over 50 models, incorporating different morphological information into each in the way described in Section 3.1. Prior to running the parsers, we trained the POS tagger described in (Collins, 2002). The output from the tagger was used to assign a POS label for unknown words. We only attempted to parse sentences under 70 words in length.

Table 3 describes some of the models we tried during development and gives results for each. Our baseline model, which we used to evaluate the effects of using morphology, was Model 1 (Collins, 1999) with a simple POS tagset containing almost no morphological information. The morphological models we show are meant to be representative of both the highest-scoring models and the performance of various morphological features. For instance, we found that, in general, gender had only a slight impact on the performance of the parser. Note that gender is not a morphological attribute of Spanish verbs, and that the inclusion of verbal features, particularly number, mode, and person, generated the strongest-performing models in our experiments.

Table 4 shows the results of running two models on the test set: the baseline model and the best-performing morphological model from the development stage. This model uses the number and mode of verbs, as well as the number of adjectives, determiners, nouns, and pronouns.

The results in Tables 3 and 4 show that adding some amount of morphological information to a parsing model is beneficial. We found, however, that adding more information does not always lead to improved performance (see, for example, rows 11 and 13 in Table 3). Presumably this is because the tagset grows too large.

Table 5 takes a closer look at the performance of the best-performing morphological model in the recovery of particular labeled dependencies. The breakdown shows the top 15 dependencies in the gold-standard trees across the entire training set. Collectively, these dependencies represent around 72% of the dependencies seen in this data.

We see an extraordinary gain in the recovery of some of these dependencies when we add morphological information. Among these are the two involving postmodifiers to verbs. When examining the output of the morphological model, we found that much of this gain is due to the fact that there are two non-terminal labels used in the treebank that specify modal information of verbs they dominate (infinitivals and gerunds): with insufficient morphological information, the baseline parser was unable to distinguish regular verb phrases from these more specific verb phrases.

Some dependencies are particularly difficult for the parser, such as that in which `SBAR` modifies a noun ({`GRUP TAG SBAR` R}). We found that around 20% of cases of this type in the training set involve structures like *el proceso de negociones que* (in English *the process of negotiation that*). This type of structure is inherently difficult to disambiguate. In Spanish, such structures may be more common than in English, since phrases involving nominal modifiers to nouns, like *negotiation process*, are always formed as *noun* + *de* + *noun*.

Dependency	Count	Model	Prec/Rec

`GRUP TAG SN` R	(1.2%)	M	51.7/50.8

Table 5: Labeled dependency accuracy for the top 15 dependencies (representing around 72% of all dependencies) in the gold-standard trees across all training data. The first column shows the type and subtype, where the subtype is specified as the 4-tuple {*parent non-terminal*, *head non-terminal*, *modifier non-terminal*, *direction*}; the second column shows the count for that subtype and the percent of the total that it represents (where the total is 62,372) . The model BL is the baseline, and M is the morphological model n(A,D,N,V,P)+m(V).

5.2 Experiments with Reranking

In the reranking experiments, we follow the procedure described in (Collins and Koo, 2005) for creation of a training set with n-best parses for each sentence. This method involves jack-knifing the data: the training set of 2,800 sentences was parsed in 200-sentence chunks by an n-best morphological parser trained on the remaining 2,600 sentences. This ensured that each sentence in the training data had n-best output from a baseline model that was not trained on that sentence. We used the optimal morphological model (n(A,D,N,V,P)+m(V)) to generate the n-best lists, and we used the feature set described in (Collins and Koo, 2005). The test results are given in Table 4.[6]

5.3 Statistical Significance

We tested the significance of the labeled precision and recall results in Table 4 using the sign test. When applying the sign test, for each sentence in the test data we calculate the sentence-level F1 constituent score for the two parses being compared. This indicates whether one model performs better on that sentence than the other model, or whether the two models perform equally well, information used by the sign test. All differences were found to be statistically significant at the level $p = 0.01$.[7]

[6]Note that we also created development sets for development of the reranking approach, and for cross-validation of the single parameter C in approach of (Bartlett et al., 2004).

[7]When comparing the baseline model to the morphological model on the 692 test sentences, F1 scores improved on 314 sentences, and became worse on 164 sentences. When comparing the baseline model to the reranked model, 358/157 sen-

6 Conclusions and Future Work

We have developed a statistical parsing model for Spanish that performs at 85.1% F1 constituency accuracy. We find that an approach that explicitly represents some of the particular features of Spanish (i.e., its morphology) does indeed help in parsing. Moreover, this approach is compatible with the reranking approach, which uses general features that were first developed for use in an English parser. In fact, our best parsing model combines both the language-specific morphological features and the non-specific reranking features. The morphological features are local, being restricted to dependencies between words in the parse tree; the reranking features are more global, relying on larger portions of parse structures. Thus, we see our final model as combining the strengths of two complementary approaches.

We are curious to know the extent to which a close analysis of the dependency errors made by the baseline parser can be corrected by the development of features tailored to addressing these problems. Some preliminary investigation of this suggests that we see much higher gains when using generic features than these more specific ones, but we leave a thorough investigation of this to future work. Another avenue for future investigation is to try using a more sophisticated baseline model such as Collins' Model 2, which incorporates both subcategorization and complement/adjunct information. Finally, we would like to use the Spanish parser in an application such as machine translation.

Acknowledgements

We would like to thank Xavier Carreras for pointing us to the Spanish 3LB treebank and Montserrat Civit for providing access to the data and answering questions about it. We also gratefully acknowledge the support of the National Science Foundation under grants 0347631 and 0434222.

tences had improved/worse parses. When comparing the morphological model to the reranked model, 199/106 sentences had improved/worse parses.

Abstract

This paper investigates some computational problems associated with probabilistic translation models that have recently been adopted in the literature on machine translation. These models can be viewed as pairs of probabilistic context-free grammars working in a 'synchronous' way. Two hardness results for the class NP are reported, along with an exponential time lower-bound for certain classes of algorithms that are currently used in the literature.

1 Introduction

State of the art architectures for machine translation are all based on mathematical models called translation models. Generally speaking, a translation model accounts for all the elementary operations that rule the process of translation between the words and the different word orderings of the source and target languages. Translation models are usually enriched with statistical parameters, to drive the search toward the most likely translation(s). Specialized algorithms are provided for the automatic estimation of these parameters from corpora of translation pairs. Besides the task of natural language translation, statistical translation models are also exploited in other applications, such as word alignment, multilingual document retrieval and automatic dictionary construction.

The most successful translation models that are found in the literature exploit finite-state machinery. The approach started with the so-called IBM models (Brown et al., 1988), implementing a set of elementary operations, such as movement, duplication and translation, that independently act on individual words in the source sentence. These word-to-word models have been later enriched with the introduction of larger units such as phrases; see for instance (Och et al., 1999; Och and Ney, 2002). Still, the generative capacity of these models lies within the realm of finite-state machinery (Kumar and Byrne, 2003), so they are unable to handle nested structures and do not provide the expressivity required to process language pairs with very different word orderings.

Recently, more sophisticated translation models have been proposed, borrowing from the theory of compilers and making use of synchronous rewriting. In synchronous rewriting, two formal grammars are exploited, one describing the source language and the other describing the target language. Furthermore, the productions of the two grammars are paired and, in the rewriting process, such pairs are always applied synchronously. Formalisms based on synchronous rewriting have been empowered with the use of statistical parameters, and specialized estimation and translation (decoding) algorithms were newly developed. Among the several proposals, we mention here the models presented in (Wu, 1997; Wu and Wong, 1998), (Alshawi et al., 2000), (Yamada and Knight, 2001), (Gildea, 2003) and (Melamed, 2003).

In this paper we consider synchronous models based on context-free grammars and probabilistic extensions thereof. This is the most common choice in statistical translation models that exceed the generative power of finite-state machinery. We focus on two associated computational problems that have been defined in the literature. One is the membership problem, which involves testing whether an input string pair can be generated by the model. The other is the translation problem (also called the decoding problem) which involves the search for a suitable translation of an input string/structure. It has been often informally stated in the literature that the use of structured models results in efficient, polynomial time algorithms for the above problems. We show here that sometimes this is not the case. The contribution of this paper can be stated as follows:

- we show that the membership problem is NP-hard, unless a constant bound is imposed on the length of the productions (Section 3);
- we show an exponential time lower bound for the membership problem, in case chart parsing is adopted (Section 3);
- we show that translating an input string into the best parse tree in the target language is NP-hard, even in case productions are bounded in length (Section 4).

Investigation of the computational complexity of translation models has started in (Knight, 1999) for word-to-word models. This paper can be seen as the continuation of that line of research.

2 Synchronous context-free grammars

Several definitions for synchronous context-free grammars have been proposed in the literature; see for instance (Chiang, 2004; Chiang, 2005). Our definition is based on syntax-directed translation schemata (SDTS; Aho and Ullman, 1972), with the difference that we do not impose the restriction that two paired context-free productions have the same left-hand side. As it will be discussed in Section 4, this results in an enriched generative capacity when probabilistic extensions are considered. We assume the reader is familiar with the definition of context-free grammar (CFG) and with the associated notion of derivation.

Let V_N and V_T be sets of nonterminal and terminal symbols, respectively. In what follows we need to represent bijections between all the occurrences of nonterminals in two strings over $V_N \cup V_T$. This can be done by annotating nonterminals with indices from an infinite set. We define $\mathcal{I}(V_N) = \{A^{(t)} \mid A \in V_N,\ t \in \mathbb{N}\}$ and $V_I = \mathcal{I}(V_N) \cup V_T$. We write $\mathsf{index}(\gamma)$, $\gamma \in V_I^*$, to denote the set of all indices (the integers t) that appear in symbols in γ. Two strings $\gamma, \gamma' \in V_I^*$ are **synchronous** if each index in $\mathsf{index}(\gamma)$ occurs only once in γ, each index in $\mathsf{index}(\gamma')$ occurs only once in γ', and $\mathsf{index}(\gamma) = \mathsf{index}(\gamma')$. Therefore synchronous strings have the general form

$$\begin{array}{c} u_{10}A_{11}^{(t_1)}u_{11}A_{12}^{(t_2)}u_{12} \quad \cdots \quad u_{1r-1}A_{1r}^{(t_r)}u_{1r}, \\ u_{20}A_{21}^{(t_{\pi(1)})}u_{21}A_{22}^{(t_{\pi(2)})}u_{22} \quad \cdots \quad u_{2r-1}A_{2r}^{(t_{\pi(r)})}u_{2r}, \end{array}$$

where $r \geq 0$, $u_{1i}, u_{2i} \in V_T^*$, $A_{1i}^{(t_i)}, A_{2i}^{(t_{\pi(i)})} \in \mathcal{I}(V_N)$, $t_i \neq t_j$ for $i \neq j$ and π is some permutation defined on set $\{1, \ldots, r\}$.

Definition 1 *A* **synchronous context-free grammar** *(SCFG) is a tuple $G = (V_N, V_T, P, S)$, where V_N, V_T are finite, disjoint sets of nonterminal and terminal symbols, respectively, $S \in V_N$ is the start symbol and P is a finite set of synchronous productions, each of the form $[A_1 \rightarrow \alpha_1,\ \ A_2 \rightarrow \alpha_2]$, with $A_1, A_2 \in V_N$ and $\alpha_1, \alpha_2 \in V_I^*$ synchronous strings.*

The size of a SCFG G is defined as $|G| = \sum_{[A_1 \rightarrow \alpha_1,\ A_2 \rightarrow \alpha_2] \in P} |A_1\alpha_1A_2\alpha_2|$. Based on an example from (Yamada and Knight, 2001), we provide a sample SCFG fragment translating from English to Japanese, specified by means of the following synchronous productions:

$$\begin{array}{ll} s_1 : & [\mathrm{VB} \rightarrow \mathrm{PRP}^{(1)}\ \mathrm{VB1}^{(2)}\ \mathrm{VB2}^{(3)}, \\ & \ \mathrm{VB} \rightarrow \mathrm{PRP}^{(1)}\ \mathrm{VB2}^{(3)}\ \mathrm{VB1}^{(1)}] \\ s_2 : & [\mathrm{VB2} \rightarrow \mathrm{VB}^{(1)}\ \mathrm{TO}^{(2)}, \\ & \ \mathrm{VB2} \rightarrow \mathrm{TO}^{(2)}\ \mathrm{VB}^{(1)}\ \mathrm{ga}] \\ s_3 : & [\mathrm{TO} \rightarrow \mathrm{TO}^{(1)}\ \mathrm{NN}^{(2)},\ \ \mathrm{TO} \rightarrow \mathrm{NN}^{(2)}\ \mathrm{TO}^{(1)}] \\ s_4 : & [\mathrm{PRP} \rightarrow \mathrm{he},\ \ \mathrm{PRP} \rightarrow \mathrm{kare\ ha}] \\ s_5 : & [\mathrm{VB1} \rightarrow \mathrm{adores},\ \ \mathrm{VB1} \rightarrow \mathrm{daisuki\ desu}] \\ s_6 : & [\mathrm{VB} \rightarrow \mathrm{listening},\ \ \mathrm{VB} \rightarrow \mathrm{kiku\ no}] \\ s_7 : & [\mathrm{TO} \rightarrow \mathrm{to},\ \ \mathrm{TO} \rightarrow \mathrm{wo}] \\ s_8 : & [\mathrm{NN} \rightarrow \mathrm{music},\ \ \mathrm{NN} \rightarrow \mathrm{ongaku}] \end{array}$$

Note that in production s_2 above, the nonterminals VB and TO generated from nonterminal VB2 in the English component are inverted in the Japanese component, where some additional lexical material is also added.

In a SCFG, the 'derives' relation is defined on synchronous strings in terms of simultaneous rewriting of two nonterminals with the same index. Some additional notation will help us defining this relation precisely. A **reindexing** is a one-to-one function on $\mathbb{N}$. We extend a reindexing f to V_I by letting $f(A^{(t)}) = A^{(f(t))}$ for $A^{(t)} \in \mathcal{I}(V_N)$ and $f(a) = a$ for $a \in V_T$. We also extend f to strings in V_I^* by letting $f(\varepsilon) = \varepsilon$ and $f(X\gamma) = f(X)f(\gamma)$, for each $X \in V_I$ and $\gamma \in V_I^*$. We say that strings $\gamma_1, \gamma_2 \in V_I^*$ are **independent** if $\mathsf{index}(\gamma_1) \cap \mathsf{index}(\gamma_2) = \emptyset$.

Definition 2 *Let $G = (V_N, V_T, P, S)$ be a SCFG and let γ_1, γ_2 be synchronous strings in V_I^*. The* **derives** *relation $[\gamma_1,\ \gamma_2] \Rightarrow_G [\delta_1,\ \delta_2]$ holds whenever there exist an index t in $\mathsf{index}(\gamma_1)$, a synchronous production $[A_1 \rightarrow \alpha_1,\ A_2 \rightarrow \alpha_2]$ in P and some reindexing f such that*

(i) *$f(\alpha_1\alpha_2)$ and $\gamma_1\gamma_2$ are independent; and*

(ii) *$\gamma_i = \gamma_i' A_i^{(t)} \gamma_i''$, $\delta_i = \gamma_i' f(\alpha_i) \gamma_i''$, for $i = 1, 2$.*

We also write $[\gamma_1,\ \gamma_2] \Rightarrow_G^s [\delta_1,\ \delta_2]$ to explicitly indicate that the derives relation holds through some synchronous production $s \in P$.

Since δ_1 and δ_2 in Definition 2 are synchronous strings, we can define the reflexive and transitive closure of $\Rightarrow_G$, written $\Rightarrow_G^*$. This relation is used to represent derivations in G. In case we have $[\gamma_{1i-1},\ \gamma_{2i-1}] \Rightarrow_G^{s_i} [\gamma_{1i},\ \gamma_{2i}]$ for $1 \leq i \leq n$, $n \geq 1$, we also write $[\gamma_{10},\ \gamma_{20}] \Rightarrow_G^{\sigma} [\gamma_{1n},\ \gamma_{2n}]$, where $\sigma = s_1 s_2 \cdots s_n$. We always assume some canonical form for derivations (as for instance leftmost derivation on the left component). Similarly to the case of context-free grammars, each derivation in G can be associated with a pair of parse trees, that is, one parse tree for each dimension.

Back to our example, we report a fragment of a derivation of the string pair [he adores listening to music, kare ha ongaku wo kiku no ga daisuki desu]:

$$\begin{aligned}
&[\mathrm{VB}^{(1)},\ \mathrm{VB}^{(1)}] \\
&\Rightarrow_G^{s_1} [\mathrm{PRP}^{(2)}\ \mathrm{VB1}^{(3)}\ \mathrm{VB2}^{(4)}, \\
&\qquad \mathrm{PRP}^{(2)}\ \mathrm{VB2}^{(4)}\ \mathrm{VB1}^{(3)}] \\
&\Rightarrow_G^{s_4} [\text{he } \mathrm{VB1}^{(3)}\ \mathrm{VB2}^{(4)}, \\
&\qquad \text{kare ha } \mathrm{VB2}^{(4)}\ \mathrm{VB1}^{(3)}] \\
&\Rightarrow_G^{s_5} [\text{he adores } \mathrm{VB2}^{(4)}, \\
&\qquad \text{kare ha } \mathrm{VB2}^{(4)} \text{ daisuki desu}] \\
&\Rightarrow_G^{s_2} [\text{he adores } \mathrm{VB}^{(5)}\ \mathrm{TO}^{(6)}, \\
&\qquad \text{kare ha } \mathrm{TO}^{(6)}\ \mathrm{VB}^{(5)} \text{ ga daisuki desu}].
\end{aligned}$$

The **translation** generated by a SCFG G is a binary relation over V_T^* defined as

$$T(G) \;=\; \{[w_1,\ w_2] \mid [S^{(1)},\ S^{(1)}] \Rightarrow_G^* [w_1,\ w_2],\ w_1, w_2 \in V_T^*\}.$$

The set of strings that are translations of a given string w_1 is defined as:

$$T(G, w_1) \;=\; \{w_2 \mid [w_1,\ w_2] \in T(G)\}.$$

A **probabilistic** SCFG (PSCFG) is a pair (G, p_G) where $G = (V_N, V_T, P, S)$ is a SCFG and p_G is a function from P to real numbers in $[0, 1]$ such that, for each $A_1, A_2 \in V_N$, we have:

$$\sum_{\alpha_1, \alpha_2} p_G([A_1 \rightarrow \alpha_1,\ A_2 \rightarrow \alpha_2] \;=\; 1.$$

If for $n \geq 1$ and $s_i \in P$, $1 \leq i \leq n$, string $\sigma = s_1 s_2 \cdots s_n$ is a canonical derivation of the form $[S^{(1)},\ S^{(1)}] \Rightarrow_G^{\sigma} [w_1,\ w_2]$, we write $p_G(\sigma) = \prod_{i=1}^{n} p_G(s_i)$. If $D([w_1, w_2])$ is the set of all canonical derivations in G for pair $[w_1, w_2]$, we write $p_G([w_1, w_2]) = \sum_{\sigma \in D([w_1, w_2])} p_G(\sigma)$.

3 The membership problem

We consider here the **membership** problem for SCFG, defined as follows: for input instance a SCFG G and a pair $[w_1,\ w_2]$, decide whether $[w_1,\ w_2]$ is in $T(G)$. This problem has been considered for instance in (Wu, 1997) for his inversion transduction grammars and has applications in the support of several tasks of automatic annotation of parallel corpora, as for instance segmentation, bracketing, phrasal and word alignment. We show that the membership problem for SCFGs is NP-hard. The result could be derived from the findings in (Melamed et al., 2004) that synchronous rewriting systems as SCFGs are related to the class of so called linear context-free rewriting systems (LCFRSs) and from the result that the membership problem for

LCFRSs is NP-hard (Satta, 1992; Kaji and others, 1994). However, we provide here a direct proof, to simplify the presentation.

Theorem 1 *The membership problem for SCFGs is NP-hard.*

Proof. We reduce from the three-satisfiability problem (3SAT, Garey and Johnson, 1979). Let $\langle U, C\rangle$ be an instance of the 3SAT problem, where $U = \{u_1, \ldots, u_p\}$ is a set of variables and $C = \{c_1, \ldots, c_n\}$ is a set of clauses. Each clause is a set of three literals from $\{u_1, \overline{u}_1, \ldots, u_p, \overline{u}_p\}$.

The general idea of the proof is to use a string pair $[w_1 w_2 \cdots w_p,\ w_c]$, where w_c is a string representation of C and each w_i is a string controlling the truth assignment for the variable u_i. We then construct a SCFG G such that each w_i can be derived in two possible ways only, using some specialized productions of G, encoding the truth assignment of variable u_i. In this way the derivation of the whole string $w_1 \cdots w_p$ in the left dimension corresponds to a guess of a truth assignment for U. Accordingly, on the right dimension only those symbols of w_c will be derived that represent clauses that hold true under the guessed assignment.

We need some additional notation. Below we treat C as an alphabet of atomic symbols. We use a function d such that, for every i with $1 \leq i \leq p$, $c_{d(i,1)}, c_{d(i,2)}, \ldots, c_{d(i,s_i)}$ is the sequence of all clauses that include literal u_i, in the left to right order in which they appear within $c_1 c_2 \cdots c_n$, and $c_{d(i,s_i+1)}, c_{d(i,s_i+2)}, \ldots, c_{d(i,t_i)}$ is the sequence of all clauses that include literal $\overline{u}_i$, again as they appear within $c_1 c_2 \cdots c_n$ from left to right. Note that we must have $\sum_{i=1}^{p} t_i = 3n$. We also use a function e such that, for every $1 \leq i \leq p$ and $1 \leq j \leq t_i$, $e(i,j) = j + \sum_{k=1}^{i-1} t_k$ (assume $\sum_{k=1}^{0} t_k = 0$).

Consider the alphabet $\{a_i, b_i \mid 1 \leq i \leq p\}$. For every i, $1 \leq i \leq p$, let w_i denote a sequence of exactly $t_i + 1$ alternating symbols a_i and b_i, i.e., $w_i \in (a_i b_i)^+ \cup (a_i b_i)^* a_i$. For every $1 \leq i \leq p$, let $x(i,1) = a_i b_i$ and let $x(i,h) = a_i$ (resp. b_i) if h is even (resp. odd), $2 \leq h \leq t_i$. Let also $\overline{x}(i,h) = a_i$ (resp. b_i) if h is odd (resp. even), $1 \leq h \leq t_i - 1$, and let $\overline{x}(i,t_i) = a_i b_i$ (resp. $b_i a_i$) if t_i is odd (resp. even). Therefore we can write $w_i = x(i,1)x(i,2)\cdots x(i,t_1) = \overline{x}(i,1)\overline{x}(i,2)\cdots\overline{x}(i,t_1)$.

Finally, we need a permutation π defined on the set $\{1, \ldots, 3n\}$ as follows. Fix i and j with $1 \leq i \leq p$ and $1 \leq j \leq t_i$, and let h be the number of occurrences of the clause $c_{d(i,j)}$ found in the sequence $c_{d(1,1)}, c_{d(1,2)}, \ldots, c_{d(1,t_1)}, c_{d(2,1)}, \ldots, c_{d(i,j)}$. Note that we must have $1 \leq h \leq 3$. Then we set $\pi(e(i,j)) = 3 \cdot [d(i,j) - 1] + h$.

We can now define the target instance $\langle G, [w, w']\rangle$ of our reduction. Let $[w, w'] = [w_1 w_2 \cdots w_p,\ c_1 c_2 \cdots c_n]$. Let also $G = (V_N, V_T, P, S)$, with $V_N = \{S\} \cup \{A_i \mid 1 \leq i \leq 3n\}$ and $V_T = C \cup \{a_i, b_i \mid 1 \leq i \leq p\}$. The productions below define set P:

(i) for every $1 \leq i \leq p$:

(a) for $1 \leq h \leq s_i$:

$$[A_{e(h,i)} \rightarrow x(i,h),\ A_{e(h,i)} \rightarrow c_{e(i,h)}],$$
$$[A_{e(h,i)} \rightarrow x(i,h),\ A_{e(h,i)} \rightarrow \varepsilon],$$
$$[A_{e(h,i)} \rightarrow \overline{x}(i,h),\ A_{e(h,i)} \rightarrow \varepsilon];$$

(b) for $s_i + 1 \leq h \leq t_i$:

$$[A_{e(h,i)} \rightarrow x(i,h),\ A_{e(h,i)} \rightarrow \varepsilon],$$
$$[A_{e(h,i)} \rightarrow \overline{x}(i,h),\ A_{e(h,i)} \rightarrow c_{e(i,h)}],$$
$$[A_{e(h,i)} \rightarrow \overline{x}(i,h),\ A_{e(h,i)} \rightarrow \varepsilon];$$

(ii)
$$[S \rightarrow A_{e(1,1)}^{(e(1,1))} A_{e(1,2)}^{(e(1,2))} \cdots A_{e(1,t_1)}^{(e(1,t_1))} A_{e(2,1)}^{(e(2,1))} \cdots A_{e(p,t_p)}^{(e(p,t_p))},$$
$$S \rightarrow A_{\pi(e(1,1))}^{(\pi(e(1,1)))} A_{\pi(e(1,2))}^{(\pi(e(1,2)))} \cdots A_{\pi(e(1,t_1))}^{(\pi(e(1,t_1)))} A_{\pi(e(2,1))}^{(\pi(e(2,1)))} \cdots A_{\pi(e(p,t_p))}^{(\pi(e(p,t_p)))}].$$

It is easy to see that $|G|$, $|w|$ and $|w'|$ are polynomially related to $|U|$ and $|C|$. From a derivation of $[w, w'] \in T(G)$, we can exhibit a truth assignment that satisfies C simply by reading off the derivation of the left string $w_1 w_2 \cdots w_p$. Conversely, starting from a truth assignment that satisfies C we can prove $w \in L(G)$ by means of (finite) induction on $|U|$: this part requires a careful inspection of all items in the definition of G. ■

From Theorem 1 we may conclude that algorithms for the membership problem for SCFGs are very unlikely to run in polynomial time. In the literature, several algorithms for this problem have been proposed using tabular methods (chart parsing). In the worst case, all these algorithms run in time $\Theta(|G| \cdot n^{k(G)})$, with G an SCFG and n the length of the input string pair. We know that, unless P = NP, $k(G)$ cannot be a constant. We now prove a lower bound on $k(G)$, providing thereby an exponential time lower bound result for our problem under the assumption of the tabular paradigm.

Tabular methods for the membership problem are based on the following representation. Given a synchronous production

$$\begin{aligned} s: \quad & [A_1 \to B_{11}^{(1)} \cdots B_{1r}^{(r)}, \\ & A_2 \to B_{21}^{(\pi(1))} \cdots B_{2r}^{(\pi(r))}], \end{aligned} \tag{1}$$

the already recognized constituent pairs $B_{1i}, B_{2\pi(i)}$ are gather together in several steps, keeping a record of the spanned substrings of the input. To provide a concrete example, if we gather all the B_{1i}'s on the left dimension from left to right, the partial analysis we obtain after the first step can be represented as a **state** $\langle s(1), (i_{11}, j_{11}), (i_{21}, j_{21})\rangle$, meaning that B_{11} and $B_{2\pi(1)}$ span substrings $w_1[i_{11}, j_{11}]$ and $w_2[i_{21}, j_{21}]$, respectively.[1] At the second step we have a state $\langle s(2), (i_{11}, j_{12}), (i_{21}, j_{21}), (i_{22}, j_{22})\rangle$, meaning that $B_{11}B_{12}$ together span $w_1[i_{11}, j_{12}]$, $B_{2\pi(1)}$ spans $w_2[i_{21}, j_{21}]$ and $B_{2\pi(2)}$ spans $w_2[i_{22}, j_{22}]$. We can see that, for some worst case permutations, the left-to-right strategy demands for increasingly more pairs of indices, so that the exponent in the time complexity linearly grows with r.

How much better can we do, if we exploit some strategy other than the left-to-right above? More precisely, we ask how many unconnected spannings a state may require for some worst case permutation π, under the choice of the best possible parsing strategy for π itself.

Theorem 2 *In the worst case, standard tabular methods for the SCFG membership problem require an amount of time $\Omega(|G|\, n^{c\cdot\sqrt{r}})$, with r the length of the longest production in G and c a constant.*

Proof. For any $r \geq 8$ we let $q = \lfloor\sqrt{r/2}\rfloor \geq \lfloor\sqrt{8/2}\rfloor = 2$, and define a permutation π_r on $\{1, \ldots, r\}$. We view the domain of π_r as composed of $2q$ **blocks** with q adjacent integers each, possibly followed by $r - 2q^2$ additional "padding" integers, and its codomain as composed of q blocks with $2q$ adjacent integers each, again possibly followed by $r - 2q^2$ "padding" integers. Permutation π_r transposes all blocks by sending the j-th element of the i-th block in the domain into the i-th element of the j-th block in the codomain, while mapping each padding integer identically into itself. Formally, for all positive integers $i \leq 2q$ and $j \leq q$, $\pi_r(q \cdot (i-1) + j) = 2q \cdot (j-1) + i$, and for all integers i with $2q^2 < i \leq r$, $\pi_r(i) = i$.

We count below how many spans are instantiated by a state that has gathered p constituent pairs, $1 \leq p \leq r$, in parsing production (1) under any possible strategy. When a constituent pair $B_{1i}, B_{2\pi_r(i)}$ is gathered, we say integer i in the domain of π_r and integer $\pi_r(i)$ in the codomain have been pebbled. In this way each span (i, j) in a state corresponds to some run $i, i+1, \ldots j$ of pebbled integers, with either $i = 1$ or $i - 1$ unpebbled, and with either $j = r$ or $j + 1$ unpebbled. We call each such run a **segment**, and show that every parsing strategy demands at least $q = \lfloor\sqrt{r/2}\rfloor$ segments either in the domain or in the codomain of π_r.

We say that a block in the domain of π_r is empty, full, or mixed if, respectively, none, all, or some but not all of its elements have been pebbled. Assume that, for a given parsing strategy, the last block that becomes mixed does so when we place the i-th pebble, and the first block that becomes full does so when we place the j-th pebble. Obviously $i \neq j$: the first pebble placed in a previously empty block can not make it full since every block contains at least 2 elements.

If $i < j$, after placing the i-th pebble and before placing the j-th pebble every block in the domain of π_r is mixed. Each of these $2q$ blocks then contains at least one pebbled element which is adjacent to an unpebbled one and must therefore be either the first or the last element of a segment. The domain of π_r then contains at least $2q/2 = q$ segments.

If $j < i$, after placing the j-th pebble and before placing the i-th pebble at least one block in the domain of π_r (e.g., the h-th block) is full, and at least one (e.g., the k-th) is empty. Then, in each of the q blocks in the codomain of π_r, the h-th element is pebbled while the k-th is not. Therefore the h-th elements of any two consecutive blocks in the codomain of π_r must belong to two distinct segments, since at least one intermediate element is not

[1]For a string $w = a_1 \cdots a_n$, we write $w[i, j]$ to denote the substring $a_{i+1} \cdots a_j$.

pebbled. The codomain of π_r then contains at least q segments. ■

4 The translation problem

In this section we consider some formulations of the translation problem for PSCFG that have been proposed in the literature. The most general definition of the **translation problem** for PSCFG is this: for an input PSCFG $G_p = (G, p_G)$ and an input string w, produce a representation of all possible parse trees, along with their probabilities, that are assigned by G to a string in the set $T(G, w)$ under some translation of w.

Variant of this definition can be found where the input is a single parse tree for w (Yamada and Knight, 2001), or where the output is a single parse tree, chosen according to some specific criteria (Wu and Wong, 1998). To formally study these problems, in what follows we focus on single parse trees associated with derivations in G_p. For a derivation σ of the form $[S^{(1)}, S^{(1)}] \Rightarrow^{\sigma}_{G} [w_1, w_2]$, we write $t_{\sigma,l}$ and $t_{\sigma,r}$ to denote the left and the right parse trees, respectively, associated with σ. The probability that $t_{\sigma,r}$ is obtained as a translation of $t_{\sigma,l}$ through G_p is thus $p_G([t_{\sigma,l},\ t_{\sigma,r}]) = p_G(\sigma)$. Let t be some parse tree; we write $y(t)$ to denote the string in the yield of t. For a string $w \in V_T^*$ and a parse tree t, we also consider the probability that t is obtained from w through G_p, defined as:

$$p_G([w,\ t]) \ = \sum_{y(t')=w} p_G([t',\ t]). \qquad (2)$$

We can now precisely define the variants of the translation problem we are interested in. Given as input a PSCFG $G_p = (G, p_G)$ and two strings $w_1, w_2 \in V_T^*$, output the pair of parse trees

$$\operatorname*{argmax}_{\substack{y(t_1)=w_1,\\ y(t_2)=w_2}} p_G([t_1,\ t_2]). \qquad (3)$$

If the synchronous productions in the underlying SCFG G have length bounded by some constant, then the above problem can be solved in polynomial time using extensions of the Viterbi search strategy to parse forests. This has been shown for instance in (Wu and Wong, 1998; Yamada and Knight, 2001; Melamed, 2004).

A second interesting problem is defined as follows. Given as input a PSCFG $G_p = (G, p_G)$ and a string $w \in V_T^*$, output the parse tree

$$\operatorname*{argmax}_{t} p_G([w,\ t]). \qquad (4)$$

Even in case we impose some constant bound on the length of the synchronous productions in G, the above problem is NP-hard, as we show in what follows.

We assume the reader is familiar with the definition of probabilistic context-free grammar (PCFG) and with the associated notion of derivation probability (Wetherell, 1980). We denote a PCFG as a pair (G, p_G), with $G = (V_N, V_T, P, S)$ the underlying context-free grammar and p_G the associated function providing the probability distributions for the productions in P, conditioned on their left-hand side. A probabilistic regular grammar (PRG) is a PCFG with underlying productions of the form $A \rightarrow aB$ or $A \rightarrow \varepsilon$, with A, B nonterminal symbols and a a terminal symbol.

We consider below a decision problem associated with PRG, called the **consensus** problem, defined as follows: Given as input a PRG (G, p_G) and a rational number $d \in [0, 1]$, decide whether there exists a string w in the language generated by G such that $p_G(w) \geq d$. It has been shown in (Casacuberta and de la Higuera, 2000) that, for a PRG G whose productions have all probabilities expressed by rational numbers, the above problem is NP-complete. (Essentially the same result is also reported in (Lyngso and Pedersen, 2002), stated in terms of hidden Markov models.) We reduce the consensus problem for PRG to a decision version of the problem in (4), called the **best translated derivation** problem and defined as follows. Given as input a PCFG $G_p = (G, p_G)$, a string $w \in V_T^*$ and a rational number $d \in [0, 1]$, decide whether $\max_t\ p_G([w,\ t]) \geq d$.

Theorem 3 *The best translated derivation problem for the class PSCFG is NP-hard.*

Proof. We provide a reduction from the consensus problem for the class PRG with rational production probabilities. The main idea is described in what follows. Given the input PRG G_p, we construct a target PSCFG G'_p that translates string \$ into \$, with \$ a special symbol. Given as input the string \$, G'_p simulates all possible derivations of G_p through its own derivations. This is done by encoding the nonterminals appearing in a derivation ρ of G_p within the left component of some derivation σ of G'_p, and by encoding the terminal string generated by ρ within the right component of σ. The probability of ρ is also preserved by σ.

Let $G_p = (G, p_G)$, d be an instance of the consensus problem as above, with $G = (V_N, V_T, P, S)$. We specify a PSCFG $G'_p = (G', p_{G'})$ with $G' = (V'_N, \{\$\}, P', S)$ and $V'_N = V_N \cup V_T$. Set P' is constructed as follows:

(i) for every $(S \rightarrow aA) \in P$, $s : [S \rightarrow A^{(1)},\ S \rightarrow a^{(1)}]$ is added to P', with $p_{G'}(s) = p_G(S \rightarrow aA)$;

(ii) for every $(S \rightarrow \varepsilon) \in P$, $s : [S \rightarrow \$,\ S \rightarrow \$]$ is added to P', with $p_{G'}(s) = p_G(S \rightarrow \varepsilon)$;

(iii) for every $a \in V_T$ and $(A \rightarrow bB) \in P$, $s : [A \rightarrow B^{(1)},\ a \rightarrow b^{(1)}]$ is added to P', with $p_{G'}(s) = p_G(A \rightarrow bB)$

(iv) for every $a \in V_T$ and $(A \rightarrow \varepsilon) \in P$, $s : [A \rightarrow \$,\ a \rightarrow \$]$ is added to P', with $p_{G'}(s) = p_G(A \rightarrow \varepsilon)$.

Note that the construction of G'_p can be carried out in quadratic time in the size of G_p. It is not difficult to see that there exists a derivation of the form $S \Rightarrow_G a_1 A_1 \Rightarrow_G a_1 a_2 A_2 \cdots \Rightarrow_G a_1 a_2 \cdots a_n A_n$ if and only if there exist a derivation in G' associated with unary trees t_1 and t_2, such that string $S A_1 A_2 \cdots A_n$ is read from the spine of t_1 and string $S a_1 a_2 \cdots a_n$ is read from the spine of t_2. Furthermore, the two derivations are composed of 'corresponding' productions with the same probabilities. We conclude that there exists a string w in $L(G)$ with $p_G(w) > d$ if and only if there exists a unary tree t with string $Sw\$$ read from the spine such that $p_{G'}([\$, t]) > d$. ■

We discuss below an interesting consequence of Theorem 3. The SDTS formalism discussed in Section 1 has been extended to the probabilistic case in (Maryanski and Thomason, 1979), called stochastic SDTS (SSDTS). As a corollary to the proof of Theorem 3, we obtain that one can define, through some PSCFG G_p and some fixed string w, a probability distribution $p_G([w, t])$ on parse trees that cannot be obtained through any SSDTS. Without providing the details of the definition of SSDTS, we give here only an outline of the proof. We also assume that the reader is familiar with probabilistic finite automata and with their distributional equivalence with PRG.

Consider the PSCFG $G'_p = (G', p_{G'})$ defined in the proof of Theorem 3, and assume there exists some SSDTS $G''_p = (G'', p_{G''})$ such that, for every tree t, we have $p_{G''}([\$, t]) = p_{G'}([\$, t])$. Since in a derivation of an SDTS the generated trees are always isomorphic, up to some reordering of sibling nodes, we obtain that the productions of G'' must have the form $[S \rightarrow a^{(1)},\ S \rightarrow a^{(1)}]$, $[a \rightarrow b^{(1)},\ a \rightarrow b^{(1)}]$ and $[a \rightarrow \$,\ a \rightarrow \$]$. From these productions we can construct a probabilistic deterministic finite automaton generating the same language as the PRG G_p, and with the same distribution. But this is impossible since there are string distributions defined by some PRG that cannot be obtained through probabilistic deterministic finite automata; see for instance (Vidal et al., 2005).

We conclude by remarking that in (Casacuberta and de la Higuera, 2000) it is shown that finding the best output string for a given input string is NP-hard for stochastic SDTS with a single nonterminal in each production's right-hand side. Our result in Theorem 3, stated for PSCFG, is stronger, since it investigates individual parse trees rather than strings.

5 Concluding remarks

The presented results are based on worst case analysis: further experimental evaluation needs to be carried out on multilingual corpora in order to asses the practical impact of these findings.

Acknowledgment

We are indebted to Dan Melamed and Mark-Jan Nederhof for technical discussion on topics related to this paper. Dan Melamed also suggested to us the problem investigated by Theorem 2. The first author is partially supported by MIUR under project PRIN No. 2003091149_005.

Abstract

We present a very efficient statistical incremental parser for LTAG-spinal, a variant of LTAG. The parser supports the full *adjoining* operation, dynamic predicate coordination, and non-projective dependencies, with a formalism of provably stronger generative capacity as compared to CFG. Using gold standard POS tags as input, on section 23 of the PTB, the parser achieves an f-score of 89.3% for syntactic dependency defined on LTAG derivation trees, which are deeper than the dependencies extracted from PTB alone with head rules (for example, in Magerman's style).

1 Introduction

Lexicalized Tree Adjoining Grammar (LTAG) is a formalism motived by both linguistic and computational perspectives (for a relatively recent review, see (Joshi and Schabes, 1997)). Because of the introduction of the *adjoining* operation, the TAG formalism is provably stronger than Context Free Grammar (CFG) both in the weak and the strong generative power. The TAG formalism provides linguistically attractive analysis of natural language (Frank, 2002). Recent psycholinguistic experiments (Sturt and Lombardo, 2005) demonstrate that the *adjoining* operation of LTAG is required for eager incremental processing.

Vijay-Shanker and Joshi (1985) introduced the first TAG parser in a CYK-like algorithm. Because of the adjoining operation, the time complexity of LTAG parsing is as large as $O(n^6)$, compared with $O(n^3)$ of CFG parsing, where n is the length of the sentence to be parsed. Many LTAG parsers were proposed, such as the head-driven Earley style parser (Lavelli and Satta, 1991) and the head-corner parser (van Noord, 1994). The high time complexity prevents LTAG parsing from real-time applications.

In this paper, we work on LTAG-spinal (Shen and Joshi, 2005), an interesting subset of LTAG, which preserves almost all of the strong generative power of LTAG, and it is both weakly and strongly more powerful than CFG [1]. We will present a statistical incremental parsing for LTAG-spinal. As far as we know, this parser is the first comprehensive attempt of efficient statistical parsing with a formal grammar with provably stronger generative power than CFG, supporting the full *adjoining* operation, dynamic predicate coordination, as well as non-projective dependencies [2].

2 LTAG-spinal and the Treebank

We first briefly describe the LTAG-spinal formalism and the LTAG-spinal treebank to be used in this paper. More details are reported in (Shen and Joshi, 2005).

In LTAG-spinal, we have two different kinds of elementary trees, *initial* trees and *auxiliary* trees, which are the same as in LTAG. However, as the name implies, an initial tree in LTAG-spinal only contains the *spine* from the root to the anchor, and an auxiliary tree only contains the spine and the foot node directly connected to a node on the spine.

Three types of operations are used to connect the elementary trees into a derivation tree, which are *attachment*, *adjunction* and *conjunction*. We show LTAG-spinal elementary trees and operations with an example in Figure 1.

In Figure 1, each arc is associated with a character which represents the type of operation. We use **T** for a*t*tach, **A** for *a*djoin, and **C** for *c*onjoin.

[1]Further formal results are described in (Shen and Joshi, 2005). There is also some relationship of LTAG-spinal to the spinal form context-free tree grammar, as in (Fujiyoshi and Kasai, 2000)

[2]In (Riezler et al., 2002), the MaxEnt model was used to rerank the K-best parses generated by a rule-based LFG parser.

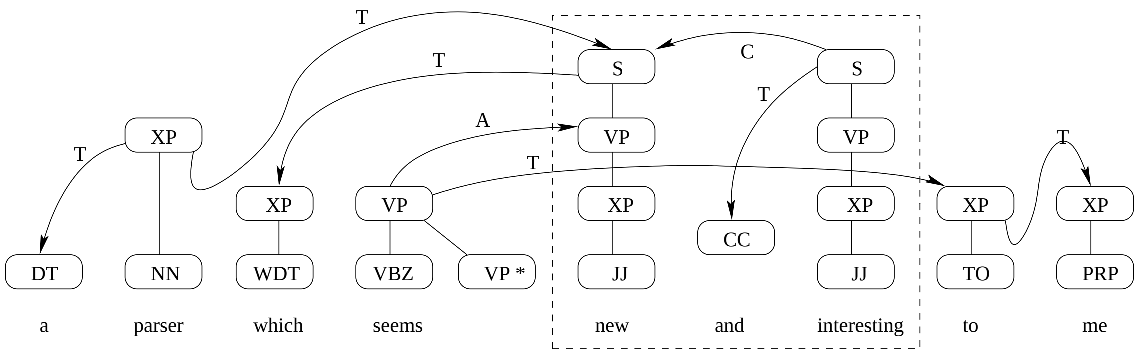

Figure 1: An example in LTAG-spinal. **A**=adjoin, **T**=attach, **C**=conjoin.

Attachment in LTAG-spinal is similar to *sister adjunction* (Chiang, 2000) in Tree Insertion Grammar (TIG) (Schabes and Waters, 1995). It represents a combination of *substitution* and *sister adjunction*. The *attachment* operation is designed to encode the ambiguity of an *argument* and an *adjunct*.

Adjunction inserts part of the spine and the foot node of an auxiliary tree into to the spine of another tree. The *adjunction* operation can effectively do wrapping, which distinguishes itself from *sister adjunction*. It is not difficult to see that adjunction only happens on the spine of a tree. This property will be exploited in the incremental parser.

Conjunction is similar to what was originally proposed in (Sarkar and Joshi, 1996). However, in LTAG-spinal, the conjunction operation is much easier to handle, since we only conjoin spinal elementary trees and we do not need to enumerate *contraction sets* for conjunction. In our formalization, *conjunction* can be treated as a special *adjunction*, however, this is beyond the scope of this paper.

We use the LTAG-spinal treebank described in (Shen and Joshi, 2005), which was extracted from the Penn Treebank (PTB) (Marcus et al., 1994) with Propbank (Palmer et al., 2005) annotations.

2.1 Relation to Traditional LTAG

LTAG-spinal preserves most of the strong generative power of LTAG. It can be shown that LTAG-spinal with adjoining restrictions (Joshi and Schabes, 1997) has stronger generative capacity as compared to CFG. For example, there exists an LTAG-spinal grammar that generates $\{a^n b^n c d^n e^n \mid n > 0\}$, which is not a context-free language.

A spinal elementary tree is smaller than a traditional LTAG elementary tree which contains all the substitution nodes of the arguments. In the LTAG-spinal formalism, both arguments and adjuncts are expected to be directly attached or adjoined onto a spine. In this sense, LTAG-spinal roughly satisfies *the fundamental TAG hypothesis: Every syntactic dependency is expressed locally within a single elementary tree* (Frank, 2002). The only difference is that, in LTAG-spinal, syntactic dependencies are represented via direct or local connections.

To better understand the meaning of this difference, we relate it to Frank's (2002) model for how the LTAG elementary trees are constructed. In Frank's model, all the elementary trees are built via *Marge* and *Move* operations, starting with a *local lexical array*. The resulting LTAG elementary trees are then combined with adjunction and substitution to build a derivation tree.

Thus, in a sense, the LTAG-spinal grammar opens a door to a *parallel* mechanism of building the elementary trees and the derivation tree. The spinal templates in LTAG-spinal only contain the path of projection from the anchor to the top node. A spinal template plus the root nodes of the subtrees attached to this template can be viewed as a traditional LTAG elementary tree. More specifically, it encodes a set of possible elementary trees if we distinguish substitution from sister adjunction. Thus, the LTAG-spinal parsing model to be proposed in Section 3 can be viewed as a parser at the meta-grammar (Candito, 1998; Kinyon and Prolo, 2002) level for traditional LTAG. Derivation tree construction and full-size elementary tree filtering are processed in parallel. Researches in statistical CFG parsing (Ratnaparkhi, 1997; Collins, 1999) and psycholinguistics

(Shieber and Johnson, 1993) showed that this strategy is desirable for NLP.

Furthermore, the way that we split a traditional LTAG elementary tree along the spine is similar to the method with which Evans and Weir (1997) compiled the XTAG English Grammar into finite state automata. In their work, this method was designed to employ shared structure in a rule-based parser. But here we extend this technique to statistical LTAG parsing.

2.2 Relation to Propbank

In building the LTAG-spinal Treebank, the Propbank information is used in the treebank extraction. As reported in (Shen and Joshi, 2005), tree transformation on PTB are employed to make it more compatible with the Propbank annotations. It was shown that 8 simple patterns of the path from a predicate to an argument account for 95.5% of the total pred-arg pairs. Thus, our high-quality parsing output will be very useful for semantic role labeling.

Arguments in Propbank are not *obligatory* complements. Therefore, we cannot treat the Propbank arguments as the *arguments* in LTAG. The ambiguity of argument and adjunct is reflected in the similarity of substitution and sister adjunction. This is one of the reasons that we do not distinguish substitution and sister adjunction in LTAG-spinal.

3 Incremental Parsing

We are especially interested in incremental parsing for the following two reasons. Firstly, the left to right strategy used in incremental parsing gives rise to a drastic boost in speed. Furthermore, there is also a strong connection between incremental parsing and psycholinguistics, and this connection is also observed in the LTAG formalism (Ferreira, 2000; Sturt and Lombardo, 2005).

In recent years, there have been many interesting works on incremental or semi-incremental parsing. By semi-incremental we mean the parsers that allow several rounds of left to right scans instead of one. Both left-corner strategy (Ratnaparkhi, 1997; Roark, 2001; Prolo, 2003; Henderson, 2003; Collins and Roark, 2004) and head-corner strategy (Henderson, 2000; Yamada and Matsumoto, 2003) were employed in incremental parsing. The head-corner approach is more natural to the LTAG formalism (Evans and Weir, 1997). In our approach, we use a stack of derivation treelets to represent the partial parsing result. Furthermore, the LTAG formalism allows us to handle non-projectivity dependencies, which cannot be generated by a CFG or a Dependency parser.

In fact, the idea of incremental parsing with LTAG is closely related to the work on Supertagging (Joshi and Srinivas, 1994). A supertager first assigns the correct LTAG elementary tree to each word. Then a Lightweight Dependency Analyzer (LDA) (Srinivas, 1997) composes the whole derivation tree with these elementary trees. We use incremental parsing to incorporate supertager and LDA dynamically.

The model of incremental LTAG parsing is also similar to Structured Language Modeling (SLM) in (Chelba and Jelinek, 2000). In SLM, the left context of history is represented with a stack of binary trees. At each step, one computes the likelihood of the current word, its tag and the operations over the new context trees.

3.1 Treatment of Coordination

Predicate coordination appears in about 1/6 of the sentences in PTB, therefore proper treatment of coordination, especially predicate coordination, is important to parsing of PTB.

Some recent results in psycholinguistic experiments (Sturt and Lombardo, 2005) showed a high degree of *eagerness* in building coordination structures which is absent in a bottom-up approach; A bottom-up parser waits for the second conjunct to be completed before combining the two conjuncts as for example in VP coordination, and then combine the coordinated VP with the subject of the left conjunct. Psycholinguistic results suggest that the right conjunct has to have access to the subject NP of the left conjunct. This can be achieved by first building the entire S on the left and then *adjoining* the right VP conjunct to the VP node of the left conjunct (Sturt and Lombardo, 2005).

We follow the strategy suggested by the psycholinguistic experiments, treating conjoining as a special adjoining operation.

3.2 The Parsing Algorithm

There are four different types of operations in our parser. Three of them are described in Section 2. The fourth operation is **generation**, which is used to generate a possible spine for a given word according to the context and the lexicon.

Our left to right parsing algorithm is a variant of the shift-reduce algorithm with beam-search. We use a stack of disconnected derivation treelets to represent the left context. When the parser reads a word, it first *generates* a list of possible spinal elementary trees for this word, For each elementary tree, we first push it into the stack. Then we recursively pop the top two treelets from the stack and push the combined tree into the stack until we choose not to combine the top two treelets with one of the three combination operations (we can also choose not to pop anything at the beginning). Then we shift to the next word. This model is called the **Flex Model** in this paper.

A potential problem with the Flex Model is that a single *LTAG derivation* tree can be generated by several *shift-reduce derivation* steps, which only differ in the order of operations. For example, we have three trees A, B and C. In LTAG derivation, A adjoins to B, and B adjoins to C. Then we have two different shift-reduce derivations, which are $(A \rightarrow (B \rightarrow C))$ and $((A \rightarrow B) \rightarrow C)$.

Now we introduce the **Eager Model**, an eager evaluation strategy. Any two elementary trees which are directly connected in the LTAG derivation tree are combined immediately when they can be combined in some context. Furthermore, they cannot be combined afterwards, if they miss the first chance. In the previous example, the parser will generate $((A \rightarrow B) \rightarrow C)$, while $(A \rightarrow (B \rightarrow C))$ is ruled out. Then for each LTAG derivation tree, there exists a unique left-to-right derivation.

The Eager Model is motived by the treatment of coordination in (Sturt and Lombardo, 2005), as we discussed in the previous section. For example, we have the following two sentences.

1. Quimby knows Tom likes Philly steak.
2. Quimby knows Tom likes Philly steak and Jerry likes pizza.

Suppose we are parsing these two sentences, and for each case the current word is *likes*, the fourth word. Now we have just the same local contexts for both cases. According to the Eager Model, the parser takes the same action according to the context, which is to combine the *knows* tree and the *likes* tree. For sentence 2, the second *likes* tree will be conjoined with the first *likes* tree later. This is compatible with the psycholinguistic preference.

In the following section, we will explain the parsing mechanism for the Eager Model with an example. The Flex Model is similar except that the order of operations is flexible to some extent.

3.3 An Example

Figure 2 shows the left to right parsing of the phrase *a parser which seems new and interesting to me* with the Eager Model.

In Figure 2, each arc is associated with a number and a character. The number represents the order of operation, and the character stands for the type of operation as in Figure 1. Furthermore we use **G** to represent Generate.

In step 1 and 2, two disconnected spines are generated for *a* and *parser*. The spine for *a* is attached to the spine for *parser* on the *NP* node in step 3.

In step 6, the spine for *new*, the first conjunct of the predicate coordination, is generated. Then the auxiliary tree for *seems* is adjoined to the spine for *new* at the node *VP*. the latter is further combined with *which*, and is attached to the tree for *parser*.

In step 13, the conjoin operation is used to combine the treelet anchored on *new* and the treelet anchored on *interesting*. Alignments between the two spines are built, through which argument sharing is implemented in an implicit and underspecified way.

In step 15, for the spine for *to*, the visible nodes of the conjoined treelet include nodes on some auxiliary trees adjoined on the left of the spines, like the root *VP* node for *seems*. In this way, a non-projective structure is generated, which is just the same as the wrapping adjoining in LTAG.

3.4 Machine Learning Algorithm

Many machine learning algorithms have been successfully applied to parsing, incremental parsing, or shallow parsing (Ratnaparkhi, 1997; Punyakanok and Roth, 2001; Lafferty et al., 2001; Taskar et al., 2003), which can be applied to our incremental parsing algorithm.

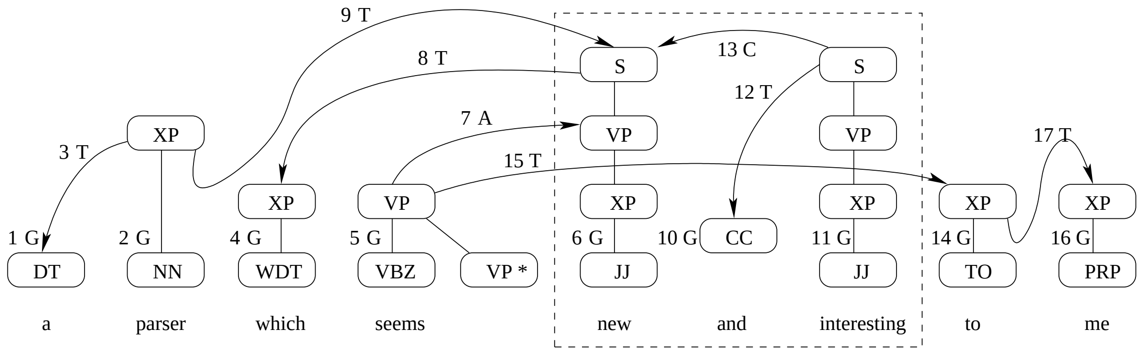

Figure 2: Incremental parsing with Eager Model. **A**=adjoin, **T**=attach, **C**=conjoin, **G**=generate

In this paper, we use the perceptron-like algorithm proposed in (Collins, 2002) which does not suffer from the label bias problem, and is fast in training. We also employ the voted perceptron algorithm (Freund and Schapire, 1999) and the *early update* technique as in (Collins and Roark, 2004).

3.5 Features

Features are defined in the format of (*operation, main spine, child spine, spine node, context*), where the *spine node* is the node on the *main spine* onto which the *child spine* is *attached* or *adjoined*. For *generate*, child spine and spine node are undefined, and for *conjoin* spine node is undefined. *context* describes the constituent label or lexical item associated with a certain node. The context of an operation includes the top two treelets involved in the operation as well as the two closest words on both sides of the current word.

- Context for *generate* :
  - The (-2, 2) window in the flat sentence.
  - The *visible* [3] spines on the topmost treelet.
- Context for *attach* and *adjoin* :
  - The (0, 2) window in the flat sentence.
  - The most recent spine previously attached or adjoined to the same location on the main spine.
  - The leftmost child spine attached to the child spines.
  - The spines that are *visible* before the operation and become *invisible* after the operation.
- Context for *conjoin* :
  - The (0, 2) window in the flat sentence.
  - The leftmost child spine attached to the main spine, which is the first adjunct.
  - The two leftmost children spines attached to the child spine, which is the current adjunct.

[3]The details are presented in (Shen, 2005).

We have about 1.4M features extracted from the gold-standard parses, and about 600K features dynamically extracted from the generated parses in 10 rounds of training with the Eager Model.

4 Experiments and Analysis

We use the LTAG-spinal treebank reported in (Shen and Joshi, 2005). The LTAG-spinal parse for the 39434 sentences extracted from WSJ section 2-21 are used as the training data. Section 24 is used as the development data. Section 23 are used for test[4].

We use syntactic dependency for evaluation. It is worth mentioning that, for predicate coordination, we define the dependency on the parent of the coordination structure and each of the conjunct predicate. For example, in Figure 1, we have dependency relation on (parser, *new*) and (parser, *interesting*). Compared with other dependency parsers on PTB, the dependency defined on LTAG-spinal reveals deeper relations because of the treatment of traditional adjoining and predicate coordination described above.

In the community of parsing, *labeled recall* and *labeled precision* on phrase structures are often used for evaluation. However, in our experiments we cannot evaluate our parser with respect to the phrase structures in PTB. As shown in (Shen and Joshi, 2005), various irrecoverable tree transformations

[4]The LTAG-spinal treebank contains 2401 out of 2416 sentences in section 23.

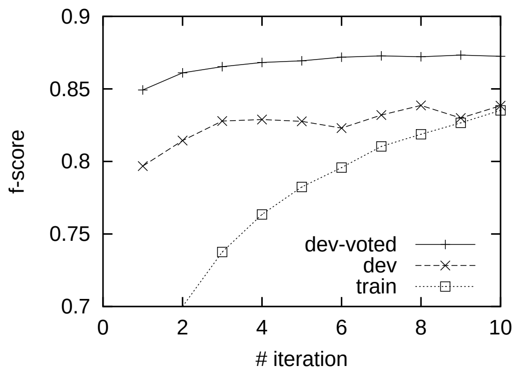

Figure 3: f-score of syntactic dependency on the *development* data with the Eager Model

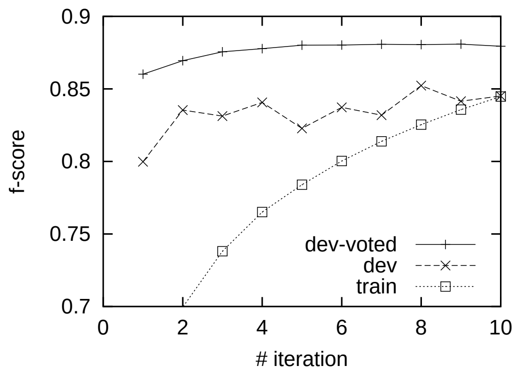

Figure 4: f-score of syntactic dependency on the *development* data with the Flex Model

were used to extract the LTAG-spinal treebank according the Propbank annotation on PTB. Therefore, we use syntactic dependency for evaluation.

4.1 Eager vs. Flex

We first train our incremental parser with Eager Model and Flex Model respectively. In the training, beam width is set to 10. Lexical features are limited to words appearing for at least 5 times in the training data. Figure 3 and Figure 4 show the learning curves on the training and the development data. The X axis represents the number of iterations of training, and the Y axis represents the f-score of dependency with respected to the LTAG derivation tree.

Since *early update* is used, the f-score on the training data is very low at the beginning. In both cases, the voted weights provide an f-score which is more than 3% higher. The voted results converge faster and are more stable. The result with Flex Model is 0.6% higher than the one with Eager Model, but the parsing time is much longer with Flex Model as we will show later.

We use the voted weights obtained after 10 rounds of iteration for the evaluation on the test data. We achieve an f-score of **88.7%** on dependency with the Eager Model, and **89.3%** with the Flex Model. The Flex Model achieves better performance because it allows the decision of operation to be delayed until there is enough context information.

4.2 K-Best Parsing

The next experiment is on K-best parsing. As a first attempt, we just use the same algorithm as in the previous section, except that we study the oracle parse, or the best parse, among the top 10 parses. The f-score on the oracle in top 10 in the development data is 88.5%, while the f-score of the top candidate is 87.3%, as shown in Table 1. However, we are not satisfied with the score on oracle, which is not good enough for post-processing, i.e. parse reranking.

Table 1: F-score of the oracle parse in the 10-best parses on the *development* data with the Eager Model

algorithm	f-score%
top (eager)	87.3
oracle (eager)	88.5
top (eager+combined parses)	87.4
oracle (eager+combined parses)	91.0

We notice that from a single partial derivation we can generate a large set of different partial derivations, just by combining the elementary tree of the next word. It is easy to see that these similar derivations may use up the search beam quickly, which is not good for parse search. Many of the new derivations share the same dependency structure. So we revised our learning procedure by combining derivations with the same dependency structure before each shift operation. We repeated the K-best parsing experiments by using **Combined Parses** as described above, and achieved significant improvement on the oracle, as shown in Table 1.

Figure 5 shows the f-score of the oracle on K-best parsing using combined parses on the test data. For each K-best oracle test, we set the beam width to K

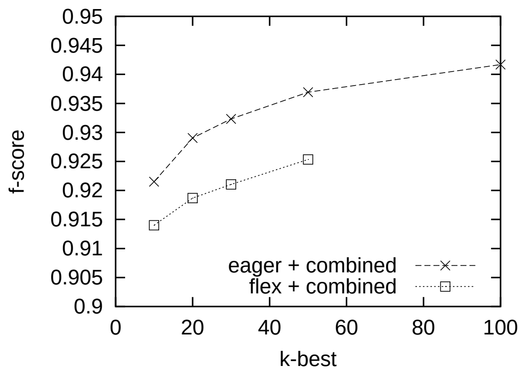

Figure 5: f-score of the oracle on the *test* data

Table 2: Speed of parsing on the *test* data set. Here cp? = whether the method of Combined Parses is used; sen/sec = sentence per second; top = top candidate given by the parser; oracle = oracle of the K-best parses where K equals the width of the beam.

model	cp?	beam	sen/sec	f-score%
single best				top
flex	no	10	0.37	89.3
eager	no	10	0.79	88.7
K-best				oracle
eager	yes	10	0.62	92.2
eager	yes	20	0.31	92.9
eager	yes	30	0.22	93.2
eager	yes	50	0.13	93.7
eager	yes	100	0.07	94.2

in parsing. The f-score of oracle in 100-best parsing is **94.2%** with the Eager Model + Combined Parses.

4.3 Speed of Parsing

Efficiency is important to the application of incremental parsing. This set of experiments is related to the speed of our parser on single best and K-best parsing with both the Eager Model and the Flex Model. All the experiments are performed on a Linux node with two 1.13GHz PIII CPUs and 2GB RAM. The parser is coded in Java.

Table 2 shows that the Eager Model is more than two times faster than the Flex Model, as we expected. The time spent on K-best parsing is proportional to the beam width.

5 Discussion and Future Work

The parser proposed in this paper is an incremental parser, so the accuracy on dependency is lower than that for chart parsers, for example like those reported in (Collins, 1999; Charniak, 2000).[5] However, it should be noted that the dependencies computed by our parser are *deeper* than those calculated by parsers working directly on PTB. This is due to the treatment of adjunction and coordination.

On the other hand, the LTAG-spinal treebank used in this paper shows a high degree of compatibility with the Propbank, as shown in (Shen and Joshi, 2005), so the LTAG derivations given by the parser are very useful for predicate-argument recognition. We plan to improve the parsing performance by reranking and extend our work to semantic parsing (Mooney, 2004).

Another interesting topic is whether this parser can be applied to languages which have various long-distance scrambling, as in German. It appears that by carefully modifying the definition of *visible* spines, we can represent scrambling structures, which at present can only be represented by Multi-Component TAG (Becker et al., 1991).

6 Conclusions

In this paper, we present an efficient incremental parser for LTAG-spinal, a variant of LTAG which is both linguistically and psycholinguistically motivated. As far as we know, the statistical incremental parser proposed in this paper is the first comprehensive attempt of efficient statistical parsing with a formal grammar with provably stronger generative power than CFG, supporting the *adjoining* operation, dynamic predicate coordination, as well as non-projective dependencies.

We have trained and tested our parser on the LTAG-spinal treebank, extracted from the Penn Treebank with Propbank annotation, Using gold standard POS tags as part of the input, the parser achieves an f-score of 89.3% for syntactic dependency on section 23 of PTB. Because of the treatment of adjunction and predicate coordination, These dependencies, which are defined on LTAG-spinal derivation trees, are deeper than the dependencies extracted from PTB alone with head rules.

[5]We plan to work on a chart parser for LTAG-spinal.

Abstract

In the REAP system, users are automatically provided with texts to read targeted to their individual reading levels. To find appropriate texts, the user's vocabulary knowledge must be assessed. We describe an approach to automatically generating questions for vocabulary assessment. Traditionally, these assessments have been hand-written. Using data from WordNet, we generate 6 types of vocabulary questions. They can have several forms, including wordbank and multiple-choice. We present experimental results that suggest that these automatically-generated questions give a measure of vocabulary skill that correlates well with subject performance on independently developed human-written questions. In addition, strong correlations with standardized vocabulary tests point to the validity of our approach to automatic assessment of word knowledge.

1 Introduction

The REAP system automatically provides users with individualized authentic texts to read. These texts, usually retrieved from the Web, are chosen to satisfy several criteria. First, they are selected to match the reading level of the student (Collins-Thompson and Callan, 2004). They must also have vocabulary terms known to the student. To meet this goal, it is necessary to construct an accurate model of the student's vocabulary knowledge (Brown and Eskenazi, 2004). Using this model, the system can locate documents that include a given percentage (e.g., 95%) of words that are known to the student. The remaining percentage (e.g. 5%) consists of new words that the student needs to learn. This percentage is controlled so that there is not so much stretch in the document that the student cannot focus their attention on understanding the new words and the meaning of the text. After reading the text, the student's understanding of new words is assessed. The student's responses are used to update the student model, to support retrieval of furture documents that take into account the changes in student word knowledge.

In this paper, we describe our work on automatic generation of vocabulary assessment questions. We also report results from a study that was designed to assess the validity of the generated questions. In addition to the importance of these assessments in the REAP system, tests of word knowledge are central to research on reading and language and are of practical importance for student placement and in enabling teachers to track improvements in word knowledge throughout the school year. Because tests such as these are traditionally hand-written, development is time-consuming and often relies on methods that are informal and subjective. The research described here addresses these issues through development of automated, explicit methods for generation of vocabulary tests. In addition, these tools are designed to capture the graded and complex nature of word knowledge, allowing for more fine-grained assessment of word learning.

2 Measuring Vocabulary Knowledge

Word knowledge is not all-or-none. Rather, there are different aspects, such as knowledge of the spoken form, the written form, grammatical behav-

Proceedings of Human Language Technology Conference and Conference on Empirical Methods in Natural Language Processing (HLT/EMNLP), pages 819–826, Vancouver, October 2005. ©2005 Association for Computational Linguistics

ior, collocation behavior, word frequency, stylistic register constraints, conceptual meaning, and the associations a word has with other related words (Nation, 1990). In this paper, we focus on knowledge of conceptual word meaning. Because word meaning itself is complex, our focus is not simply on all-or-none estimates of vocabulary knowledge, but also on graded and incomplete knowledge of meanings that readers possess for different words and at different stages of acquisition.

Several models have been proposed to account for these multiple levels of word knowledge. For example, Dale posited four stages of knowledge of word meaning (Dale and O'Rourke, 1965). In stage 1, the subject has never seen the word. In stage 2, she has seen the word but is unable to verbalize its meaning. In stage 3, the subject recognizes the word in a given context and has partial word knowledge. In stage 4, the subject has full word knowledge, and can explain the word meaning so that its usage is clear in multiple contexts.

Stahl (1986) proposed a similar model of word knowledge, the levels of which overlap with Dale's last two stages. According to this model, the first level is characterized by association processing, or the passive association of the new word meaning with other, familiar concepts. The second level, comprehension processing, involves active comprehension of the word in a particular context. The third level, generation processing, requires usage of a word in a novel context reflecting a deep (and multidimensional) understanding of its meaning.

Taking Stahl's framework as a working model, we constructed multiple types of vocabulary questions designed to assess different "stages" or "levels" of word knowledge.

3 Question Generation

In this section, we describe the process used to generate vocabulary questions. After introducing the WordNet resource we discuss the six question types and the forms in which they appear. The use of distractors is covered in section 3.3.

3.1 WordNet

WordNet is a lexical resource in which English nouns, verbs, adjectives, and adverbs are grouped into synonym sets. A word may appear in a number of these synonym sets, or synsets, each corresponding to a single lexical concept and a single sense of the word (Fellbaum ed., 1998). The word "bat" has ten distinct senses and thus appears in ten synsets in WordNet. Five of these senses correspond to noun senses, and the other five correspond to verb senses. The synset for the verb sense of the word which refers to batting one's eyelashes contains the words "bat" and "flutter", while the synset for the noun sense of the word which refers to the flying mammal contains the words "bat" and "chiropteran". Each sense or synset is accompanied by a definition and, often, example sentences or phrases. A synset can also be linked to other synsets with various relations, including synonym, antonym, hypernym, hyponym, and other syntactic and semantic relations (Fellbaum ed., 1998). For a particular word sense, we programmatically access WordNet to find definitions, example phrases, etc.

3.2 Question Types

Given Stahl's three levels of word mastery and the information available in WordNet, we generated 6 types of questions: definition, synonym, antonym, hypernym, hyponym, and cloze questions.

In order to retrieve data from WordNet, we must choose the correct sense of the word. The system can work with input of varying specificity. The most specific case is when we have all the data: the word itself and a number indicating the sense of the word with respect to WordNet's synsets. When the target words are known beforehand and the word list is short enough, the intended sense can be hand-annotated. More often, however, the input is comprised of just the target word and its part of speech (POS). It is much easier to annotate POS than it is to annotate the sense. In addition, POS tagging can be done automatically in many cases. In the REAP system, where the user has just read a specific text, the words of the document were already automatically POS annotated. When there is only one sense of the word per part of speech, we can simply select the correct sense of the word in WordNet. Otherwise, we select the most frequently used sense of the word with the correct POS, using WordNet's frequency data. If we have only the word, we select the most frequent sense, ignoring part of speech. Future work will use word sense disambiguation techniques to automatically determine the correct word sense given a document that includes the target word, as in REAP (Brown and Eskenazi, 2004).

Once the system has determined the word sense, it can retrieve data from WordNet for each of the 6 question types. The definition question requires a definition of the word, available in WordNet's gloss for the chosen sense. The system chooses the first definition which does not include the target word. This question should provide evidence for the first of Stahl's three levels, association processing, although this was not explicitly evaluated.

The synonym question has the testee match the target word to a synonym. The system can extract this synonym from WordNet using two methods. One method is to select words that belong to the same synset as the target word and are thus synonyms. In addition, the synonym relation in WordNet may connect this synset to another synset, and all the words in the latter are acceptable synonyms. The system prefers words in the synset to those in synonym synsets. It also restricts synonyms to single words and to words which are not morphological variants of the target word. When more than one word satisfies all criteria, the most frequently used synonym is chosen, since this should make the question easier. This question could be considered either association processing or comprehension processing. If the testee has seen this synonym (e.g. as a hint), this question type would require association processing as a word is simply being associated with another already-presented word. Otherwise, this may require comprehension processing – understanding beyond memorization.

The antonym question requires matching a word with an antonymous word. WordNet provides two kinds of relations that can be used to procure antonyms: direct and indirect antonyms. Direct antonyms are antonyms of the target word, whereas indirect antonyms are direct antonyms of a synonym of the target. The words "fast" and "slow" are direct antonyms of one another. The word "quick" does not have a direct antonym, but it does have an indirect antonym, "slow", via "fast", its synonym. When more than one antonym is available, the most frequently used is chosen. Unless the testee has already seen the antonym, this type of question is normally considered to provide evidence for Stahl's second level, comprehension processing.

The hypernym and hyponym questions are similar in structure. Hypernym is the generic term used to describe a whole class of specific instances. The word "organism" is a hypernym of "person". Hyponyms are members of a class. The words "adult", "expert" and "worker" are hyponyms of "person". For the questions the testee matches the target word to either a hypernym or hyponym. For more than one possibility, the most frequently used term is chosen. Unless the testee has previously seen the hypernym or hyponym, these questions are normally regarded as providing evidence for Stahl's second level.

Cloze is the final question type. It requires the use of the target word in a specific context, either a complete sentence or a phrase. The example sentence or phrase is retrieved from the gloss for a specific word sense in WordNet. There is often more than one example phrase. The system prefers longer phrases, a feature designed to increase the probability of retrieving complete sentences. Passages using the target word are preferred, although examples for any of the words in the synset are appropriate. The present word is replaced by a blank in the cloze question phrase. Some consider a cloze question to be more difficult than any of the other question types, but it is still expected to provide evidence for Stahl's second level.

Although our question types provide evidence for the highest level of schemes such as Dale's four stages, they do not provide evidence for Stahl's highest level, generation processing, where the testee must, for instance, write a sentence using the word in a personalized context. We expect questions that provide evidence of this level to require free-form or near-free-form responses, which we do not yet allow. We expect the six question types to be of increasing difficulty, with definition or synonym being the easiest and cloze the hardest.

3.3 Question Forms

Each of the 6 types of questions can be generated in several forms, the primary ones being wordbank and multiple-choice. In wordbank, the testee sees a list of answer choices, followed by a set of questions or statements (see Figure 1). For the definition version, each of the items below the wordbank is a definition. The testee must select the word which best corresponds to the definition. For the synonym and antonym questions, the testee selects the word which is the most similar or the most opposite in meaning to the synonym or antonym. For the hypernym and hyponym question types, the testee is asked to complete phrases such as "___ is a kind of person" (with target "adult") or "person is a kind of ___" (with target "organism"). In the cloze question, the testee fills in the blank with the appropriate word. There is traditionally one question for each target word in the wordbank. These questions require no information beyond the target words and their definitions, synonyms, hypernyms, etc.

Wordbank:

verbose   infallible   obdurate   opaque

Choose the word from the wordbank that best completes each phrase below:

1. ___ windows of the jail
2. the Catholic Church considers the Pope ___
3. ___ and ineffective instructional methods
4. the child's misery would move even the most ___ heart

Fig. 1. Example Wordbank Question

The second generated form is multiple-choice, with one question per target word. The testee sees the main question, the stem, followed by several answer choices, of which only one is correct (see Figure 2). Depending on the question type, the target word may appear in either the stem or the answer choices. For the definition question type, the stem holds the definition of the target word and one of the answer choices is the target word. For the word "verbose", the stem would be "using or containing too many words" and the choices "ancillary", "churlish", "verbose", and "convivial". The cloze question is of a similar form, with the stem containing the example sentence or phrase with a blank where the target word should be used. For "verbose", we have the stem "___ and ineffective instructional methods" and choices "verbose", "incipient", "invidious", and "titular". For the synonym, antonym, hypernym, and hyponym questions, the target word appears in the stem instead of the answer choices. The synonym question for the word "verbose" would have the stem "Select the word that is most similar in meaning to the word verbose" with choices "inflammable", "piping", matrilineal", and "long-winded". The antonym question would have the stem "Select the word that is most opposite in meaning to the word verbose" and the choices "discernable", "concise", "unbroken", and "soused". Figure 2 shows a formatted example of an automatically generated multiple-choice cloze question for the word "obdurate".

Choose the word that best completes the phrase below:

the child's misery would move even the most ___ heart

A) torpid
B) invidious
C) stolid
D) obdurate

Fig. 2. Example Multiple-Choice Cloze Question

Two issues to consider when creating multiple-choice format questions are the wording or appearance of the questions and the criteria for selection of distractors. We followed the guidelines for good multiple-choice questions described by researchers such as Graesser and Wisher (2001). In accord with these guidelines, our questions had 4 choices, although the number of choices is a variable supplied to the question generation software. We also considered the most appropriate wording for these questions, leading us to choose stems such as "Select the word that is most similar in meaning to the word *plausible*" for the synonym question rather than "Choose the word that means the same as the word *plausible*." The latter would be problematic when the correct answer is a near-synonym rather than a word with precisely the same meaning.

Concerning distractor choice, the question generation system chooses distractors of the same part of speech and similar frequency to the correct answer, as recommended by Coniam (1997). For the synonym, antonym, hypernym, and hyponym questions, the correct answer is the highest frequency word of *all* the words chosen from WordNet that satisfy all the criteria. Thus, the distractors are of the same POS and similar frequency to the synonym, antonym, or whatever word is the correct answer, as opposed to the target word. The system chooses distractors from Kilgarriff's (1995) word frequency database, based on the British National Corpus (BNC) (Burnage, 1991). The system chooses 20 words from this database that are of the same POS and are equal or similar in frequency to the correct answer, and randomly chooses the distractors from these words. Since the distractors may be different for each run of the question generation software, slightly different versions of the same basic question may appear. The words of the BNC and the word frequency database have been POS tagged using the CLAWS tagger (Leech, 1994). This tagger uses detailed POS tags, enabling us to choose distractors that are, for instance, verbs in the past tense, when the correct answer is such as verb, instead of selecting verbs of unknown tense. In the definition and cloze questions, the correct answer is the target word itself, so distractors are chosen based on this word. The system also restricts distractors to be in the list of target words so that the testee cannot simply choose the word that appears in the stems of other questions.

An alternate multiple-choice question format is used when the testee has just read a document using the target word, as in the REAP system (Brown and Eskenazi, 2004). In this case, the system also attempts to finds words which may be semantically related to the correct answer, as in (Nagy, 1985). This is done by choosing distractors that satisfy the standard criteria and were present in the document. This should increase the chance that the distractors are semantically related and eliminate the chance that a testee will simply select as the correct answer the word that appeared in the document they just read, without understanding the word meaning.

4 Question Assessment

The validity of the automatically generated vocabulary questions was examined in reference to human-generated questions for 75 low-frequency English words. We compared student performance (accuracy and response time) on the computer and human-generated questions. We focused on the automatically generated multiple-choice questions, with distractors based on frequency and POS. We did not examine using more complicated strategies for picking distractors or assume there was an associated text. Four of the six computer-generated question types were assessed: the definition, synonym, antonym, and cloze questions. Hypernym and hyponym questions were excluded, since we were unable to generate a large number of these questions for adjectives, which constitute a large portion of the word list. Subject scores on the computer and human-generated assessments were compared with scores on standardized measures of reading and vocabulary skill, as described below.

4.1 Question Coverage

Potential experimental stimuli comprised 156 low-frequency and rare English words that have been used in previous studies of vocabulary skill in native English-speaking adults. We first examined the percentage of words for which we could generate various question types. We were unable to generate any questions for 16 of these words, or ~9% of the list, since they were not in WordNet. Table 1 shows the percentage of words for which each of the four question types was generated. All four questions were able to be generated for only 75 (about half) of the words. Therefore, the experimental word list included only these 75 items. Given the rarity of the words, we predicted that the percentage of words for which we could generate questions would be lower than average. However, we expected that the percentage of words for which we could generate synonym and antonym questions to be higher than average, due to the heavy focus on adjectives in this list.

Question type	Percentage of Questions Generated
Definition Question	91%
Synonym Question	80%
Antonym Question	60%
Cloze Question	60%

Table 1. Question Coverage for the 156-Word List

4.2 Experiment Design

Behavioral measures of vocabulary knowledge were acquired for the 75 target words using the four computer-generated question types described above, as well as five human-generated question types. The human-generated questions were developed by a group of three learning researchers, without knowledge of the computer-generated question types. Researchers were asked merely to develop a set of question types that could be used to assess different levels, or different aspects, of word knowledge. Examples of each question type (including distractors) were hand-written for each of the 75 words.

Two of the five human-generated assessments, the synonym and cloze questions, were similar in form to the corresponding computer-generated question types in that they had the same type of stem and answer. The other three human-generated questions included an inference task, a sentence completion task, and a question based on the Osgood semantic differential (Osgood, 1970). In the inference task, participants were asked to select a context where the target word could be meaningfully applied. For example, the correct response to the question "Which of the following is most likely to be lenitive?" was "a glass of iced tea," and distractors were "a shot of tequila," "a bowl of rice," and "a cup of chowder." In the sentence completion task, the participant was presented with a sentence fragment containing the target word and was asked to choose the most probable completion. For example, the stem could be "The music was so lenitive…," with the correct answer "…it was tempting to lie back and go to sleep," and with distractors such as "…it took some concentration to appreciate the complexity." The fifth question type was based on the Osgood semantic differential, a factor-analytic model of word-level semantic dimensions (Osgood, 1970). Numerous studies using the Osgood paradigm have shown that variability in the semantic "structure" of word meanings can largely be accounted for in terms of three dimensions, valence (good–bad), potency (strong–weak), and activity (active–passive). In our version of the Osgood task, subjects were asked to classify a word such as "lenitive" along one of these dimensions (e.g., more good or more bad).

In addition to the human-generated questions, we administered a battery of standardized tests, including the Nelson-Denny Reading Test, the Raven's Matrices Test, and the Lexical Knowledge Battery. The Nelson-Denny Reading Test is a standardized test of vocabulary and reading comprehension (Brown, 1981). The Raven's Matrices Test is a test of non-verbal reasoning (Raven, 1960). The Lexical Knowledge Battery has multiple subsections that test orthographic and phonological skills (Perfetti and Hart, 2001).

Twenty-one native-English speaking adults participated in two experiment sessions. Session 1 lasted for about one hour and included the battery of vocabulary and reading-related assessments described above. Session 2 lasted between two and three hours and comprised 10 tasks, including the five human and four computer-generated questions. The experiment began with a confidence-rating task, in which participants indicated with a key press how well they knew the meaning of each target word (on a 1–5 scale). This task was not speeded. For the remaining tasks, subjects were asked to respond "as quickly as possible without making errors." Test items for a given question type were answered together. The order of the tasks (question types) and the order of the 75 items within each task were randomized across subjects.

4.3 Experiment Results

We report on four aspects of this study: participant performance on questions, correlations between question types, correlations with confidence ratings, and correlations with external assessments.

Mean accuracy scores for each question type varied from .5286 to .6452. Performance on individual words and across subjects (averaging across words) varied widely. The easiest question types (those with the highest average accuracy), were the computer-generated definition task and the human-generated semantic differential task, both having mean accuracy scores of .6452. The hardest was the computer-generated cloze task, with a mean score of .5286. The accuracy on computer-generated synonym and antonym questions fall between these two limits, with slightly greater accuracy on the synonym type. This implies a general ordering of difficulty from definition to cloze, as expected. The accuracies on the other human-generated questions also fall into this range.

We also computed correlations between the different question types. Mean accuracies were highly and statistically significantly correlated across the nine question types ($r>.7$, $p<.01$ for all correlations). The correlation between participant accuracy on the computer-generated synonym and the human-generated synonym questions was particularly high ($r=.906$), as was the correlation between the human and computer cloze questions ($r= .860$). The pattern of correlations for the response-time (RT) data was more complicated and is discussed elsewhere (Frishkoff et al, In Prep). Importantly, RTs for the human versus computer versions of both the synonym and cloze questions were strongly correlated ($r>.7$, $p<.01$), just as for the accuracy results. The accuracy correlations imply that the computer-generated questions are giving a measure of vocabulary skill for specific words that correlates well with that of the human-generated questions.

An item analysis (test item discrimination) was also performed. For each word, scores on a particular question type were compared with the composite test score for that word. This analysis revealed relatively low correlations ($.12 < r < .25$) between the individual question types and the test as a whole (without that question type). Since the question types were designed to test different aspects of vocabulary knowledge, this result is encouraging.

In addition, the average total-score correlations for the four computer-generated questions (r=.18) and for the five human-generated questions (r=.19) were not significantly different. This is positive, since it suggests that the human and computer-generated vocabulary test are accounting for similar patterns of variance across the different question types.

The average correlation between accuracy on the question types and confidence ratings for a particular word was .265. This correlation was unexpectedly low. This may be because participants thought they knew these words, but were confused by their rarity, or because confidence simply does not correlate well with accuracy. Further work is needed to determine whether confidence ratings can be accurate predictors of vocabulary knowledge.

Finally, we examined correlations between participant performance on the nine question types and the external assessments. The correlations between the accuracy on each of the nine question types and the Nelson-Denny vocabulary subtest were fairly high (.61 < r < .85, p=.01 for all comparisons). Thus, both the computer and human-generated questions show good correspondence with an external assessment of vocabulary skill. Correlations between the accuracy on the question types and the Nelson-Denny reading comprehension test were mixed, showing a higher correlation with vocabulary than reading comprehension. Correlations between the accuracy on the nine question types and the Raven's Matrices test of nonverbal reasoning were positive, but low and not statistically significant. This provides strong evidence that the computer-generated vocabulary questions tap vocabulary knowledge specifically, rather than intelligence in general.

5 Related Work

Cloze tests are one area of related work. They were originally intended to measure text readability (Taylor, 1953) since native speakers should be able to reproduce certain removed words in a readable text. Other researchers have used it to assess reading comprehension (Ruddell, 1964), with students filling in the blanks, given a high quality text. The main issue in automating the creation of cloze tests is determining which words to remove from the text. Coniam (1997) examined a several options for determining the words to remove and produced relatively good-quality cloze tests by removing words with the same POS or similar frequency.

Wolfe (1976) automatically generated reading comprehension questions. This involved various techniques for rewriting sentences into questions, testing syntactic understanding of individual sentences. Of the 50 questions Wolfe was able to generate for a single text, 34 were found to be satisfactory. More recently, Kunichika (2003) carried out work in automatically generating reading comprehension questions that included both syntactic and semantic questions, and was able to generate several different types of questions, including asking about the content of a sentence, using dictionaries of synonyms and antonyms to generate questions such as "Is Jane busy?" from sentences like "Jane is free.", and testing semantic understanding across sentence boundaries. Approx. 93% of the generated questions were found to be satisfactory.

Aist (2001) automatically generated factoids to assist students reading. The factoids gave a synonym, an antonym, or a hypernym for the word, which were automatically extracted from WordNet. He also automated the creation of a single type of vocabulary question, with the target word in the stem and the correct answer a synonym, hypernym, or sibling from WordNet. It is unclear what type of vocabulary knowledge this question would tap, given the different possible answers.

6 Conclusions

Extending our experiments to the question types that we have not yet assessed is an important next step. In addition, we want to assess questions individually, evaluating their use of distractors. Finally, we need to assess questions generated on word lists with different characteristics.

There are also a number of ongoing extensions to this project. One is the creation of new question types to test other aspects of word knowledge. Another is using other resources such as text collections to enable us to generate more questions per word, especially for the cloze questions. In addition, we are looking at ways to predict word knowledge using confidence ratings and morphological and semantic cohorts in situations where we cannot perform a standard assessment or cannot test all the vocabulary words we would like to.

In this paper, we have described our work in automatically generating questions for vocabulary assessment. We have described the six types of computer-generated questions and the forms in which they appear. Finally, we have presented evidence that the computer-generated questions give a measure of vocabulary skill for individual words that correlates well with human-written questions and standardized assessments of vocabulary skill.

Parallelism in Coordination as an Instance of Syntactic Priming: Evidence from Corpus-based Modeling

Abstract

Experimental research in psycholinguistics has demonstrated a parallelism effect in coordination: speakers are faster at processing the second conjunct of a coordinate structure if it has the same internal structure as the first conjunct. We show that this phenomenon can be explained by the prevalence of parallel structures in corpus data. We demonstrate that parallelism is not limited to coordination, but also applies to arbitrary syntactic configurations, and even to documents. This indicates that the parallelism effect is an instance of a general syntactic priming mechanism in human language processing.

1 Introduction

Experimental work in psycholinguistics has provided evidence for the so-called parallelism preference effect: speakers processes coordinated structures more quickly when the two conjuncts have the same internal syntactic structure. The processing advantage for parallel structures has been demonstrated for a range coordinate constructions, including NP coordination (Frazier et al., 2000), sentence coordination (Frazier et al., 1984), and gapping and ellipsis (Carlson, 2002; Mauner et al., 1995).

The parallelism preference in NP coordination can be illustrated using Frazier et al.'s (2000) Experiment 3, which recorded subjects' eye-movements while they read sentences like (1):

(1) a. Terry wrote a long novel and <u>a short poem</u> during her sabbatical.
 b. Terry wrote a novel and <u>a short poem</u> during her sabbatical

Total reading times for the underlined region were faster in (1-a), where *short poem* is coordinated with a syntactically parallel noun phrase (*a long novel*), compared to (1-b), where it is coordinated with a syntactically non-parallel phrase.

These results raise an important question that the present paper tries to answer through corpus-based modeling studies: what is the mechanism underlying the parallelism preference? One hypothesis is that the effect is caused by low-level processes such as *syntactic priming*, i.e., the tendency to repeat syntactic structures (e.g., Bock, 1986). Priming is a very general mechanism that can affect a wide range of linguistic units, including words, constituents, and semantic concepts. If the parallelism effect is an instance of syntactic priming, then we expect it to apply to a wide range of syntactic construction, and both within and between sentences. Previous work has demonstrated priming effects in corpora (Gries, 2005; Szmrecsanyi, 2005); however, these results are limited to instances of priming that involve a choice between two structural alternatives (e.g., dative alternation). In order to study the parallelism effect, we need to model priming as general syntactic repetition (independent of the structural choices available). This is what the present paper attempts.

Frazier and Clifton (2001) propose an alternative account of the parallelism effect in terms of a *copying mechanism*. Unlike priming, this mechanism is highly specialized and only applies to coordinate structures: if the second conjunct is encountered, then instead of building new structure, the language processor simply copies the structure of the first conjunct; this explains why a speed-up is observed if the second conjunct is parallel to the first one. If the copying account is correct, then we would expect parallelism effects to be restricted to coordinate structures and would not apply in other contexts.

In the present paper, we present corpus evidence that allows us to distinguish between these two competing explanations. Our investigation will proceed as follows: we first establish that there is evidence for a parallelism effect in corpus data (Section 3). This is a crucial prerequisite for our wider investigation: previous work has only dealt with parallelism in comprehension, hence we need to establish that parallelism is also present in production data, such as corpus data. We then investigate whether the parallelism effect is restricted to coordination, or whether it also applies also arbitrary syntactic configurations. We also test if parallelism can be found for larger segments of text, including, in the limit, the whole document (Section 4). Then we investigate parallelism in dialog, testing the psycholinguistic prediction that parallelism in dialog occurs between speakers (Section 5). In the next section, we discuss a number of methodological issues and explain the way we measure parallelism in corpus data.

2 Adaptation

Psycholinguistic studies have shown that priming affects both speech production (Bock, 1986) and comprehension (Branigan et al., 2005). The importance of comprehension priming has also been noted by the speech recognition community (Kuhn and de Mori, 1990), who use so-called caching language models to improve the performance of speech comprehension software. The concept of caching language models is quite simple: a cache of recently seen words is maintained, and the probability of words in the cache is higher than those outside the cache.

While the performance of caching language models is judged by their success in improving speech recognition accuracy, it is also possible to use an abstract measure to diagnose their efficacy more closely. Church (2000) introduces such a diagnostic for lexical priming: adaptation probabilities. Adaptation probabilities provide a method to separate the general problem of priming from a particular implementation (i.e., caching models). They measure the amount of priming that occurs for a given construction, and therefore provide an upper limit for the performance of models such as caching models.

Adaptation is based upon three concepts. First is the *prior*, which serves as a baseline. The prior measures the probability of a word appearing, ignoring the presence or absence of a prime. Second is the *positive adaptation*, which is the probability of a word appearing given that it has been primed. Third is the *negative adaptation*, the probability of a word appearing given it has not been primed.

In Church's case, the prior and adaptation probabilities are estimated as follows. If a corpus is divided into individual documents, then each document is then split in half. We refer to the halves as the prime set (or prime half) and the target set (or target half).[1] We measure how frequently a document half contains a particular word. For each word w, there are four combinations of the prime and target halves containing the word. This gives us four frequencies to measure, which are summarized in the following table:

$f_{w_{p,t}}$	$f_{w_{\bar{p},t}}$
$f_{w_{p,\bar{t}}}$	$f_{w_{\bar{p},\bar{t}}}$

These frequencies represent:

$f_{w_{p,t}}$	=	# of times w occurs in prime set and target set
$f_{w_{\bar{p},t}}$	=	# of times w occurs in target set but not prime set
$f_{w_{p,\bar{t}}}$	=	# of times w occurs in prime set but not target set
$f_{w_{\bar{p},\bar{t}}}$	=	# of times w does not occur in either target set or prime set

In addition, let N represent the sum of these four frequencies. From the frequencies, we may formally define the prior, positive adaptation and negative adaptation:

(1) **Prior** $$P_{\text{prior}}(w) = \frac{f_{w_{p,t}} + f_{w_{\bar{p},t}}}{N}$$

(2) **Positive Adaptation** $$P_{+}(w) = \frac{f_{w_{p,t}}}{f_{w_{p,t}} + f_{w_{p,\bar{t}}}}$$

(3) **Negative Adaptation** $$P_{-}(w) = \frac{f_{w_{\bar{p},t}}}{f_{w_{\bar{p},t}} + f_{w_{\bar{p},\bar{t}}}}$$

In the case of lexical priming, Church observes that $P_{+} \gg P_{\text{prior}} > P_{-}$. In fact, even in cases when P_{prior} quite small, P_{+} may be higher than 0.8. Intuitively, a positive adaptation which is higher than the prior entails that a word is likely to reappear in the target set given that it has already appeared in the prime set. We intend to show that adaptation probabilities provide evidence that syntactic constructions behave

[1]Our terminology differs from that of Church, who uses 'history' to describe the first half, and 'test' to describe the second. Our terms avoid the ambiguity of the phrase 'test set' and coincide with the common usage in the psycholinguistic literature.

similarity to lexical priming, showing positive adaptation P_+ greater than the prior. As P_- must become smaller than P_{prior} whenever P_+ is larger than P_{prior}, we only report the positive adaptation P_+ and the prior P_{prior}.

While Church's technique was developed with speech recognition in mind, we will show that it is useful for investigating psycholinguistic phenomenon. However, the connection between cognitive phenomenon and engineering approaches go in both directions: it is possible that syntactic parsers could be improved using a model of syntactic priming, just as speech recognition has been improved using models of lexical priming.

3 Experiment 1: Parallelism in Coordination

In this section, we investigate the use of Church's adaptation metrics to measure the effect of syntactic parallelism in coordinated constructions. For the sake of comparison, we restrict our study to several constructions used in Frazier et al. (2000). All of these constructions occur in NPs with two coordinate sisters, i.e., constructions such as NP_1 CC NP_2, where CC represents a coordinator such as *and*.

3.1 Method

The application of the adaptation metric is straightforward: we pick NP_1 as the prime set and NP_2 as the target set. Instead of measuring the frequency of lexical elements, we measure the frequency of the following syntactic constructions:

SBAR An NP with a relative clause, i.e., NP $\rightarrow$ NP SBAR.

PP An NP with a PP modifier, i.e., NP $\rightarrow$ NP PP.

NN An NP with a single noun, i.e., NP $\rightarrow$ NN.

DT NN An NP with a determiner and a noun, i.e., NP $\rightarrow$ DT NN.

DT JJ NN An NP with a determiner, an adjective and a noun, i.e., NP $\rightarrow$ DT JJ NN.

Parameter estimation is accomplished by iterating through the corpus for applications of the rule NP $\rightarrow$ NP CC NP. From each rule application, we create a list of prime-target pairs. We then estimate adaptation probabilities for each construction, by counting the number of prime-target pairs in which the construction does or does not occur. This is done similarly to the document half case described above. There are four frequencies of interest, but now they refer to the frequency that a particular construction (rather than a word) either occurs or does not occur in the prime and target set.

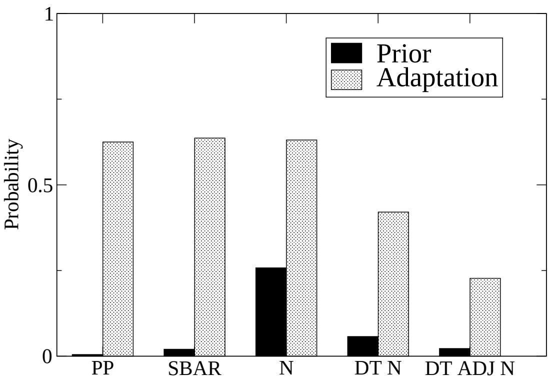

Figure 1: Adaptation within coordinate structures in the Brown corpus

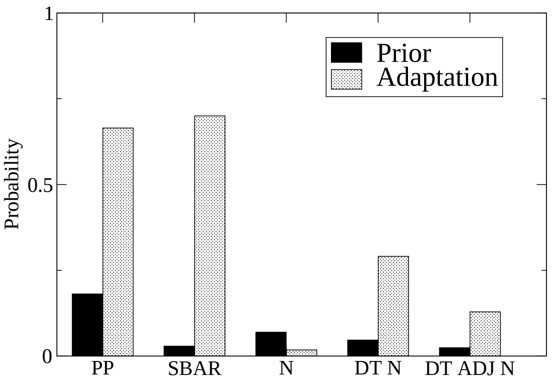

Figure 2: Adaptation within coordinate structures in the WSJ corpus

To ensure results were general across genres, we used all three parts of the English Penn Treebank: the Wall Street Journal (WSJ), the balanced Brown corpus of written text (Brown) and the Switchboard corpus of spontaneous dialog. In each case, we use the entire corpus.

Therefore, in total, we report 30 probabilities: the prior and positive adaptation for each of the five constructions in each of the three corpora. The primary objective is to observe the difference between the prior and positive adaptation for a given construction in a particular corpus. Therefore, we also perform a χ^2 test to determine if the difference between these two probabilities are statistically significant.

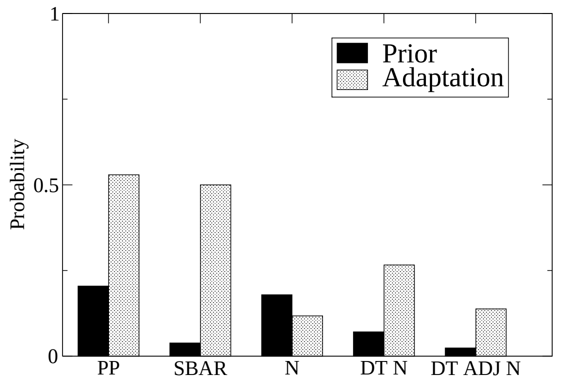

Figure 3: Adaptation within coordinate structures in the Switchboard corpus

3.2 Results

The results are shown in Figure 1 for the Brown corpus, Figure 2 for the WSJ and Figure 3 for Switchboard. Each figure shows the prior and positive adaptation for all five constructions: relative clauses (SBAR) a PP modifier (PP), a single common noun (N), a determiner and noun (DT N), and a determiner adjective and noun (DT ADJ N). Only in the case of a single common noun in the WSJ and Switchboard corpora is the prior probability higher than the positive adaptation. In all other cases, the probability of the given construction is more likely to occur in NP_2 given that it has occurred in NP_1. According to the χ^2 tests, all differences between priors and positive adaptations were significant at the 0.01 level. The size of the data sets means that even small differences in probability are statistically significant. All differences reported in the remainder of this paper are statistically significant; we omit the details of individual χ^2 tests.

3.3 Discussion

The main conclusion we draw is that the parallelism effect in corpora mirrors the ones found experimentally by Frazier et al. (2000), if we assume higher probabilities are correlated with easier human processing. This conclusion is important, as the experiments of Frazier et al. (2000) only provided evidence for parallelism in *comprehension* data. Corpus data, however, are *production* data, which means that the our findings are first ones to demonstrate parallelism effects in production.

The question of the relationship between comprehension and production data is an interesting one. We can expect that production data, such as corpus data, are generated by speakers through a process that involves self-monitoring. Written texts (such as the WSJ and Brown) involve proofreading and editing, i.e., explicit comprehension processes. Even the data in a spontaneous speech corpus such as Swtichboard can be expected to involve a certain amount of self-monitoring (speakers listen to themselves and correct themselves if necessary). It follows that it is not entirely unexpected that similar effects can be found in both comprehension and production data.

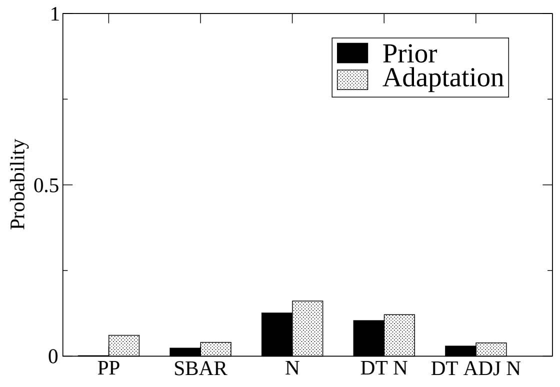

Figure 4: Adaptation within sentences in the Brown corpus

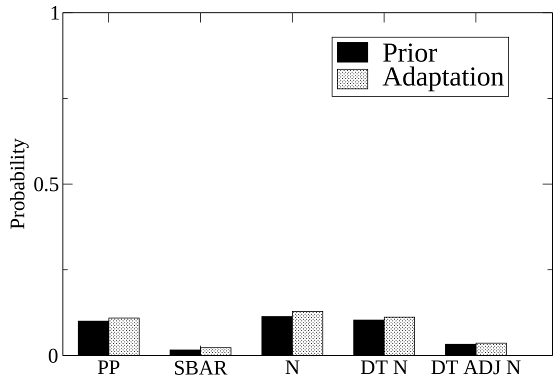

Figure 5: Adaptation within sentences in the WSJ corpus

4 Experiment 2: Parallelism in Documents

The results in the previous section showed that the parallelism effect, which so far had only been demonstrated in comprehension studies, is also attested in corpora, i.e., in production data. In the present experiment, we will investigate the mechanisms underlying the parallelism effect. As discussed in Section 1, there are two possible explana-

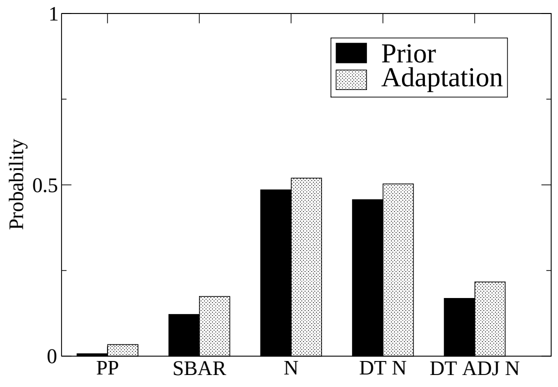

Figure 6: Adaptation between sentences in the Brown corpus

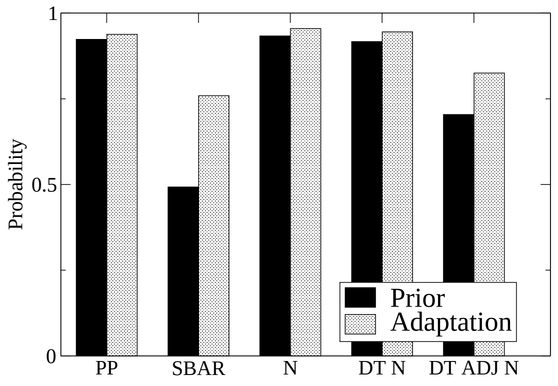

Figure 9: Adaptation within documents in the WSJ corpus

tion for the effect: one in terms of a construction-specific copying mechanism, and one in terms of a generalized syntactic priming mechanism. In the first case, we predict that the parallelism effect is restricted to coordinate structures, while in the second case, we expect that parallelism (a) is independent of coordination, and (b) occurs in the wider discourse, i.e., not only within sentences but also between sentences.

4.1 Method

The method used was the same as in Experiment 1 (see Section 3.1), with the exception that the prime set and the target set are no longer restricted to being the first and second conjunct in a coordinate structure. We investigated three levels of granularity: within sentences, between sentences, and within documents. *Within-sentence parallelism* occurs when the prime NP and the target NP occur within the same sentence, but stand in an arbitrary structural relationship. Coordinate NPs were excluded from this analysis, so as to make sure that any within-sentence parallelism is not confounded coordination parallelism as established in Experiment 1. *Between-sentence parallelism* was measured by regarding as the target the sentence immediately following the prime sentence. In order to investigate *within-document parallelism*, we split the documents into equal-sized halves; then the adaptation probability was computed by regarding the first half as the prime and the second half as the target (this method is the same as Church's method for measuring lexical adaptation).

The analyses were conducted using the Wall Street Journal and the Brown portion of the Penn Treebank. The document boundary was taken to be the file boundary in these corpora. The Switchboard corpus is a dialog corpus, and therefore needs to be treated differently: turns between speakers rather than sentences should be level of analysis. We will investigate this separately in Experiment 3 below.

4.2 Results

The results for the within-sentence analysis are graphed in Figures 4 and 5 for the Brown and WSJ corpus, respectively. We find that there is a parallelism effect in both corpora, for all the NP types investigated. Figures 6–9 show that the same is true also for the between-sentence and within-document analysis: parallelism effects are obtained for all NP types and for both corpora, even it the parallel structures occur in different sentences or in different document halves. (The within-document probabilities for the Brown corpus (in Figure 8) are close to one in most cases; the differences between the prior and adaptation are nevertheless significant.)

In general, note that the parallelism effects uncovered in this experiment are smaller than the effect demonstrated in Experiment 1: The differences between the prior probabilities and the adaptation probabilities (while significant) are markedly smaller than those uncovered for parallelism in coordinate structure.[2]

4.3 Discussion

This experiment demonstrated that the parallelism effect is not restricted to coordinate structures. Rather, we found that it holds across the board: for NPs that occur in the same sentence (and are not part of a coordinate structure), for NPs that occur in adjacent sentences, and for NPs that occur in different document halves. The between-sentence effect has been demonstrated in a more restricted from by Gries (2005) and Szmrecsanyi (2005), who investigate priming in corpora for cases of structural choice (e.g., between a dative object and a PP object for verbs like *give*). The present results extend this finding to arbitrary NPs, both within and between sentences.

The fact that parallelism is a pervasive phenomenon, rather than being limited to coordinate structures, strongly suggests that it is an instance of a general syntactic priming mechanism, which has been an established feature of accounts of the human sentence production system for a while (e.g., Bock, 1986). This runs counter to the claims made by Frazier et al. (2000) and Frazier and Clifton (2001), who have argued that parallelism only occurs in coordinate structures, and should be accounted for using a specialized copying mechanism. (It is important to bear in mind, however, that Frazier et al. only make explicit claims about comprehension, not about production.)

However, we also found that parallelism effects are clearly strongest in coordinate structures (compare the differences between prior and adaptation in Figures 1–3 with those in Figures 4–9). This could explain why Frazier et al.'s (2000) experiments failed to find a significant parallelism effect in non-coordinated structures: the effect is simply too week to detect (especially using the self-paced reading paradigm they employed).

5 Experiment 3: Parallelism in Spontaneous Dialog

Experiment 1 showed that parallelism effects can be found not only in written corpora, but also in the Switchboard corpus of spontaneous dialog. We did not include Switchboard in our analysis in Experiment 2, as this corpus has a different structure from the two text corpora we investigated: it is organized in terms of turns between two speakers. Here, we exploit this property and conduct a further experiment in which we compare parallelism effects between speakers and within speakers.

The phenomenon of structural repetition between speakers has been discussed in the experimental psycholinguistic literature (see Pickering and Garrod 2004 for a review). According to Pickering and Garrod (2004), the act of engaging in a dialog facilitates the use of similar representations at all linguistic levels, and these representations are shared between speech production and comprehension processes. Thus structural adaptation should be observed in a dialog setting, both within and between speakers. An alternative view is that production and comprehension processes are distinct. Bock and Loebell (1990) suggest that syntactic priming in speech production is due to facilitation of the retrieval and assembly procedures that occur during the formulation of utterances. Bock and Loebell point out that this production-based procedural view predicts a lack of priming between comprehension and production or vice versa, on the assumption that

[2]The differences between the priors and adaptation probabilities are also much smaller than noted by Church (2000). The probabilities of the rules we investigate have a higher marginal probability than the lexical items of interest to Church.

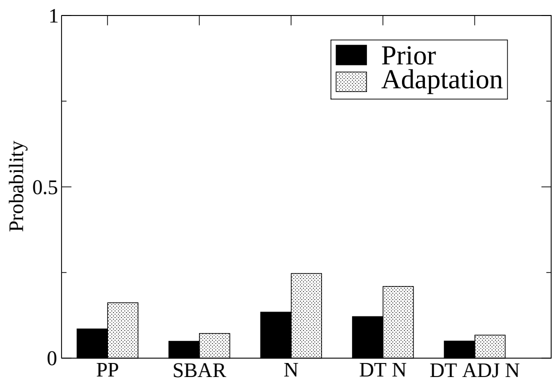

Figure 10: Adaptation between speakers in the Switchboard corpus

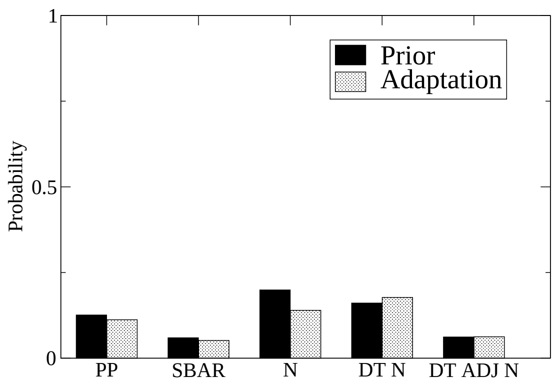

Figure 11: Adaptation within speakers in the Switchboard corpus

production and parsing use distinct mechanisms. In our terms, it predicts that between-speaker positive adaptation should not be found, because it can only result from priming from comprehension to production, or vice versa. Conversely, the prodedural view outlined by Bock and Loebell predicts that positive adaptation *should* be found within a given speaker's dialog turns, because such adaptation can indeed be the result of the facilitation of production routines within a given speaker.

5.1 Method

We created two sets of prime and target data to test within-speaker and between-speaker adaptation. The prime and target sets were defined in terms of pairs of utterances. To test between-speaker adaptation, we took each adjacent pair of utterances spoken by speaker A and speaker B, in each dialog, and these were treated as prime and target sets respectively. In the within-speaker analysis, the prime and target sets were taken from the dialog turns of only one speaker—we took each adjacent pair of dialog turns uttered by a given speaker, excluding the intervening utterance of the other speaker. The earlier utterance of the pair was treated as the prime, and the later utterance as the target. The remainder of the method was the same as in Experiments 1 and 2 (see Section 3.1).

5.2 Results

The results for the between-speaker and within-speaker adaptation are shown in Figure 10 and Figure 11 for same five phrase types as in the previous experiments.

A positive adaptation effect can be seen in the between-speaker data. For each phrase type, the adaptation probability is greater than the prior. In the within-speaker data, by comparison, the magnitude of the adaptation advantage is greatly decreased, in comparison with Figure 10. Indeed, for most phrase types, the adaptation probability is lower than the prior, i.e., we have a case of negative adaptation.

5.3 Discussion

The results of the two analyses confirm that adaptation can indeed be found between speakers in dialog, supporting the results of experimental work reviewed by Pickering and Garrod (2004). The results do not support the notion that priming is due to the facilitation of production processes within a given speaker, an account which would have predicted adaptation within speakers, but not between speakers.

The lack of clear positive adaptation effects in the within-speaker data is harder to explain—all current theories of priming would predict some effect here. One possibility is that such effects may have been obscured by decay processes: doing a within-speaker analysis entails skipping an intervening turn, in which priming effects were lost. We intend to address these concerns using more elaborate experimental designs in future work.

6 Conclusions

In this paper, we have demonstrated a robust, pervasive effect of parallelism for noun phrases. We found the tendency for structural repetition in two different corpora of written English, and also in a dialog corpus. The effect occurs in a wide range of contexts: within coordinate structures (Experiment 1), within sentences for NPs in an arbitrary structural configuration, between sentences, and within documents (Experiment 2). This strongly indicates that the parallelism effect is an instance of a general processing mechanism, such as syntactic priming (Bock, 1986), rather than specific to coordination, as suggested by (Frazier and Clifton, 2001). However, we also found that the parallelism effect is strongest in coordinate structures, which could explain why comprehension experiments so far failed to demonstrate the effect for other structural configurations (Frazier et al., 2000). We leave it to future work to explain *why* adaptation is much stronger in co-ordination: is co-ordination special because of extra constrains (i.e., some kind of expected contrast/comparison between co-ordinate sisters) or because of fewer constraints (i.e., both co-ordinate sisters have a similar grammatical role in the sentence)?

Another result (Experiment 3) is that the parallelism effect occurs between speakers in dialog. This finding is compatible with Pickering and Garrod's (2004) interactive alignment model, and strengthens the argument for parallelism as an instance of a general priming mechanism.

Previous experimental work has found parallelism effects, but only in comprehension data. The present work demonstrates that parallelism effects also occur in production data, which raises an interesting question of the relationship between the two data types. It has been hypothesized that the human language processing system is tuned to mirror the probability distributions in its environment, including the probabilities of syntactic structures (Mitchell et al., 1996). If this *tuning hypothesis* is correct, then the parallelism effect in comprehension data can be explained as an adaptation of the human parser to the prevalence of parallel structures in its environment (as approximated by corpus data) that we demonstrated in this paper.

Note that the results in this paper not only have an impact on theoretical issues regarding human sentence processing, but also on engineering problems in natural language processing, e.g., in probabilistic parsing. To avoid sparse data problems, probabilistic parsing models make strong independence assumptions; in particular, they generally assume that sentences are independent of each other. This is partly due to the fact it is difficult to parameterize the many possible dependencies which may occur between adjacent sentences. However, in this paper, we show that structure re-use is one possible way in which the independence assumption is broken. A simple and principled approach to handling structure re-use would be to use adaptation probabilities for probabilistic grammar rules, analogous to cache probabilities used in caching language models (Kuhn and de Mori, 1990). We are currently conducting further experiments to investigate of the effect of syntactic priming on probabilistic parsing.

Using the Web as an Implicit Training Set: Application to Structural Ambiguity Resolution

Preslav Nakov and **Marti Hearst**

Abstract

Recent work has shown that very large corpora can act as training data for NLP algorithms even without explicit labels. In this paper we show how the use of surface features and paraphrases in queries against search engines can be used to infer labels for structural ambiguity resolution tasks. Using unsupervised algorithms, we achieve 84% precision on PP-attachment and 80% on noun compound coordination.

1 Introduction

Resolution of structural ambiguity problems such as noun compound bracketing, prepositional phrase (PP) attachment, and noun phrase coordination requires using information about lexical items and their cooccurrences. This in turn leads to the data sparseness problem, since algorithms that rely on making decisions based on individual lexical items must have statistics about every word that may be encountered. Past approaches have dealt with the data sparseness problem by attempting to generalize from semantic classes, either manually built or automatically derived.

More recently, Banko and Brill (2001) have advocated for the creative use of very large text collections as an alternative to sophisticated algorithms and hand-built resources. They demonstrate the idea on a lexical disambiguation problem for which labeled examples are available "for free". The problem is to choose which of 2-3 commonly confused words (e.g., {*principle, principal*}) are appropriate for a given context. The labeled data comes "for free" by assuming that in most edited written text, the words are used correctly, so training can be done directly from the text. Banko and Brill (2001) show that even using a very simple algorithm, the results continue to improve log-linearly with more training data, even out to a billion words. A potential limitation of this approach is the question of how applicable it is for NLP problems more generally – how can we treat a large corpus as a labeled collection for a wide range of NLP tasks?

In a related strand of work, Lapata and Keller (2004) show that computing n-gram statistics over very large corpora yields results that are competitive with if not better than the best supervised and knowledge-based approaches on a wide range of NLP tasks. For example, they show that for the problem of noun compound bracketing, the performance of an n-gram based model computed using search engine statistics was not significantly different from the best supervised algorithm whose parameters were tuned and which used a taxonomy. They find however that these approaches generally fail to outperform supervised state-of-the-art models that are trained on smaller corpora, and so conclude that web-based n-gram statistics should be the baseline to beat.

We feel the potential of these ideas is not yet fully realized. We are interested in finding ways to further exploit the availability of enormous web corpora as implicit training data. This is especially important for structural ambiguity problems in which the decisions must be made on the basis of the behavior of individual lexical items. The trick is to figure out how to use information that is latent in the web as a corpus, and web search engines as query interfaces to that corpus.

In this paper we describe two techniques – *surface features* and *paraphrases* – that push the ideas of Banko and Brill (2001) and Lapata and Keller (2004) farther, enabling the use of statistics gathered from very large corpora in an unsupervised manner. In recent work (Nakov and Hearst, 2005) we showed that a variation of the techniques, when applied to the problem of noun compound bracketing, produces higher accuracy than Lapata and Keller (2004) and the best supervised results. In this paper we adapt the techniques to the structural disambiguation problems of prepositional phrase attachment and noun compound coordination.

2 Prepositional Phrase Attachment

A long-standing challenge for syntactic parsers is the attachment decision for prepositional phrases. In a configuration where a verb takes a noun complement that is followed by a PP, the problem arises of whether the PP attaches to the noun or to the verb. Consider the following contrastive pair of sentences:

(1) *Peter spent millions of dollars.* (noun)

(2) *Peter spent time with his family.* (verb)

In the first example, the PP *millions of dollars* attaches to the noun *millions*, while in the second the PP *with his family* attaches to the verb *spent*.

Past work on PP-attachment has often cast these associations as the quadruple (v, n_1, p, n_2), where v is the verb, n_1 is the head of the direct object, p is the preposition (the head of the PP) and n_2 is the head of the NP inside the PP. For example, the quadruple for (2) is (*spent, time, with, family*).

2.1 Related Work

Early work on PP-attachment ambiguity resolution relied on syntactic (e.g., "minimal attachment" and "right association") and pragmatic considerations. Most recent work can be divided into supervised and unsupervised approaches. Supervised approaches tend to make use of semantic classes or thesauri in order to deal with data sparseness problems. Brill and Resnik (1994) used the supervised transformation-based learning method and lexical and conceptual classes derived from WordNet, achieving 82% precision on 500 randomly selected examples. Ratnaparkhi et al. (1994) created a benchmark dataset of 27,937 quadruples (v, n_1, p, n_2), extracted from the Wall Street Journal. They found the human performance on this task to be 88%[1]. Using this dataset, they trained a maximum entropy model and a binary hierarchy of word classes derived by mutual information, achieving 81.6% precision. Collins and Brooks (1995) used a supervised back-off model to achieve 84.5% precision on the Ratnaparkhi test set. Stetina and Makoto (1997) use a supervised method with a decision tree and WordNet classes to achieve 88.1% precision on the same test set. Toutanova et al. (2004) use a supervised method that makes use of morphological and syntactic analysis and WordNet synsets, yielding 87.5% accuracy.

In the unsupervised approaches, the attachment decision depends largely on co-occurrence statistics drawn from text collections. The pioneering work in this area was that of Hindle and Rooth (1993). Using a partially parsed corpus, they calculate and compare lexical associations over subsets of the tuple (v, n_1, p), ignoring n_2, and achieve 80% precision at 80% recall.

More recently, Ratnaparkhi (1998) developed an unsupervised method that collects statistics from text annotated with part-of-speech tags and morphological base forms. An extraction heuristic is used to identify unambiguous attachment decisions, for example, the algorithm can assume a noun attachment if there is no verb within k words to the left of the preposition in a given sentence, among other conditions. This extraction heuristic uncovered 910K unique tuples of the form (v, p, n_2) and (n, p, n_2), although the results are very noisy, suggesting the correct attachment only about 69% of the time. The tuples are used as training data for classifiers, the best of which achieves 81.9% precision on the Ratnaparkhi test set. Pantel and Lin (2000) describe an unsupervised method that uses a collocation database, a thesaurus, a dependency parser, and a large corpus (125M words), achieving 84.3% precision on the Ratnaparkhi test set. Using sim-

[1]When presented with a whole sentence, average humans score 93%.

ple combinations of web-based n-grams, Lapata and Keller (2005) achieve lower results, in the low 70's.

Using a different collection consisting of German PP-attachment decisions, Volk (2000) uses the web to obtain n-gram counts. He compared $\Pr(p|n_1)$ to $\Pr(p|v)$, where $\Pr(p|x) = \#(x,p)/\#(x)$. Here x can be n_1 or v. The bigram frequencies $\#(x,p)$ were obtained using the Altavista NEAR operator. The method was able to make a decision on 58% of the examples with a precision of 75% (baseline 63%). Volk (2001) then improved on these results by comparing $\Pr(p,n_2|n_1)$ to $\Pr(p,n_2|v)$. Using inflected forms, he achieved P=75% and R=85%.

Calvo and Gelbukh (2003) experimented with a variation of this, using exact phrases instead of the NEAR operator. For example, to disambiguate *Veo al gato con un telescopio*, they compared frequencies for phrases such as "ver con telescopio" and "gato con telescopio". They tested this idea on 181 randomly chosen Spanish disambiguation examples, labelling 89.5% recall with a precision of 91.97%.

2.2 Models and Features

2.2.1 n-gram Models

We computed two co-occurrence models;

(*i*) $\Pr(p|n_1)$ vs. $\Pr(p|v)$

(*ii*) $\Pr(p,n_2|n_1)$ vs. $\Pr(p,n_2|v)$.

Each of these was computed two different ways: using $\Pr$ (probabilities) and $\#$ (frequencies). We estimate the n-gram counts using exact phrase queries (with inflections, derived from WordNet 2.0) using the MSN Search Engine. We also allow for determiners, where appropriate, e.g., between the preposition and the noun when querying for $\#(p,n_2)$. We add up the frequencies for all possible variations. Web frequencies were reliable enough and did not need smoothing for (*i*), but for (*ii*), smoothing using the technique described in Hindle and Rooth (1993) led to better recall. We also tried back-off from (*ii*) to (*i*), as well as back-off plus smoothing, but did not find improvements over smoothing alone. We found n-gram counts to be unreliable when pronouns appear in the test set rather than nouns, and disabled them in these cases. Such examples can still be handled by paraphrases or surface features (see below).

2.2.2 Web-Derived Surface Features

Authors sometimes (consciously or not) disambiguate the words they write by using surface-level markers to suggest the correct meaning. We have found that exploiting these markers, when they occur, can prove to be very helpful for making disambiguation decisions. The enormous size of web search engine indexes facilitates finding such markers frequently enough to make them useful.

For example, *John opened the door with a key* is a difficult verb attachment example because doors, keys, and opening are all semantically related. To determine if this should be a verb or a noun attachment, we search for cues that indicate which of these terms tend to associate most closely. If we see parentheses used as follows:

"open the door (with a key)"

this suggests a verb attachment, since the parentheses signal that "with a key" acts as its own unit. Similarly, hyphens, colons, capitalization, and other punctuation can help signal disambiguation decisions. For *Jean ate spaghetti with sauce*, if we see

"eat: spaghetti with sauce"

this suggests a noun attachment.

Table 1 illustrates a wide variety of surface features, along with the attachment decisions they are assumed to suggest (events of frequency 1 have been ignored). The surface features for PP-attachment have low recall: most of the examples have no surface features extracted.

We gather the statistics needed by issuing queries to web search engines. Unfortunately, search engines usually ignore punctuation characters, thus preventing querying directly for terms containing hyphens, brackets, etc. We collect these numbers indirectly by issuing queries with exact phrases and then post-processing the top 1,000 resulting summaries[2], looking for the surface features of interest. We use Google for both the surface feature and paraphrase extractions (described below).

2.2.3 Paraphrases

The second way we extend the use of web counts is by paraphrasing the relation of interest and seeing if it can be found in its alternative form, which

[2]We often obtain more than 1,000 summaries per example because we usually issue multiple queries per surface pattern, by varying inflections and inclusion of determiners.

suggests the correct attachment decision. We use the following patterns along with their associated attachment predictions:

(1)	$v\ n_2\ n_1$	(noun)
(2)	$v\ p\ n_2\ n_1$	(verb)
(3)	$p\ n_2$ * $v\ n_1$	(verb)
(4)	$n_1\ p\ n_2\ v$	(noun)
(5)	v *pronoun* $p\ n_2$	(verb)
(6)	*be* $n_1\ p\ n_2$	(noun)

The idea behind Pattern (1) is to determine if "$n_1\ p\ n_2$" can be expressed as a noun compound; if this happens sufficiently often, we can predict a noun attachment. For example, *meet/*v *demands/*n_1 *from/*p *customers/*n_2 becomes *meet/*v *the customers/*n_2 *demands/*n_1.

Note that the pattern could wrongly target ditransitive verbs: e.g., it could turn *gave/*v *an apple/*n_1 *to/*p *him/*n_2 into *gave/*v *him/*n_2 *an apple/*n_1. To prevent this, we do not allow a determiner before n_1, but we do require one before n_2. In addition, we disallow the pattern if the preposition is *to* and we require both n_1 and n_2 to be nouns (as opposed to numbers, percents, pronouns, determiners etc.).

Pattern (2) predicts a verb attachment. It presupposes that "$p\ n_2$" is an indirect object of the verb v and tries to switch it with the direct object n_1, e.g., *had/*v *a program/*n_1 *in/*p *place/*n_2 would be transformed into *had/*v *in/*p *place/*n_2 *a program/*n_1. We require n_1 to be preceded by a determiner (to prevent "$n_2\ n_1$" forming a noun compound).

Pattern (3) looks for appositions, where the PP has moved in front of the verb, e.g., *to/*p *him/*n_2 *I gave/*v *an apple/*n_1. The symbol * indicates a wildcard position where we allow up to three intervening words.

Pattern (4) looks for appositions, where the PP has moved in front of the verb together with n_1. It would transform *shaken/*v *confidence/*n_1 *in/*p *markets/*n_2 into *confidence/*n_1 *in/*p *markets/*n_2 *shaken/*v.

Pattern (5) is motivated by the observation that if n_1 is a pronoun, this suggests a verb attachment (Hindle and Rooth, 1993). (A separate feature checks if n_1 is a pronoun.) The pattern substitutes n_1 with a dative pronoun (we allow *him* and *her*), e.g., it will convert *put/*v *a client/*n_1 *at/*p *odds/*n_2 into *put/*v *him at/*p *odds/*n_2.

Pattern (6) is motivated by the observation that the verb *to be* is typically used with a noun attachment. (A separate feature checks if v is a form of the verb *to be*.) The pattern substitutes v with *is* and *are*, e.g. it will turn *eat/*v *spaghetti/*n_1 *with/*p *sauce/*n_2 into *is spaghetti/*n_1 *with/*p *sauce/*n_2.

These patterns all allow for determiners where appropriate, unless explicitly stated otherwise. For a given example, a prediction is made if at least one instance of the pattern has been found.

2.3 Evaluation

For the evaluation, we used the test part (3,097 examples) of the benchmark dataset by Ratnaparkhi et al. (1994). We used all 3,097 test examples in order to make our results directly comparable.

Unfortunately, there are numerous errors in the test set[3]. There are 149 examples in which a bare determiner is labeled as n_1 or n_2 rather than the actual head noun. Supervised algorithms can compensate for this problem by learning from the training set that "the" can act as a noun in this collection, but unsupervised algorithms cannot.

In addition, there are also around 230 examples in which the nouns contain special symbols like: %, slash, &, ', which are lost when querying against a search engine. This poses a problem for our algorithm but is not a problem with the test set itself.

The results are shown in Table 2. Following Ratnaparkhi (1998), we predict a noun attachment if the preposition is *of* (a very reliable heuristic). The table shows the performance for each feature in isolation (excluding examples whose preposition is *of*). The surface features are represented by a single score in Table 2: for a given example, we sum up separately the number of noun- and verb-attachment pattern matches, and assign the attachment with the larger number of matches.

We combine the bold rows of Table 2 in a majority vote (assigning noun attachment to all *of* instances), obtaining P=85.01%, R=91.77%. To get 100% recall, we assign all undecided cases to *verb* (since the majority of the remaining non-*of* instances attach to the verb, yielding P=83.63%, R=100%. We show 0.95-level confidence intervals for the precision, computed by a general method based on constant chi-square boundaries (Fleiss, 1981).

A test for statistical significance reveals that our results are as strong as those of the leading unsuper-

[3]Ratnaparkhi (1998) notes that the test set contains errors, but does not correct them.

Example	Predicts	P(%)	R(%)

vised approach on this collection (Pantel and Lin, 2000). Unlike that work, we do not require a collocation database, a thesaurus, a dependency parser, nor a large domain-dependent text corpus, which makes our approach easier to implement and to extend to other languages.

3 Coordination

Coordinating conjunctions (*and, or, but*, etc.) pose major challenges to parsers and their proper handling is essential for the understanding of the sentence. Consider the following "cooked" example:

The Department of Chronic Diseases ***and*** *Health Promotion leads* ***and*** *strengthens global efforts to prevent* ***and*** *control chronic diseases* ***or*** *disabilities* ***and*** *to promote health* ***and*** *quality of life.*

Conjunctions can link two words, two constituents (e.g., NPs), two clauses or even two sentences. Thus, the first challenge is to identify the boundaries of the conjuncts of each coordination. The next problem comes from the interaction of the coordinations with other constituents that attach to its conjuncts (most often prepositional phrases). In the example above we need to decide between *[health and [quality of life]]* and *[[health and quality] of life]*. From a semantic point of view, we need to determine whether the *or* in *chronic diseases or disabilities* really means *or* or is used as an *and* (Agarwal and Boggess, 1992). Finally, we need to choose between a *non-elided* and an *elided* reading: *[[chronic diseases] or disabilities]* vs. *[chronic [diseases or disabilities]]*.

Below we focus on a special case of the latter problem: noun compound (NC) coordination. Consider the NC *car and truck production*. Its real meaning is *car production and truck production*. However, due to the principle of economy of expression, the first instance of *production* has been compressed out by means of ellipsis. By contrast, in *president and chief executive*, *president* is simply linked to *chief executive*. There is also an all-way coordination, where the conjunct is part of the whole, as in *Securities and Exchange Commission*.

More formally, we consider configurations of the kind $n_1\ c\ n_2\ h$, where n_1 and n_2 are nouns, c is a coordination (*and* or *or*) and h is the head noun[4]. The task is to decide whether there is an ellipsis or not, independently of the local context. Syntactically, this can be expressed by the following bracketings: $[[n_1\ c\ n_2]\ h]$ versus $[n_1\ c\ [n_2\ h]]$. (Collins' parser (Collins, 1997) always predicts a flat NP for such configurations.) In order to make the task more

[4]The configurations of the kind $n\ h_1\ c\ h_2$ (e.g., *company/n cars/*h_1 *and/c trucks/*h_2) can be handled in a similar way.

realistic (from a parser's perspective), we ignore the option of all-way coordination and try to predict the bracketing in Penn Treebank (Marcus et al., 1994) for configurations of this kind. The Penn Treebank brackets NCs with ellipsis as, e.g.,
(NP car/NN and/CC truck/NN production/NN).
and without ellipsis as
(NP (NP president/NN) and/CC (NP chief/NN executive/NN))
The NPs with ellipsis are flat, while the others contain internal NPs. The all-way coordinations can appear bracketed either way and make the task harder.

3.1 Related Work

Coordination ambiguity is under-explored, despite being one of the three major sources of structural ambiguity (together with prepositional phrase attachment and noun compound bracketing), and belonging to the class of ambiguities for which the number of analyses is the number of binary trees over the corresponding nodes (Church and Patil, 1982), and despite the fact that conjunctions are among the most frequent words.

Rus et al. (2002) present a deterministic rule-based approach for bracketing *in context* of coordinated NCs of the kind n_1 c n_2 h, as a necessary step towards logical form derivation. Their algorithm uses POS tagging, syntactic parses, semantic senses of the nouns (manually annotated), lookups in a semantic network (WordNet) and the type of the coordination conjunction to make a 3-way classification: ellipsis, no ellipsis and all-way coordination. Using a back-off sequence of 3 different heuristics, they achieve 83.52% precision (baseline 61.52%) on a set of 298 examples. When 3 additional context-dependent heuristics and 224 additional examples with local contexts are added, the precision jumps to 87.42% (baseline 52.35%), with 71.05% recall.

Resnik (1999) disambiguates two kinds of patterns: n_1 and n_2 n_3 and n_1 n_2 and n_3 n_4 (e.g., *[food/*n_1 *[handling/*n_2 *and/*c *storage/*n_3*] procedures/*n_4*]*). While there are two options for the former (all-way coordinations are not allowed), there are 5 valid bracketings for the latter. Following Kurohashi and Nagao (1992), Resnik makes decisions based on similarity of form (i.e., number agreement: P=53%, R=90.6%), similarity of meaning (P=66%, R=71.2%) and conceptual association (P=75.0%, R=69.3%). Using a decision tree to combine the three information sources, he achieves 80% precision (baseline 66%) at 100% recall for the 3-noun coordinations. For the 4-noun coordinations the precision is 81.6% (baseline 44.9%), 85.4% recall.

Example	Predicts	P(%)	R(%)
(buy) and sell orders	NO ellipsis	33.33	1.40

buy and sell[...] orders	ellipsis	85.19	18.93

Table 3: **Coordination surface features.** Precision and recall shown are across all examples, not just the *buy and sell orders* shown.

Chantree et al. (2005) cover a large set of ambiguities, not limited to nouns. They allow the head word to be a noun, a verb or an adjective, and the modifier to be an adjective, a preposition, an adverb, etc. They extract distributional information from the British National Corpus and distributional similarities between words, similarly to (Resnik, 1999). In two different experiments they achieve P=88.2%, R=38.5% and P=80.8%, R=53.8% (baseline P=75%).

Goldberg (1999) resolves the *attachment of ambiguous coordinate phrases* of the kind n_1 p n_2 c n_3, e.g., *box/*n_1 *of/*p *chocolates/*n_2 *and/*c *roses/*n_3. Using an adaptation of the algorithm proposed by Ratnaparkhi (1998) for PP-attachment, she achieves P=72% (baseline P=64%), R=100.00%.

Agarwal and Boggess (1992) focus on the *identification of the conjuncts of coordinate conjunctions*. Using POS and case labels in a deterministic algorithm, they achieve P=81.6%. Kurohashi and Nagao (1992) work on the same problem for Japanese. Their algorithm looks for similar word sequences among with sentence simplification, and achieves a precision of 81.3%.

3.2 Models and Features

3.2.1 n-gram Models

We use the following n-gram models:

(*i*) $\#(n_1, h)$ vs. $\#(n_2, h)$

(*ii*) $\#(n_1, h)$ vs. $\#(n_1, c, n_2)$

Model (*i*) compares how likely it is that n_1 modifies h, as opposed to n_2 modifying h. Model (*ii*) checks which association is stronger: between n_1 and h, or between n_1 and n_2. Regardless of whether the coordination is *or* or *and*, we query for both and we add up the corresponding counts.

3.2.2 Web-Derived Surface Features

The set of surface features is similar to the one we used for PP-attachment. These are brackets, slash, comma, colon, semicolon, dot, question mark, exclamation mark, and any character. There are two additional ellipsis-predicting features: a dash after n_1 and a slash after n_2, see Table 3.

3.2.3 Paraphrases

We use the following paraphrase patterns:

(1)	n_2 *c* n_1 h	(ellipsis)
(2)	n_2 h *c* n_1	(NO ellipsis)
(3)	n_1 h *c* n_2 h	(ellipsis)
(4)	n_2 h *c* n_1 h	(ellipsis)

If matched frequently enough, each of these patterns predicts the coordination decision indicated in parentheses. If found only infrequently or not found at all, the opposite decision is made. Pattern (1) switches the places of n_1 and n_2 in the coordinated NC. For example, *bar and pie graph* can easily become *pie and bar graph*, which favors ellipsis. Pattern (2) moves n_2 and h together to the left of the coordination conjunction, and places n_1 to the right. If this happens frequently enough, there is no ellipsis. Pattern (3) inserts the elided head h after n_1 with the hope that if there is ellipsis, we will find the full phrase elsewhere in the data. Pattern (4) combines pattern (1) and pattern (3); it not only inserts h after n_1 but also switches the places of n_1 and n_2.

As shown in Table 4, we included four of the heuristics by Rus et al. (2002). Heuristic 1 predicts no coordination when n_1 and n_2 are the same, e.g., *milk and milk products*. Heuristics 2 and 3 perform a lookup in WordNet and we did not use them. Heuristics 4, 5 and 6 exploit the local context, namely the adjectives modifying n_1 and/or n_2. Heuristic 4 predicts no ellipsis if both n_1 and n_2 are modified by adjectives. Heuristic 5 predicts ellipsis if the coordination is *or* and n_1 is modified by an adjective, but n_2 is not. Heuristic 6 predicts no ellipsis if n_1 is not modified by an adjective, but n_2 is. We used versions of heuristics 4, 5 and 6 that check for determiners rather than adjectives.

Model	**P**(%)	**R**(%)
Baseline: ellipsis	56.54	100.00
(n_1, h) vs. (n_2, h)	**80.33**	28.50
(n_1, h) vs. (n_1, c, n_2)	61.14	45.09
(n_2, c, n_1, h)	**88.33**	14.02
(n_2, h, c, n_1)	**76.60**	21.96
(n_1, h, c, n_2, h)	**75.00**	6.54
(n_2, h, c, n_1, h)	**78.67**	17.52
Heuristic 1	**75.00**	0.93
Heuristic 4	64.29	6.54
Heuristic 5	61.54	12.15
Heuristic 6	**87.09**	7.24
Number agreement	**72.22**	46.26
Surface sum	**82.80**	21.73
Majority vote	83.82	80.84
Majority vote, N/A → no ellipsis	***80.61***	***100.00***

Table 4: **Coordination results, in percentages.**

Finally, we included the number agreement feature (Resnik, 1993): (a) if n_1 and n_2 match in number, but n_1 and h do not, predict ellipsis; (b) if n_1 and n_2 do not match in number, but n_1 and h do, predict no ellipsis; (c) otherwise leave undecided.

3.3 Evaluation

We evaluated the algorithms on a collection of 428 examples extracted from the Penn Treebank. On extraction, determiners and non-noun modifiers were allowed, but the program was only presented with the quadruple (n_1, c, n_2, h). As Table 4 shows, our overall performance of 80.61 is on par with other approaches, whose best scores fall into the low 80's for precision. (Direct comparison is not possible, as the tasks and datasets all differ.)

As Table 4 shows, n-gram model (*i*) performs well, but n-gram model (*ii*) performs poorly, probably because the (n_1, c, n_2) contains three words, as opposed to two for the alternative (n_1, h), and thus a priori is less likely to be observed.

The surface features are less effective for resolving coordinations. As Table 3 shows, they are very good predictors of ellipsis, but are less reliable when predicting NO ellipsis. We combine the bold rows of Table 4 in a majority vote, obtaining P=83.82%, R=80.84%. We assign all undecided cases to no ellipsis, yielding P=80.61%, R=100%.

4 Conclusions and Future Work

We have shown that simple unsupervised algorithms that make use of bigrams, surface features and paraphrases extracted from a very large corpus are effective for several structural ambiguity resolutions tasks, yielding results competitive with the best unsupervised results, and close to supervised results. The method does not require labeled training data, nor lexicons nor ontologies. We think this is a promising direction for a wide range of NLP tasks. In future work we intend to explore better-motivated evidence combination algorithms and to apply the approach to other NLP problems.

Abstract

We here propose a new method which sets apart domain-specific terminology from common non-specific noun phrases. It is based on the observation that terminological multi-word groups reveal a considerably lesser degree of distributional variation than non-specific noun phrases. We define a measure for the observable amount of paradigmatic modifiability of terms and, subsequently, test it on bigram, trigram and quadgram noun phrases extracted from a 104-million-word biomedical text corpus. Using a community-wide curated biomedical terminology system as an evaluation gold standard, we show that our algorithm significantly outperforms a variety of standard term identification measures. We also provide empirical evidence that our methodolgy is essentially domain- and corpus-size-independent.

1 Introduction

As we witness the ever-increasing proliferation of volumes of medical and biological documents, the available dictionaries and terminological systems cannot keep up with this pace of growth and, hence, become more and more incomplete. What's worse, the constant stream of new terms is increasingly getting unmanageable because human curators are in the loop. The costly, often error-prone and time-consuming nature of manually identifying new terminology from the most recent literature calls for advanced procedures which can automatically assist database curators in the task of assembling, updating and maintaining domain-specific controlled vocabularies. Whereas the recognition of single-word terms usually does not pose any particular challenges, the vast majority of biomedical or any other domain-specific terms typically consists of multi-word units.[1] Unfortunately these are much more difficult to recognize and extract than their singleton counterparts. Moreover, although the need to assemble and extend technical and scientific terminologies is currently most pressing in the biomedical domain, virtually any (sub-)field of human research/expertise in which we deal with terminologically structured knowledge calls for high-performance terminology identification and extraction methods. We want to target exactly this challenge.

2 Related Work

The automatic extraction of complex multi-word terms from domain-specific corpora is already an active field of research (cf., e.g., for the biomedical domain Rindflesch et al. (1999), Collier et al. (2002), Bodenreider et al. (2002), or Nenadić et al. (2003)). Typically, in all of these approaches term candidates are collected from texts by various forms of linguistic filtering (part-of-speech tagging, phrase chunking, etc.), through which candidates obeying various linguistic patterns are identified (e.g., *noun-noun*, *adjective-noun-noun* combinations). These candidates are then submitted to frequency- or statistically-based evidence measures

[1]Nakagawa and Mori (2002) claim that more than 85% of domain-specific terms are multi-word units.

(such as the C-value (Frantzi et al., 2000)), which compute scores indicating to what degree a candidate qualifies as a term. Term mining, as a whole, is a complex process involving several other components (orthographic and morphological normalization, acronym detection, conflation of term variants, term context, term clustering; cf. Nenadić et al. (2003)). Still, the measure which assigns a *termhood value* to a term candidate is the essential building block of any term identification system.

For multi-word automatic term recognition (ATR), the C-value approach (Frantzi et al., 2000; Nenadić et al., 2004), which aims at improving the extraction of nested terms, has been one of the most widely used techniques in recent years. Other potential association measures are mutual information (Damerau, 1993) and the whole battery of statistical and information-theoretic measures (t-test, log-likelihood, entropy) which are typically employed for the extraction of general-language collocations (Manning and Schütze, 1999; Evert and Krenn, 2001). While these measures have their statistical merits in terminology identification, it is interesting to note that they only make little use of linguistic properties inherent to complex terms.[2]

More linguistically oriented work on ATR by Daille (1996) or on term variation by Jacquemin (1999) builds on the deep syntactic analysis of term candidates. This includes morphological and head-modifier dependency analysis and thus presupposes accurate, high-quality parsing which, for sublanguages at least, can only be achieved by a highly domain-dependent type of grammar. As sublanguages from different domains usually reveal a high degree of syntactic variability among each other (e.g., in terms of POS distribution, syntactic patterns), this property makes it difficult to port grammatical specifications to different domains.

Therefore, one may wonder whether there are cross-domain linguistic properties which might be beneficial to ATR and still could be accounted for by only *shallow* syntactic analysis. In this paper, we propose the *limited paradigmatic modifiability* of terms as a criterion which meets these requirements and will elaborate on it in detail in Subsection 3.3.

[2]A notable exception is the C-value method which incorporates a term's likelihood of being nested in other multi-word units.

3 Methods and Experiments

3.1 Text Corpus

We collected a biomedical training corpus of approximately 513,000 MEDLINE abstracts using the following query composed of MESH terms from the biomedical domain: *transcription factors*, *blood cells* and *human*.[3] We then annotated the resulting 104-million-word corpus with the GENIA part-of-speech tagger[4] and identified noun phrases (NPs) with the YAMCHA chunker (Kudo and Matsumoto, 2001). We restrict our study to NP recognition (i.e., determining the extension of a noun phrase but refraining from assigning any internal constituent structure to that phrase), because the vast majority of technical or scientific terms surface as noun phrases (Justeson and Katz, 1995). We filtered out a number of stop words (determiners, pronouns, measure symbols, etc.) and also ignored noun phrases with coordination markers (*"and"*, *"or"*, etc.).[5]

n-gram length	cut-off	NP term candidates tokens	types
bigrams	no cut-off	5,920,018	1,055,820
	$c \geq 10$	4,185,427	67,308
trigrams	no cut-off	3,110,786	1,655,440
	$c \geq 8$	1,053,651	31,017
quadgrams	no cut-off	1,686,745	1,356,547
	$c \geq 6$	222,255	10,838

Table 1: Frequency distribution for noun phrase term candidate tokens and types for the MEDLINE text corpus

In order to obtain the term candidate sets (see Table 1), we counted the frequency of occurrence of noun phrases in our training corpus and categorized them according to their length. For this study, we restricted ourselves to noun phrases of length 2 (word bigrams), length 3 (word trigrams) and length 4 (word quadgrams). Morphological normalization of term candidates has shown to be beneficial for ATR (Nenadić et al., 2004). We thus normalized the nom-

[3]MEDLINE (`http://www.ncbi.nlm.nih.gov`) is the largest biomedical bibliographic database. For information retrieval purposes, all of its abstracts are indexed with a controlled indexing vocabulary, the *Medical Subject Headings* (MESH, 2004).

[4]`http://www-tsujii.is.s.u-tokyo.ac.jp/GENIA/postagger/`

[5]Of course, terms can also be contained within coordinative structures (e.g., *"B and T cell"*). However, analyzing their inherent ambiguity is a complex syntactic operation, with a comparatively marginal benefit for ATR (Nenadić et al., 2004).

inal head of each noun phrase (typically the rightmost noun in English) via the full-form UMLS SPECIALIST LEXICON (UMLS, 2004), a large repository of both general-language and domain-specific (medical) vocabulary. To eliminate noisy low-frequency data (cf. also Evert and Krenn (2001)), we defined different frequency cut-off thresholds, c, for the bigram, trigram and quadgram candidate sets and only considered candidates above these thresholds.

3.2 Evaluating Term Extraction Quality

Typically, terminology extraction studies evaluate the goodness of their algorithms by having their ranked output examined by domain experts who identify the true positives among the ranked candidates. There are several problems with such an approach. First, very often only one such expert is consulted and, hence, inter-annotator agreement cannot be determined (as, e.g., in the studies of Frantzi et al. (2000) or Collier et al. (2002)). Furthermore, what constitutes a relevant term for a particular domain may be rather difficult to decide – even for domain experts – when judges are just exposed to a list of candidates without any further context information. Thus, rather than relying on *ad hoc* human judgment in identifying true positives in a candidate set, as an alternative we may take already existing terminolgical resources into account. They have evolved over many years and usually reflect community-wide consensus achieved by expert committees. With these considerations in mind, the biomedical domain is an ideal test bed for evaluating the goodness of ATR algorithms because it hosts one of the most extensive and most carefully curated terminological resources, viz. the UMLS METATHESAURUS (UMLS, 2004). We will then take the mere existence of a term in the UMLS as the decision criterion whether or not a candidate term is also recognized as a biomedical term.

Accordingly, for the purpose of evaluating the quality of different measures in recognizing multi-word terms from the biomedical literature, we assign every word bigram, trigram, and quadgram in our candidate sets (see Table 1) the status of being a term (i.e., a true positive), if it is found in the 2004 edition of the UMLS METATHESAURUS.[6] For example, the word trigram *"long terminal repeat"* is listed as a term in one of the UMLS vocabularies, *viz.* MESH (2004), whereas *"t cell response"* is not. Thus, among the 67,308 word bigram candidate types, 14,650 (21.8%) were identified as true terms; among the 31,017 word trigram candidate types, their number amounts to 3,590 (11.6%), while among the 10,838 word quadgram types, 873 (8.1%) were identified as true terms.[7]

[6]We exclude UMLS vocabularies not relevant for molecular biology, such as nursing and health care billing codes.

3.3 Paradigmatic Modifiability of Terms

For most standard association measures utilized for terminology extraction, the frequency of occurrence of the term candidates either plays a major role (e.g., C-value), or has at least a significant impact on the assignment of the degree of termhood (e.g., t-test). However, frequency of occurrence in a training corpus may be misleading regarding the decision whether or not a multi-word expression is a term. For example, taking the two trigram multiword expressions from the previous subsection, the non-term "*t cell response*" appears 2410 times in our 104-million-word MEDLINE corpus, whereas the term "*long terminal repeat*" (long repeating sequences of DNA) only appears 434 times (see also Tables 2 and 3 below).

The linguistic property around which we built our measure of termhood is the *limited paradigmatic modifiability* of multi-word terminological units. A multi-word expression such as "*long terminal repeat*" contains three token slots in which slot 1 is filled by "*long*", slot 2 by "*terminal*" and slot 3 by "*repeat*". The *limited paradigmatic modifiability* of such a trigram is now defined by the probability with which one or more such slots *cannot* be filled by other tokens. We estimate the likelihood of precluding the appearance of alternative tokens in particular slot positions by employing the standard combinatory formula without repetitions. For an n-gram (of size n) to select k slots (i.e., in an unordered selection) we thus define:

$$C(n,k) = \frac{n!}{k!(n-k)!} \tag{1}$$

[7]As can be seen, not only does the number of candidate types drop with increasing n-gram length but also the proportion of true terms. In fact, their proportion drops more sharply than can actually be seen from the above data because the various cut-off thresholds have a leveling effect.

For example, for $n = 3$ (word trigram) and $k = 1$ and $k = 2$ slots, there are three possible selections for each k for "*long terminal repeat*" and for "*t cell response*" (see Tables 2 and 3). k is actually a placeholder for any possible token (and its frequency) which fills this position in the training corpus.

n-gram		freq	$P\text{-}Mod$ (k=1,2)
long terminal repeat		434	0.03
k slots	possible selections *sel*	freq	mod_{sel}
$k = 1$	k_1 terminal repeat	460	0.940
	long k_2 repeat	448	0.970
	long terminal k_3	436	0.995
			mod_1 =0.91
$k = 2$	k_1 k_2 repeat	1831	0.23
	k_1 terminal k_3	1062	0.41
	long k_2 k_3	1371	0.32
			mod_2 =0.03

Table 2: $P\text{-}Mod$ and k-modifiabilities for $k = 1$ and $k = 2$ for the trigram term *"long terminal repeat"*

n-gram		freq	$P\text{-}Mod$ (k=1,2)
t cell response		2410	0.00005
k slots	possible selections *sel*	freq	mod_{sel}
$k = 1$	k_1 cell response	3248	0.74
	t k_2 response	2665	0.90
	t cell k_3	27424	0.09
			mod_1 =0.06
$k = 2$	k_1 k_2 response	40143	0.06
	k_1 cell k_3	120056	0.02
	t k_2 k_3	34925	0.07
			mod_2 =0.00008

Table 3: $P\text{-}Mod$ and k-modifiabilities for $k = 1$ and $k = 2$ for the trigram non-term *"t cell response"*

Now, for a particular k ($1 \leq k \leq n$; n = length of n-gram), the frequency of each possible selection, sel, is determined. The paradigmatic modifiability for a particular selection sel is then defined by the n-gram's frequency scaled against the frequency of sel. As can be seen in Tables 2 and 3, a *lower* frequency induces a *more limited* paradigmatic modifiability for a particular sel (which is, of course, expressed as a higher probability value; see the column labeled mod_{sel} in both tables). Thus, with s being the number of distinct possible selections for a particular k, the *k-modifiability*, mod_k, of an n-gram can be defined as follows (f stands for frequency):

$$mod_k(n\text{-}gram) := \prod_{i=1}^{s} \frac{f(n\text{-}gram)}{f(sel_i, n\text{-}gram)} \quad (2)$$

The *paradigmatic modifiability*, $P\text{-}Mod$, of an n-gram is the product of all its k-modifiabilities:[8]

$$P\text{-}Mod(n\text{-}gram) := \prod_{k=1}^{n} mod_k(n\text{-}gram) \quad (3)$$

Comparing the trigram $P\text{-}Mod$ values for $k = 1, 2$ in Tables 2 and 3, it can be seen that the term "*long terminal repeat*" gets a much higher weight than the non-term "*t cell response*", although their mere frequency values suggest the opposite. This is also reflected in the respective list rank (see Subsection 4.1 for details) assigned to both trigrams by the t-test and by our $P\text{-}Mod$ measure. While "*t cell response*" has rank 24 on the t-test output list (which directly reflects its high frequency), $P\text{-}Mod$ assigns rank 1249 to it. Conversely, "*long terminal repeat*" is ranked on position 242 by the t-test, whereas it occupies rank 24 for $P\text{-}Mod$. In fact, even lower-frequency multi-word units gain a prominent ranking, if they exhibit limited paradigmatic modifiability. For example, the trigram term "*porphyria cutanea tarda*" is ranked on position 28 by $P\text{-}Mod$, although its frequency is only 48 (which results in rank 3291 on the t-test output list). Despite its lower frequency, this term is judged as being relevant for the molecular biology domain.[9] It should be noted that the termhood values (and the corresponding list ranks) computed by $P\text{-}Mod$ also include $k = 3$ and, hence, take into account a reasonable amount of frequency load. As can be seen from the previous ranking examples, still this factor does not override the paradigmatic modifiability factors of the lower ks.

On the other hand, $P\text{-}Mod$ will also demote true terms in their ranking, if their paradigmatic modifiability is less limited. This is particularly the case if one or more of the tokens of a particular term often occur in the same slot of other equal-length n-grams. For example, the trigram term *"bone marrow cell"* occurs 1757 times in our corpus and is thus ranked quite high (position 31) by the t-test. $P\text{-}Mod$, however, ranks this term on position 550 because the to-

[8]Setting the upper limit of k to n (e.g., $n = 3$ for trigrams) actually has the pleasant side effect of including frequency in our modifiability measure. In this case, the only possible selection $k_1k_2k_3$ as the denominator of Formula (2) is equivalent to summing up the frequencies of all trigram term candidates.

[9]It denotes a group of related disorders, all of which arise from a deficient activity of the heme synthetic enzyme uroporphyrinogen decarboxylase (URO-D) in the liver.

ken *"cell"* also occurs in many other trigrams and thus leads to a less limited paradigmatic modifiability. Still, the underlying assumption of our approach is that such a case is more an exception than the rule and that terms are linguistically more 'frozen' than non-terms, which is exactly the intuition behind our measure of limited paradigmatic modifiability.

3.4 Methods of Evaluation

As already described in Subsection 3.2, standard procedures for evaluating the quality of termhood measures usually involve identifying the true positives among a (usually) arbitrarily set number of the m highest ranked candidates returned by a particular measure, a procedure usually carried out by a domain expert. Because this is labor-intensive (besides being unreliable), m is usually small, ranging from 50 to several hundreds.[10] By contrast, we choose a large and already consensual terminology to identify the true terms in our candidate sets. Thus, we are able to dynamically examine various m-highest ranked samples, which, in turn, allows for the plotting of standard precision and recall graphs for the entire candidate set. We thus provide a more reliable evaluation setting for ATR measures than what is common practice in the literature.

We compare our $P\text{-}Mod$ algorithm against the t-test measure,[11] which, of all standard measures, yields the best results in general-language collocation extraction studies (Evert and Krenn, 2001), and also against the widely used C-value, which aims at enhancing the common frequency of occurrence measure by making it sensitive to nested terms (Frantzi et al., 2000). Our baseline is defined by the proportion of true positives (i.e., the proportion of terms) in our bi-, tri- and quadgram candidate sets. This is equivalent to the likelihood of finding a true positive by blindly picking from one of the different sets (see Subsection 3.2).

[10]Studies on collocation extraction (e.g., by Evert and Krenn (2001)) also point out the inadequacy of such evaluation methods. In essence, they usually lead to very superficial judgments about the measures under scrutiny.

[11]Manning and Schütze (1999) describe how this measure can be used for the extraction of multi-word expressions.

4 Results and Discussion

4.1 Precision/Recall for Terminology Extraction

For each of the different candidate sets, we incrementally examined portions of the ranked output lists returned by each of the three measures we considered. The precision values for the various portions were computed such that for each percent point of the list, the number of true positives found (i.e., the number of terms) was scaled against the overall number of candidate items returned. This yields the (descending) precision curves in Figures 1, 2 and 3 and some associated values in Table 4.

	Portion of ranked list considered	**Precision** scores of measures		
		$P\text{-}Mod$	t-test	C-value
Bigrams	1%	0.82	0.62	0.62
	10%	0.53	0.42	0.41
	20%	0.42	0.35	0.34
	30%	0.37	0.32	0.31
	baseline	0.22	0.22	0.22
Trigrams	1%	0.62	0.55	0.54
	10%	0.37	0.29	0.28
	20%	0.29	0.23	0.23
	30%	0.24	0.20	0.19
	baseline	0.12	0.12	0.12
Quadgrams	1%	0.43	0.50	0.50
	10%	0.26	0.24	0.23
	20%	0.20	0.16	0.16
	30%	0.18	0.14	0.14
	baseline	0.08	0.08	0.08

Table 4: Precision scores for biomedical term extraction at selected portions of the ranked list

First, we observe that, for the various n-gram candidate sets examined, all measures outperform the baselines by far, and, thus, all are potentially useful measures for grading termhood. Still, the $P\text{-}Mod$ criterion substantially outperforms all other measures at almost all points for all n-grams examined. Considering 1% of the bigram list (i.e., the first 673 candidates) precision for $P\text{-}Mod$ is 20 points higher than for the t-test and the C-value. At 1% of the trigram list (i.e., the first 310 candidates), $P\text{-}Mod$'s lead is 7 points. Considering 1% of the quadgrams (i.e., the first 108 candidates), the t-test actually leads by 7 points. At 10% of the quadgram list, however, the $P\text{-}Mod$ precision score has overtaken the other ones. With increasing portions of all ranked lists considered, the precision curves start to converge toward the baseline, but $P\text{-}Mod$ maintains a steady advantage.

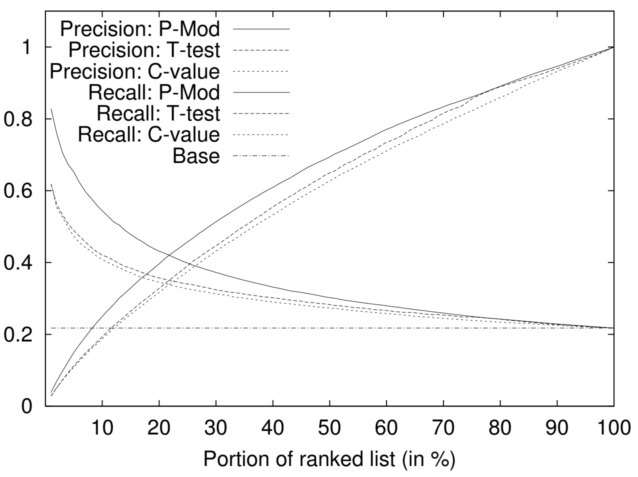

Figure 1: Precision/Recall for bigram biomedical term extraction

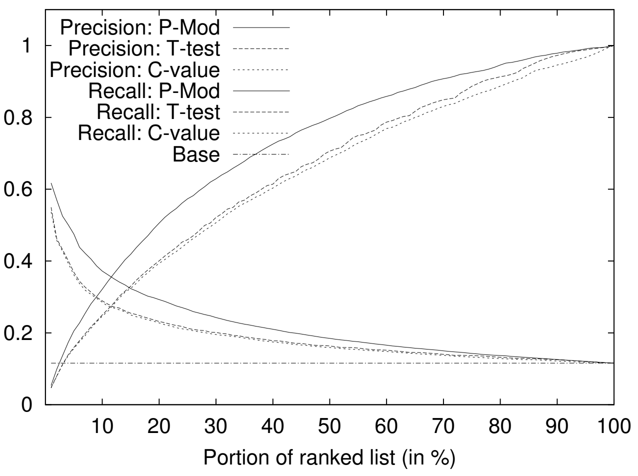

Figure 2: Precision/Recall for trigram biomedical term extraction

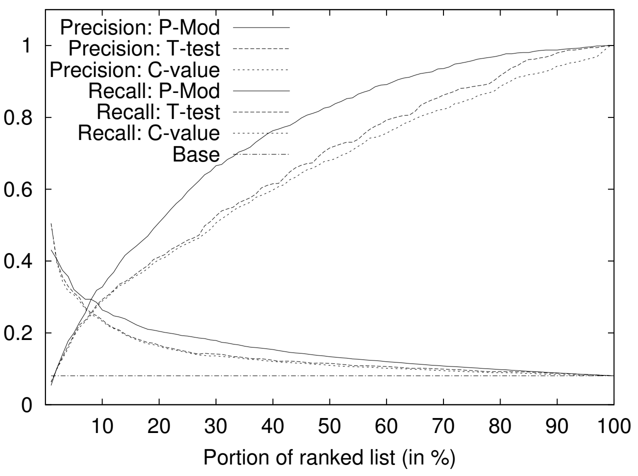

Figure 3: Precision/Recall for quadgram biomedical term extraction

The (ascending) recall curves in Figures 1, 2 and 3 and their corresponding values in Table 5 indicate which *proportion of all true positives* (i.e., the proportion of all terms in a candidate set) is identified by a particular measure at a certain point of the ranked list. For term extraction, recall is an even better indicator of a particular measure's performance because finding a bigger proportion of the true terms at an early stage is simply more economical.

	Recall scores of measures	Portion of Ranked List		
		$P\text{-}Mod$	t-test	C-value
Bigrams	0.5	29%	35%	37%
	0.6	39%	45%	47%
	0.7	51%	56%	59%
	0.8	65%	69%	72%
	0.9	82%	83%	85%
Trigrams	0.5	19%	28%	30%
	0.6	27%	38%	40%
	0.7	36%	50%	53%
	0.8	50%	63%	66%
	0.9	68%	77%	84%
Quadgrams	0.5	20%	28%	30%
	0.6	26%	38%	40%
	0.7	34%	49%	53%
	0.8	45%	62%	65%
	0.9	61%	79%	82%

Table 5: Portions of the ranked list to consider for selected recall scores for biomedical term extraction

Again, our linguistically motivated terminology extraction algorithm outperforms its competitors, and with respect to tri- and quadgrams, its gain is even more pronounced than for precision. In order to get a 0.5 recall for bigram terms, $P\text{-}Mod$ only needs to winnow 29% of the ranked list, whereas the t-test and C-value need to winnow 35% and 37%, respectively. For trigrams and quadgrams, $P\text{-}Mod$ only needs to examine 19% and 20% of the list, whereas the other two measures have to scan almost 10 additional percentage points. In order to obtain a 0.6, 0.7, 0.8 and 0.9 recall, the differences between the measures narrow for bigram terms, but they widen substantially for tri- and quadgram terms. To obtain a 0.6 recall for trigram terms, $P\text{-}Mod$ only needs to winnow 27% of its output list while the t-test and C-value must consider 38% and 40%, respectively. For a level of 0.7 recall, $P\text{-}Mod$ only needs to analyze 36%, while the t-test already searches 50% of the ranked list. For 0.8 recall, this relation is 50%

(*P-Mod*) to 63% (t-test), and at recall point 0.9, 68% (*P-Mod*) to 77% (t-test). For quadgram term identification, the results for *P-Mod* are equally superior to those for the other measures, and at recall points 0.8 and 0.9 even more pronounced than for trigram terms.

We also tested the significance of differences for these results, both comparing *P-Mod vs.* t-test and *P-Mod vs.* C-value. Because in all cases the ranked lists were taken from the same set of candidates (*viz.* the set of bigram, trigram, and quadgram candidate types), and hence constitute dependent samples, we applied the McNemar test (Sachs, 1984) for statistical testing. We selected 100 measure points in the ranked lists, one after each increment of one percent, and then used the two-tailed test for a confidence interval of 95%. Table 6 lists the number of significant differences for these measure points at intervals of 10 for the bi-, tri-, and quadgram results. For the bigram differences between *P-Mod* and C-value, all of them are significant, and between *P-Mod* and t-test, all are significantly different up to measure point 70.[12] Looking at the tri- and quadgrams, although the number of significant differences is less than for bigrams, the vast majority of measure points is still significantly different and thus underlines the superior performance of the *P-Mod* measure.

# of measure points	# of significant differences comparing *P-Mod* with					
	t-test	C-val	t-test	C-val	t-test	C-val
10	10	10	9	9	3	3
20	20	20	19	19	13	13
30	30	30	29	29	24	24
40	40	40	39	39	33	33
50	50	50	49	49	43	43
60	60	60	59	59	53	53
70	70	70	69	69	63	63
80	75	80	79	79	73	73
90	84	90	89	89	82	83
100	93	100	90	98	82	91
	bigrams		trigrams		quadgrams	

Table 6: Significance testing of differences for bi-, tri- and quadgrams using the two-tailed McNemar test at 95% confidence interval

[12]As can be seen in Figures 1, 2 and 3, the curves start to merge at the higher measure points and, thus, the number of significant differences decreases.

4.2 Domain Independence and Corpus Size

One might suspect that the results reported above could be attributed to the corpus size. Indeed, the text collection we employed in this study is rather large (104 million words). Other text genres and domains (e.g., clinical narratives, various engineering domains) or even more specialized biological subdomains (e.g., plant biology) do not offer such a plethora of free-text material as the molecular biology domain. To test the effect a drastically shrunken corpus size might have, we assessed the terminology extraction methods for trigrams on a much smaller-sized subset of our original corpus, *viz.* on 10 million words. These results are depicted in Figure 4.

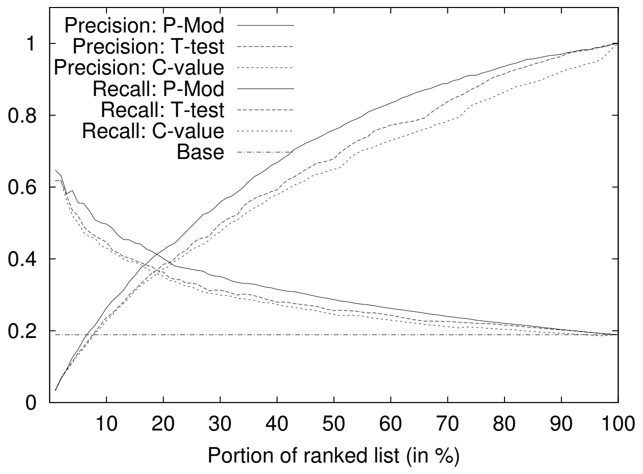

Figure 4: Precision/Recall for trigram biomedical term extraction on the 10-million-word corpus (cutoff $c \geq 4$, with 6,760 term candidate types)

The *P-Mod* extraction criterion still clearly outperforms the other ones on that 10-million-word corpus, both in terms of precision and recall. We also examined whether the differences were statistically significant and applied the two-tailed McNemar test on 100 selected measure points. Comparing *P-Mod* with t-test, most significant differences could be observed between measure points 20 and 80, with almost 80% to 90% of the points being significantly different. These significant differences were even more pronounced when comparing the results between *P-Mod* and C-value.

5 Conclusions

We here proposed a new terminology extraction method and showed that it significantly outperforms two of the standard approaches in distinguishing terms from non-terms in the biomedical literature. While mining scientific literature for new terminological units and assembling those in controlled vocabularies is a task involving several components, one essential building block is to measure the *degree of termhood* of a candidate. In this respect, our study has shown that a criterion which incorporates a vital linguistic property of terms, *viz.* their *limited paradigmatic modifiability*, is much more powerful than linguistically more uninformed measures. This is in line with our previous work on general-language collocation extraction (Wermter and Hahn, 2004), in which we showed that a linguistically motivated criterion based on the limited *syntagmatic* modifiability of collocations outperforms alternative standard association measures as well.

We also collected evidence that the superiority of the $P\text{-}Mod$ method relative to other term extraction approaches holds independent of the underlying corpus size (given a reasonable offset). This is a crucial finding because other domains might lack large volumes of free-text material but still provide sufficient corpus sizes for valid term extraction. Finally, since we only require shallow syntactic analysis (in terms of NP chunking), our approach might be well suited to be easily portable to other domains. Hence, we may conclude that, although our methodology has been tested on the biomedical domain only, there are essentially no inherent domain-specific restrictions.

A Backoff Model for Bootstrapping Resources for Non-English Languages*

Chenhai Xi and Rebecca Hwa
Department of Computer Science
University of Pittsburgh
{chenhai,hwa}@cs.pitt.edu

Abstract

The lack of annotated data is an obstacle to the development of many natural language processing applications; the problem is especially severe when the data is non-English. Previous studies suggested the possibility of acquiring resources for non-English languages by bootstrapping from high quality English NLP tools and parallel corpora; however, the success of these approaches seems limited for dissimilar language pairs. In this paper, we propose a novel approach of combining a bootstrapped resource with a small amount of manually annotated data. We compare the proposed approach with other bootstrapping methods in the context of training a Chinese Part-of-Speech tagger. Experimental results show that our proposed approach achieves a significant improvement over EM and self-training and systems that are only trained on manual annotations.

1 Introduction

Natural language applications that use supervised learning methods require annotated training data, but annotated data is scarce for many non-English languages. It has been suggested that annotated data for these languages might be automatically created by leveraging parallel corpora and high-accuracy English systems (Yarowsky and Ngai, 2001; Diab and Resnik, 2002). The studies are centered around the assumption that linguistic analyses for English (e.g., Part-of-Speech tags, Word sense disambiguation, grammatical dependency relationships) are also valid analyses in the translation of the English. For example, in the English noun phrase *the red apples*, *red* modifies *apples*; the same modifier relationship also exists in its French translations *les pommes rouges*, even though the word orders differ. To the extent that the assumption is true, annotated data in the non-English language can be created by projecting English analyses across a word aligned parallel corpus. The resulting projected data can then serve as (albeit noisy) training examples to develop applications in the non-English language.

The projection approach faces both a theoretical and a practical challenge. Theoretically, it is well-known that two languages often do not express the same meaning in the same way (Dorr, 1994). Practically, the projection framework is sensitive to component errors. In particular, poor word alignments significantly degrade the accuracy of the projected annotations. Previous research on resource projection attempts to address these problems by redistributing the parameter values (Yarowsky and Ngai, 2001) or by applying transformation rules (Hwa et al.,

*We thank Stephen Clark, Roger Levy, Carol Nichols, and the three anonymous reviewers for their helpful comments.

2002). Their experimental results suggest that while these techniques can overcome some errors, they are not sufficient for projected data that are very noisy.

In this work, we tackle the same problems by relaxing the *zero manual annotation* constraint. The main question we address is: how can we make the most out of a small set of manually labeled data (on the non-English side). Following the work of Yarowsky and Ngai (2001) we focus on the task of training a Part-of-Speech (POS) tagger, but we conduct our experiments with the more dissimilar language pair of English-Chinese instead of English-French. Through empirical studies, we show that when the word alignment quality is sufficiently poor, the error correction techniques proposed by Yarowsky and Ngai are unable to remove enough mistakes in the projected data. We propose an alternative approach that is inspired by backoff language modeling techniques in which the parameters of two tagging models (one trained on manually labeled data; the other trained on projected data) are combined to achieve a more accurate final model.

2 Background

The idea of trying to squeeze more out of annotated training examples has been explored in a number of ways in the past. Most popular is the family of bootstrapping algorithms, in which a model is seeded with a small amount of labeled data and iteratively improved as more unlabeled data are folded into the training set, typically, through unsupervised learning. Another approach is *active learning* (Cohn et al., 1996), in which the model is also iteratively improved but the training examples are chosen by the learning model, and the learning process is supervised. Finally, the work that is the closest to ours in spirit is the idea of joint estimation (Smith and Smith, 2004).

Of the bootstrapping methods, perhaps the most well-known is the Expectation Maximization (EM) algorithm. This approach has been explored in the context of many NLP applications; one example is text classification (Nigam et al., 1999). Another bootstrapping approach reminiscent of EM is *self-training.* Yarowsky (1995) used this method for word sense disambiguation. In self-training, annotated examples are used as seeds to train an initial classifier with any supervised learning method. This initial classifier is then used to automatically annotate data from a large pool of unlabeled examples. Of these newly labeled data, the ones labeled with the highest confidence are used as examples to train a new classifier. Yarowsky showed that repeated application of this process resulted in a series of word sense classifiers with improved accuracy and coverage. Also related is the co-training algorithm (Blum and Mitchell, 1998) in which the bootstrapping process requires multiple learners that have different *views* of the problem. The key to co-training is that the views should be *conditionally independent* given the label. The strong independence requirement on the views is difficult to satisfy. For practical applications, different features sets or models (that are not conditionally independent) have been used as an approximation for different views. Co-training has been applied to a number of NLP applications, including POS-tagging (Clark et al., 2003), parsing (Sarkar, 2001), word sense disambiguation (Mihalcea, 2004), and base noun phrase detection (Pierce and Cardie, 2001). Due to the relaxation of the view independence assumption, most empirical studies suggest a marginal improvement. The common thread between EM, self-training, and co-training is that they all bootstrap off of unannotated data. In this work, we explore an alternative to "pure" unannotated data; our data have been automatically annotated with projected labels from English. Although the projected labels are error-prone, they provide us with more information than automatically predicted labels used in bootstrapping methods.

With a somewhat different goal in mind, active learning addresses the problem of choosing the most informative data for annotators to label so that the model would achieve the greatest improvement. Active learning also has been applied to many NLP applications, including POS tagging (Engelson and Dagan, 1996) and parsing (Baldridge and Osborne, 2003). The drawback of an active learning approach is that it assumes that a staff of annotators is waiting on call, ready to label the examples chosen by the system at every iteration. In practice, it is more likely that one could only afford to staff annotators for a limited period of time. Although active learning is not a focus in this paper, we owe some ideas to active learning in choosing a small initial set of training examples; we discuss these ideas in section 3.2.

More recently, Smith and Smith (2004) proposed to merge an English parser, a word alignment model, and a Korean PCFG parser trained from a small number of Korean parse trees under a unified log linear model. Their results suggest that a joint model produces somewhat more accurate Korean parses than a PCFG Korean parser trained on a small amount of annotated Korean parse trees alone. Their motivation is similar to the starting point of our work: that a word aligned parallel corpus and a small amount of annotated data in the foreign language side offer information that might be exploited. Our approach differs from theirs in that we do not optimize the three models jointly. One concern is that joint optimization might not result in optimal parameter settings for the individual components. Because our focus is primarily on acquiring non-English language resources, we only use the parallel corpus as a means of projecting resources from English.

3 Our Approach

This work explores developing a Chinese POS tagger without a large manually annotated corpus. Our approach is to train two separate models from two different data sources: a large corpus of automatically tagged data (projected from English) and a small corpus of manually tagged data; the two models are then combined into one via the Whitten-Bell backoff language model.

3.1 Projected Data

One method of acquiring a large corpus of automatically POS tagged Chinese data is by *projection* (Yarowsky and Ngai, 2001). This approach requires a sentence-aligned English-Chinese corpus, a high-quality English tagger, and a method of aligning English and Chinese words that share the same meaning. Given the parallel corpus, we tagged the English words with a publicly available maximum entropy tagger (Ratnaparkhi, 1996), and we used an implementation of the IBM translation model (Al-Onaizan et al., 1999) to align the words. The Chinese words in the parallel corpus would then receive the same POS tags as the English words to which they are aligned. Next, the basic projection algorithm is modified to accommodate two complicating factors. First, word alignments are not always one-to-one. To compensate, we assign a default tag to unaligned Chinese words; in the case of one-Chinese-to-many-English, the Chinese word would receive the tag of the final English word. Second, English and Chinese do not share the same tag set. Following Yarowsky and Ngai (2001), we define 12 equivalence classes over the 47 Penn-English-Treebank POS tags. We refer to them as *Core Tags*. With the help of 15 hand-coded rules and a Naive Bayes model trained on a small amount of manually annotated data, the Core Tags can be expanded to the granularity of the 33 Penn-Chinese-Treebank POS tags (which we refer to as *Full Tags*).

3.2 Manually Annotated Data

Since the amount of manual annotation is limited, we must decide what type of data to annotate. In the spirit of active learning, we aim to select sentences that may bring about the greatest improvements in the accuracy of our model. Because it is well known that handling unknown words is a serious problem for POS taggers, our strategy for selecting sentences for manual annotation is to maximize the word coverage of the in ital model. That is, we wish to find a small set of sentences that would lead to the greatest reduction of currently unknown words Finding these sentences is a NP-hard problem because the 0/1 knapsack problem could be reduced to this problem in polynomial-time (Gurari, 1989). Thus, we developed an approximation algorithm for finding sentences with the maximum word

```
$M$ : number of tokens will be annotated.
$S$={$s_1, s_2, \ldots, s_n$}: the unannotated corpus.
$S_{sel}$ : set of selected sentences in $S$.
$S_{unsel}$ : set of unselected sentences in $S$.
$|S_{sel}|$ : number of tokens in $S_{sel}$.
$TYPE(S_{sel})$ : number of types in $S_{sel}$.
**MWC:**
    randomly choose $S_{sel} \subset S$
     such that $|S_{sel}| \leq M$.
 **For** each sentence $s_i$ in $S_{sel}$
    find a sentence $r_j$ in $S_{unsel}$
      which maximizes **swap_score**($s_i, r_j$).
    if **swap_score**($s_i, r_j$) $> 0$
    {
        $S_{sel} = (S_{sel} - s_i) \cup r_j$;
        $S_{unsel} = (S_{unsel} - r_j) \cup s_i$;
    }

**swap_score**($s_i, r_j$)
{
   $S_{sel\_new} = (S_{sel} - s_i) \cup r_j$;
   if ( $|S_{sel\_new}| > M$ ) return -1;
   else return $TYPE(S_{sel\_new}) - TYPE(S_{sel})$;
}
```

coverage of unknown words (MWC). This algorithm is described in Figure 1,

3.3 Basic POS Tagging Model

It is well known that a POS tagger can be trained with an HMM (Weischedel et al., 1993). Given a trained model, the most likely tag sequence $\hat{T} = \{t_1, t_2, \ldots t_n\}$ is computed for the input word sentence: $\hat{W} = \{w_1, w_2, \ldots w_n\}$:

$$\hat{T} = \arg\max_T P(T|W) = \arg\max_T P(T|W)P(T)$$

The transition probability $P(T)$ is approximated by a trigram model:

$$P(T) \approx p(t_1)p(t_2|t_1)\prod_{i=3}^{n} p(t_i|t_{i-1}, t_{i-2}),$$

and the observation probability $P(W|T)$ is computed by

$$P(W|T) \approx \prod_{i=1}^{n} p(w_i|t_i).$$

3.4 Combined Models

From the two data sources, two separate trigram taggers have been trained (T_{anno} from manually annotated data and T_{proj} from projected data). This section considers ways of combining them into a single tagger. The key insight that drives our approach is based on reducing the effect of unknown words. We see the two data sources as complementary in that the large projected data source has better word coverage while the manually labeled one is good at providing tag-to-tag transitions. Based on this principle, one way of merging these two taggers into a single HMM (denoted as T_{interp}) is to use interpolation:

$$\begin{aligned} p_{interp}(w|t) &= \lambda \times p_{anno}(w|t) \\ &\quad +(1-\lambda) \times p_{proj}(w|t) \\ p_{interp}(t_i|t_{i-1}, t_{i-2}) &= p_{anno}(t_i|t_{i-1}, t_{i-2}) \end{aligned}$$

where λ is a tunable weighting parameter[1] of the merged tagger. This approach may be problematic because it forces the model to always include some fraction of poor parameter values. Therefore, we propose to estimate the observation probabilities using backoff. The parameters of T_{back} are estimated as follows:

$$p_{back}(w|t) = \begin{cases} \alpha(t) \times p_{anno}(w|t) \text{ if } p_{anno}(w|t) > 0 \\ \beta(t) \times p_{proj}(w|t) \text{ if } p_{anno}(w|t) = 0 \end{cases}$$

$$p_{back}(t_i|t_{i-1}, t_{i-2}) = p_{anno}(t_i|t_{i-1}, t_{i-2})$$

where $\alpha(t)$ is a discounting coefficient and β is set to satisfy that $\sum_{\text{all words}} P(w|t) = 1$. The discounting coefficient is computed using the Witten-Bell discounting method:

$$\alpha(t) = \frac{C_{anno}(t)}{C_{anno}(t) + S_{anno}(t)},$$

where $C_{anno}(t)$ is the count of tokens whose tag is t in the manually annotated corpus and

[1]In our experiments, the value of λ is set to 0.8 based on held-out data.

$S_{anno}(t)$ is the seen types of words with tag t. In other words, we trust the parameter estimates from the model trained on manual annotation by default unless it is based on unreliable statistics.

4 Experiments

We conducted a suite of experiments to investigate the effect of allowing a small amount of manually annotated data in conjunction with using annotations projected from English. We first establish a baseline of training on projected data alone in Section 4.1. It is an adaptation of the approach described by Yarowsky and Ngai (2001). Next, we consider the case of using manually annotated data alone in Section 4.2. We show that there is an increase in accuracy when the MWC active learning strategy is used. In Section 4.3, we show that with an appropriate merging strategy, a tagger trained from both data sources achieves higher accuracy. Finally, in Section 4.4, we evaluate our approach against other semi-supervised methods to verify that the projected annotations, though noisy, contain useful information.

We use an English-Chinese Federal Broadcast Information Service (FBIS) corpus as the data source for the projected annotation. We simulated the manual annotation process by using the POS tags provided by the Chinese Treebank version 4 (CHTB). We used about a thousand sentences from CHTB as held-out data. The remaining sentences are split into ten-fold cross validation sets. Each test set contains 1400 sentences. Training data are selected (using MWC) from the remaining 12600 sentences. The reported results are the average of the ten trials. One tagger is considered to be better than another if, according to the paired t-test, we are at least 95% confident that their difference in accuracy is non-zero. Performance is measured in terms of the percentage of correctly tagged tokens in the test data. For comparability with T_{proj} (which assumes no availability of manually annotated data), most experimental results are reported with respect to the reduced Core Tag gold standard; evaluation against the full 33 CHTB tag gold standard is reported in Section 4.4.

4.1 Tagger Trained from Projected Data

To determine the quality of T_{proj} for Chinese, we replicate the POS-tagging experiment in Yarowsky and Ngai (2001). Trained on all projected data, the tagger has an accuracy of 58.2% on test sentences. The low accuracy rate suggests that the projected data is indeed very noisy. To reduce the noise in the projected data, Yarowsky and Ngai developed a re-estimation technique based on the observation that words in French, English and Czech have a strong tendency to exhibit only a single core POS tag and very rarely have more than two. Applying the same re-estimation technique that favors this bias to the projected Chinese data raises the final tagger accuracy to 59.1%. That re-estimation did not help English-Chinese projection suggests that the dissimilarity between the two languages is an important factor. A related reason for the lower accuracy rate is due to poor word alignments in the English-Chinese corpus. As a further noise reduction step, we automatically filter out sentence pairs that were poorly aligned (i.e., the sentence pairs had too many unaligned words or too many one-to-many alignments). This results in a corpus of about 9000 FBIS sentences. A tagger trained on the filtered data has an improved accuracy of 64.5%. We take this to be T_{proj} used in later experiments.

4.2 Taggers Trained from Manually Labeled Data

This experiment verifies that the Maximum Word Coverage (MWC) selection scheme presented in Section 3.2 is helpful in selecting data for training T_{anno}. We compare it against random selection. Figure 2 plots the taggers' performances on test sentences as the number of manually annotated tokens increase from 100 to 30,000. We see that the taggers trained on data selected by MWC outperform those trained on randomly selected data. Thus, in the main experiments, we always use MWC to select the set of manually tagged data for training T_{anno}.

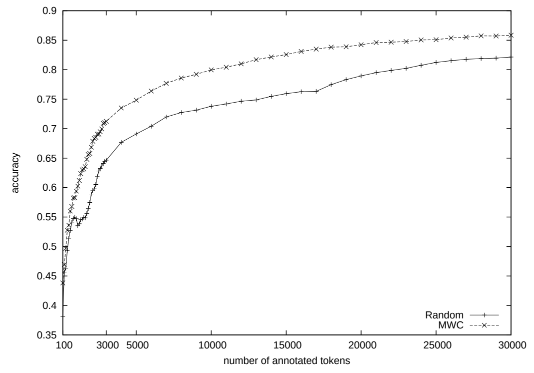

Figure 2: A comparison between MWC and random selection.

4.3 Evaluation of the Combined Taggers

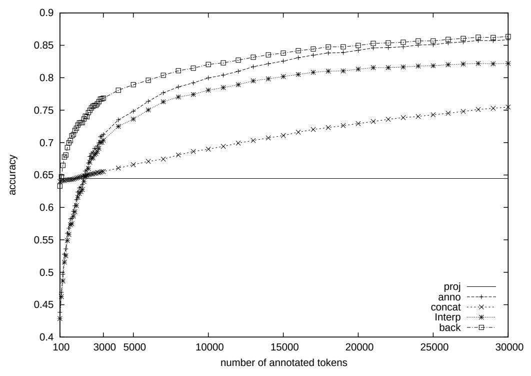

Figure 3: A comparison of the proposed backoff approach against alternative methods of combining T_{proj} and T_{anno}

To investigate how T_{anno} and T_{proj} might be merged to form a higher quality tagger, we conduct an experiment to evaluate the different alternatives described in section 3.4: T_{interp}, and T_{back}. They are compared against three baselines: T_{anno}, T_{proj}, and T_{concat}, a tagger trained from the concatenation of the two data sources. To determine the effect of manual annotation, we vary the size of the training set for T_{anno} from 100 tokens (fewer than 10 sentences) to 30,000 tokens (about 1000 sentences). The learning curves are plotted in Figure 3. The result suggests that T_{back} successfully incorporates information from both the manually annotated data and the projected data. The improvement over training on manually annotated data alone (T_{anno}) is especially high when fewer than 10,000 manually annotated tokens are available. As expected, T_{interp}, and T_{concat} perform worse than T_{anno} because they are not as effective at discounting the erroneous projected annotations.

4.4 Comparisons with Other Semi-Supervised Approaches

This experiment evaluates the proposed backoff approach against two other semi-supervised approaches: self-training (denoted as T_{self}) and EM (denoted as T_{em}). Both start with a fully supervised model (T_{anno}) and iteratively improve it by seeing more unannotated data.[2] As discussed earlier, a major difference between our proposed approach and the bootstrapping methods is that our approach makes use of annotations projected from English while the bootstrapping methods rely on unannotated data alone. To investigate the effect of leveraging from English resources, we use the Chinese portion of the FBIS parallel corpus (the same 9000 sentences as the training corpus of T_{proj} but without the projected tags) as the unannotated data source for the bootstrapping methods.

Figure 4 compares the four learning curves. We have evaluated them both in terms of the Core Tag gold standard and in terms of Full Tag gold standard. Although all three approaches produce taggers with higher accuracies than that of T_{anno}, our backoff approach outperforms both self-training and EM. The difference is especially prominent when manual annotation is severely limited. When more manual annotations are made available, the gap narrows; however, the differences are still statistically significant at 30,000 manually annotated tokens. These results suggest that projected data have more useful information than unannotated data.

[2]In our implementation of self-training, the top 10% of the unannoated sentences with the highest confidence scores is selected. The confidence score is computed as: $\frac{\log P(T|W)}{\text{length of the sentence}}$.

5 Discussion

While the experimental results support our intuition that T_{back} is effective in making use of both data sources, there are still two questions worth addressing. First, there may be other ways of estimating the parameters of a merged HMM from the parameters of T_{anno} and T_{proj}. For example, a natural way of merging the two taggers into a single HMM (denoted as T_{merge}) is to use the values of the observation probabilities from T_{proj} and the values of the transition probabilities from T_{anno}:

$$\begin{aligned} p_{merge}(w|t) &= p_{proj}(w|t), \\ p_{merge}(t_i|t_{i-1}, t_{i-2}) &= p_{anno}(t_i|t_{i-1}, t_{i-2}). \end{aligned}$$

Another is the reverse of T_{merge}:

$$\begin{aligned} p_{rev\_merge}(w|t) &= p_{anno}(w|t) \\ p_{rev\_merge}(t_i|t_{i-1}, t_{i-2}) &= p_{proj}(t_i|t_{i-1}, t_{i-2}) \end{aligned}$$

T_{merge} is problematic because it ignores all manual word-tag annotations; however, T_{rev_merge}'s learning curve is nearly identical to that of T_{anno} (graph not shown). Its models do not take advantage of the broader word coverage of the projected data, so it does not perform as well as T_{back}. T_{rev_merge} outperforms T_{merge} when trained from more than 2000 manually annotated tokens. We make two observations from this finding. One is that the differences between $p_{proj}(t_i|t_{i-1}, t_{i-2})$ and $p_{anno}(t_i|t_{i-1}, t_{i-2})$ are not large. Another is that the success of the merged HMM tagger hinges on the goodness of the observation probabilities, $p(w|t)$. This is in accord with our motivation in improving the reliability of $p(w|t)$ through backoff.

Second, while our experimental results suggest that T_{back} outperforms self-training and EM, these approaches are not incompatible with one another. Because T_{back} is partially estimated from the noisy corpus of projected annotations, it might be further improved by applying a bootstrapping algorithm over the noisy corpus (with the projected tags removed). To test our hypothesis, we initialized the self-training algorithm with a backoff tagger that used 3000 manually annotated tokens. This led to a slight but statistically significant improvement, from 74.3% to 74.9%.

6 Conclusion and Future Work

In summary, we have shown that backoff is an effective technique for combining manually annotated data with a large but noisy set of automatically annotated data (from projection). Our approach is the most useful when a small amount of annotated tokens is available. In our experiments, the best results were achieved when we used 3000 manually annotated tokens (approximately 100 sentences).

The current study points us to several directions for future work. One is to explore ways of applying the proposed approach to other learning models. Another is to compare against other methods of combining evidences from multiple learners. Finally, we will investigate whether the proposed approach can be adapted to more complex tasks in which the output is not a class label but a structure (e.g. parsing).

Abstract

This paper considers the problem of automatically inducing role-semantic annotations in the FrameNet paradigm for new languages. We introduce a general framework for semantic projection which exploits parallel texts, is relatively inexpensive and can potentially reduce the amount of effort involved in creating semantic resources. We propose projection models that exploit lexical and syntactic information. Experimental results on an English-German parallel corpus demonstrate the advantages of this approach.

1 Introduction

Shallow semantic parsing, the task of automatically identifying the semantic roles conveyed by sentential constituents, has recently attracted much attention, partly because of its increasing importance for potential applications. For instance, information extraction (Surdeanu et al., 2003), question answering (Narayanan and Harabagiu, 2004) and machine translation (Boas, 2002) could stand to benefit from broad coverage semantic processing.

The FrameNet project (Fillmore et al., 2003) has played a central role in this endeavour by providing a large lexical resource based on semantic roles. In FrameNet, meaning is represented by frames, schematic representations of situations. Semantic roles are frame-specific, and are called frame elements. The database associates frames with lemmas (verbs, nouns, adjectives) that can evoke them (called frame-evoking elements or FEEs), lists the possible syntactic realisations of their semantic roles, and provides annotated examples from the British National Corpus (Burnard, 1995). The availability of rich annotations for the surface realisation of semantic roles has triggered interest in semantic parsing and enabled the development of data-driven models (e.g., Gildea and Jurafsky, 2002).

Frame: DEPARTING		
Frame Elements	THEME	**The officer** left the house. **The plane** leaves at seven. **His** departure was delayed.
	SOURCE	We departed **from New York**. He retreated **from his opponent**. The woman left the **house**.
FEEs	abandon.v, desert.v, depart.v, departure.n, emerge.v, emigrate.v, emigration.n, escape.v, escape.n, leave.v, quit.v, retreat.v, retreat.n, split.v, withdraw.v, withdrawal.n	

Table 1: Example of FrameNet frame

Table 1 illustrates an example from the FrameNet database, the DEPARTING frame. It has two roles, a THEME which is the moving object and a SOURCE expressing the initial position of the THEME. The frame elements are realised by different syntactic expressions. For instance, the THEME is typically an NP, whereas the SOURCE is often expressed by a prepositional phrase (see the expressions in boldface in Table 1). The DEPARTING frame can be evoked by *abandon*, *desert*, *depart*, and several other verbs as well as nouns (see the list of FEEs in Table 1).

Although recent advances in semantic parsing[1] have greatly benefited from the availability of the English FrameNet, unfortunately such resources are largely absent for other languages. The English FrameNet (Version 1.1) contains 513 frames covering 7,125 lexical items and has been under development for approximately six years. Although FrameNets are currently under construction for German, Spanish, and Japanese, these resources are still in their infancy and of limited value for modelling purposes. Methods for acquiring FrameNets from corpora automatically would greatly reduce the human effort involved and facilitate their development for new languages.

In this paper, we propose a method which employs parallel corpora for acquiring frame elements

[1]Approaches to modelling semantic parsing are too numerous to list; see Carreras and Màrquez (2005) for an overview.

and their syntactic realisations (see the upper half of Table 1) for new languages. Our method leverages the existing English FrameNet to overcome the resource shortage in other languages by exploiting the translational and structural equivalences present in aligned data. The idea underlying our approach can be summarised as follows: (1) given a pair of sentences *E* (English) and *L* (new language) that are translations of each other, annotate *E* with semantic roles; and then (2) *project* these roles onto *L*. In this manner, we induce semantic structure on the *L* side of the parallel text, which can then serve as data for training a statistical semantic parser for *L* that is independent of the parallel corpus.

We first assess if the main assumption of semantic projection is warranted (Section 3), namely whether frames and semantic roles exhibit a high degree of parallelism across languages. Then we propose two broad classes of projection models that utilise lexical and syntactic information (Section 4), and show experimentally that roles can be projected from English onto German with high accuracy (Section 5). We conclude the paper by discussing the implications of our results and future work (Section 6).

2 Related work

A number of recent studies exploit parallel corpora for cross-linguistic knowledge induction. In this paradigm, annotations for resource-rich languages like English are projected onto another language through aligned parallel texts. Yarowsky et al. (2001) propose several projection algorithms for deriving monolingual tools (ranging from part-of-speech taggers, to chunkers and morphological analysers) without additional annotation cost. Hwa et al. (2002) assess the degree of syntactic parallelism in dependency relations between English and Chinese. Their results show that, although assuming direct correspondence is often too restrictive, syntactic projection yields good enough annotations to train a dependency parser. Smith and Smith (2004) explore syntactic projection further by proposing an English-Korean bilingual parser integrated with a word translation model.

Previous work has primarily focused on the projection of morphological and grammatico-syntactic information. Inducing semantic resources from low density languages still poses a significant challenge to data-driven methods. The challenge is recognised by Fung and Chen (2004) who construct a Chinese FrameNet by mapping English FrameNet entries to concepts listed in HowNet[2], an on-line ontology for Chinese, however without exploiting parallel texts.

The present work extends previous approaches on annotation projection by inducing FrameNet semantic roles from parallel corpora. Analogously to Hwa et al. (2002), we investigate whether there are indeed semantic correspondences between two languages, since there is little hope for projecting meaningful annotations in nonparallel semantic structures. Similarly to Fung and Chen (2004) we automatically induce semantic role annotations for a target language. In contrast to them, we resort to parallel corpora as a source of semantic equivalence. Thus, we avoid the need for a target concept dictionary in addition to the English FrameNet. We propose a general framework for semantic projection that can incorporate different knowledge sources. To our knowledge, the framework and its application to semantic role projection are novel.

3 Creation of a Gold Standard Corpus

Sample Selection. To evaluate the output of our projection algorithms, we created a gold standard corpus of English-German sentence pairs with manual FrameNet frame and role annotations. The sentences were sampled from Europarl (Koehn, 2002), a corpus of professionally translated proceedings of the European Parliament. Europarl is available in 11 languages with up to 20 million words per language aligned at the document and sentence level.

Recall that frame projection is only meaningful if the same frame is appropriate for both sentences in a projection pair. This constrains sample selection for two reasons: first, FrameNet is as yet incomplete with respect to its coverage. So, a randomly selected sentence pair may evoke novel frames or novel senses of already existing frames (e.g., the "greeting" sense of *hail* which is currently not listed in FrameNet). Second, due to translational variance, there is no a priori guarantee that words which are mutual translations evoke the same frame. For example, the English verb *finish* is often translated in German by the adverb *abschließend*, which arguably cannot have a role set identical to *finish*. Relying solely on the English FrameNet database for sampling would yield many sentence pairs which are either inappropriate for the present study (because they do not evoke the same frames) or simply problematic for annotation since they are outside the

[2]See `http://www.keenage.com/zhiwang/e_zhiwang.html`.

present coverage of the database.

For the above reasons, our sample selection procedure was informed by two existing resources, the English FrameNet and SALSA, a FrameNet-compatible database for German currently under development (Erk et al., 2003). We first used the publicly available GIZA++ (Och and Ney, 2003) software to induce English-German word alignments. Next, we gathered all German-English sentences in the corpus that had at least one pair of aligned words (w_e, w_g), which were listed in FrameNet and SALSA, respectively, and had at least one frame in common. These sentences exemplify 83 frame types, 696 lemma pairs, and 265 unique English and 178 unique German lemmas. Sentence pairs were grouped into three bands according to their frame frequency (High, Medium, Low). We randomly selected 380 pairs from each band. The total sample consisted of ,140 sentence pairs.

This procedure produces a realistic corpus sample for the role projection task; similar samples can be drawn for new language pairs using either existing bilingual dictionaries (Fung and Chen, 2004) or automatically constructed semantic lexicons (Padó and Lapata, 2005).

Annotation. Two annotators, with native-level proficiency in German and English, manually labelled the parallel corpus with semantic information. Their task was to identify the frame for a given predicate in a sentence, and assign the corresponding roles. They were provided with detailed guidelines that explained the task using multiple examples. During annotation, they had access to parsed versions of the sentences in question (see Section 5 for details), and to the English FrameNet and SALSA.

The annotation proceeded in three phases: a training phase (40 sentences), a calibration phase (100 sentences), and a production mode phase (1000 sentences). In the calibration phase, sentences were doubly annotated to assess inter-annotator agreement. In production mode, sentences were split into two distinct sets, each of which was annotated by a single coder. We ensured that no annotator saw both parts of any sentence pair to guarantee independent annotation of the bilingual data. Each coder annotated approximately the same amount of data in English and German.

Table 2 shows the results of our inter-annotator agreement study. In addition to the widely used Kappa statistic, we computed a number of different agreement measures: the ratio of frames common between two sentences (Frame Match), the ratio of common roles (Role Match), and the ratio of roles with identical spans (Span Match). As can be seen, annotators tend to agree in frame assignment; disagreements are mainly due to fuzzy distinctions between frames (e.g., between AWARENESS and CERTAINTY). As can be seen from Table 2, annotators agree in what roles to assign (Role Match is 0.95 for both English and German); agreeing on their exact spans is a harder problem.

Measure	English	German	All
Frame Match	0.90	0.87	0.88
Role Match	0.95	0.95	0.95
Span Match	0.85	0.83	0.84
Kappa	0.86	0.90	0.87

Table 2: Monolingual inter-annotation agreement on the calibration set

Measure	Precision	Recall	F-score
Frame Match	0.72	0.72	0.72
Role Match	0.91	0.92	0.91

Table 3: Cross-lingual semantic parallelism between English and German

Semantic Parallelism. Since we obtained parallel FrameNet annotations for English and German, we were able to investigate the degree of semantic parallelism between the two languages. More specifically, we treated the German annotation as gold standard against which we compared the English annotations. To facilitate comparisons with the output of our automatic projection methods (see Section 4), we measured parallelism using precision and recall. Frames and frame roles were counted as matching if they were annotated in a sentence, regardless of their spans. The results are shown in Table 3.

The cross-lingual data exhibit more than twice the amount of frame differences than monolingual data (compare Tables 2 and 3). This indicates that frame disambiguation methods must be employed in automatic role projection to ensure that two aligned tokens evoke the same frame. However, frame disambiguation is outside the scope of the present paper.

On the positive side, role agreement is relatively high (0.91 F-score). This indicates that in cases where frames match across languages, semantic roles could be accurately transferred (provided that these languages diverge little in their argument structure). This observation offers support for the projection approach put forward in this paper. Note, however, that a practical projection system could attain this level of performance only if it could employ an oracle to recover annotators' decisions about the span of roles. We can obtain a more realistic upper bound for an automatic system from the monolingual Role Span agreement figure (F-score 0.84). The latter represents a ceiling for the agreement we can expect from sentences annotated by different annotators.

4 Projection of Semantic Information

In this section, we formalise the semantic projection task and give the details of our modelling approach. All models discussed here project semantic annotations from a source language to a target language. As explained earlier, our present study is only concerned with the projection of roles between matching frames.

4.1 Problem Formulation

We assume that we are provided with source and target sentences represented as sets of entities $e_s \in E_s$ and $e_t \in E_t$. These entities can be words, constituents, phrases, or other groupings. In addition, we are given the semantic annotation of the source sentences from which we can directly read off the source semantic role assignment $a_s : R \rightarrow 2^{E_s}$, where R is the set of semantic roles. The goal of the projection is to specify the target semantic role assignments $a_t : R \rightarrow 2^{E_t}$, which are unknown.[3]

Clearly, effecting the projection requires establishing some form of match between the source and target entities. We therefore formalise projection as a function which maps the source role assignment and a set of matches $M \subseteq E_s \times E_t$ onto a new target role assignment:

$$proj : (A_s \times M) \rightarrow (R \rightarrow 2^{E_t}) \qquad (1)$$

By way of currying, we can state the new target role assignment as a function which directly computes a set of target entities, given the source role assignment, a set of entity matches, and a role:

$$a_t : (A_s \times M \times R) \rightarrow 2^{E_t} \qquad (2)$$

According to this formalisation, the crucial part of semantic projection is to identify a correct and exhaustive set of entity matches. Obviously, this raises the question of what linguistic information is appropriate for establishing M. Unfortunately, any attempt to compute a match based on categorical data derived from linguistic analyses (e.g., parts of speech, phrase types or grammatical relations), needs to empirically derive cross-linguistic similarities between categories, a task which must be repeated for every new language pair, and requires additional data.

$r \in R$	Semantic role
$t_s \in T_s, t_t \in T_t$	Source, target tokens
$al \in Al : T_s \rightarrow 2^{T_t}$	Word alignment
$a_s \in A_s : R \rightarrow 2^{T_s}$	Source role assignment
$a_t : (A_s \times Al \times R) \rightarrow 2^{T_t}$	Projected target role assignment

Table 4: Notation and signature summary for word-based projection

Rather than postulating an ad hoc similarity function, we use word alignments to derive information about semantic roles in the target language. Our first model family (Section 4.2) relies exclusively on this knowledge source. Although potentially useful as a proxy for semantic equivalence, automatically induced alignments are often noisy, thus leading to errors in annotation projection (Yarowsky et al., 2001). For example, function words commonly diverge across languages and are systematically misaligned; furthermore, alignments are restricted to single words rather than word combinations. This observation motivates a second model family with a bias towards linguistically meaningful entities (Section 4.3). Such entities can be constituents derived from the output of a parser or non-recursive syntactic structures (i.e., chunks).

In this paper we compare simple word alignment models against more resource intensive models that utilise constituent-based information and examine whether syntactic knowledge significantly contributes to semantic projection.

4.2 Word-based Projection Model

The first model family uses source and target *word tokens* as entities for projection. In this framework, projection models can be defined by deriving the set of matches M directly from word alignments. The resulting signatures are shown in Table 4.

Our first projection model assigns to each role r with source span $s(r)$ the set of all target tokens which are aligned to a token in the source span:

$$a_w(a_s, al, r) = \bigcup_{t_s \in a_s(r)} al(t_s) \qquad (3)$$

[3]Without loss of generality, we limit ourselves to one frame per sentence, as does FrameNet.

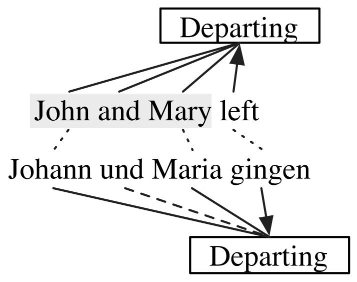

Figure 1: Word alignment-based semantic projection of Role THEME (shadowed), Frame DEPARTING

The main shortcoming of this model is that it cannot capture an important linguistic property of semantic roles, namely that they almost always cover contiguous stretches of text. We can repair non-contiguous projections by applying a "convex complementing" heuristic to the output of (3), which fills all holes in a sequence of tokens, without explicit recourse to syntactic information. We define the convex complementing heuristic as:

$$a_{cw}(a_s, al, r) = \{t_t \mid \min(i(a_{t_1})) \leq i(t_t) \leq \max(i(a_{t_1}))\} \quad (4)$$

where i returns the index of a token t.

The two models just described are illustrated in Figure 1. The frame DEPARTING is introduced by *left* and *gingen* in English and German, respectively. For simplicity, we only show the edges corresponding to the THEME role. In English, the THEME is realised by the words *John and Mary*. The dotted lines show the available word alignments. The projection of the THEME role according to (3) consists only of the tokens {*Johann*, *Maria*} (shown by the plain black lines); the convex complementing heuristic in model (4) adds the token *und*, resulting in the (correct) convex set {*Johann*, *und*, *Maria*}.

4.3 Constituent-based Projection Model

Our second model family attempts to make up for errors in the word alignment by projecting from and to *constituents*. In this study, our constituents are obtained from full parse trees (see Section 5 for details). Models which use non-recursive structures are also possible; however, we leave this to future work.

The main difference from word-based projection models is the introduction of constituent information as an intermediate level; we thus construct a *constituent alignment* for which only a subset of word alignments has to be accurate. The appropriate signatures and notation for constituent-based projection are summarised in Table 5.

In order to keep the model as flexible as possible, and to explore the influence of different design decisions, we model constituent-based projection as two independently parameterisable subtasks: first we compute a real-valued *similarity function* between source and target constituents; then, we employ the similarity function to align relevant constituents and project the role information.

Similarity functions. In principle, any function which matches the signature in Table 5 could be used. In practice, the use of linguistic knowledge runs into the problem of defining similarity between category-based representations discussed above. For this reason, we limit ourselves to two simple similarity functions based on word overlap: Given source and target constituents c_s and c_t, we define the *word overlap* o_w of c_s with c_t as the proportion of tokens within c_t aligned to tokens within c_s. Let $yield(c)$ denote the set of tokens in the yield of a constituent c, then:

$$o_w(c_s, c_t) = \frac{|(\bigcup_{t_s \in yield(c_s)} al(t_s)) \cap yield(c_t)|}{|yield(c_t)|} \quad (5)$$

Since the asymmetry of this overlap measure leads to high overlap scores for small target constituents, we define *word overlap similarity*, as the product of two constituents' mutual overlap:

$$sim(c_s, c_t) = o(c_s, c_t) \cdot o(c_t, c_s) \quad (6)$$

Simple word-based overlap has one undesired characteristic: larger constituents tend to be less similar because of missing alignments (e.g., between function words). Since content words are arguably more important for the role projection task, we define a second overlap measure, *content word overlap* o_{wc}, which takes only nouns, verbs and adjectives into account. Let $yield_c(c)$ denote the set of tokens in the yield of c that are content words, then:

$$o_{wc}(c_s, c_t) = \frac{|(\bigcup_{t_s \in yield_c(c_s)} al(t_s)) \cap yield_c(c_t)|}{|yield_c(c_t)|} \quad (7)$$

Constituent alignment. Considerable latitude is available in interpreting a similarity function to derive a constituent alignment. Due to space limitations, we demonstrate two basic models.

Our first *forward constituent alignment* model (a_{fc}), aligns source constituents that form the span

$r \in R$	Semantic role
$c_s \in C_s, c_t \in C_t$	Source and target constituents
$yield : C \rightarrow T$	Yield of a constituent
$yield_c : C \rightarrow T$	Content word yield of a constituent
$al \in Al : T_s \rightarrow 2^{T_t}$	Word alignment
$a_s \in A_s : R \rightarrow 2^{C_s}$	Source role assignment
$sim : C_s \times C_t \rightarrow \mathbb{R}^+$	Constituent similarity
$a_t : A_s \times Sim \times R \rightarrow 2^{C_t}$	Projected target role assignment

Table 5: Notation and signature summary for constituent-based projection

of a role to a single target constituent. We compute the similarity of a target constituent c_t to a set of source constituents $c_s \in a_s(r)$ by taking the product similarity for each source and target constituent pair:

$$a_{fc}(a_s, sim, r) = \underset{c_t \in C_t}{\operatorname{argmax}} \prod_{c_s \in a_s(r)} sim(c_s, c_t) \quad (8)$$

This projection model forces the target role assignment to be a function, i.e., it makes the somewhat simplifying assumption that each role corresponds to a single target constituent.

Our second *backward constituent alignment* model (a_{bc}) proceeds in the opposite direction: it iterates over target constituents and attempts to determine their most similar source constituent for each c_t. If the aligned source constituent is labelled with a role, it is projected onto c_t:

$$a_{bc}(a_s, sim, r) = \{c_t \,|\, (\underset{c_s \in C_s}{\operatorname{argmax}}\, sim(c_s, c_t)) \in a_s(r)\} \quad (9)$$

In general, a_{bc} allows for more flexible role projection: it will sometimes decide not to project a role at all (if the source constituents are dissimilar to any target constituents), or it can assign a role to more than one target constituent; however, this means that there is less control over what is projected, and wrong alignments can lead to wrong results more easily.

Finally, if no word alignments are found for complete source or target constituents, the maximal similarity rating in a_{bc} or a_{bf} will be zero. This is often the case for semantically weak single-word constituents such as demonstrative pronouns (e.g., *[That] is right./ [Das] ist richtig.*). When we observe this phenomenon, we heuristically skip unaligned constituents (*zero skipping*).

Figure 2 contrasts the two constituent-based projection models using the frame QUESTIONING as

	NP_1	PP_2	NP_3
NP_4	0.33	0.5	1
PP_5	**0.67**	1	0.5
NP_6	<u>0.33</u>	0	0

Figure 2: Constituent-based semantic projection of role ADDRESSEE (shadowed), frame QUESTIONING. Below: Constituent similarity matrix.

an example. Again, we only show one role, ADDRESSEE, indicated by the shadowed box in Figure 2. Note that the object NP in German was misparsed as an NP and a PP, a relatively frequent error. The difference between the two decision procedures can be explained straightforwardly by looking at the table below the graph, which shows the similarity matrix for the constituents according to equation (6). In this table, the source constituents (indices 1–3) correspond to columns, and the target constituents (indices 4–6) to rows. The alignment model in (8) iterates over labelled source constituents (here only NP_1) and chooses the row with the highest value as the target constituent for a candidate role. In our case, this is the PP_5 (cell in boldface). In contrast, model (9) iterates over all target constituents (i.e., rows) and checks if the most similar source constituent bears a role label. Since NP_1 is the most similar constituent for NP_6 (underlined cell), (9) assigns the QUESTIONING role to NP_6.

5 Experiments

Evaluation Framework. We implemented the models described in the previous section and used them to project semantic information from English onto German. For the constituent-based models, constituent information was obtained from the output of Collins' parser (1997) for English and Dubey's parser (2004) for German. Words were

Model	Precision	Recall	F-score
w	0.41	0.40	0.41
cw	0.46	0.45	0.46
Upper bound	0.85	0.84	0.84

Table 6: Results for word-based projection models

aligned using the default setting[4] of GIZA++ (Och and Ney, 2003), a publicly available implementation of the IBM models and HMM word alignment models. We evaluated the projected roles against the "gold standard" roles obtained from the manual annotation (see Section 3). We also compared our results to the upper bound given by the inter-annotator agreement on the calibration data set.

Results. Table 6 shows our results for the word-based projection models. The simplest word-based model (a_w), obtains an F-score of 0.41. This is a good result considering that the model does not exploit any linguistic information (e.g., parts of speech or syntactic structure). It also supports our hypothesis that word alignments are useful for the role projection task. The convex complementing heuristic (a_{cw}) delivers an F-score increase of five points over the "words only" model, simply by making up for holes in the word alignment.

We evaluated eight instantiations of the constituent-based projection models; the results are shown in Table 7. The best model (in boldface) uses forward constituent alignment, content word-based overlap similarity, and zero skipping. We observe that backward constituent alignment-based models (1–4) perform similarly to word-based projection models (the F-score ranges between 0.40 and 0.45). However, they obtain considerably higher precision (albeit lower recall) than the word-based models. This may be an advantage if the projected data is destined for training target-language semantic parsers. This precision/recall pattern appears to be a direct result of a_{bc}, which only projects a role from c_s to c_t if c_s "wins" against all other source constituents, thus resulting in reliable, but overly cautious projections, which cannot not be further improved by zero skipping.

The forward constituent alignment models (5–8) show consistently higher performance than word-based models and models 1–4, indicating that the stronger assumptions made by forward alignment

[4]The training scheme involved five iterations of Model 1, five iterations of the HMM model, five iterations of Model 3, and five iterations of Model 4.

Model	*al*	*o*	0-skip	Precision	Recall	F-score
1	*bc*	*w*	no	0.70	0.33	0.45
2	*bc*	*w*	yes	0.70	0.33	0.45
3	*bc*	*wc*	no	0.65	0.32	0.42
4	*bc*	*wc*	yes	0.65	0.32	0.42
5	*fc*	*w*	no	0.61	0.60	0.60
6	*fc*	*w*	yes	0.66	0.60	0.63
7	*fc*	*wc*	no	0.62	0.60	0.61
8	*fc*	*wc*	**yes**	**0.70**	**0.60**	**0.65**
Upper bound				0.85	0.84	0.84

Table 7: Results for constituent-based projection models (*al*: constituent alignment model; *o*: overlap measure; 0-skip: zero skipping)

are justified in the data. In addition, we also find that we can increase precision by concentrating on reliable alignments. This is achieved by using the zero skipping heuristic (compare the odd vs. even-numbered models in Table 7) and by computing overlap on content words (compare Models 6 vs. 8, and 5 vs. 7).

We used the χ^2 test to examine whether the differences observed between the two classes of models are statistically significant. The best constituent-based model significantly outperforms the best word-based model both in terms of precision ($\chi^2 = 114.47$, $p < 0.001$) and recall ($\chi^2 = 400.40$, $p < 0.001$). Both projection models perform significantly worse than humans ($p < 0.001$).

Discussion. Our results confirm that constituent information is important for the semantic projection task. Our best model adopts a conservative strategy which enforces a one-to-one correspondence between roles and target constituents. This strategy leads to high precision, however recall lags behind (see Model 8 in Table 7). Manual inspection of the projection output revealed that an important source of missing roles are word alignments gaps. Such gaps are not only due to noisy alignments, but also reflect genuine structural differences between translated sentences. Consider the following (simplified) example for the STATEMENT frame (introduced by *say*) and its semantic role STATEMENT (introduced by *we*):

(10) We claim X and we say Y
Wir behaupten X und — sagen Y

The word alignment correctly aligns the German pronoun *wir* with the first English *we* and leaves the second occurrence unaligned. Since there is no corresponding German word for the second *we*, projection of the SPEAKER role fails. In future work, this problem could be handled with explicit identification of empty categories (see Dienes and Dubey, 2003).

6 Conclusions

In this paper, we argue that parallel corpora show promise in relieving the lexical acquisition bottleneck for low density languages. We proposed semantic projection as a means of obtaining FrameNet annotations automatically without additional human effort. We examined semantic parallelism, a prerequisite for accurate projection, and showed that semantic roles can be successfully projected for predicate pairs with matching frame assignments. Similarly to previous work (Hwa et al., 2002), we find that some mileage can be gained by assuming direct correspondence between two languages. However, linguistic knowledge is key in obtaining meaningful projections. Our experiments show that the use of constituent information yields substantial improvements over relying on word alignment alone. Nevertheless, the word-based models offer a good starting point for low-density languages for which parsers are not available. Their output could be further post-processed manually or automatically using bootstrapping techniques (Riloff and Jones, 1999).

We have presented a general, flexible framework for semantic projection which can be easily applied to other languages. An important direction for future work lies in the assessment of more shallow syntactic information (i.e., chunks) which can be obtained more easily for new languages, and generally in the integration of more linguistic knowledge to guide projection. Finally, we will incorporate into our projection approach automatic semantic role annotations for the source language and investigate the potential of the projected annotations for training semantic parsers for the target language.

Abstract

We present a lexicon-free post-processing method for optical character recognition (OCR), implemented using weighted finite state machines. We evaluate the technique in a number of scenarios relevant for natural language processing, including creation of new OCR capabilities for low density languages, improvement of OCR performance for a native commercial system, acquisition of knowledge from a foreign-language dictionary, creation of a parallel text, and machine translation from OCR output.

1 Introduction

The importance of rapidly retargeting existing natural language processing (NLP) technologies to new languages is widely accepted (Oard, 2003). Statistical NLP models have a distinct advantage over rule based approaches to achieve this goal, as they require far less manual labor; however, training statistical NLP methods requires on-line text, which can be hard to find for so-called “low density” languages — that is, languages where few on-line resources exist. In addition, for many languages of interest input data are available mostly in printed form, and must be converted to electronic form prior to processing.

Optical character recognition (OCR) is often the only feasible method to perform this conversion, owing to its speed and cost-effectiveness. Unfortunately, the performance of OCR systems is far from perfect and recognition errors significantly degrade the performance of NLP applications. This is true both in resource acquisition, such as automated bilingual lexicon generation (Kolak et al., 2003), and for end-user applications such as rapid machine translation (MT) in the battlefield for document filtering (Voss and Ess-Dykema, 2000). Moreover, for low density languages, there simply may not be an OCR system available.

In this paper, we demonstrate that via statistical post-processing of existing systems, it is possible to achieve reasonable recognition accuracy for low density languages altogether lacking an OCR system, to significantly improve on the performance of a trainable commercial OCR system, and even to improve significantly on a native commercial OCR system.[1] By taking a post-processing approach, we require minimal assumptions about the OCR system used as a starting point.

The proper role of our post-processing approach depends on the language. For languages with little commercial potential for OCR, it may well provide the most practical path for language-specific OCR development, given the expensive and time consuming nature of OCR development for new languages and the “black box” nature of virtually all state-of-the-art OCR systems. For languages where native OCR development may take place, it is a fast, practical method that allows entry into a new language until native OCR development catches up. For these, and also for languages where native systems exist,

[1]Currently we assume the availability of an OCR system that supports the script of the language-of-interest, or which is script independent (Natarajan et al., 2001).

Proceedings of Human Language Technology Conference and Conference on Empirical Methods in Natural Language Processing (HLT/EMNLP), pages 867–874, Vancouver, October 2005. ©2005 Association for Computational Linguistics

we show that post-processing can yield improvements in performance.

Sections 2 and 3 describe the method and its implementation. In Section 4 we cover a variety of relevant NLP scenarios: Creating OCR capabilities for Igbo, performing OCR on a dictionary for Cebuano, using OCR to acquire the Arabic side of a common parallel text, and evaluating the value of OCR post-processing for machine translation of Arabic and Spanish. In Sections 5 and 6 we discuss related work and summarize our findings.

2 Post-Processing System

We use the noisy channel framework to formulate the correction problem, revising our previous model (Kolak et al., 2003). That model takes the form

$$P(O,b,a,C,W) = P(O,b|a,C,W)P(a|C,W)P(C|W)P(W)$$

whose components are a word-level source model $P(W)$, a word-to-character model $P(C|W)$, a segmentation model $P(a|C,W)$, and a model for character sequence transformation, $P(O,b|a,C,W)$. W is the correct word sequence and C is the corresponding character sequence, which is recognized as O by the OCR system. a and b are segmentation vectors for C and O.

The original model requires a lexicon that covers all words in the processed text — a strong assumption, especially for low density languages. We converted the model into a character-based one, removing the need for a lexicon. Generation of W is replaced by generation of C, which renders $P(C|W)$ irrelevant, and the model becomes

$$P(O,b,a,C) = P(O,b|a,C)P(a|C)P(C)$$

Although word-based models generally perform better, moving from words to characters is a necessary compromise because word-based models are useless in the absence of a lexicon, which is the case for many low-density languages.

In addition to eliminating the need for a lexicon, we developed a novel method for handling word merge/split errors.[2] Rather than modeling these errors explicitly using a segmentation model, we simply treat them as character deletion/insertion errors involving the space character, allowing us to handle them within the error model. The segmentation step is absorbed into the character transformation step, so a and b are no longer necessary, hence the final equation becomes

$$P(O,C) = P(O|C)P(C)$$

which is a direct application of the noisy channel model. We can describe the new generative process as follows: First, a sequence of characters C are generated, with probability $P(C)$, and the OCR system converts it into O with probability $P(O|C)$. For example, if the actual input was a_car and it was recognized as $ajar$, $P(ajar, a\_car) = P(ajar|a\_car)P(a\_car)$. Using the channel model to address word merge/split errors without actually using a word level model is, to our knowledge, a novel contribution of our approach.

3 Implementation

We implemented our post-processing system using the framework of weighted finite state machines (WFSM), which provides a strong theoretical foundation and reduces implementation time, thanks to freely available toolkits, such as the AT&T FSM Toolkit (Mohri et al., 1998). It also allows easy integration of our post-processor with numerous NLP applications that are implemented using FSMs (e.g. (Knight and Graehl, 1997; Kumar and Byrne, 2003)).

3.1 Source Model

The source model assigns probability $P(C)$ to original character sequences, C. We use character level n-gram language models as the source model, since n-gram models are simple, easy to train, and usually achieve good performance. More complicated models that make use of constraints imposed by a particular language, such as vowel harmony, can be utilized if desired. We used the CMU-Cambridge Language Modeling Toolkit v2 (Clarkson and Rosenfeld, 1997) for training, using Witten-Bell smoothing and vocabulary type 1; all other parameters were left at their default values.

[2] A merge error occurs when two or more adjacent items are recognized as one, and a split error occurs when an item is recognized as two or more items. These errors can happen both at word level and character level.

3.2 Channel Model

The channel model assigns a probability to O given that it was generated from C. We experimented with two probabilistic string edit distance models for implementing the channel model. The first, following our earlier model (2003), permits single-character substitutions, insertions, and deletions, with associated probabilities. For example, $P(ajar|a\textvisiblespace car) \approx P(a{\mapsto}a)P(\textvisiblespace{\mapsto}\epsilon)P(c{\mapsto}j)P(a{\mapsto}a)P(r{\mapsto}r)$. Note that we are only considering the most likely edit sequence here, as opposed to summing over all possible ways to convert $a\textvisiblespace car$ to $ajar$. The second is a slightly modified version of the spelling correction model of Brill and Moore (2000).[3] This model allows many-to-many edit operations, which makes $P(liter|litre) \approx P(l{\mapsto}l)P(i{\mapsto}i)P(tre{\mapsto}ter)$ possible. We will refer to the these as the single-character (SC) and multi-character (MC) error models, respectively.

We train both error models over a set of corresponding ground truth and OCR sequences, $\langle C, O\rangle$. Training is performed using expectation-maximization: We first find the most likely edit sequence for each training pair to update the edit counts, and then use the updated counts to re-estimate edit probabilities. For MC, after finding the most likely edit sequence, extended versions of each non-copy operation that include neighboring characters are also considered, which allows learning any common multi-character mappings. Following Brill and Moore, MC training performs only one iteration of expectation-maximization.

In order to reduce the time and space requirements of the search at correction time, we impose a limit on number of errors per token. Note that this is not a parameter of the model, but a limit required by its computational complexity. A lower limit will almost always result in lower correction performance, so the highest possible limit allowed by time and memory constraints should be used. It is possible to correct more errors per token by iterating the correction process. However, iterative correction cannot guarantee that the result is optimal under the model.

[3]We ignore the location of the error within the word, since it is not as important for OCR as it is for spelling.

3.3 Chunking

Since we do not require a lexicon, we work on lines of text rather than words. Unfortunately the search space for correcting a complete line is prohibitively large and we need a way to break it down to smaller, independent chunks. The chunking step is not part of the model, but rather a pre-processing step: chunks are identified, each chunk is corrected independently using the model, and the corrected chunks are put back together to generate the output.

Spaces provide a natural break point for chunks. However, split errors complicate the process: if parts of a split word are placed in different chunks, the error cannot be corrected. For example, in Figure 1, chunking (b) allows the model to produce the desired output, but chunking (a) simply does not allow combining “sam” and “ple” into “sample”, as each chunk is corrected independently.

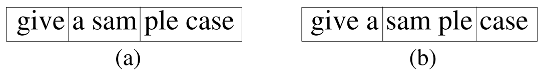

Figure 1: Example of a bad and a good chunking

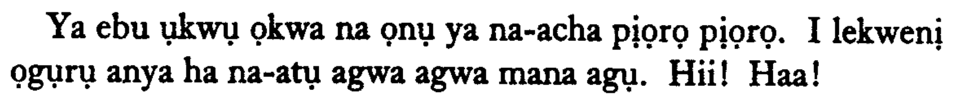
We address this by using the probabilities assigned to spaces by the source model for chunking. We break the line into two chunks using the space with the highest probability and repeat the process recursively until all chunks are reduced to a reasonable size, as defined by time and memory limitations. Crucially, spurious spaces that cause split errors are expected to have a low probability, and therefore breaking the line using high probability spaces reduces the likelihood of placing parts of a split word in different chunks.

If a lexicon does happen to be available, we can use it to achieve more reliable chunking, as follows. The tokens of the input line that are present in the lexicon are assumed to be correct. We identify runs of out-of-lexicon tokens and attempt to correct them together, allowing us to handle split errors. Note that in this case the lexicon is used only to improve chunking, not for correction. Consequently, coverage of the lexicon is far less important.

Our lexicon-free chunking algorithm placed an erroneous boundary at 11.3% of word split points for Arabic test data (Section 4.3). However, correction performance was identical to that of error-



Ya ebu ụkwụ ọkwa na ọnụ ya na-acha pịọrọ pịọrọ. I lekwenị ọgụrụ anya ha na-atụ agwa agwa mana agụ. Hii! Haa!

Figure 2: A small excerpt from Akụkọ

free chunking.[4] Incorrect decisions did not hurt because the correction method was not able to fix those particular split errors, regardless. The errors of the chunking and correction models coincided as they both rely on the same language model. Therefore, chunking errors are unlikely to reduce the correction performance.

3.4 Correction

Correction is performed by estimating the most probable source character sequence $\hat{C}$ for a given observed character sequence O, using the formula:

$$\hat{C} = \underset{C}{\operatorname{argmax}}\{P(O|C)P(C)\}$$

We first encode O as an FSA and compose it with the inverted error model FST.[5] The resulting FST is then composed with the language model FSA. The final result is a lattice that encodes all feasible sequences C, along with their probabilities, that could have generated O. We take the sequence associated with the most likely path through the lattice as $\hat{C}$.

4 Evaluation

We evaluate our work on OCR post-processing in a number of scenarios relevant for NLP, including creation of new OCR capabilities for low density languages, improvement of OCR performance for a native commercial system, acquisition of knowledge from a foreign-language dictionary, creation of a parallel text, and machine translation from OCR output. The languages studied include Igbo, Cebuano, Arabic, and Spanish.

For intrinsic evaluation, we use the conventional Word Error Rate (WER) metric, which is defined as

$$WER(C, O) = \frac{WordEditDistance(C, O)}{WordCount(C)}$$

We do not use the Character Error Rate (CER) metric, since for almost all NLP applications the unit of information is the words. For extrinsic evaluation of machine translation, we use the BLEU metric (Papineni et al., 2002).

4.1 Igbo: Creating an OCR System

Igbo is an African language spoken mainly in Nigeria by an estimated 10 to 18 million people, written in Latin script. Although some Igbo texts use diacritics to mark tones, they are not part of the official orthography and they are absent in most printed materials. Other than grammar books, texts for Igbo, even hardcopy, are extremely difficult to obtain. To our knowledge, the work reported here creates the first OCR system for this language.

For the Igbo experiments, we used two sources. The first is a small excerpt containing 6727 words from the novel "Juo Obinna" (Ubesie, 1993). The second is a small collection of short stories named "Akụkọ Ife Nke Ndị Igbo" (Green and Onwuamaegbu, 1970) containing 3544 words. We will refer to the former as "Juo" and the latter as "Akụkọ" hereafter. We generated the OCR data using a commercial English OCR system.[6] Juo image files were generated by scanning 600dpi laser printer output at 300dpi resolution. Akụkọ image files were generated by scanning photocopies from the bound hardcopy at 300dpi. Figure 2 provides a small excerpt from the actual Akụkọ page images used for recognition. For both texts, we used the first two thirds for training and the remaining third for testing.

We trained error and language models (EMs and LMs) using the training sets for Juo and Akụkọ separately, and performed corrections of English OCR output using different combinations of these models on both test sets. Table 1 shows the results for the Juo test set while Table 2 presents the results for Akụkọ. The relative error reduction ranges from 30% to almost 80%. The SC error model performs better than the MC error model under all conditions.

[4]Ignoring errors that result in valid words, lexicon-based chunking is always error-free.

[5]Inversion reverses the direction of the error model, mapping observed sequences to possible ground truth sequences.

Table 2: Post-correction WER for English OCR on Akụkọ

This is due to the fact that MC requires more training data than SC. Furthermore, most of the errors in the data did not require many-to-many operations. Results in Tables 1 and 2 are for 6-gram language model and error limit of 5; corresponding 3-gram error rates were 1% to 2% (absolute) higher.

The best correction performance is achieved when both the EM and LM training data come from the same source as the test data, almost doubling the performance achieved when they were from a different source.[7] Note that the amount of training data is small, four to eight pages, so optimizing performance via manual entry of document-specific training text is not unrealistic for scenarios involving long documents such as books.

4.1.1 Using a Trainable OCR System

In an additional experiment with Igbo, we found that post-processing can improve performance substantially even when an OCR system trained on Igbo characters is the starting point. In particular, the commercial OCR system used for Igbo experiments supports user-trained character shape models. Using Juo as the source, we trained the commercial OCR system manually on Igbo characters, resulting in a 7.43% WER on Juo without postprocessing.[8] Note that this is slightly higher than the 7.11% WER achieved using an English OCR system together with our post-processing model. We used a 6-gram LM, and a SC EM with error limit of 5. Table 3 shows that by post-processing the Igbo-trained OCR system, we reduce the word error rate by 50%.

Conditions		Results	
LM Data	EM Data	WER (%)	Red. (%)

Akụkọ	Akụkọ	7.38	0.67
Original OCR Output		**7.43**	-

Table 3: Post-correction WER for trained OCR system on Juo

4.2 Cebuano: Acquiring a Dictionary

Cebuano is a language spoken by about 15 million people in the Philippines, written in Latin script. The scenario for this experiment is converting a Cebuano hardcopy dictionary into electronic form, as in DARPA's Surprise Language Dry Run (Oard, 2003). The dictionary that we used had diacritics, probably to aid in pronunciation. The starting-point OCR data was generated using a commercial OCR system.[9] The fact that the tokens to be corrected come from a dictionary means (1) there is little context available and (2) word usage frequencies are not reflected. Character-based models may be affected by these considerations, but probably not to the extent that word-based models would be.

Table 4 shows WER for Cebuano after post-processing. The *size* column represents the number of dictionary entries used for training, where each entry consists of one or more Cebuano words. As can be seen from the table, our model reduces WER substantially for all cases, ranging from 20% to 50% relative reduction. As expected, the correction performance increases with the amount of training data; note, however, that we achieve reasonable correction performance even using only 500 dictionary entries for training.

[7]There was no overlap between training and test data under any circumstance.

[8]The system trains by attempting OCR on a document and asking for the correct character whenever it is not confident.

[9]ScanSoft Developer's Kit 2000, which has no built-in support for Cebuano.

Conditions			Results	
Size	LM	EM	WER (%)	Red. (%)

1000	6-gram	MC	4.67	41.77
27363	3-gram	SC	4.34	45.89
27363	3-gram	MC	4.14	48.38
27363	6-gram	SC	4.55	43.27
27363	**6-gram**	**MC**	**3.97**	**50.50**
Original OCR Output			**8.02**	-

Table 4: Post-correction WER for Cebuano

Contrary to the Igbo results, the MC error model performs better than the SC error model. And, interestingly, the 3-gram language model performs better than the 6-gram model, except for the largest training data and MC error model combination. Both differences are most likely caused by the implications of using a dictionary as discussed above.

4.3 Arabic: Acquiring Parallel Text

We used Arabic to illustrate conversion from hardcopy to electronic text for a widely available parallel text, the Bible (Resnik et al., 1999; Kanungo et al., 2005; Oard, 2003). We divided the Bible into ten equal size segments, using the first segment for training the error model, the first nine segments for the language model, and the first 500 verses from the last segment for testing. Since diacritics are only used in religious text, we removed all diacritics. The OCR data was generated using a commercial Arabic OCR system.[10] Note that this evaluation differs from Igbo and Cebuano, as the experiments were performed using an existing *native* OCR system. It also allowed us to evaluate chunking, as Arabic data has far more word merge/split errors compared to Igbo and Cebuano.

Table 5 shows the correction performance for Arabic under various conditions. The *Limit* column lists the maximum number of errors per token allowed and the *M/S* column indicates whether correction of word merge/split errors was allowed. We achieve significant reductions in WER for Arabic. The first two rows show that the 6-gram language model performs much better than the 3-gram model. Interestingly, higher order n-grams perform worse when we allow word merge/split errors. Note that for handling word merge/split errors we need to learn the character distributions within lines, rather than within words as we normally do. Consequently, more training data is required for reliable parameter estimation. Handling word merge/split errors improve the performance, which is expected. Allowing fewer errors per token reduces the performance, since it is not possible to correct words that have more character errors than the limit. Unfortunately, increasing the error limit increases the search space exponentially, making it impossible to use high limits. As mentioned in Section 3.2, iterative correction is a way to address this problem.

Table 5: Post-correction WER for Arabic

4.4 Extrinsic Evaluation: MT

While our post-processing methods reduce WER, our main interest is their impact on NLP applications. We have performed machine translation experiments to measure the effects of OCR errors and the post-processing approach on NLP application performance.

For Arabic, we trained a statistical MT system using the first nine sections of the Bible data. The language model is trained using the CMU-Cambridge toolkit and the translation model using the GIZA++ toolkit (Och and Ney, 2000). We used the ReWrite decoder (Germann, 2003) for translation.

BLEU scores for OCR, corrected, and clean text were 0.0116, 0.0141, and 0.0154, respectively. This establishes that OCR errors degrade the performance of the MT system, and we are able to bring the performance much closer to the level of performance on clean text by using post-processing. Clearly the BLEU scores are quite low; we are planning to perform experiments on Arabic using a more advanced translation system, such as Hiero (Chiang, 2005).

MT System	Input Text	BLEU Score
Systran	OCR	0.2000
Systran	Corrected	0.2606
Systran	Clean	0.3188
ReWrite	OCR	0.1792
ReWrite	Corrected	0.2234

Table 6: Spanish-English translation results

In order to test in a scenario with better translation performance, we performed MT evaluations using Spanish. We used a commercial translation system, Systran, in addition to statistical translation. More resources being available for this language, corrected text for Spanish experiments was obtained using our original model that takes advantage of a lexicon (2003). Table 6 shows that scores are much higher compared to Arabic, but the pattern of improvements using post-processing is the same.

5 Related Work

There has been considerable research on automatic error correction in text. Kukich (1992) provides a general survey of the research in the area. Unfortunately, there is no standard evaluation benchmark for OCR correction, and implementations are usually not publicly available, making a direct comparison difficult.

Most correction methods are not suitable for low density languages as they rely on lexicons. Goshtasby and Ehrich (1988) present a lexicon-free method based on probabilistic relaxation labeling. However, they use the probabilities assigned to individual characters by the OCR system, which is not always available. Perez-Cortes et al. (2000) describe a method which does not have this limitation. They use a stochastic FSM that accepts the smallest k-testable language consistent with a representative sample. While the method can handle words not in its lexicon in theory, it was evaluated using a large k to restrict corrections to the lexicon. They report reducing error rate from 33% to below 2% on OCR output of hand-written Spanish names.

In addition to providing alternatives, the literature provides complementary methods. Guyon and Pereira (1995) present a linguistic post-processor based on variable memory length Markov models that is designed to be used as the language model component of character recognizers. Their model can be used as the source model for our method. Since it is a variable length model, it can allow us to handle higher order n-grams.

A script-independent OCR system is presented by Natarajan et al. (2001). The system is evaluated on Arabic, Chinese, and English, achieving 0.5% to 5% CER under various conditions. Since our post-processing method can be used to reduce the error rate of a trained OCR system, the two methods can be combined to better adapt to new languages.

Voss and Ess-Dykema (2000) evaluated the effects of OCR errors on MT in the context of the FALCon project, which combines off-the-shelf OCR and MT components to provide crude translations for filtering. They report significant degradation in translation performance as a result of OCR errors. For instance, for the Spanish system, OCR process reduced the number of words that can be recognized by the translation module by more than 60%.

6 Conclusions

We have presented a statistical post-processing method for OCR error correction that requires minimal resources, aimed particularly at low density languages and NLP scenarios. The technique gains leverage from existing OCR systems, enabling both minimal-labor adaptation of systems to new low density languages and improvements in native OCR performance.

We rigorously evaluated our approach using real OCR data, and have shown that we can achieve recognition accuracy lower than that achieved by a trainable OCR system for a new language. For Igbo, a very low density language, adapting English OCR achieved relative error reductions as high as 78%, resulting in 7.11% WER. We also showed that the error rate of a trainable OCR system after training can be further reduced up to 50% using post-processing, achieving a WER as low as 3.7%. Post-processing experiments using Cebuano validate our approach in a dictionary-acquisition scenario, with a 50.5% relative reduction in error rate from 8.02% to 3.97%. Evaluation on Arabic demonstrated that the error rate for a native commercial OCR system can be reduced by nearly 30%. In addition, we measured the impact of post-processing on machine translation, quantifying OCR degradation of MT performance and showing that our technique moves the performance of MT on OCR data significantly closer to performance on clean input. See Kolak (forthcoming) for more details and discussion.

One limitation of our approach is its reliance on an existing OCR system that supports the script of the language of interest. Trainable OCR systems are the only option if there is no OCR system that supports the script of interest; however, training an OCR system from scratch is usually a tedious and time consuming task. Post-processing can be used to reduce the training time and improve recognition accuracy by aiding generation of more training data once basic recognition capability is in place.

Acknowledgments

This research was supported in part by Department of Defense contract RD-02-5700 and DARPA/ITO Cooperative Agreement N660010028910. We are grateful to Mohri et al. for the AT&T FSM Toolkit and Clarkson and Rosenfeld for the CMU-Cambridge Toolkit. We thank David Doermann and his students for the Cebuano text; Chinedu Uchechukwu for the Igbo text and useful information on the language. We also thank Mustafa Murat Tıkır for his help in generating Igbo ground truth for Akụkọ, and for useful discussion.

Inducing a multilingual dictionary from a parallel multitext in related languages

Abstract

Dictionaries and word translation models are used by a variety of systems, especially in machine translation. We build a multilingual dictionary induction system for a family of related resource-poor languages. We assume only the presence of a single medium-length multitext (the Bible). The techniques rely upon lexical and syntactic similarity of languages as well as on the fact that building dictionaries for several pairs of languages provides information about other pairs.

1 Introduction and Motivation

Modern statistical natural language processing techniques require large amounts of human-annotated data to work well. For practical reasons, the required amount of data exists only for a few languages of major interest, either commercial or governmental. As a result, many languages have very little computational research done in them, especially outside the borders of the countries in which these languages are spoken. Some of these languages are, however, major languages with hundreds of millions of speakers. Of the top 10 most spoken languages, Linguistic Data Consortium at University of Pennsylvania, the premier U.S. provider of corpora, offers text corpora only in 7 (The World Factbook (2004), 2000 estimate) Only a few of the other languages (French, Arabic, and Czech) have resources provided by LDC. Many Asian and Eastern European languages number tens of millions of speakers, yet very few of these seem to have any related computational linguistics work, at least as presented at the international conferences, such as the ACL.[1]

The situation is not surprising, nor is it likely to significantly change in the future. Luckily, most of these less-represented languages belong to language families with several prominent members. As a result, some of these languages have siblings with more resources and published research. [2] Interestingly, the better-endowed siblings are not always the ones with more native speakers, since political considerations are often more important.[3] If one is able to use the resources available in one language (henceforth referred to as *source*) to facilitate the creation of tools and resource in another, related language (*target*), this problem would be alleviated. This is the ultimate goal of this project, but in the first stage we focus on multi-language dictionary induction.

Building a high-quality dictionary, or even better, a joint word distribution model over all the languages in a given family is very important, because using such a model one can use a variety of techniques to project information across languages, e.g. to parse or to translate. Building a unified model for more than a pair of languages improves the quality over building several unrelated pairwise models, because relating them to each other provides additional information. If we know that word a in language A has as its likely translation word b in language B, and b is translated as c in C, then we also know that a is likely to be translated as c, without looking at

[1]The search through ACL Anthology, for e.g., Telugu (∼70 million speakers) shows only casual mention of the language.

[2]Telugu's fellow Dravidian language *Tamil* (∼65 million speakers) has seen some papers at the ACL

[3]This is the case with Tamil vs. Telugu.

the A to C model.

2 Previous Work

There has been a lot of work done on building dictionaries, by using a variety of techniques. One good overview is Melamed (2000). There is work on lexicon induction using string distance or other phonetic/orthographic comparison techniques, such as Mann and Yarowsky (2001) or semantic comparison using resources such as WordNet (Kondrak, 2001). Such work, however, primarily focuses on finding cognates, whereas we are interested in translations of all words. Moreover, while some techniques (e.g., Mann and Yarowsky (2001)) use multiple languages, the languages used *have* resources such as dictionaries between some language pairs. We do not require any dictionaries for any language pair.

An important element of our work is focusing on more than a pair of languages. There is an active research area focusing on multi-source translation (e.g., Och and Ney (2001)). Our setting is the reverse: we do not use multiple dictionaries in order to translate, but translate (in a very crude way) in order to build multiple dictionaries.

Many machine translation techniques require dictionary building as a step of the process, and therefore have also attacked this problem. They use a variety of approaches (a good overview is Koehn and Knight (2001)), many of which require advanced tools for both languages which we are not able to use. They also use bilingual (and to some extent monolingual) corpora, which we do have available. They do not, however, focus on related languages, and tend to ignore lexical similarity [4], nor are they able to work on more than a pair of languages at a time.

It is also worth noting that there has been some MT work on related languages which explores language similarity in an opposite way: by using dictionaries and tools for both languages, and assuming that a near word-for-word approach is reasonable (Hajic et al., 2000).

[4]Much of recent MT research focuses on pairs of languages which are not related, such as English-Chinese, English-Arabic, etc.

3 Description of the Problem

Let us assume that we have a group of related languages, $L_1 \ldots L_n$, and a parallel sentence-aligned multitext C, with corresponding portions in each language denoted as $C_1 \ldots C_n$. Such a multitext exists for virtually all the languages in the form of the Bible. Our goal is to create a multilingual dictionary by learning the joint distribution $P(x_1 \ldots x_n)_{x_i \in L_i}$ which is simply the expected frequency of the n-tuple of words in a completely word-aligned multitext. We will approach the problem by learning pairwise language models, although leaving some parameters free, and then combine the models and learn the remaining free parameters to produce the joint model.

Let us, therefore, assume that we have a set of models $\{P(x, y|\theta_{ij})_{x \in L_i, y \in L_j}\}_{i \neq j}$ where θij is a parameter vector for pairwise model for languages L_i and L_j. We would like to learn how to combine these models in an optimal way. To solve this problem, let us first consider a simpler and more general setting.

3.1 Combining Models of Hidden Data

Let X be a random variable with distribution $P_{\text{true}}(x)$, such that no direct observations of it exist. However, we may have some indirect observations of X and have built several models of X's distribution, $\{P_i(x|\theta_i)\}_{i=1}^n$, each parameterized by some parameter vector θ_i. P_i also depends on some other parameters that are fixed. It is important to note that the space of models obtained by varying θ_i is only a small subspace of the probability space. Our goal is to find a good estimate of $P_{\text{true}}(x)$.

The main idea is that if some P_i and P_j are close (by some measure) to P_{true}, they have to be close to each other as well. We will therefore make the assumption that if some models of X are close to each other (and we have reason to believe they are fair approximations of the true distribution) they are also close to the true distribution. Moreover, we would like to set the parameters θ_i in such a way that $P(x_i|\theta_i)$ is as close to the other models as possible. This leads us to look for an estimate that is as close to all of our models as possible, under the optimal values of θ_i's, or more formally:

$$P_{\text{est}} = \arg\min_{\hat{P}(\cdot)} \min_{\theta_1} \ldots \min_{\theta_n} d(\hat{P}(\cdot), P_1(\cdot|\theta_1), \ldots P_n(\cdot|\theta_n))$$

where d measures the distance between $\hat{P}$ and all the P_i under the parameter setting θ_i. Since we have no reason to prefer any of the P_i, we choose the following symmetric form for d:

$$\sum_{i=1}^{n} D(\hat{P}(\cdot)||P_i(\cdot|\theta_i))$$

where D is a reasonable measure of distance between probability distributions. The most appropriate and the most commonly used measure in such cases in the Kullback-Leibler divergence, also known as relative entropy:

$$D(p||q) = \sum_x p(x) \log \frac{p(x)}{q(x)}$$

It turns out that it is possible to find the optimal $\hat{P}$ under these circumstances. Taking a partial derivative and solving, we obtain:

$$\hat{P}(x) = \frac{\prod_{i=1}^{n} P_i(x|\theta_i)^{1/n}}{\sum_{x' \in X} \prod_{i=1}^{n} P_i(x'|\theta_i)^{1/n}}$$

Substituting this value into the expression for function d, we obtain the following distance measure between the P_i's:

$$\begin{aligned} & d'(P_1(X|\theta_1) \ldots P_n(X|\theta_n)) \\ &= \min_{\hat{P}} d(\hat{P}, P_1(X|\theta_1), \ldots P_n(X|\theta_n)) \\ &= -\log \textstyle\sum_{x \in X} \prod_{i=1}^{n} P_i(x|\theta_i)^{1/n} \end{aligned}$$

This function is a generalization of the well-known Bhattacharyya distance for two distributions (Bhattacharyya, 1943):

$$b(p, q) = \sum_i \sqrt{p_i q_i}$$

These results suggest the following **Algorithm 1** to optimize d (and d'):

```
• Set all $\theta_i$ randomly
• Repeat until change in $d$ is very small:
    – Compute $\hat{P}$ according to the above formula
    – For $i$ from 1 to $n$
        ∗ Set $\theta_i$ in such a way as to minimize $D(\hat{P}(X)||P_i(X|\theta_i))$
    – Compute $d$ according to the above formula
```

Each step of the algorithm minimizes d. It is also easy to see that minimizing $D(\hat{P}(X)||P_i(X|\theta_i))$ is the same as setting the parameters θ_i in order to maximize $\prod_{x \in X} P_i(x|\theta_i)^{\hat{P}(x)}$, which can be interpreted as maximizing the probability under P_i of a corpus in which word x appears $\hat{P}(x)$ times. In other words, we are now optimizing $P_i(X)$ given an observed corpus of X, which is a much easier problem. In many types of models for P_i the Expectation-Maximization algorithm is able to solve this problem.

3.2 Combining Pairwise Models

Following the methods outlined in the previous section, we can find an optimal joint probability $P(x_1 \ldots x_n)_{x_i \in L_i}$ if we are given several models $P_j(x_1 \ldots x_n|\theta_j)$. Instead, we have a number of pairwise models. Depending on which independence assumptions we make, we can define a joint distribution over all the languages in various ways. For example, for three languages, A, B, and C, and we can use the following set of models:

$$\begin{aligned} P_1(A, B, C) &= P(A|B)P(B|C)P(C) \\ P_2(A, B, C) &= P(C|A)P(A|B)P(B) \\ P_3(A, B, C) &= P(B|C)P(C|A)P(A) \end{aligned}$$

and

$$\begin{aligned} & d'(\hat{P}, P_1, P_2, P_3) \\ &= D(\hat{P}||P_1) + D(\hat{P}||P_2) + D(\hat{P}||P_3) \\ &= 2H(\hat{P}(A, C), P(A, C)) \\ &+ 2H(\hat{P}(A, B), P(A, B)) \\ &+ 2H(\hat{P}(B, C), P(B, C)) - 3H(\hat{P}) \\ &- H(\hat{P}(A), P(A)) - H(\hat{P}(B), P(B)) \\ &- H(\hat{P}(C), P(C)) \end{aligned}$$

where $H(\cdot)$ is entropy, $H(\cdot, \cdot)$ is cross-entropy, and $\hat{P}(A, B)$ means $\hat{P}$ marginalized to variables A, B. The last three cross-entropy terms involve monolingual models which are not parameterized. The entropy term does not involve any of the pairwise distributions. Therefore, if $\hat{P}$ is fixed, to maximize d'

we need to maximize each of the bilingual cross-entropy terms.

This means we can apply the algorithm from the previous section with a small modification (**Algorithm 2**):

- Set all θ_{ij} (for each language pair i, j) randomly

- Repeat until change in d is very small:
  - Compute P_i for $i = 1 \dots k$ where k is the number of the joint models we have chosen
  - Compute $\hat{P}$ from $\{P_i\}$
  - For i, j such that $i \neq j$
    - Marginalize $\hat{P}$ to (L_i, L_j)
    - Set θ_{ij} in such a way as to minimize $D(\hat{P}(L_i, L_j)||P_i(L_i, L_j|\theta_{ij}))$
  - Compute d according to the above formula

Most of the θ parameters in our models can be set by performing EM, and the rest are discrete with only a few choices and can be maximized over by trying all combinations of them.

4 Building Pairwise Models

We now know how to combine pairwise translation models with some free parameters. Let us now discuss how such models might be built.

Our goal at this stage is to take a parallel bitext in related languages A and B and produce a joint probability model $P(x, y)$, where $x \in A, y \in B$. Equivalently, since the models $P_A(x)$ and $P_B(y)$ are easily estimated by maximum likelihood techniques from the bitext, we can estimate $P_{A\to B}(y|x)$ or $P_{B\to A}(x|y)$. Without loss of generality, we will build $P_{A\to B}(y|x)$.

The model we are building will have a number of free parameters. These parameters will be set by the algorithm discussed above. In this section we will assume that the parameters are fixed.

Our model is a mixture of several components, each discussed in a separate section below:

$$\begin{aligned} P_{A\to B}(y|x) &= \lambda_{fw}(x)P_{fwA\to B}(y|x) \\ &+ \lambda_{bw}(x)P_{bwA\to B}(y|x) \\ &+ \lambda_{char}(x)P_{charA\to B}(y|x) \\ &+ \lambda_{pref}(x)P_{prefA\to B}(y|x) \\ &+ \lambda_{suf}(x)P_{sufA\to B}(y|x) \\ &+ \lambda_{cons}(x)P_{consA\to B}(y|x) \end{aligned} \quad (1)$$

where all λs sum up to one. The λs are free parameters, although to avoid over-training we tie the λs for x's with similar frequencies. These lambdas form a part of the θ_{ij} parameter mentioned previously, where $L_i = A$ and $L_j = B$.

The components represent various constraints that are likely to hold between related languages.

4.1 GIZA (forward)

This component is in fact GIZA++ software, originally created by John Hopkins University's Summer Workshop in 1999, improved by Och (2000). This software can be used to create word alignments for sentence-aligned parallel corpora as well as to induce a probabilistic dictionary for this language pair.

The general approach taken by GIZA is as follows. Let L_A and L_B be the portions of the parallel text in languages A and B respectively, and $L_A = (x_i)_{i=1\dots n}$ and $L_B = (y_i)_{i=1\dots m}$. We can define $P(L_B|L_A)$ as

$$\max_{P_{A\to B}} \max_{P_{\text{aligns}}} \sum_{i=1}^{n} \sum_{j=1}^{m} P_{A\to B}(y_j|x_i)\, P_{\text{aligns}}(x_i|j)$$

The GIZA software does the maximization by building a variety of models, mostly described by Brown et al. (1993). GIZA can be tuned in various ways, most importantly by choosing which models to run and for how many iterations. We treat these parameters as free, to be set along with the rest at a later stage.

As a side effect of GIZA's optimization, we obtain the $P_{A\to B}(y|x)$ that maximizes the above expression. It is quite reasonable to believe that a model of this sort is also a good model for our purposes. This model is what we refer to as $P_{fwA\to B}(y|x)$ in the model overview.

GIZA's approach is not, however, perfect. GIZA builds several models, some quite complex, yet it does not use all the information available to it, notably the lexical similarity between the languages. Furthermore, GIZA tries to map words (especially rare ones) into other words if possible, even if the sentence has no direct translation for the word in question.

These problems are addressed by using other models, described in the following sections.

4.2 GIZA (backward)

In the previous section we discussed using GIZA to try to optimize $P(L_B|L_A)$. It is, however, equally reasonable to try to optimize $P(L_A|L_B)$ instead. If we do so, we can obtain $P_{fwB\to A}(x|y)$ that produces maximal probability for $P(L_A|L_B)$. We, however need a model of $P_{A\to B}(y|x)$. This is easily obtained by using Bayes' rule:

$$P_{bwA\to B}(y|x) = \frac{P_{fwB\to A}(x|y)P_B(y)}{P_A(x)}$$

which requires us to have $P_B(y)$ and $P_A(x)$. These models can be estimated directly from L_B and L_A, by using maximum likelihood estimators:

$$P_A(x) = \frac{\sum_i \delta(x_i, x)}{n}$$

and

$$P_B(y) = \frac{\sum_i \delta(y_i, y)}{m}$$

where $\delta(x, y)$ is the Kronecker's delta function, which is equal to 1 if its arguments are equal, and to 0 otherwise.

4.3 Character-based model

This and the following models all rely on having a model of $P_{A\to B}(y|x)$ to start from. In practice it means that this component is estimated following the previous components and uses the models they provide as a starting point.

The basic idea behind this model is that in related languages words are also related. If we have a model P_c of translating characters in language A into characters in language B, we can define the model for translating entire words.

Let word x in language A consists of characters x_1 through x_n, and word y in language B consist of characters y_1 through y_m.

Let us define (the unnormalized) character model:

$$P_{uchar}(y|x) = P_{charlen}(y|x, m)P_{length}(m|x)$$

i.e., estimating the length of y first, and y itself afterward. We make an independence assumption that the length of y depends only on length of x, and are able to estimate the second term above easily. The first term is harder to estimate.

First, let us consider the case where lengths of x and y are the same ($m = n$). Then,

$$P_{charlen}(y|x, n) = \prod_{i=1}^{n} P_c(y_i|x_i)$$

Let y^j be word y with j's character removed. Let us now consider the case when $m > n$. We define (recursively):

$$P_{charlen}(y|x, m) = \sum_{i=1}^{m} \frac{1}{m} P_{charlen}(y^i|x, m-1)$$

Similarly, if $n > m$:

$$P_{charlen}(y|x) = \sum_{i=1}^{n} \frac{1}{n} P_{charlen}(y|x^i, m)$$

It is easy to see that this is a valid probability model over all sequences of characters. However, y is not a random sequence of characters, but a word in language B, moreover, it is a word that can serve as a potential translation of word x. So, to define a proper distribution over words y given a word x and a set of possible translations of x, $T(x)$

$$\begin{aligned} P_{char}(y|x) &= P_{uchar}\left(y|x, y \in T(x)\right) \\ &= \delta_{y' \in T(x)} \frac{P_{uchar}(y, y \in T(x)|x)}{\sum_{y' \in T(x)} P_{uchar}(y'|x)} \end{aligned}$$

This is the complete definition of P_{char}, except for the fact that we are implicitly relying upon the character-mapping model, P_c, which we need to somehow obtain. To obtain it, we rely upon GIZA again. As we have seen, GIZA can find a good word-mapping model if it has a bitext to work from. If we have a $P_{A\to B}$ word-mapping model of some sort, it is equivalent to having a parallel bitext with words y and x treated as a sequence of characters, instead of indivisible tokens. Each (x, y) word pair would occur $P_{A\to B}(x, y)$ times in this corpus. GIZA would then provide us with the P_c model we need, by optimizing the probability B language part of the model given the language A part.

4.4 Prefix Model

This model and the two models that follow are built on the same principle. Let there be a function $f : A \rightarrow C_A$ and a function $g : B \rightarrow C_B$. These functions group words in A and B into some finite set of classes. If we have some $P_{A\rightarrow B}(y|x)$ to start with, we can define

$$\begin{aligned} & P_{fgA\rightarrow B}(y|x) \\ = \;& P\left(y|g(y)\right) P\left(g(y)|f(x)\right) P\left(f(x)|x\right) \\ = \;& P(y) \frac{\sum_{x':f(x')=f(x)} \sum_{y':g(y')=g(y)} P(x',y')}{\left(\sum_{x':f(x')=f(x)} P(x')\right)\left(\sum_{y':g(y')=g(y)} P(y')\right)} \end{aligned}$$

For the prefix model, we rely upon the following idea: words that have a common prefix often tend to be related. Related words probably should translate as related words in the other language as well. In other words, we are trying to capture word-level semantic information. So we define the following set of f and g functions:

$$f_n(x) = \text{prefix}(x, n)$$

$$g_m(y) = \text{prefix}(y, m)$$

where n and m are free parameters, whose values we will determine later. We therefore define $P_{prefA\rightarrow B}$ as P_{fg} with f and g specified above.

4.5 Suffix Model

Similarly to a prefix model mentioned above, it is also useful to have a suffix model. Words that have the same suffixes are likely to be in the same grammatical case or share some morphological feature which may persist across languages. In either case, if a strong relationship exists between the resulting classes, it provides good evidence to give higher likelihood to the word belonging to these classes. It is worth noting that this feature (unlike the previous one) is unlikely to be helpful in a setting where languages are not related.

The functions f and g are defined based on a set of suffixes S_A and S_B which are learned automatically. $f(x)$ is defined as the longest possible suffix of x that is in the set S_A, and g is defined similarly, for S_B.

The sets S_A and S_B are built as follows. We start with all one-character suffixes. We then consider two-letter suffixes. We add a suffix to the list if it occurs much more often than can be expected based on the frequency of its first letter in the penultimate position, times the frequency of its second letter in the last position. We then proceed in a similar way for three-letter suffixes. The threshold value is a free parameter of this model.

4.6 Constituency Model

If we had information about constituent boundaries in either language, it would have been useful to make a model favoring alignments that do not cross constituent boundaries. We do not have this information at this point. We can assume, however, that any sequence of three words is a constituent of sorts, and build a model based on that assumption.

As before, let $L_A = (x_i)_{i=1...n}$ and $L_B = (y_i)_{i=1...m}$. Let us define as $C_A(i)$ a triple of words (x_{i-1}, x_i, x_{i+1}) and as $C_B(j)$ a triple (y_{j-1}, y_j, y_{j+1}). If we have some model $P_{A\rightarrow B}$, we can define

$$\begin{aligned} P_{C_A\rightarrow C_B}(j|i) &= \tfrac{1}{C} P_{A\rightarrow B}(y_{j-1}|x_{i-1}) P_{A\rightarrow B}(y_j|x_i) \\ &\times \; P_{A\rightarrow B}(y_{j+1}|x_{i+1}) \end{aligned}$$

where C is the sum over j of the above products, and serves to normalize the distribution.

$$\begin{aligned} & P_{consA\rightarrow B}(y|x) \\ = \;& \textstyle\sum_{i=1}^{n} \sum_{j=1}^{m} P(y|C_B(j)) P_{C_A\rightarrow C_B}(j|i) P(C_A(i)|x) \\ = \;& \textstyle\sum_{i:x_i=x} \sum_{j=1}^{m} P(y|C_B(j)) P_{C_A\rightarrow C_B}(j|i) \\ = \;& \frac{1}{\sum_{j=1} \delta(y_j, y)} \textstyle\sum_{i:x_i=x} \sum_{j:y_j=y} P_{C_A\rightarrow C_B}(j|i) \end{aligned}$$

5 Evaluation

The output of the system so far is a multi-lingual word translation model. We will evaluate it by producing a tri-lingual dictionary (Russian-Ukrainian-Belorussian), picking a highest probability translation for each word, from the corresponding Bibles. Unfortunately, we do not have a good hand-built tri-lingual dictionary to compare it to, but only one good bilingual one, Russian-Ukrainian[5]. We will therefore take the Russian-Ukrainian portion of our dictionary and compare it to the hand-built one.

Our evaluation metric is the number of entries that match between these dictionaries. If a word has several translations in the hand-built dictionary, match-

[5]The lack of such dictionaries is precisely *why* we do this work

ing any of them counts as correct. It is worth noting that for all the dictionaries we generate, the total number of entries is the same, since all the words that occur in the source portion of the corpus have an entry. In other words, precision and recall are proportional to each other and to our evaluation metric.

Not all of the words that occur in our dictionary occur in the hand-built dictionary and vice versa. An absolute upper limit of performance, therefore, for this evaluation measure is the number of left-hand-side entries that occur in both dictionaries.

In fact, we cannot hope to achieve this number. First, because the dictionary translation of the word in question might never occur in the corpus. Second, even if it does, but never co-occurs in the same sentence as its translation, we will not have any basis to propose it as a translation.[6]. Therefore we have a "achievable upper limit", the number of words that have their "correct" translation co-occur at least once. We will compare our performance to this upper limit.

Since there is no manual tuning involved we do not have a development set, and use the whole bible for training (the dictionary is used as a test set, as described above).

We evaluate the performance of the model with just the GIZA component as the baseline, and add all the other components in turn. There are two possible models to evaluate at each step. The pairwise model is the model given in equation 1 under the parameter setting given by Algorithm 2, with Belorussian used as a third language. The joint model is the full model over these three languages as estimated by Algorithm 2. In either case we pick a highest probability Ukrainian word as a translation of a given Russian word.

The results for Russian-Ukrainian bibles are presented in Table 1. The "oracle" setting is the setting obtained by tuning on the test set (the dictionary). We see that using a third language to tune works just as well, obtaining the true global maximum for the model. Moreover, the joint model (which is more flexible than the model in Equation 1) does even better. This was unexpected for us, because the joint model relies on three pairwise models equally, and Russian-Belorussian and Ukrainian-Belorussian models are bound to be less reliable for Russian-Ukrainian evaluation. It appears, however, that our Belorussian bible is translated directly from Russian rather than original languages, and parallels Russian text more than could be expected.

[6]Strictly speaking, we might be able to infer the word's existence in some cases, by performing morphological analysis and proposing a word we have not seen, but this seems too hard at the moment

Table 1: Evaluation for Russian-Ukrainian (with Belorussian to tune)

Stage	**Pair**	**Joint**
Forward (baseline)	62.3%	71.7%
Forward+chars	77.1%	84.2%
Forward+chars+backward	81.3%	84.1%
Fw+chars+bw+prefix	83.5%	84.5%
Fw+chars+bw+prefix+suffix	84.5%	85%
Fw+chars+bw+pref+suf+const	84.5%	85.2%
"Oracle" setting for λ's	84.6%	

Table 2: Evaluation for Russian-Ukrainian (with Belorussian and Polish)

Tuned by	**Pair**	**Joint**
Belorussian (prev. table)	84.5%	85.2% &
Polish	84.6%	78.6%
Both	84.5%	85.2%
"Oracle" tuning	84.5%	

To insure our results are not affected by this fact we also try Polish separately and in combination with Belorussian (i.e. a model over 4 languages), as shown in Table 2.

These results demonstrate that the joint model is not as good for Polish, but it still finds the optimal parameter setting. This leads us to propose the following extension: let us marginalize joint Russian-Ukrainian-Belorussian model into just Russian-Ukrainian, and add this model as yet another component to Equation 1. Now we cannot use Belorussian as a third language, but we can use Polish, which we know works just as well for tuning. The resulting performance for the model is **85.7%**, our best result to date.

6 Discussion and Future Work

We have built a system for multi-dictionary induction from parallel corpora which significantly improves quality over the standard existing tool (GIZA) by taking advantage of the fact that languages are related and we have a group of more than two of them. Because the system attempts to be completely agnostic about the languages it works on, it might be used successfully on many language groups, requiring almost no linguistic knowledge on the part of the user. Only the prefix and suffix components are somewhat language-specific, but even they are sufficiently general to work, with varying degree of success, on most inflective and agglutinative languages (which form a large majority of languages). For generality, we would also need a model of infixes, for languages such as Hebrew or Arabic. We must admit, however, that we have not tested our approach on other language families yet. It is our short term plan to test our model on several Romance languages, e.g. Spanish, Portuguese, French.

Looking at the first lines of Table 1, one can see that using more than a pair of languages with a model using only a small feature set can dramatically improve performance (compare second and third columns), while able to find the optimal values for all internal parameters.

As discussed in the introduction, the ultimate goal of this project is to produce tools, such as a parser, for languages which lack them. Several approaches are possible, all involving the use of the dictionary we built. While working on this project, we would no longer be treating all languages in the same way. We would use the tools available for that language to further improve the performance of pairwise models involving that language and, indirectly, even the pairs not involving this language. Using these tools, we may be able to improve the word translation model even further, simply as a side effect.

Once we build a high-quality dictionary for a special domain such as the Bible, it might be possible to expand to a more general setting by mining the Web for potential parallel texts.

Our technique is limited in the coverage of the resulting dictionary which can only contain words which occur in our corpus. Whatever the corpus may be, however, it will include the most common words in the target language. These are the words that tend to vary the most between related (and even unrelated) languages. The relatively rare words (e.g. domain-specific and technical terms) can often be translated simply by inferring morphological rules transforming words of one language into another. Thus, one may expand the dictionary coverage using non-parallel texts in both languages, or even in just one language if its morphology is sufficiently regular.

Exploiting a Verb Lexicon in Automatic Semantic Role Labelling

Abstract

We develop an unsupervised semantic role labelling system that relies on the direct application of information in a predicate lexicon combined with a simple probability model. We demonstrate the usefulness of predicate lexicons for role labelling, as well as the feasibility of modifying an existing role-labelled corpus for evaluating a different set of semantic roles. We achieve a substantial improvement over an informed baseline.

1 Introduction

Intelligent language technologies capable of full semantic interpretation of domain-general text remain an elusive goal. However, statistical advances have made it possible to address core pieces of the problem. Recent years have seen a wealth of research on one important component of semantic interpretation—automatic role labelling (e.g., Gildea and Jurafsky, 2002; Pradhan et al., 2004; Hacioglu et al., 2004, and additional papers from Carreras and Marquez, 2004). Such work aims to annotate each constituent in a clause with a semantic tag indicating the role that the constituent plays with respect to the target predicate, as in (1):

(1) [Yuka]$_{Agent}$ [whispered]$_{Pred}$ to [Dar]$_{Recipient}$

Semantic role labelling systems address a crucial first step in the automatic extraction of semantic relations from domain-general text, taking us closer to the goal of comprehensive semantic mark-up.

Most work thus far on domain-general role labelling depends on supervised learning over statistical features extracted from a hand-labelled corpus. The reliance on such a resource—one in which the arguments of each predicate are manually identified and assigned a semantic role—limits the portability of such methods to other languages or even to other genres of corpora.

In this study, we explore the possibility of using a verb lexicon, rather than a hand-labelled corpus, as the primary resource in the semantic role labelling task. Perhaps because of the focus on what can be gleaned from labelled data, existing supervised approaches have made little use of the additional knowledge available in the predicate lexicon associated with the labelled corpus. By contrast, we exploit the explicit knowledge of the role assignment possibilities for each verb within an existing lexicon. Moreover, we utilize a very simple probability model within a highly efficient algorithm.

We use VerbNet (Kipper et al., 2000), a computational lexicon which lists the possible semantic role assignments for each of its verbs. Our algorithm extracts automatically parsed arguments from a corpus, and assigns to each a list of the compatible roles according to VerbNet. Arguments which are given only a single role possibility are considered to have been assigned an unambiguous role label. This set of arguments constitutes our *primary-labelled* data, which serves as the noisy training data for a simple probability model which is then used to label the remaining (role ambiguous) arguments.

This method has several advantages, the foremost of which is that it eliminates the dependence on a role labelled corpus, a very expensive resource to produce. Of course, a verb lexicon is also an expensive resource, but one that is highly reusable across a range of NLP tasks. Moreover, the approach points at some potentially useful information that current supervised methods have failed to exploit. Even if one has access to an annotated corpus for training, our work shows that directly calling on additional information from the lexicon itself may prove useful in restricting the possible labels for an argument.

The method has disadvantages as well. The information available in a predicate lexicon is less directly applicable to building a learning model. Inevitably, our results are noisier than in a supervised approach which has access to a labelled sample of what it must produce. Still, the method shows promise: on unseen test data, the system yields an F-measure of .83 on labelling of correctly extracted arguments, compared to an informed baseline of .74, and an F-measure of .65 (compared to .52) on the overall identification and labelling task. The latter is well below the best supervised performance of about .80 on similar tasks, but it must be emphasized that it is achieved with a simple probability model and without the use of hand-labelled data. We view this as a starting point by which to demonstrate the utility of deriving more explicit knowledge from a predicate lexicon, which can be later extended through the use of additional probabilistic features.

We face a methodological challenge arising from the particular choice of VerbNet for the prototyping of our method: the lexicon has no associated semantic role labelled corpus. While this underscores the need for approaches which do not rely on such a resource, it also means that we lack a labelled sample of data against which to evaluate our results. To address this, we use the existing labelled corpus of FrameNet (Baker et al., 1998), and develop a mapping for converting the FrameNet roles to corresponding VerbNet roles. Our mapping method demonstrates the possibility of leveraging existing resources to support the development of role labelling systems based on verb lexicons that do not have an associated hand-labelled corpus.

2 VerbNet Roles and the Role Mapping

Before describing our labelling algorithm, we first briefly introduce the semantic role information available in VerbNet, and describe how we map FrameNet roles to VerbNet roles.

whisper
Frames:
  Agent V
  Agent V Prep(+dest) Recipient
  Agent V Topic
Verbs in same (sub)class:
  [bark, croon, drone, grunt, holler, ...]

Figure 1: A portion of a VerbNet entry.

2.1 The VerbNet Lexicon

VerbNet is a manually developed hierarchical lexicon based on the verb classification of Levin (1993). For each of almost 200 classes containing a total of 3000 verbs, VerbNet specifies the syntactic frames along with the semantic role assigned to each argument position of a frame.[1] Figure 1 shows an example VerbNet entry. The thematic roles used in VerbNet are more general than the situation-specific roles of FrameNet. For example, the roles Speaker, Message, and Addressee of a Communication verb such as *whisper* in FrameNet would be termed Agent, Topic, and Recipient in VerbNet. These coarser-grained roles are often assumed in linguistic theory, and have some advantages in terms of capturing commonalities of argument relations across a wide range of predicates.

2.2 Mapping FrameNet to VerbNet Roles

As noted, VerbNet lacks a corpus of example role assignments against which to evaluate a role labelling based upon it. We create such a resource by adapting the existing FrameNet corpus. We formulate a mapping between FrameNet's larger role set and VerbNet's much smaller one, and create a new corpus with our mapped roles substituted for the original roles in the FrameNet corpus.

We perform the mapping in three steps. First we use an existing mapping between the semantically-specific roles in FrameNet and a much smaller intermediate set of 39 semantic roles which subsume all FrameNet roles.[2] The associations in this mapping are straightforward—e.g., the Place role for Abusing verbs and the Area role for Operate-vehicle verbs are both mapped to Location.

[1]Throughout the paper we use the term "frame" to refer to a syntactic frame—a configuration of syntactic arguments of a verb—possibly labelled with roles, as in Figure 1.

[2]This mapping was provided by Roxana Girju, UIUC.

Second, from this intermediate set we create a simple mapping to the set of 22 VerbNet roles. Some roles are unaffected by the mapping (e.g., Cause alone in the intermediate set maps to Cause in the VerbNet set). Other roles are merged (e.g., Degree and Measure both map to Amount). Moreover, some roles in FrameNet (and the intermediate set) must be mapped to more than one VerbNet role. For example, an Experiencer role in FrameNet is considered Experiencer by some VerbNet classes, but Agent by others. In such cases, our mappings in this step must be specific to the VerbNet class.

In this second step, some roles have no subsuming VerbNet role, because FrameNet provides roles for a wider variety of relations. For example, both FrameNet and the intermediate role set contain a Manner role, which VerbNet does not have. We create a catch-all label, "NoRole," to which we map eight such intermediate roles: Condition, Manner, Means, Medium, Part-Whole, Property, Purpose, and Result. These phrases labelled NoRole are adjuncts—constituents not labelled by VerbNet.

In the third step of our mapping, some of the roles in VerbNet—such as Theme and Topic, Asset and Amount—which appear to be too-fine grained for us to distinguish reliably, are mapped to a more coarse-grained set of VerbNet roles. The final set consists of 16 roles: Agent, Amount, Attribute, Beneficiary, Cause, Destination, Experiencer, Instrument, Location, Material, Predicate, Recipient, Source, Stimulus, Theme and Time; plus the NoRole label.

3 The Frame Matching Process

A main goal of our system is to demonstrate the usefulness of predicate lexicons for the role labelling task. The primary way that we apply the knowledge in our lexicon is via a process we call *frame matching*, adapted from Swier and Stevenson (2004). The automatic frame matcher aligns arguments extracted from an automatically parsed sentence with the frames in VerbNet for the target verb in the sentence. The output of this process is a highly constrained set of candidate roles (possibly of size one) for each potential argument. The resulting singleton sets constitute a (noisy) role assignment for their corresponding arguments, forming our primary-labelled data. This data is then used to train a probability model, described in Section 4, which we employ to label the remaining arguments (those having more than one candidate role).

3.1 Initialization of Candidate Roles

The frame matcher construes extracted arguments from the parsed sentence as being in one of the four main types of syntactic positions (or *slots*) used by VerbNet frames: subject, object, indirect object, and PP-object.[3] Additionally, we specialize the latter by the individual preposition, such as "object of *for*." For the first three slot types, alignment between the extracted arguments and the frames is relatively straightforward. An extracted subject would be aligned with the subject position in a VerbNet frame, for instance, and the subject role from the frame would be listed as a possible label for the extracted subject.

The alignment of PP-objects is similar to that of the other slot types, except that we add an additional constraint that the associated prepositions must match. For PP-object slots, VerbNet frames often provide an explicit list of allowable prepositions. Alternatively, the frame may specify a required semantic feature such as `+path` or `+loc`. In order for an extracted PP-object to align with one of these frame slots, its associated preposition must be included in the list provided by the frame, or have the specified feature. To determine the latter, we manually create lists of prepositions that we judge to have each of the possible semantic features.

In general, this matching procedure assumes that frames describing a syntactic argument structure similar to that of the parsed sentence are more likely to correctly describe the semantic roles of the extracted arguments. Thus, the frame matcher only chooses roles from frames that are the best syntactic matches with the extracted argument set. This is achieved by adopting the scoring method of Swier and Stevenson (2004), in which we compute the portion *%Frame* of frame slots that can be mapped to an extracted argument, and the portion *%Sent* of extracted arguments from the sentence that can be mapped to the frame. The score for each frame is given by *%Frame*+*%Sent*, and only frames having the highest score contribute candidate roles to the

[3]Since VerbNet has very few verbs with sentential complements, we do not consider them for now.

Possible Frames for Verb V	Extracted Slots SUBJ	OBJ	%Frame	%Sent	Score
Agent V	Agent		100	50	150
Agent V Theme	**Agent**	**Theme**	**100**	**100**	**200**
Instrument V Theme	**Instrument**	**Theme**	**100**	**100**	**200**
Agent V Recipient Theme	Agent	Theme	67	100	167

Table 1: An example of frame matching.

extracted arguments. An example scoring is shown in Table 1. Note that two of the frames are tied for the highest score of 200, resulting in two possible roles for the subject (Agent and Instrument), and Theme as the only possible role for the object.

As mentioned, this frame matching step is very restrictive, and it greatly reduces role ambiguity. Many potential arguments receive only a single candidate role, providing the primary-labelled data we use to train our probability model. Some slots receive *no* candidate roles, which is an error for argument slots but which is correct for adjuncts. The reduction of candidate roles in general is very helpful in lightening the subsequent load on the probability model to be applied next, but note that it may also cause the correct role to be omitted. We experiment with choosing roles from the frames that are the best syntactic matches, and from all possible frames.

3.2 Adjustments to the Role Mapping

We further extend the frame matcher, which has extensive knowledge of VerbNet, for the separate task of helping to eliminate some of the inconsistencies that are introduced by our role mapping procedure. This is a process that applies concurrently with the initialization of candidate roles described above, but only affects the gold standard labelling of evaluation data.[4]

For instance, FrameNet assigns the role Side2 to the object of the preposition *with* occurring with the verb *brawl*. Side2 is mapped to Theme by our role mapping; however, in VerbNet, *brawl* does not accept Theme as the object of *with*. Our mapping thus creates a target (i.e., gold standard) label in the evaluation data that is inconsistent with VerbNet. Since there is no possibility of the role labeller assigning a label that matches such a target, this unfairly raises the task difficulty. However, since *brawl* does accept Theme in another slot, it is not an option to entirely eliminate this role in the mapping for the verb. Instead, we use our frame matcher to verify that each target role generated by our mapping from FrameNet is allowed by VerbNet in the relevant slot. If the target role is not allowed, then it is converted to NoRole in the evaluation set. Constituents labelled as NoRole are not considered target arguments, and it is correct for the system to not assign labels in these cases.

The NoRole conversions help to ensure that our gold standard evaluation data is consistent with our lexicon, but the method does have limitations. For instance, some of the arguments which the system fails to extract might have had their target role changed to NoRole if they were properly extracted. Additionally, in some cases a target role is converted to NoRole when there is an actual role that VerbNet would have assigned instead.

4 The Probability Model

Once argument slots are initialized with sets of possible roles, the algorithm uses a probability model to label slots having two or more possibilities. Since our primary goal is to demonstrate how much can be accomplished through the frame matcher, we compare a number of very simple probability models:

- $\mathbf{P}(\mathbf{r}|\mathbf{v},\mathbf{s})$: the probability of a role given the target verb and the slot; the latter includes subject, object, indirect object, and prepositional object, where each PP slot is specialized by the identity of the preposition;
- $\mathbf{P}(\mathbf{r}|\mathbf{s})$: the probability of a role given the slot;
- $\mathbf{P}(\mathbf{r}|\mathbf{sc})$: the probability of a role given the slot class, in which all prepositional slots are treated together.

[4]Of course, the fact that the frame matcher "sees" the evaluation set as part of its dual duties is not allowed to influence its assignment of candidate roles.

Each probability model predicts a role given certain conditioning information, with maximum likelihood estimates determined by the primary-labelled data directly resulting from the frame matching step.[5]

We also compare one non-probabilistic model to resolve the same set of ambiguous cases:

- **Default assignment**: candidate roles for ambiguous slots are ignored; the four slot classes of subject, object, indirect object and PP-object are assigned the roles Agent, Theme, Recipient, and Location, respectively.

These are the most likely roles assigned by the frame matcher over our development data.

For comparison, we also apply the iterative algorithm developed by Swier and Stevenson (2004), using the same bootstrapping parameters. The method uses backoff over three levels of specificity of probabilities.

5 Materials and Methods

5.1 The Target Verbs

For ease of comparison, we use the same verbs as in Swier and Stevenson (2004), except that we measure performance over a much larger superset of verbs. In that work, a core set of 54 target verbs are selected to represent a variety of classes with interesting role ambiguities, and the system is evaluated against only those verbs. An additional 1105 verbs—all verbs sharing at least one class with the target verbs—are also labelled, in order to provide more data for the probability estimations. Here, we consider our system's performance over the 1159 target verbs that consist of the union of these two sets of verbs.

5.2 The Corpus and Preprocessing

The majority of sentences in FrameNet II are taken from the British National Corpus (BNC Reference Guide, 2000). Our development and test data consists of a percentage of these sentences. For some experiments, these sentences are then merged with a random selection of additional sentences from the BNC in order to provide more training data for the probability estimations. We evaluate performance only on FrameNet sentences that include our target verbs.

All of our corpus data was parsed using the Collins parser (Collins, 1999). Next, we use TGrep2 (Rohde, 2004) to automatically extract from the parse trees the constituents forming potential arguments of the target verbs. For each verb, we label as the subject the lowest NP node, if it exists, that is immediately to the left of a VP node which dominates the verb. Other arguments are identified by finding sister NP or PP nodes to the right of the verb. Heads of noun phrases are identified using the method of Collins (1999), which primarily chooses the rightmost noun in the phrase that is not inside a prepositional phrase or subordinate clause. Error may be introduced at each step of this preprocessing—the sentence may be misparsed, some arguments (such as distant subjects) may not be extracted, or the wrong word may be found as the phrase head.

5.3 Validation and Test Data

A random selection of 30% of the preprocessed FrameNet data is set aside for testing, and another random 30% is used for development and validation. For experiments involving additional BNC data, each 30% of the FrameNet sentences is embedded in a random selection of 20% of the BNC. We selected these percentages to yield a sufficient amount of data for experimentation, while reserving some unseen data for future work. The FrameNet portion of the validation set includes 515 types of our target verbs (across 161 VerbNet classes) in 4300 sentences, and contains a total of 6636 target constituents—i.e., constituents that receive a valid VerbNet role as their gold standard label, not NoRole. The test set includes 517 of the target verbs (from 163 classes) in 4308 sentences, yielding 6705 target constituents.[6]

To create an evaluation set, we map the manually annotated FrameNet roles in the corpus to VerbNet roles (or NoRole), as described in Sections 2.2 and 3.2. We use this role information to calculate performance: the system should assign roles matching the target VerbNet roles, and make no assignment when the target is NoRole.

[5]Note that we assume the probability of a role for a slot is independent of other slots—that is, we do not ensure a consistent role assignment to all arguments across an instance of a verb.

[6]The verbs appearing in the validation and test sets occur respectively across 161 and 165 FrameNet classes (what in FrameNet are called "frames").

5.4 Methods of Argument Identification

One of the decisions we face is how to evaluate the identification of extracted arguments generated by the system against the manually annotated target arguments provided by FrameNet. We try two methods, the most strict of which is to require full-phrase agreement: an extracted argument and a target argument must cover exactly the same words in the sentence in order for the argument to be considered correctly extracted. This means, for instance, that a prepositional phrase incorrectly attached to an extracted object would render the object incompatible with the target argument, and any system label on it would be counted as incorrect. This evaluation method is commonly used in other work (e.g., Carreras and Marquez, 2004).

The other method we use is to require that only the head of an extracted argument and a target argument match. This latter method helps to provide a fuller picture of the range of arguments found by the system, since there are fewer near-misses caused by attachment errors. Since heads of phrases are often the most semantically relevant part of an argument, labels on heads provide much of the same information as labels on whole phrases. For these reasons, we use head matching for most of our experiments below. For comparison, however, we provide results based on full-phrase matching as well.

6 Experimental Results

6.1 Experimental Setup

We evaluate our system's performance on several aspects of the overall role labelling task; all results are given in terms of F-measure, $2PR/(P+R)$.[7] The first task is argument identification, in which constituents considered by our system to be arguments (i.e., those that are extracted and labelled) are evaluated against actual target arguments. The second task is labelling extracted arguments, which evaluates the labelling of only those arguments that were correctly extracted. Last is the overall role labelling task, which evaluates the system on the combined tasks of identification and labelling of all target arguments.

We compare our results to an informed baseline that has access to the same set of extracted arguments as does the frame matcher. The baseline labels all extracted arguments using the default role assignments described in Section 4.

In addition to experiments in which we employ various methods of resolving ambiguous assignments, we also evaluate the system with varying types and amounts of training data, and with two alternate methods for choosing frames from which to draw candidate roles.

6.2 Evaluation of Probability Models

We first evaluate our system with the three very simple probability models, as well as the non-probabilistic default assignment, to determine roles for the extracted arguments that the frame matcher considers to be ambiguous. We also report results after only the frame matcher has been applied, to indicate how much work is being done by it alone. Because we have constructed the frame matcher to be highly restrictive in assigning candidate roles to extracted arguments, a large number (about 62%) become primary-labelled data and so do not require resolution of ambiguous roles. Only about 16% of our extracted arguments have role ambiguities, and about 22% (many of which are adjuncts) do not receive any candidates and remain unlabelled.

Task:	Id.	Lab.	Id. + Lab.
Baseline	.80	.74	.52
FM + $P(r\|sc)$	.83	.83	.65
FM + $P(r\|s)$	.83	.84	.65
FM + $P(r\|v,s)$	.83	.78	.61
FM + Dflt. Assgnmt.	.83	.82	.64
FM only	.83	.76	.60

As shown in the table, all models perform equally well on identification, which is determined by the frame matcher (FM); i.e., any extracted argument receiving one or more candidate roles is "identified" as an argument. Performance is somewhat above the baseline, which must label *all* extracted arguments. For the task of labelling correctly extracted arguments and for the combined task, the simplest probability models, $P(r|sc)$ and $P(r|s)$, perform about the same. On the combined task, they achieve .13 above the informed baseline, indicating the effectiveness of such simple models when combined with the frame matcher. The more specific model, $P(r|v,s)$, performs less well, and may be over-fitting on this relatively small amount of training data.

[7]In each case, P and R are close in value.

Two observations indicate the power of the frame matcher. First, even using the non-probabilistic default assignments to resolve ambiguous roles substantially outperforms the baseline (and indeed performs quite close to the best results, since the default role assignment is often the same as that chosen by the probability models). Importantly, the baseline uses the *same* default assignments, but without the benefit of the frame matcher to further narrow down the possible arguments. Second, the frame matcher alone achieves .60 F-measure on the combined task, not far below the performance of the best models. These results show that once arguments have been extracted, much of the labelling work is performed by the frame matcher's careful application of lexical information.

Henceforth we consider the use of the frame matcher plus $P(r|sc)$ as our basic system, since this is our simplest model, and no other outperforms it.

6.3 Evaluation of Training Methods

In our above experiments, the probabilistic models are trained only on primary-labelled data from the frame matcher run on the FrameNet data. We would like to determine whether using either more data or less noisy data may improve results. To provide more data, we ran the frame matcher on the additional 20% of the BNC. This provides almost 600K more sentences containing our target verbs, yielding a much higher amount of primary-labelled data. To provide less-noisy data, we trained the probability models on manually annotated target labels from system-identified arguments in 1000 sentences. While fewer sentences are used, all arguments in the training data are guaranteed to have a correct role assignment, in contrast to the primary-labelled data output by the frame matcher. (We chose 1000 sentences as an upper bound on an amount of data that could be relatively easily annotated by human judges.)

Training Data:	Prim.-lab. FN	Prim.-lab. BNC	1K sents annot'd
Baseline	.52		
FM + $P(r\|sc)$	.65	.65	.65
FM + $P(r\|v,s)$	.61	.62	.63

For our basic model, $P(r|sc)$, these variations in training data do not affect performance. Only the most specific model, $P(r|v,s)$, shows improvement when trained on more data or on manually annotated data, although it still does not perform as well as the simplest model. Because the models only choose from among candidate roles selected by the frame matcher, differences in the learned probability estimations must be quite large to have an effect. At least for the simplest model, these estimations do not vary with a larger corpus or one lacking in noise. However, the increase in performance seen here for the more specific model, albeit small, may indicate that richer probability models may require more or cleaner training data.

6.4 Evaluation of Frame Choice

	"Best" frames	All Frames
Baseline	.52	
FM + $P(r\|sc)$	.65	.63

The frame matcher has been shown to shoulder much of the responsibility in our system, and it is worth considering variations in its operation. For example, by having the frame matcher only choose roles from the frames that are the best syntactic matches to the sentence, role ambiguity is minimized at the cost of possibly excluding the correct role. To determine whether we may do better by relying more on the probability model and less on the frame matcher, we instead include role candidates from all frames in a verb's lexical entry. The effect of this choice is more role ambiguity, decreasing the number of primary-labelled slots by roughly 30%. We see that performance using $P(r|sc)$ is slightly worse with the greater ambiguity admitted by using all frames, indicating the benefit of precise selection of candidate roles.

6.5 Differing Argument Evaluation Methods

	Heads	Full Phrase
Baseline	.52	.49
FM + $P(r\|sc)$	.65	.61

As mentioned, for most of our evaluations we match the arguments extracted by the system to the target arguments via a match on phrase heads, since head labels provide much useful semantic information. When we instead require that the extracted arguments match the targets exactly, the number of correctly extracted arguments falls from about 80% of the roughly 6700 targets to about 74%, due to increased parsing difficulty. As expected, this results in both the system and the baseline having performance decreases on the overall task.

7 Related Work

Most role labelling systems have required hand-labelled training data. Two exceptions are the subcategorization frame based work of Atserias et al. (2001) and the bootstrapping labeller of Swier and Stevenson (2004), but both are evaluated on only a small number of verbs and arguments. In related unsupervised tasks, Riloff and colleagues have learned "case frames" for verbs (e.g., Riloff and Schmelzenbach, 1998), while Gildea (2002) has learned role-slot mappings (but does not apply the knowledge for the labelling task).

Other role labelling systems have also relied on the extraction of much more complex features or probability models than we adopt here. As a point of comparison, we apply the iterative backoff model from Swier and Stevenson (2004), trained on 20% of the BNC, with our frame matcher and test data. The backoff model achieves an F-measure of .63, slightly below the performance of .65 for our simplest probability model, which uses less training data and takes far less time to run (minutes rather than hours).

In general, it is not possible to make direct comparisons between our work and most other role labellers because of differences in corpora and role sets, and, perhaps more significantly, differences in the selection of target arguments. However, the best supervised systems, using automatic parses to identify full argument phrases in PropBank, achieve about .82 on the task of identifying and labelling arguments (Pradhan et al., 2004). Though this is higher than our performance of .61 on full phrase arguments, our system does not require manually annotated data.

8 Conclusion

In this work, we employ an expensive but highly reusable resource—a verb lexicon—to perform role labelling with a simple probability model and a small amount of unsupervised training data. We outperform similar work that uses much more data and a more complex model, showing the benefit of exploiting lexical information directly. To achieve performance comparable to that of supervised methods may require human filtering or augmentation of the initial labelling. However, given the expense of producing a large semantically annotated corpus, even such "human in the loop" approaches may lead to a decrease in overall resource demands. We use such a corpus for evaluation purposes only, modifying it with a role mapping to correspond to our lexicon. We thus demonstrate that such existing resources can be bootstrapped for lexicons lacking an associated annotated corpus.

Acknowledgments

We gratefully acknowledge the support of NSERC of Canada. We also thank Afsaneh Fazly, who assisted with much of our corpus pre-processing.

Abstract

This paper addresses the automatic classification of the *semantic relations* expressed by the English genitives. A learning model is introduced based on the statistical analysis of the distribution of genitives' semantic relations on a large corpus. The semantic and contextual features of the genitive's noun phrase constituents play a key role in the identification of the semantic relation. The algorithm was tested on a corpus of approximately 2,000 sentences and achieved an accuracy of 79% , far better than 44% accuracy obtained with C5.0, or 43% obtained with a Naive Bayes algorithm, or 27% accuracy with a Support Vector Machines learner on the same corpus.

1 Introduction

1.1 Problem Description

The identification of semantic relations in open text is at the core of Natural Language Processing and many of its applications. Detecting semantic relations is useful for syntactic and semantic analysis of text and thus plays an important role in automatic text understanding and generation. Furthermore, semantic relations represent the core elements in the organization of lexical semantic knowledge bases used for inferences. Recently, there has been a renewed interest in text semantics fueled in part by the complexity of some major research initiatives in Question Answering, Text Summarization, Text Understanding and others, launched in the United States and abroad.

Two of the most frequently used linguistic constructions that encode a large set of semantic relations are the s-genitives, e.g. "*man's brother*", and the of-genitives, e.g. "*dress of silk*". The interpretation of these phrase-level constructions is paramount for various applications that make use of lexical semantics.

Example: "*The child's mother* had moved the child from a car safety seat to an area near the open *passenger-side door of the car*." (The Desert Sun, Monday, October 18th, 2004).

There are two semantic relations expressed by genitives: (1) "*child's mother*" is an s-genitive encoding a KINSHIP relation, and (2) "*passenger-side door of the car*" is an of-genitive encoding a PART-WHOLE relation.

This paper provides a detailed corpus analysis of genitive constructions and a model for their automatic interpretation in English texts.

1.2 Semantics of Genitives

In English there are two kinds of genitives. In general, in one, the modifier is morphologically linked to the possessive clitic *'s* and precedes the head noun (*s-genitive*, i.e. NP_{modif}*'s* NP_{head}), and in the second one the modifier is syntactically marked by the preposition *of* and follows the head noun (*of-genitive*, i.e. NP_{head} *of* NP_{modif}).

Although the genitive constructions have been studied for a long time in cognitive linguistics, their semantic investigation proved to be very difficult, as the meanings of the two constructions are difficult to pin down. There are many factors that contribute to the genitives' semantic behavior, such as the type of the genitive, the semantics of the constituent nouns, the surrounding context, and others.

A characteristic of genitives is that they are very productive, as the construction can be given various semantic interpretations. However, in some situations, the number of interpretations can be reduced by employing world knowledge. Consider the examples, *"Mary's book"* and *"Shakespeare's book"*. *"Mary's book"* can mean the book Mary owns, the book Mary wrote, the book Mary is reading, or the book Mary is very fond of. Each of these interpretations is possible in the right context. In *"Shakespeare's book"*, however, the preferred interpretation, provided by a world knowledge dictionary, is the book written by Shakespeare.

1.3 Previous Work

There has been much interest recently on the discovery of semantic relations from open-text using symbolic and statistical techniques. This includes the seminal paper of (Gildea and Jurafsky, 2002), Senseval 3 and coNLL competitions on automatic labeling of semantic roles detection of noun compound semantics (Lapata, 2000), (Rosario and Hearst, 2001) and many others. However, not much work has been done to automatically interpret the genitive constructions.

In 1999, Berland and Charniak (Berland and Charniak, 1999) applied statistical methods on a very large corpus to find PART-WHOLE relations. Following Hearst's method for the automatic acquisition of hypernymy relations (Hearst, 1998), they used the genitive construction to detect PART-WHOLE relations based on a list of six seeds representing *whole* objects, (i.e. *book, building, car, hospital, plant, and school*). Their system's output was an ordered list of possible *parts* according to some statistical metrics (Dunning's log-likelihood metric and Johnson's significant-difference metric). They presented the results for two specific patterns (*"NN's NN"* and *"NN of DT NN"*). The accuracy obtained for the first 50 parts was 55% and for the first 20 parts was 70%.

In 2003, Girju, Badulescu, and Moldovan (Girju, Badulescu, and Moldovan, 2003) detected the PART-WHOLE relations for some of the most frequent patterns (including the genitives) using the Iterative Semantic Specialization, a learning model that searches for constraints in the WordNet noun hierarchies. They obtained an f-measure of 93.62% for s-genitives and 91.12% for of-genitives for the PART-WHOLE relation.

Given the importance of the semantic relations encoded by the genitive, the disambiguation of these relations has long been studied in cognitive linguistics (Nikiforidou, 1991), (Barker, 1995), (Taylor, 1996), (Vikner and Jensen, 1999), (Stefanowitsch, 2001), and others.

2 Genitives' Corpus Analysis

2.1 The Data

In order to provide a general model of the genitives, we analyzed the syntactic and semantic behavior of both constructions on a large corpus of examples selected randomly from an open domain text collection, LA Times articles from TREC-9. This analysis is justified by our desire to answer the following questions: "*What are the semantic relations encoded by the genitives?*" and "*What is their distribution on a large corpus?*"

A set of 20,000 sentences were randomly selected from the LA Times collection. In these 20,000 sentences, there were 3,255 genitive instances (2,249 of-constructions and 1,006 s-constructions). From these, 80% were used for training and 20% for testing.

Each genitive instance was tagged with the corresponding semantic relations by two annotators, based on a list of 35 most frequently used semantic relations proposed by (Moldovan et al., 2004) and shown in Table 1. The genitives' noun components were manually disambiguated with the corresponding WordNet 2.0 senses or the named entities if they are not in WordNet (e.g. names of persons, names of locations, etc).

2.2 Inter-annotator Agreement

The annotators, two graduate students in Computational Semantics, were given the genitives and the sentences in which they occurred. Whenever the annotators found an example encoding a semantic relation other than those provided, they had to tag it as "OTHER". Besides the type of relation, the annotators were asked to provide the correct WordNet 2.0 senses of the two nouns and information about the *order* of the modifier and the head nouns in the genitive construction. For example, although in of-constructions the head is followed by the modifier most of the time, this is not always true. For instance, in "*owner of car*[POSSESSION]" the head *owner* is followed by the modifier *car*, while in "*John's car*[POSSESSION/R]" the order is reversed. Approximately one third of the training examples had the nouns in reverse order.

Most of the time, one genitive instance was tagged with one semantic relation, but there were also situations in which an example could belong to more than one relation in the same context. For example, the genitive "*city of USA*" was tagged as a PART-WHOLE relation and as a LOCATION relation. There were 21 such cases in the training corpus.

The judges' agreement was measured using the Kappa statistics (Siegel and Castelan, 1988), one of the most frequently used measure of inter-annotator agreement for classification tasks: $K = \frac{Pr(A)-Pr(E)}{1-Pr(E)}$, where $Pr(A)$ is the proportion of times the raters agree and $Pr(E)$ is the probability of agreement by chance.

The K coefficient is 1 if there is a total agreement among the annotators, and 0 if there is no agreement other than that expected to occur by chance.

On average, the K coefficient is close to 0.82 for both of and s-genitives, showing a good level of agreement for the training and testing data on the set of 35 relations, taking into consideration the task difficulty. This can be explained by the instructions the annotators received prior to annotation and by their expertise in lexical semantics.

2.3 Distribution of Semantic Relations

Table 1 shows the distribution of the semantic relations in the annotated corpus.

In the case of of-genitives, there were 19 relations found from the total of 35 relations considered. The most frequently occurring relations were POSSESSION, KINSHIP, PROPERTY, PART-WHOLE, LOCATION, SOURCE, THEME, and MEASURE.

There were other relations (107 for of-genitives) that do not belong to the predefined list of 35 relations, such as "*state of emergency*". These examples were clustered in different undefined subsets based on their semantics. The largest subsets did not cover more than 3% of the OTHER set of examples. This observation shows that the set of 35 semantic relations from Table 1 is representative for genitives.

No.	Freq.		Semantic Relations	Examples
	Of	S		
1	36	220	POSSESSION	*"Mary's book"*
2	25	61	KINSHIP	*"Mary's brother"*
3	109	75	PROPERTY	*"John's coldness"*
4	11	123	AGENT	*"investigation of the crew"*
5	5	109	TIME-EVENT	*"last year's exhibition"*
6	30	7	DEPICTION-DEPICTED	*"a picture of my nice"*
7	328	114	PART-WHOLE	*"the girl's mouth"*
8	0	0	HYPERNYMY (IS-A)	*"city of Dallas"*
9	0	0	ENTAILMENT	N/A
10	10	3	CAUSE	*"death of cancer"*
11	11	62	MAKE/PRODUCE	*"maker of computer"*
12	0	0	INSTRUMENT	N/A
13	32	46	LOCATION/SPACE	*"university of Texas"*
14	0	0	PURPOSE	N/A
15	56	33	SOURCE/FROM	*"president of Bolivia"*
16	70	5	TOPIC	*"museum of art"*
17	0	0	MANNER	N/A
18	0	0	MEANS	*"service of bus"*
19	10	4	ACCOMPANIMENT	*"solution of the problem"*
20	1	2	EXPERIENCER	*"victim of lung disease"*
21	49	41	RECIPIENT	*"Josephine's reward"*
22	0	0	FREQUENCY	N/A
23	0	0	INFLUENCE	N/A
24	5	2	ASSOCIATED WITH	*"contractors of shipyard"*
25	115	1	MEASURE	*"hundred of dollars"*
26	0	0	SYNONYMY	N/A
27	0	0	ANTONYMY	N/A
28	0	0	PROB. OF EXISTENCE	N/A
29	0	0	POSSIBILITY	N/A
30	0	0	CERTAINTY	N/A
31	120	50	THEME	*"acquisition of the holding"*
32	8	2	RESULT	*"result of the review"*
33	0	0	STIMULUS	N/A
34	0	0	EXTENT	N/A
35	0	0	PREDICATE	N/A
36	107	49	OTHER	*"state of emergency"*

Table 1: The distribution of the semantic relations in the annotated corpus of 20,000 sentences.

Table 1 also shows the semantic preferences of each genitive form. For example, POSSESSION, KINSHIP, and some kinds of PART-WHOLE relations are most of the time encoded by the s-genitive, while some specific PART-WHOLE relations, such as "*dress of silk*" and "*array of flowers*", cannot be encoded but only by the of-genitive. This simple analysis leads to the important conclusion that the two constructions must be treated separately as their semantic content is different. This observation is also consistent with other recent work in linguistics on the grammatical variation of the English genitives (Stefanowitsch, 2001).

3 The Model

3.1 Problem Formulation

Given a genitive, the goal is to develop a procedure for the automatic labeling of the semantic relation it conveys. The semantic relation derives from the semantics of the noun phrases participating in genitives as well as the surrounding context.

Semantic classification of syntactic patterns in general can be formulated as a learning problem. This is a multi-class classification problem since the output can be one of the semantic relations in the set. We cast this as a supervised learning problem where input/ output pairs are available as training data.

An important first step is to map the characteristics of each genitive construction into a feature vector. Let's define with $\mathbf{x}_i$ the feature vector of an instance i and let X be the space of all instances; i.e. $\mathbf{x}_i \in X$. The multi-class classification is performed by a function that maps the feature space X into a semantic space S

$F : X \rightarrow S$, where S is the set of semantic relations from Table 1, i.e. $r_k \in S$.

Let T be the training set of examples or instances $T = (\mathbf{x}_1 r_1, \mathbf{x}_2 r_2, ..., \mathbf{x}_n r_n) \subseteq (X \times S)^n$ where n is the number of examples $\mathbf{x}$ each accompanied by its semantic relation label r. The problem is to decide which semantic relation r to assign to a new, unseen example $\mathbf{x}_{n+1}$. In order to classify a given set of examples (members of X), one needs some kind of measure of the similarity (or the difference) between any two given members of X.

3.2 Feature Space

An essential aspect of our approach below is the word sense disambiguation (WSD) of the noun. Using a state-of-the-art open-text WSD system with 70% accuracy for nouns (Novischi et al., 2004), each word is mapped into its corresponding WordNet 2.0 sense. The disambiguation process takes into account surrounding words, and it is through this process that *context* gets to play a role in labeling the genitives' semantics.

So far, we have identified and experimented with the following NP **features**:

1. **Semantic class of head noun** specifies the WordNet sense (synset) of the head noun and implicitly points to all its hypernyms. It is extracted automatically via a word sense disambiguation module. The genitive semantics is influenced heavily by the meaning of the noun constituents. For example: "*child's mother*" is a KINSHIP relation where as "*child's toy*" is a POSSESSION relation.

2. **Semantic class of modifier noun** specifies the WordNet synset of the modifier noun. The following examples show that the semantic of a genitive is also influenced by the semantic of the modifier noun; "*Mary's apartment*" is a POSSESSION relation, and "*apartment of New York*" is a LOCATION relation.

The positive and negative genitive examples of the training corpus are pairs of concepts of the format:

<modifier_semclass#WNsense;
head_semclass#WNsense; target>,

where `target` is a set of at least one of the 36 semantic relations. The `modifier_semclass` and `head_semclass` concepts are WordNet semantic classes tagged with their corresponding WordNet senses.

3.3 Semantic Scattering Learning Model

For every pair of <modifier - head> noun genitives, let us define with f_i^m and f_j^h the WordNet 2.0 senses of the modifier and head respectively. For convenience we replace the tuple $< f_i^m, f_j^h >$ with f_{ij}. The Semantic Scattering Model is based on the following observations:

Observation 1. f_i^m and f_j^h can be regarded as nodes on some paths that link the senses of the most specific noun concepts with the top of the noun hierarchies.

Observation 2. The closer the pair of noun senses f_{ij} is to the bottom of noun hierarchies the fewer the semantic relations associated with it; the more general f_{ij} is the more semantic relations.

The probability of a semantic relation *r* given feature pair f_{ij}

$$P(r|f_{ij}) = \frac{n(r, f_{ij})}{n(f_{ij})}, \quad (1)$$

is defined as the ratio between the number of occurrences of a relation *r* in the presence of feature pair f_{ij} over the number of occurrences of feature pair f_{ij} in the corpus. The most probable relation $\hat{r}$ is

$$\hat{r} = argmax_{r \in R} P(r|f_{ij}) \quad (2)$$

From the training corpus, one can measure the quantities $n(r, f_{ij})$ and $n(f_{ij})$. Depending on the level of abstraction of f_{ij} two cases are possible:

Case 1. The feature pair f_{ij} is specific enough such that there is only one semantic relation r for which

$P(r|f_{ij}) = 1$ and 0 for all the other semantic relations.

Case 2. The feature pair f_{ij} is general enough such that there are at least two semantic relations for which $P(r|f_{ij}) \neq 0$. In this case equation (2) is used to find the most appropriate $\hat{r}$.

Definition. A boundary G^* in the WordNet noun hierarchies is a set of synset pairs such that :

a) for any feature pair on the boundary, denoted $f_{ij}^{G^*} \in G^*$, $f_{ij}^{G^*}$ maps uniquely into only one relation r, and

b) for any $f_{ij}^u \succ f_{ij}^{G^*}$, f_{ij}^u maps into more than one relation r, and

c) for any $f_{ij}^l \prec f_{ij}^{G^*}$, f_{ij}^l maps uniquely into a semantic relation r. Here relations $\succ$ and $\prec$ mean "semantically more general" and "semantically more specific" respectively. This is illustrated in Figure 1.

Observation 3. We have noticed that there are more concept pairs under the boundary G^* than above, i.e. $| \{f_{ij}^l\} | \gg | \{f_{ij}^u\} |$.

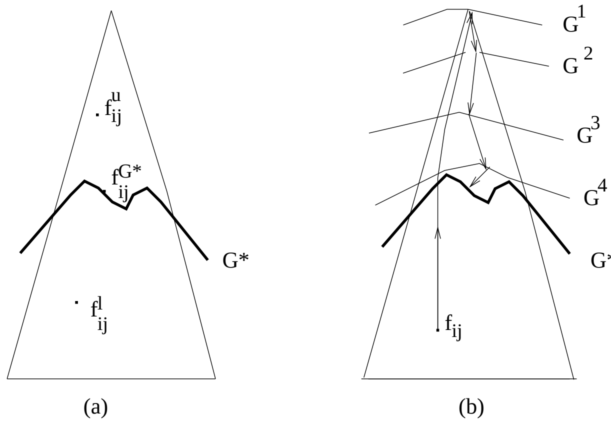

Figure 1: (a) Conceptual view of the noun hierarchies separated by the boundary G^*; (b) Boundary G^* is found through an iterative process called "semantic scattering".

3.4 Boundary Detection Algorithm

An approximation to boundary G^* is found using the training set through an iterative process called *semantic scattering*. We start with the most general boundary corresponding to the nine noun WordNet hierarchies and then specialize it based on the training data until a good approximation is reached.

Step 1. Create an initial boundary

The initial boundary denoted G^1 is formed from combinations of the nine WordNet hierarchies: *abstraction#6, act#2, entity#1, event#1, group#1, possession#2, phenomenon#1, psychological_feature#1, state#4.* To each training example a corresponding feature $f_{ij} =< f_i^m, f_j^h >$ is first determined, after which is replaced with the most general corresponding feature consisting of top WordNet hierarchy concepts denoted with f_{ij}^1. For instance, to the example "*apartment of the woman*" it corresponds the general feature *entity#1-entity#1* and POSSESSION relation, to "*husband of the woman*" it corresponds *entity#1-entity#1* and KINSHIP relation, and to "*hand of the woman*" it corresponds *entity#1-entity#1* and PART-WHOLE relation. At this high level G^1, to each feature pair f_{ij}^1 it corresponds a number of semantic relations. For each feature, one can determine the most probable relation using equation (2). For instance, to feature *entity#1-entity#1* there correspond 13 relations and the most probable one is the PART-WHOLE relation as indicated by Table 2.

Step 2. Specialize the boundary

2.1 Constructing a lower boundary

This step consists of specializing the semantic classes of the ambiguous features. A feature f_{ij}^k on boundary G^k is ambiguous if it corresponds to more then one relation and its most relevant relation has a conditional probability less then 0.9. To eliminate non-important specializations, we specialize only the ambiguous classes that occurs in more than 1% of the training examples.

The specialization procedure consists of first identifying features f_{ij}^k to which correspond more than one semantic relation, then replace these features with their hyponyms synsets. Thus one feature breaks into several new specialized features. The net effect is that the semantic relations that were attached to f_{ij}^k will be "scattered" across the new specialized features. This process continues till each feature will have only one semantic relation attached. Each iteration creates a new boundary, as shown in Figure 1. Table 3 shows statistics of semantic features f_{ij}^k for each level of specialization G^k. Note the average number of relations per feature decreasing asymptotically to 1 as k increases.

2.2 Testing the new boundary

R	1	2	3	6	7	11	13	15	16	19	21	24	25	Others
$P(r\|entity - entity)$	0.048	0.120	0.006	0.032	0.430	0.016	0.035	0.285	0.012	0.004	0.010	0.001	0.001	0

Table 2: Sample row from the conditional probability table where the feature pair is *entity-entity*. The numbers in the top row identify the semantic relations (as in Table 1).

Boundary	Of-genitives			S-genitives		
	G^1	**G**^{2}	**G**^{3}	**G**^{1}	**G**^{2}	**G**^{3}
Number of modifi er features	9	31	74	9	37	91
Number head features	9	34	66	9	24	36
No. of feature pairs	63 out of 81	216 out of 1054	314 out of 4884	41 of 81	157 out of 888	247 out of 3276
Number of features with only one relation	26	153	281	14	99	200
Average number of relations per feature	3	1.46	1.14	3.59	1.78	1.36

Table 3: Statistics for the semantic class features by level of specialization.

The new boundary is more specific then the previous boundary and it is closer to the ideal boundary. However, we do not know how well it behaves on unseen examples and we are looking for a boundary that classifies with a high accuracy the unseen examples. We test the boundary on unseen examples. For that we used 10% of the annotated examples (different from the 10% of the examples used for testing) and compute the accuracy (f-measure) of the new boundary on them.

If the accuracy is larger than the previous boundary's accuracy, we are converging toward the best approximation of the boundary and thus we should repeat Step 2 for the new boundary.

If the accuracy is lower than the previous boundary's accuracy, the new boundary is too specific and the previous boundary is a better approximation of the ideal boundary.

For the automatic detection of the semantic relations encoded by genitives, the boundary constructed by the Semantic Scattering model is more apppropriate than a “tree cut”, like the ones used for verb disambiguation (McCarthy, 1997) (Li and Abe, 1998) and constructed using the Minimum Description Length model (Rissanen, 1978). The developement of a ”tree cut” model for the detection of the semantic relations encoded by genitives involves the construction of a different ”tree cut” for each head noun and threfore the usage of these cuts is restricted to those head nouns. On the other hand, Semantic Scattering constructs only one boundary that, unlike the ”tree cut” model, is general enough to classify any genitive construction, including the ones with constituents unseen during training.

4 Semantic Relations Classification Algorithm

The ideal boundary G^* is used for classifying the semantic relations encoded by genitives. The algorithm consists of:
Step 1. Process the sentence. Perform Word Sense Disambiguation and syntactic parsing of the sentence containing the genitive.
Step 2. Identify the head and modifier noun concepts.
Step 3. Identify the feature pair. Using the results from WSD and WordNet noun hierarchies, map the head and modifier concepts into the corresponding classes from the boundary and identify a feature pair f_{ij} that has the closest euclidean distance to the two classes.
Step 4. Find the semantic relation. Using the feature f_{ij}, determine the semantic relation that corresponds to that feature on the boundary. If there is no such relation, mark it as OTHER.

5 Results

For testing, we considered 20% of the annotated examples. We used half of the examples for detecting the boundary G^* and half for testing the system.

G^* Boundary Detection

The algorithm ran iteratively performing boundary

Results	Of-genitives			S-genitives		
	Baseline1	Baseline2	Results	Baseline1	Baseline2	Results
Number of correctly retrieved relations	49	59	**81**	15	27	**71**
Number of relations retrieved	73	75	**99**	63	66	**85**
Number of correct relations	104	104	**104**	96	96	**96**
Precision	67.12%	76.62%	**81.82%**	23.81%	40.91%	**83.53%**
Recall	47.12%	56.73%	**77.88%**	15.63%	28.13%	**73.96%**
F-measure	55.37%	65.92%	**79.80%**	18.87%	33.34%	**78.45%**

Table 4: Overall results for the semantic interpretation of genitives

specializations on the WordNet IS-A noun hierarchies in order to eliminate the ambiguities of the training examples. Boundary G^1 corresponds to the semantic classes of the nine WordNet noun hierarchies and boundaries G^2 and G^3 to their subsequent immediate hyponyms. For both s-genitives and of-genitives, boundary G^2 was more accurate then boundary G^1 and therefore we repeated Step 2. However, boundary G^3 was less accurate then boundary G^2 and thus boundary G^2 is the best approximation of the ideal boundary.

Semantic Relations Classification

Table 4 shows the results obtained when classifying the 36 relations (the 36th relation being OTHER) for of-genitives and s-genitives. The results are presented for the Semantic Scattering system that uses G^2 as the best approximation of the G^* together with two baselines. *Baseline1* system obtained the results without any word sense disambiguation (WSD) feature, i.e. using only the default sense number 1 for the concept pairs, and without any specialization. *Baseline2* system applied two iterations of the boundary detection algorithm but without any word sense disambiguation.

Overall, the Semantic Scattering System achieves an 81.82% precision and 77.88% recall for of-genitives and an 83.53% precision and 73.96% recall for s-genitives.

Both the WSD and the specialization are important for our system as indicated by the Baseline systems performance. The impact of specialization on the f-measure (Baseline2 minus Baseline1) is 10.55% for of-genitives and 14.47% for s-genitives, while the impact of WSD (final result minus Baseline2) is 14% for of-genitives and 45.11% for s-genitives.

Error Analysis

An important way of improving the performance of a system is to perform a detailed error analysis of the results. We have analyzed the various error sources encountered in our experiments and summarized the results in Table 5.

Error Type	Of-genitives %Error	S-genitives %Error
Missing feature	28.57	29.17
General semantic classes	28.57	20.83
WSD System	19.05	29.17
Reversed order of constituents	14.29	12.5
Named Entity Recognizer	4.76	8.33
Missing WordNet sense	4.76	0

Table 5: The error types encountered on the testing corpus.

6 Comparison with other Models

To evaluate our model, we have conducted experiments with other frequently used machine learning models, on the same dataset, using the same features. Table 6 shows a comparison between the results obtained with the Semantic Scattering algorithm and the decision trees (C5.0, http://www.rulequest.com/see5-info.html), the naive Bayes model (jBNC, Bayesian Network Classifier Toolbox, http://jbnc.sourceforge.net), and Support Vector Machine (libSVM, Chih-Chung Chang and Chih-Jen Lin. 2004. LIBSVM: a Library for Support Vector Machines, http://www.csie.ntu.edu.tw/ cjlin/papers/libsvm.pdf). The reason for the superior performance of Semantic Scattering is because the classification of genitives is feature poor relying only on the semantics of the noun components, and the other three models normally work better with a larger set of features.

Accuracy	Of-genitives	S-genitives
Semantic Scattering	79.85%	78.75%
Decision Trees (C5.0)	40.60%	47.0%
Naive Bayes (JBNC)	42.31%	43.7%
SVM (LibSVM)	31.45 %	23.51%

Table 6: Accuracy performance of four learning models on the same testing corpus.

7 Discussion and Conclusions

The classification of genitives is an example of a learning problem where a tailored model outperforms other generally applicable models.

This paper presents a model for the semantic classification of genitives. A set of 35 semantic relations was identified, and we provided statistical evidence that when it comes to genitives, some relations are more frequent than others, while some are absent. The model relies on the semantic classes of noun constituents. The algorithm was trained and tested on 20,000 sentences containing 2,249 of-genitives and 1006 s-genitives and achieved an average precision of 82%, a recall of 76%, and an f-measure of 79%. For comparison, we ran a C5.0 learning system on the same corpus and obtained 40.60% accuracy for of-genitives and 47% for s-genitives. A similar experiment with a Naive Bayes learning system led to 42.31% accuracy for of-genitives and 43.7% for s-genitives. The performance with a Support Vector Machines learner was the worst, achieving only a 31.45% accuracy for of-genitives and 23.51% accuracy for s-genitives. We have also identified the sources of errors which when addressed may bring further improvements.

Abstract

Measuring the relative compositionality of Multi-word Expressions (MWEs) is crucial to Natural Language Processing. Various collocation based measures have been proposed to compute the relative compositionality of MWEs. In this paper, we define novel measures (both collocation based and context based measures) to measure the relative compositionality of MWEs of V-N type. We show that the correlation of these features with the human ranking is much superior to the correlation of the traditional features with the human ranking. We then integrate the proposed features and the traditional features using a SVM based ranking function to rank the collocations of V-N type based on their relative compositionality. We then show that the correlation between the ranks computed by the SVM based ranking function and human ranking is significantly better than the correlation between ranking of individual features and human ranking.

1 Introduction

The main goal of the work presented in this paper is to examine the relative compositionality of collocations of V-N type using a SVM based ranking function. Measuring the relative compositionality of V-N collocations is extremely helpful in applications such as machine translation where the collocations that are highly non-compositional can be handled in a special way (Schuler and Joshi, 2004) (Hwang and Sasaki, 2005).

Multi-word expressions (MWEs) are those whose structure and meaning cannot be derived from their component words, as they occur independently. Examples include conjunctions like 'as well as' (meaning 'including'), idioms like 'kick the bucket' (meaning 'die'), phrasal verbs like 'find out' (meaning 'search') and compounds like 'village community'. A typical natural language system assumes each word to be a lexical unit, but this assumption does not hold in case of MWEs (Becker, 1975) (Fillmore, 2003). They have idiosyncratic interpretations which cross word boundaries and hence are a 'pain in the neck' (Sag et al., 2002). They account for a large portion of the language used in day-to-day interactions (Schuler and Joshi, 2004) and so, handling them becomes an important task.

A large number of MWEs have a standard syntactic structure but are non-compositional semantically. An example of such a subset is the class of non-compositional verb-noun collocations (V-N collocations). The class of non-compositional V-N collocations is important because they are used very frequently. These include verbal idioms (Nunberg et al., 1994), support-verb constructions (Abeille, 1988), (Akimoto, 1989), among others. The expression 'take place' is a MWE whereas 'take a gift' is not a MWE.

[1]Part of the work was done at Institute for Research in Cognitive Science (IRCS), University of Pennsylvania, Philadelphia, PA 19104, USA, when he was visiting IRCS as a Visiting Scholar, February to December, 2004.

It is well known that one cannot really make a binary distinction between compositional and non-compositional MWEs. They do not fall cleanly into mutually exclusive classes, but populate the continuum between the two extremes (Bannard et al., 2003). So, we rate the MWEs (V-N collocations in this paper) on a scale from 1 to 6 where 6 denotes a completely compositional expression, while 1 denotes a completely opaque expression.

Various statistical measures have been suggested for ranking expressions based on their compositionality. Some of these are Frequency, Mutual Information (Church and Hanks, 1989) , distributed frequency of object (Tapanainen et al., 1998) and LSA model (Baldwin et al., 2003) (Schutze, 1998). In this paper, we define novel measures (both collocation based and context based measures) to measure the relative compositionality of MWEs of V-N type (see section 6 for details). Integrating these statistical measures should provide better evidence for ranking the expressions. We use a SVM based ranking function to integrate the features and rank the V-N collocations according to their compositionality. We then compare these ranks with the ranks provided by the human judge. A similar comparison between the ranks according to Latent-Semantic Analysis (LSA) based features and the ranks of human judges has been made by McCarthy, Keller and Caroll (McCarthy et al., 2003) for verb-particle constructions. (See Section 3 for more details). Some preliminary work on recognition of V-N collocations was presented in (Venkatapathy and Joshi, 2004).

We show that the measures which we have defined contribute greatly to measuring the relative compositionality of V-N collocations when compared to the traditional features. We also show that the ranks assigned by the SVM based ranking function correlated much better with the human judgement that the ranks assigned by individual statistical measures.

This paper is organized in the following sections **(1)** Basic Architecture, **(2)** Related work, **(3)** Data used for the experiments, **(4)** Agreement between the Judges, **(5)** Features, **(6)** SVM based ranking function, **(7)** Experiments & Results, and **(8)** Conclusion.

2 Basic Architecture

Every V-N collocation is represented as a vector of features which are composed largely of various statistical measures. The values of these features for the V-N collocations are extracted from the British National Corpus. For example, the V-N collocation 'raise an eyebrow' can be represented as
[Frequency = 271, Mutual Information = 8.43, Distributed frequency of object = 1456.29, etc.]. A SVM based ranking function uses these features to rank the V-N collocations based on their relative compositionality. These ranks are then compared with the human ranking.

3 Related Work

(Breidt, 1995) has evaluated the usefulness of the Point-wise Mutual Information measure (as suggested by (Church and Hanks, 1989)) for the extraction of V-N collocations from German text corpora. Several other measures like Log-Likelihood (Dunning, 1993), Pearson's χ^2 (Church et al., 1991), Z-Score (Church et al., 1991) , Cubic Association Ratio (MI3), etc., have been also proposed. These measures try to quantify the association of two words but do not talk about quantifying the non-compositionality of MWEs. Dekang Lin proposes a way to automatically identify the non-compositionality of MWEs (Lin, 1999). He suggests that a possible way to separate compositional phrases from non-compositional ones is to check the existence and mutual-information values of phrases obtained by replacing one of the words with a similar word. According to Lin, a phrase is probably non-compositional if such substitutions are not found in the collocations database or their mutual information values are significantly different from that of the phrase. Another way of determining the non-compositionality of V-N collocations is by using 'distributed frequency of object' (DFO) in V-N collocations (Tapanainen et al., 1998). The basic idea in there is that "if an object appears only with one verb (or few verbs) in a large corpus we expect that it has an idiomatic nature" (Tapanainen et al., 1998).

Schone and Jurafsky (Schone and Jurafsky, 2001) applied Latent-Semantic Analysis (LSA) to the analysis of MWEs in the task of MWE discovery, by way of rescoring MWEs extracted from the corpus. An interesting way of quantifying the relative compositionality of a MWE is proposed by Baldwin, Bannard, Tanaka and Widdows (Baldwin et al., 2003). They use LSA to determine the similarity between an MWE and its constituent words, and claim that higher similarity indicates great decomposability. In terms of compositionality, an expression is likely to be relatively more compositional if it is decomposable. They evaluate their model on English NN compounds and verb-particles, and showed that the model correlated moderately well with the Wordnet based decomposability theory (Baldwin et al., 2003).

McCarthy, Keller and Caroll (McCarthy et al., 2003) judge compositionality according to the degree of overlap in the set of most similar words to the verb-particle and head verb. They showed that the correlation between their measures and the human ranking was better than the correlation between the statistical features and the human ranking. We have done similar experiments in this paper where we compare the correlation value of the ranks provided by the SVM based ranking function with the ranks of the individual features for the V-N collocations. We show that the ranks given by the SVM based ranking function which integrates all the features provides a significantly better correlation than the individual features.

4 Data used for the experiments

The data used for the experiments is British National Corpus of 81 million words. The corpus is parsed using Bikel's parser (Bikel, 2004) and the Verb-Object Collocations are extracted. There are 4,775,697 V-N collocations of which 1.2 million are unique. All the V-N collocations above the frequency of 100 (n=4405) are taken to conduct the experiments so that the evaluation of the system is feasible. These 4405 V-N collocations were searched in Wordnet, American Heritage Dictionary and SAID dictionary (LDC,2003). Around 400 were found in at least one of the dictionaries. Another 400 were extracted from the rest so that the evaluation set has roughly equal number of compositional and non-compositional expressions. These 800 expressions were annotated with a rating from 1 to 6 by using guidelines independently developed by the authors. 1 denotes the expressions which are totally non-compositional while 6 denotes the expressions which are totally compositional. The brief explanation of the various ratings is as follows: **(1)** No word in the expression has any relation to the actual meaning of the expression. Example : "**leave a mark**". **(2)** Can be replaced by a single verb. Example : "**take a look**". **(3)** Although meanings of both words are involved, at least one of the words is not used in the usual sense. Example : "**break news**". **(4)** Relatively more compositional than (3). Example : "**prove a point**". **(5)** Relatively less compositional than (6). Example : "**feel safe**". **(6)** Completely compositional. Example : "**drink coffee**".

5 Agreement between the Judges

The data was annotated by two fluent speakers of English. For 765 collocations out of 800, both the annotators gave a rating. For the rest, at least one of the annotators marked the collocations as "don't know". Table 1 illustrates the details of the annotations provided by the two judges.

Ratings	6	5	4	3	2	1
Annotator1	141	122	127	119	161	95
Annotator2	303	88	79	101	118	76

Table 1: Details of the annotations of the two annotators

From the table 1 we see that annotator1 distributed the rating more uniformly among all the collocations while annotator2 observed that a significant proportion of the collocations were completely compositional. To measure the agreement between the two annotators, we used the Kendall's TAU (τ) (Siegel and Castellan, 1988). τ is the correlation between the rankings[1] of collocations given by the two annotators. τ ranges between 0 (little agreement) and 1 (full agreement). τ is defined as,

$$\tau = \frac{\sum_{i<j} sgn(x_i - x_j)\ sgn(y_i - y_j)}{\sqrt{(t_0 - t_1)\ (t_0 - t_2)}}$$

$$t_1 = \frac{\sum u_i\ (u_i - 1)}{2}\ ,\ t_2 = \frac{\sum v_i\ (v_i - 1)}{2}\ ,\ t_0 = \frac{n\ (n-1)}{2}$$

[1]computed from the ratings

where x_i's are the rankings of annotator1 and y_i's are the rankings of annotator2, n is the number of collocations, u_i is the number of values in the i^{th} group of tied x values and v_i is the number of values in the i^{th} group of tied y values.

We obtained a τ score of **0.61** which is highly significant. This shows that the annotators were in a good agreement with each other in deciding the rating to be given to the collocations. We also compare the ranking of the two annotators using Pearson's Rank-Correlation coefficient (r_s) (Siegel and Castellan, 1988). We obtained a r_s score of **0.71** indicating a good agreement between the annotators. A couple of examples where the annotators differed are **(1)** "perform a task" was rated 3 by annotator1 while it was rated 6 by annotator2 and **(2)** "pay tribute" was rated 1 by annotator1 while it was rated 4 by annotator2.

The 765 samples annotated by both the annotators were then divided into a training set and a testing set in several possible ways to cross-validate the results of ranking (section 8).

6 Features

Each collocation is represented by a vector whose dimensions are the statistical features obtained from the British National Corpus. The features used in our experiments can be classified as (1) Collocation based features and (2) Context based features.

6.1 Collocation based features

Collocation based features consider the entire collocation as an unit and compute the statistical properties associated with it. The collocation based features that we considered in our experiments are (1) Frequency, (2) Point-wise Mutual Information, (3) Least mutual information difference with similar collocations, (4) Distributed frequency of object and (5) Distributed frequency of object using the verb information.

6.1.1 Frequency (f)

This feature denotes the frequency of a collocation in the British National Corpus. Cohesive expressions have a high frequency. Hence, greater the frequency, the more is the likelihood of the expression to be a MWE.

6.1.2 Point-wise Mutual Information (m)

Point-wise Mutual information of a collocation (Church and Hanks, 1989) is defined as,

$$m(v,o) = \frac{f(v,o) * f(-,-)}{f(v,-) * f(-,o)}$$

where, v is the verb and o is the object of the collocation. The higher the Mutual information of a collocation, the more is the likelihood of the expression to be a MWE.

6.1.3 Least mutual information difference with similar collocations (μ)

This feature is based on Lin's work (Lin, 1999). He suggests that a possible way to separate compositional phrases from non-compositional ones is to check the existence and mutual information values of *similar collocations* (phrases obtained by replacing one of the words with a similar word). For example, 'eat apple' is a similar collocation of 'eat pear'.

For a collocation, we find the similar collocations by substituting the verb and the object with their *similar words*[2]. The similar collocation having the least mutual information difference is chosen and the difference in their mutual information values is noted.

If a collocation c has a set of similar collocations S, then we define μ as

$$\mu(v_c, o_c) = min_{s \in S} \ [\ abs \ (m(c) - m(s)) \ ]$$

where $abs(x)$ returns the absolute value of x and v_c and o_c are the verb and object of the collocation c respectively. If similar collocations do not exist for a collocation, then this feature is assigned the highest among the values assigned in the previous equation. In this case, μ is defined as,

$$\mu(v,o) = max_{i,j} \ [\ \mu(v_i, o_j) \ ]$$

where v and o are the verb and object of collocations for which similar collocations do not exist. The higher the value of μ, the more is the likelihood of the collocation to be a MWE.

[2]obtained from Lin's (Lin, 1998) automatically generated thesaurus (http://www.cs.ualberta.ca/∼lindek/downloads.htm). We obtained the best results (section 8) when we substituted top-5 similar words for both the verb and the object. To measure the compositionality, semantically similar words are more suitable than synomys. Hence, we choose to use Lin's thesaurus (Lin, 1998) instead of Wordnet (Miller et al., 1990).

6.1.4 Distributed Frequency of Object (d)

The distributed frequency of object is based on the idea that "if an object appears only with one verb (or few verbs) in a large corpus, the collocation is expected to have idiomatic nature" (Tapanainen et al., 1998). For example, 'sure' in 'make sure' occurs with very few verbs. Hence, 'sure' as an object is likely to give a special sense to the collocation as it cannot be used with any verb in general. It is defined as,

$$d(o) = \frac{\sum_i^n f(v_i, o)}{n}$$

where n is the number of verbs occurring with the object (o), v_i's are the verbs cooccuring with o and $f(v_i, o) > T$. As the number of verbs (n) increases, the value of $d(o)$ decreases. Here, T is a threshold which can be set based on the corpus. This feature treats 'point finger' and 'polish finger' in the same way as it does not use the information specific to the verb in the collocation. Here, both the collocations will have the value $d(``finger'')$. The 3 collocations having the highest value of this feature are (1) come true, (2) become difficult and (3) make sure.

6.1.5 Distributed Frequency of Object using the Verb information (ρ)

Here, we have introduced an extension to the feature d such that the collocations like 'point finger' and 'polish finger' are treated differently and more appropriately. This feature is based on the idea that "a collocation is likely to be idiomatic in nature if there are only few other collocations with the same object and dissimilar verbs". We define this feature as,

$$\rho(v, o) = \frac{\sum_i^n f(v_i, o) \ * \ dist(v, v_i)}{n}$$

where $n < 50$ is the number of verbs occurring with o, v_i's are the verbs cooccuring with o and $f(v_i, o) > T$. $dist(v, v_i)$ is the distance between the verb v and v_i. It is calculated using the wordnet similarity measure defined by Hirst and Onge (Hirst and St-Onge, 1998). In our experiments, we considered top-50 verbs which co-occurred with the object o. We used a Perl package Wordnet::Similarity by Patwardhan[3] to conduct our experiments.

[3]http://www.d.umn.edu/~tpederse/similarity.html

6.2 Context based features

Context based measures use the context of a word/collocation to measure their properties. We represented the context of a word/collocation using a LSA model. LSA is a method of representing words/collocations as points in vector space.

The LSA model we built is similar to that described in (Schutze, 1998) and (Baldwin et al., 2003). First, 1000 most frequent content words (i.e., not in the stop-list) were chosen as "content-bearing words". Using these content-bearing words as column labels, the 50,000 most frequent terms in the corpus were assigned row vectors by counting the number of times they occurred within the same sentence as content-bearing words. Principal component analysis was used to determine the principal axis and we get the transformation matrix $A_{1000X100}$ which can be used to reduce the dimensions of the 1000 dimensional vectors to 100 dimensions.

We will now describe in Sections 6.2.1 and 6.2.2 the features defined using LSA model.

6.2.1 Dissimilarity of the collocation with its constituent verb using the LSA model (ι)

If a collocation is highly dissimilar to its constituent verb, it implies that the usage of the verb in the specific collocation is not in a general sense. For example, the sense of 'change' in 'change hands' would be very different from its usual sense. Hence, the greater the dissimilarity between the collocation and its constituent verb, the more is the likelihood that it is a MWE. The feature is defined as

$$\iota(c, v_c) = 1 - sim_{LSA}(c, v_c)$$

$$sim_{LSA}(c, v_c) = \frac{lsa(c) \ . \ lsa(v_c)}{|lsa(c)| * |lsa(v_c)|}$$

where, c is the collocation, v_c is the verb of the collocation and lsa(x) is representation of x using the LSA model.

6.2.2 Similarity of the collocation to the verb-form of the object using the LSA model (ψ)

If a collocation is highly similar to the verb form of an object, it implies that the verb in the collocation does not contribute much to the meaning of the collocation. The verb either acts as a sort of support verb, providing perhaps some additional aspectual meaning. For example, the verb 'give' in 'give a smile' acts merely as a support verb. Here, the collocation 'give a smile' means the same as the verb-form of the object i.e., 'to smile'. Hence, the greater is the similarity between the collocation and the verb-form of the object, the more is the likelihood that it is a MWE. This feature is defined as

$$\psi(c, vo_c) = \frac{lsa(c)\ .\ lsa(vo_c)}{|lsa(c)| * |lsa(vo_c)|}$$

where, c is the collocation and vo_c is the verb-form of the object o_c. We obtained the verb-form of the object from the wordnet (Miller et al., 1990) using its 'Derived forms'. If the object doesn't have a verbal form, the value of this feature is 0. Table 2 contains the top-6 collocations according to this feature. All the collocations in Table 2 (except 'receive award' which does not mean the same as 'to award') are good examples of MWEs.

Collocation	Value		Collocation	Value
pay visit	0.94		provide assistance	0.92
provide support	0.93		give smile	0.92
receive award	0.92		fi nd solution	0.92

Table 2: Top-6 collocations according to this feature

7 SVM based ranking function/algorithm

The optimal rankings on the training data is computed using the average ratings of the two users. The goal of the learning function is to model itself according to this rankings. It should take a ranking function f from a family of ranking functions F that maximizes the empirical τ (Kendall's Tau). τ expresses the similarity between the optimal ranking (r^*) and the ranking (r_f) computed by the function f. SVM-Light[4] is a tool developed by Joachims (Joachims, 2002) which provides us such a function. We briefly describe the algorithm in this section.

Maximizing τ is equivalent to minimizing the number of discordant pairs (the pairs of collocations which are not in the same order as in the optimal ranking). This is equivalent to finding the weight vector $\bar{w}$ so that the maximum number of inequalities are fulfilled.

$$\forall (c_i, c_j) \in r^* : \bar{w}\ \phi(c_i) > \bar{w}\ \phi(c_j)$$

where c_i and c_j are the collocations, $(c_i, c_j) \in r^*$ if the collocation c_i is ranked higher than c_j for the optimal ranking r^*, $\phi(c_i)$ and $\phi(c_j)$ are the mapping onto features (section 6) that represent the properties of the V-N collocations c_i and c_j respectively and $\bar{w}$ is the weight vector representing the ranking function f_w.

Adding SVM regularization for margin maximization to the objective leads to the following optimization problem (Joachims, 2002).

$$minimize: \quad V(\bar{w}, \bar{\epsilon}) = \frac{1}{2}\, \bar{w}\bar{w} + C \sum \epsilon_{i,j}$$

$$constr: \bar{w}(\phi(c_i) - \phi(c_j)) \geq 1 - \epsilon_{i,j},\ \forall_{i,j}\ \epsilon_{i,j} \geq 0$$

where $\epsilon_{i,j}$ are the (non-negative) slack variables and C is the margin that allows trading-off margin size against training error. This optimization problem is equivalent to that of a classification SVM on pairwise difference vectors $\phi(c_i)$ - $\phi(c_j)$. Due to similarity, it can be solved using decomposition algorithms similar to those used for SVM classification (Joachims, 1999).

Using the learnt function $f_{\bar{w}^*}$ ($\bar{w}^*$ is the learnt weight vector), the collocations in the test set can be ranked by computing their values using the formula below.

$$rc(c_i) = \bar{w}^* \phi(c_i)$$

8 Experiments and Results

For training, we used 10% of the data and for testing, we use 90% of the data as the goal is to use only a small portion of the data for training (Data was divided in 10 different ways for cross-validation. The results presented here are the average results).

All the statistical measures show that the expressions ranked higher according to their decreasing values are more likely to be non-compositional. We compare these ranks with the human rankings (obtained using the average ratings of the users). To compare, we use Pearson's Rank-Order Correlation Coefficient (r_s) (Siegel and Castellan, 1988).

We integrate all the seven features using the SVM based ranking function (described in section 7). We

[4]http://svmlight.joachims.org

see that the correlation between the relative compositionality of the V-N collocations computed by the SVM based ranking function is significantly higher than the correlation between the individual features and the human ranking (Table 3).

Feature	Correlation		Feature	Correlation
f (f1)	0.129		ρ (f5)	0.203
m (f2)	0.117		ι (f6)	0.139
μ (f3)	0.210		ψ (f7)	*0.300*
d (f4)	0.111		Ranking f	**0.448**

Table 3: The correlation values of the ranking of individual features and the ranking of SVM based ranking function with the ranking of human judgements

In table 3, we also see that the contextual feature which we proposed, 'Similarity of the collocation to the verb-form of the object' (ψ), correlated significantly higher than the other features which indicates that it is a good measure to represent the semantic compositionality of V-N expressions. Other expressions which were good indicators when compared to the traditional features are 'Least mutual information difference with similar collocations' (μ) and 'Distributed frequency of object using the verb information' (ρ).

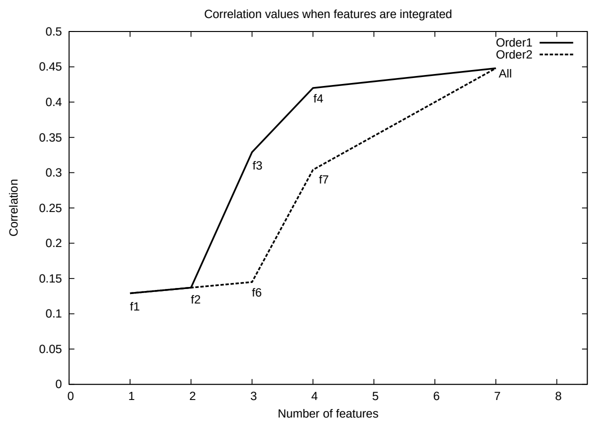

Figure 1: The change in r_s as more features are added to the ranking function

To observe the contribution of the features to the SVM based ranking function, we integrate the features (section 6) one after another (in two different ways) and compute the relative order of the collocations according to their compositionality. We see that as we integrate more number of relevant compositionality based features, the relative order correlates better (better r_s value) with the human ranking (Figure 1). We also see that when the feature 'Least mutual information difference with similar collocations' is added to the SVM based ranking function, there is a high rise in the correlation value indicating it's relevance. In figure 1, we also observe that the context-based features did not contribute much to the SVM based ranking function even though they performed well individually.

9 Conclusion

In this paper, we proposed some collocation based and contextual features to measure the relative compositionality of MWEs of V-N type. We then integrate the proposed features and the traditional features using a SVM based ranking function to rank the V-N collocations based on their relative compositionality. Our main results are as follows, **(1)** The properties 'Similarity of the collocation to the verb-form of the object', ' Least mutual information difference with similar collocations' and 'Distributed frequency of object using the verb information' contribute greatly to measuring the relative compositionality of V-N collocations. **(2)** The correlation between the ranks computed by the SVM based ranking function and the human ranking is significantly better than the correlation between ranking of individual features and human ranking.

In future, we will evaluate the effectiveness of the techniques developed in this paper for applications like Machine Translation. We will also extend our approach to other types of MWEs and to the MWEs of other languages (work on Hindi is in progress).

Acknowledgments

We want to thank the anonymous reviewers for their extremely useful reviews. We are grateful to Roderick Saxey and Pranesh Bhargava for annotating the data which we used in our experiments.

Abstract

In this paper we investigate an application of feature clustering for word sense disambiguation, and propose a semi-supervised feature clustering algorithm. Compared with other feature clustering methods (ex. supervised feature clustering), it can infer the distribution of class labels over (unseen) features unavailable in training data (labeled data) by the use of the distribution of class labels over (seen) features available in training data. Thus, it can deal with both seen and unseen features in feature clustering process. Our experimental results show that feature clustering can aggressively reduce the dimensionality of feature space, while still maintaining state of the art sense disambiguation accuracy. Furthermore, when combined with a semi-supervised WSD algorithm, semi-supervised feature clustering outperforms other dimensionality reduction techniques, which indicates that using unlabeled data in learning process helps to improve the performance of feature clustering and sense disambiguation.

1 Introduction

This paper deals with word sense disambiguation (WSD) problem, which is to assign an appropriate sense to an occurrence of a word in a given context. Many corpus based statistical methods have been proposed to solve this problem, including supervised learning algorithms (Leacock et al., 1998; Towel and Voorheest, 1998), weakly supervised learning algorithms (Dagan and Itai, 1994; Li and Li, 2004; Mihalcea, 2004; Niu et al., 2005; Park et al., 2000; Yarowsky, 1995), unsupervised learning algorithms (or word sense discrimination) (Pedersen and Bruce, 1997; Sch$\ddot{u}$tze, 1998), and knowledge based algorithms (Lesk, 1986; McCarthy et al., 2004).

In general, the most common approaches start by evaluating the co-occurrence matrix of features versus contexts of instances of ambiguous word, given sense-tagged training data for this target word. As a result, contexts are usually represented in a high-dimensional sparse feature space, which is far from optimal for many classification algorithms. Furthermore, processing data lying in high-dimensional feature space requires large amount of memory and CPU time, which limits the scalability of WSD model to very large datasets or incorporation of WSD model into natural language processing systems.

Standard dimentionality reduction techniques include (1) supervised feature selection and supervised feature clustering when given labeled data, (2) unsupervised feature selection, latent semantic indexing, and unsupervised feature clustering when only unlabeled data is available. Supervised feature selection improves the performance of an examplar based learning algorithm over SENSEVAL-2 data (Mihalcea, 2002), Naive Bayes and decision tree over SENSEVAL-1 and SENSEVAL-2 data (Lee and Ng, 2002), but feature selection does not improve SVM and Adaboost over SENSEVAL-1 and SENSEVAL-2 data (Lee and Ng, 2002) for word sense disambiguation. Latent semantic indexing (LSI) studied in (Sch$\ddot{u}$tze, 1998) improves the performance of sense discrimination, while unsupervised feature selection also improves the performance of word sense discrimination (Niu et al., 2004). But little work is done on using feature clustering to conduct dimensionality reduction for WSD. This paper will describe an application of feature clustering technique to WSD task.

Feature clustering has been extensively studied for the benefit of text categorization and document clustering. In the context of text categorization, supervised feature clustering algorithms (Baker and McCallum, 1998; Bekkerman et al., 2003; Slonim and Tishby, 2001) usually cluster words into groups based on the distribution of class labels over features, which can compress the feature space much more aggressively while still maintaining state of the art classification accuracy. In the context of document clustering, unsupervised feature clustering algorithms (Dhillon, 2001; Dhillon et al., 2002; Dhillon et al., 2003; El-Yaniv and Souroujon, 2001; Slonim and Tishby, 2000) perform word clustering by the use of word-document co-occurrence matrix, which can improve the performance of document clustering by clustering documents over word clusters.

Supervised feature clustering algorithm groups features into clusters based on the distribution of class labels over features. But it can not group unseen features (features that do not occur in labeled data) into meaningful clusters since there are no class labels associated with these unseen features. On the other hand, while given labeled data, unsupervised feature clustering method can not utilize class label information to guide feature clustering procedure. While, as a promising classification strategy, semi-supervised learning methods (Zhou et al., 2003; Zhu and Ghahramani, 2002; Zhu et al., 2003) usually utilize all the features occurring in labeled data and unlabeled data. So in this paper we propose a semi-supervised feature clustering algorithm to overcome this problem. Firstly, we try to induce class labels for unseen features based on the similarity among seen features and unseen features. Then all the features (including seen features and unseen features) are clustered based on the distribution of class labels over them.

This paper is organized as follows. First, we will formulate a feature clustering based WSD problem in section 2. Then in section 3 we will describe a semi-supervised feature clustering algorithm. Section 4 will provide experimental results of various dimensionality reduction techniques with combination of state of the art WSD algorithms on SENSEVAL-3 data. Section 5 will provide a review of related work on feature clustering. Finally we will conclude our work and suggest possible improvement in section 6.

2 Problem Setup

Let $X = \{x_i\}_{i=1}^{n}$ be a set of contexts of occurrences of an ambiguous word w, where x_i represents the context of the i-th occurrence, and n is the total number of this word's occurrences. Let $S = \{s_j\}_{j=1}^{c}$ denote the sense tag set of w. The first l examples $x_g (1 \leq g \leq l)$ are labeled as y_g ($y_g \in S$) and other u ($l+u = n$) examples $x_h (l+1 \leq h \leq n)$ are unlabeled. The goal is to predict the sense of w in context x_h by the use of label information of x_g and similarity information among examples in X.

We use $\widetilde{F}$ to represent feature clustering result into $N_{\widetilde{F}}$ clusters when F is a set of features. After feature clustering, any context x_i in X can be represented as a vector over feature clusters $\widetilde{F}$. Then we can use supervised methods (ex. SVM) (Lee and Ng, 2002) or semi-supervised methods (ex. label propagation algorithm) (Niu et al., 2005) to perform sense disambiguation on unlabeled instances of target word.

3 Semi-Supervised Feature Clustering Algorithm

In supervised feature clustering process, F consists of features occurring in the first l labeled examples, which can be denoted as F_L. But in the setting of transductive learning, semi-supervised learning algorithms will utilize not only the features in labeled examples (F_L), but also unseen features in unlabeled examples (denoted as $F_{\overline{L}}$). $F_{\overline{L}}$ consists of the features that occur in unlabeled data, but never appear in labeled data.

Supervised feature clustering algorithm usually performs clustering analysis over feature-class matrix, where each entry (i, j) in this matrix is the number of times of the i-th feature co-occurring with the j-th class. Therefore it can not group features in $F_{\overline{L}}$ into meaningful clusters since there are no class labels associated with these features. We overcome this problem by firstly inducing class labels for unseen features based on the similarity among features in F_L and $F_{\overline{L}}$, then clustering all the features (including F_L and $F_{\overline{L}}$) based on the distribution of class labels over them.

This semi-supervised feature clustering algorithm is defined as follows:

Input:

Feature set $F = F_L \bigcup F_{\overline{L}}$ (the first $|F_L|$ features in F belong to F_L, and the remaining $|F_{\overline{L}}|$ features belong to $F_{\overline{L}}$), context set X, the label information of $x_g (1 \leq g \leq l)$, $N_{\widetilde{F}}$ (the number of clusters in $\widetilde{F}$);

Output:

Clustering solution $\widetilde{F}$;

Algorithm:

1. Construct $|F| \times |X|$ feature-example matrix $M^{F,X}$, where entry $M^{F,X}_{i,j}$ is the number of times of f_i co-occurring with example x_j ($1 \leq j \leq n$).

2. Form $|F| \times |F|$ affinity matrix W defined by $W_{ij} = exp(-\frac{d^2_{ij}}{\sigma^2})$ if $i \neq j$ and $W_{ii} = 0$ ($1 \leq i, j \leq |F|$), where d_{ij} is the distance (ex. Euclidean distance) between f_i (the i-th row in $M^{F,X}$) and f_j (the j-th row in $M^{F,X}$), and σ is used to control the weight W_{ij}.

3. Construct $|F_L| \times |S|$ feature-class matrix $Y^{F_L,S}$, where the entry $Y^{F_L,S}_{i,j}$ is the number of times of feature f_i ($f_i \in F_L$) co-occurring with sense s_j.

4. Obtain hard label matrix for features in F_L (denoted as $Y^{F_L,S}_{hard}$) based on $Y^{F_L,S}$, where entry $Y^{F,S}_{hard\ i,j} = 1$ if the hard label of f_i is s_j, otherwise zero. Obtain hard labels for features in $F_{\overline{L}}$ using a classifier based on W and $Y^{F_L,S}_{hard}$. In this paper we use label propagation (LP) algorithm (Zhu and Ghahramani, 2002) to get hard labels for $F_{\overline{L}}$.

5. Construct $|F| \times |S|$ feature-class matrix $Y^{F,S}_{hard}$, where entry $Y^{F,S}_{hard\ i,j} = 1$ if the hard label of f_i is s_j, otherwise zero.

6. Construct the matrix $L = D^{-1/2} W D^{-1/2}$ in which D is a diagonal matrix with its (i, i)-element equal to the sum of the i-th row of W.

7. Label each feature in F as soft label $\widehat{Y}^{F,S}_i$, the i-th row of $\widehat{Y}^{F,S}$, where $\widehat{Y}^{F,S} = (I - \alpha L)^{-1} Y^{F,S}_{hard}$.

8. Obtain the feature clustering solution $\widetilde{F}$ by clustering the rows of $\widehat{Y}^{F,S}_i$ into $N_{\widetilde{F}}$ groups. In this paper we use sequential information bottleneck (sIB) algorithm (Slonim and Tishby, 2000) to perform clustering analysis.

End

Step $3 \sim 5$ are the process to obtain hard labels for features in F, while the operation in step 6 and 7 is a local and global consistency based semi-supervised learning (LGC) algorithm (Zhou et al., 2003) that smooth the classification result of LP algorithm to acquire a soft label for each feature.

At first sight, this semi-supervised feature clustering algorithm seems to make little sense. Since we run feature clustering in step 8, why not use LP algorithm to obtain soft label matrix $Y^{F_{\overline{L}},S}$ for features in $F_{\overline{L}}$ by the use of $Y^{F_L,S}$ and W, then just apply sIB directly to soft label matrix $\widehat{Y}^{F,S}$ (constructed by catenating $Y^{F_L,S}$ and $Y^{F_{\overline{L}},S}$)?

The reason for using LGC algorithm to acquire soft labels for features in F is that in the context of transductive learning, the size of labeled data is rather small, which is much less than that of unlabeled data. This makes it difficult to obtain reliable estimation of class label's distribution over features from only labeled data. This motivates us to use raw information (hard labels of features in F_L) from labeled data to estimate hard labels of features in $F_{\overline{L}}$. Then LGC algorithm is used to smooth the classification result of LP algorithm based on the assumption that a good classification should change slowly on the coherent structure aggregated by a large amount of unlabeled data. This operation makes our algorithm more robust to the noise in feature-class matrix $Y^{F_L,S}$ that is estimated from labeled data.

In this paper, σ is set as the average distance between labeled examples from different classes, and $N_{\widetilde{F}} = |F|/10$. Latent semantic indexing technique (LSI) is used to perform factor analysis in $M^{F,X}$ before calculating the distance between features in step 2.

4 Experiments and Results

4.1 Experiment Design

For empirical study of dimensionality reduction techniques on WSD task, we evaluated five dimensionality reduction algorithms on the data in English lexical sample (ELS) task of SENSEVAL-3 (Mihalcea et al., 2004)(including all the 57 English words) [1]: supervised feature clustering (SuFC) (Baker and McCallum, 1998; Bekkerman et al., 2003; Slonim

[1]Available at http://www.senseval.org/senseval3

and Tishby, 2001), iterative double clustering (IDC) (El-Yaniv and Souroujon, 2001), semi-supervised feature clustering (SemiFC) (our algorithm), supervised feature selection (SuFS) (Forman, 2003), and latent semantic indexing (LSI) (Deerwester et. al., 1990) [2].

We used sIB algorithm [3] to cluster features in F_L into groups based on the distribution of class labels associated with each feature. This procedure can be considered as our re-implementation of supervised feature clustering. After feature clustering, examples can be represented as vectors over feature clusters.

IDC is an extension of double clustering method (DC) (Slonim and Tishby, 2000), which performs iterations of DC. In the transductive version of IDC, they cluster features in F as distributions over class labels (given by the labeled data) during the first stage of the IDC first iteration. This phase results in feature clusters $\widetilde{F}$. Then they continue as usual; that is, in the second phase of the first IDC iteration they group X into $N_{\widetilde{X}}$ clusters, where X is represented as distribution over $\widetilde{F}$. Subsequent IDC iterations use all the unlabeled data. This IDC algorithm can result in two clustering solutions: $\widetilde{F}$ and $\widetilde{X}$. Following (El-Yaniv and Souroujon, 2001), the number of iterations is set as 15, and $N_{\widetilde{X}} = |S|$ (the number of senses of target word) in our re-implementation of IDC. After performing IDC, examples can be represented as vectors over feature clusters $\widetilde{F}$.

Supervised feature selection has been extensively studied for text categorization task (Forman, 2003). Information gain (IG) is one of state of the art criteria for feature selection, which measures the decrease in entropy when the feature is given vs. absent. In this paper, we calculate IG score for each feature in F_L, then select top $|F|/10$ features with highest scores to form reduced feature set. Then examples can be represented as vectors over the reduced feature set.

LSI is an unsupervised factor analysis technique based on Singular Value Decomposition of a $|X| \times |F|$ example-feature matrix. The underlying technique for LSI is to find an orthogonal basis for the feature-example space for which the axes lie along the dimensions of maximum variance. After using LSI on the example-feature matrix, we can get vector representation for each example in X in reduced feature space.

For each ambiguous word in ELS task of SENSEVAL-3, we used three types of features to capture contextual information: part-of-speech of neighboring words with position information, unordered single words in topical context, and local collocations (as same as the feature set used in (Lee and Ng, 2002) except that we did not use syntactic relations). We removed the features with occurrence frequency (counted in both training set and test set) less than 3 times.

We ran these five algorithms for each ambiguous word to reduce the dimensionality of feature space from $|F|$ to $|F|/10$ no matter which training data is used (ex. full SENSEVAL-3 training data or sampled SENSEVAL-3 training data). Then we can obtain new vector representation of X in new feature space acquired by SuFC, IDC, SemiFC, and LSI or reduced feature set by SuFS.

Then we used SVM [4] and LP algorithm to perform sense disambiguation on vectors in dimensionality reduced feature space. SVM and LP were evaluated using accuracy [5] (fine-grained score) on test set of SENSEVAL-3. For LP algorithm, the test set in SENSEVAL-3 data was also used as unlabeled data in tranductive learning process.

We investigated two distance measures for LP: cosine similarity and Jensen-Shannon (JS) divergence (Lin, 1991). Cosine similarity measures the angle between two feature vectors, while JS divergence measures the distance between two probability distributions if each feature vector is considered as probability distribution over features.

For sense disambiguation on SENSEVAL-3 data, we constructed connected graphs for LP algorithm following (Niu et al., 2005): two instances u, v will be connected by an edge if u is among v's k nearest neighbors, or if v is among u's k nearest neighbors

[2]Following (Baker and McCallum, 1998), we use LSI as a representative method for unsupervised dimensionality reduction.

[3]Available at http://www.cs.huji.ac.il/∼noamm/

[4]We used SVM^{light} with linear kernel function, available at http://svmlight.joachims.org/.

[5]If there are multiple sense tags for an instance in training set or test set, then only the first tag is considered as correct answer. Furthermore, if the answer of the instance in test set is "U", then this instance will be removed from test set.

as measured by cosine or JS distance measure. k is 5 in later experiments.

4.2 Experiments on Full SENSEVAL-3 Data

In this experiment, we took the training set in SENSEVAL-3 as labeled data, and the test set as unlabeled data. In other words, all of dimensionality reduction methods and classifiers can use the label information in training set, but can not access the label information in test set. We evaluated different sense disambiguation processes using test set in SENSEVAL-3.

We use features with occurrence frequency no less than 3 in training set and test set as feature set F for each ambiguous word. F consists of two disjoint subsets: F_L and $F_{\overline{L}}$. F_L consists of features occurring in training set of target word in SENSEVAL-3, while $F_{\overline{L}}$ consists of features that occur in test set, but never appear in training set.

Table 1 lists accuracies of SVM and LP without or with dimensionality reduction on full SENSEVAL-3 data. From this table, we have some findings as follows:

(1) If without dimensionality reduction, the best performance of sense disambiguation is 70.3% (LP_{JS}), while if using dimensionality reduction, the best two systems can achieve 69.8% ($SuFS + LP_{JS}$) and 69.0% ($SemiFC + LP_{JS}$) accuracies. It seems that feature selection and feature clustering can significantly reduce the dimensionality of feature space while losing only about 1.0% accuracy.

(2) Furthermore, LP_{JS} algorithm performs better than SVM when combined with the same dimensionality reduction technique (except IDC). Notice that LP algorithm uses unlabelled data during its disambiguation phase while SVM doesn't. This indicates that using unlabeled data helps to improve the performance of sense disambiguation.

(3) When using LP algorithm for sense disambiguation, SemiFC performs better than other feature clustering algorithms, such as SuFC, IDC. This indicates that clustering seen and unseen features can satisfy the requirement of semi-supervised learning algorithm, which does help the classification process.

(4) When using SuFC, IDC, SuFS, or SemiFC for dimensionality reduction, the performance of sense disambiguation is always better than that using LSI as dimensionality reduction method. SuFC, IDC, SuFS, and SemiFC use label information to guide feature clustering or feature selection, while LSI is an unsupervised factor analysis method that can conduct dimensionality reduction without the use of label information from labeled data. This indicates that using label information in dimensionality reduction procedure can cluster features into better groups or select better feature subsets, which results in better representation of contexts in reduced feature space.

4.3 Additional Experiments on Sampled SENSEVAL-3 Data

For investigating the performance of various dimensionality reduction techniques with very small training data, we ran them with only l_w examples from training set of each word in SENSEVAL-3 as labeled data. The remaining training examples and all the test examples were used as unlabeled data for SemiFC or LP algorithm. Finally we evaluated different sense disambiguation processes using test set in SENSEVAL-3. For each labeled set size l_w, we performed 20 trials. In each trial, we randomly sampled l_w labeled examples for each word from training set. If any sense was absent from the sampled labeled set, we redid the sampling. l_w is set as $N_{w,train} \times 10\%$, where $N_{w,train}$ is the number of examples in training set of word w. Other settings of this experiment is as same as that of previous one in section 4.2.

In this experiment, feature set F is as same as that in section 4.2. F_L consists of features occurring in sampled training set of target word in SENSEVAL-3, while $F_{\overline{L}}$ consists of features that occur in unlabeled data (including unselected training data and all the test set), but never appear in labeled data (sampled training set).

Table 2 lists accuracies of SVM and LP without or with dimensionality reduction on sampled SENSEVAL-3 training data [6]. From this table, we have some findings as follows:

(1) If without dimensionality reduction, the best performance of sense disambiguation is 54.9% (LP_{JS}), while if using dimensionality reduction, the

[6]We can not obtain the results of IDC over 20 trials since it costs about 50 hours for each trial (Pentium 1.4 GHz CPU/1.0 GB memory).

Table 1: This table lists the accuracies of SVM and LP without or with dimensionality reduction on full SENSEVAL-3 data. There is no result for $LSI + LP_{JS}$, since the vectors obtained by LSI may contain negative values, which prohibits the application of JS divergence for measuring the distance between these vectors.

Classifier	Without dimensionality reduction	With various dimensionality reduction techniques SuFC	IDC	SuFS	LSI	SemiFC
SVM	69.7%	66.4%	65.1%	65.2%	59.1%	64.0%
LP_{cosine}	68.4%	66.7%	64.9%	66.0%	60.7%	67.6%
LP_{JS}	70.3%	67.2%	64.0%	69.8%	-	69.0%

Table 2: This table lists the accuracies of SVM and LP without or with dimensionality reduction on sampled SENSEVAL-3 training data. For each classifier, we performed paired t-test between the system using SemiFC for dimensionality reduction and any other system with or without dimensionality reduction. $\gg$ (or $\ll$) means p-value ≤ 0.01, while $>$ (or $<$) means p-value falling into $(0.01, 0.05]$. Both $\gg$ (or $\ll$) and $>$ (or $<$) indicate that the performance of current WSD system is significantly better (or worse) than that using SemiFC for dimensionality reduction, when given same classifier.

Classifier	Without dimensionality reduction	With various dimensionality reduction techniques SuFC	SuFS	LSI	SemiFC
SVM	53.4±1.1% ($\gg$)	50.4±1.1% ($\ll$)	52.2±1.2% ($>$)	49.8±0.8% ($\ll$)	51.5±1.0%
LP_{cosine}	54.4±1.2% ($\gg$)	49.5±1.1% ($\ll$)	51.1±1.0% ($\ll$)	49.8±1.0% ($\ll$)	52.9±1.0%
LP_{JS}	54.9±1.1% ($\gg$)	52.0±0.9% ($\ll$)	52.5±1.0% ($\ll$)	-	54.1±1.2%

best performance of sense disambiguation is 54.1% ($SemiFC + LP_{JS}$). Feature clustering can significantly reduce the dimensionality of feature space while losing only 0.8% accuracy.

(2) LP_{JS} algorithm performs better than SVM when combined with most of dimensionality reduction techniques. This result confirmed our previous conclusion that using unlabeled data can improve the sense disambiguation process. Furthermore, SemiFC performs significantly better than SuFC and SuFS when using LP as the classifier for sense disambiguation. The reason is that when given very few labeled examples, the distribution of class labels over features can not be reliably estimated, which deteriorates the performance of SuFC or SuFS. But SemiFC uses only raw label information (hard label of each feature) estimated from labeled data, which makes it robust to the noise in very small labeled data.

(3) SuFC, SuFS and SemiFC perform better than LSI no matter which classifier is used for sense disambiguation. This observation confirmed our previous conclusion that using label information to guide dimensionality reduction process can result in better representation of contexts in feature subspace, which further improves the results of sense disambiguation.

5 Related Work

Feature clustering has been extensively studied for the benefit of text categorization and document clustering, which can be categorized as supervised feature clustering, semi-supervised feature clustering, and unsupervised feature clustering.

Supervised feature clustering algorithms (Baker and McCallum, 1998; Bekkerman et al., 2003; Slonim and Tishby, 2001) usually cluster words into groups based on the distribution of class labels over features. Baker and McCallum (1998) apply supervised feature clustering based on distributional clustering for text categorization, which can compress the feature space much more aggressively while still maintaining state of the art classification accuracy. Slonim and Tishby (2001) and Bekkerman et. al. (2003) apply information bottleneck method to find word clusters. They present similar results with the work by Baker and McCallum (1998). Slonim and Tishby (2001) goes further to show that when the training sample is small, word clusters can yield significant improvement in classification accuracy.

Unsupervised feature clustering algorithms (Dhillon, 2001; Dhillon et al., 2002; Dhillon et al., 2003; El-Yaniv and Souroujon, 2001; Slonim and Tishby, 2000) perform word clustering by the use of word-document co-occurrence matrix, which do not utilize class labels to guide clustering process. Slonim and Tishby (2000), El-Yaniv and Souroujon (2001) and Dhillon et. al. (2003) show that word clusters can improve the performance of document clustering.

El-Yaniv and Souroujon (2001) present an iterative double clustering (IDC) algorithm, which performs iterations of double clustering (Slonim and Tishby, 2000). Furthermore, they extend IDC algorithm for semi-supervised learning when given both labeled and unlabeled data.

Our algorithm belongs to the family of semi-supervised feature clustering techniques, which can utilize both labeled and unlabeled data to perform feature clustering.

Supervised feature clustering can not group unseen features (features that do not occur in labeled data) into meaningful clusters since there are no class labels associated with these unseen features. Our algorithm can overcome this problem by inducing class labels for unseen features based on the similarity among seen features and unseen features, then clustering all the features (including both seen features and unseen features) based on the distribution of class labels over them.

Compared with the semi-supervised version of IDC algorithm, our algorithm is more efficient, since we perform feature clustering without iterations.

The difference between our algorithm and unsupervised feature clustering is that our algorithm depends on both labeled and unlabeled data, but unsupervised feature clustering requires only unlabeled data.

O'Hara et. al. (2004) use semantic class-based collocations to augment traditional word-based collocations for supervised WSD. Three separate sources of word relatedness are used for these collocations: 1) WordNet hypernym relations; 2) cluster-based word similarity classes; and 3) dictionary definition analysis. Their system achieved 56.6% fine-grained score on ELS task of SENSEVAL-3. In contrast with their work, our data-driven method for feature clustering based WSD does not require external knowledge resource. Furthermore, our $SemiFC+LP_{JS}$ method can achieve 69.0% fine-grained score on the same dataset, which shows the effectiveness of our method.

6 Conclusion

In this paper we have investigated feature clustering techniques for WSD, which usually group features into clusters based on the distribution of class labels over features. We propose a semi-supervised feature clustering algorithm to satisfy the requirement of semi-supervised classification algorithms for dimensionality reduction in feature space. Our experimental results on SENSEVAL-3 data show that feature clustering can aggressively reduce the dimensionality of feature space while still maintaining state of the art sense disambiguation accuracy. Furthermore, when combined with a semi-supervised WSD algorithm, semi-supervised feature clustering outperforms supervised feature clustering and other dimensionality reduction techniques. Our additional experiments on sampled SENSEVAL-3 data indicate that our semi-supervised feature clustering method is robust to the noise in small labeled data, which achieves better performance than supervised feature clustering.

In the future, we may extend our work by using more datasets to empirically evaluate this feature clustering algorithm. This semi-supervised feature clustering framework is quite general, which can be applied to other NLP tasks, ex. text categorization.

Using Random Walks for Question-focused Sentence Retrieval

Jahna Otterbacher[1], **Güneş Erkan**[2], **Dragomir R. Radev**[1,2]

Abstract

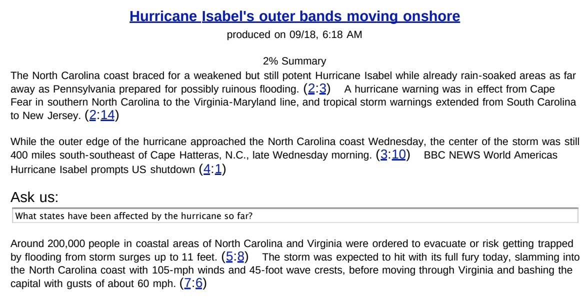
We consider the problem of question-focused sentence retrieval from complex news articles describing multi-event stories published over time. Annotators generated a list of questions central to understanding each story in our corpus. Because of the dynamic nature of the stories, many questions are time-sensitive (e.g. "How many victims have been found?") Judges found sentences providing an answer to each question. To address the sentence retrieval problem, we apply a stochastic, graph-based method for comparing the relative importance of the textual units, which was previously used successfully for generic summarization. Currently, we present a topic-sensitive version of our method and hypothesize that it can outperform a competitive baseline, which compares the similarity of each sentence to the input question via IDF-weighted word overlap. In our experiments, the method achieves a TRDR score that is significantly higher than that of the baseline.

1 Introduction

Recent work has motivated the need for systems that support "Information Synthesis" tasks, in which a user seeks a global understanding of a topic or story (Amigo et al., 2004). In contrast to the classical question answering setting (e.g. TREC-style Q&A (Voorhees and Tice, 2000)), in which the user presents a single question and the system returns a corresponding answer (or a set of likely answers), in this case the user has a more complex information need.

Similarly, when reading about a complex news story, such as an emergency situation, users might seek answers to a set of questions in order to understand it better. For example, Figure 1 shows the interface to our Web-based news summarization system, which a user has queried for information about Hurricane Isabel. Understanding such stories is challenging for a number of reasons. In particular, complex stories contain many sub-events (e.g. the devastation of the hurricane, the relief effort, etc.) In addition, while some facts surrounding the situation do not change (such as "Which area did the hurricane first hit?"), others may change with time ("How many people have been left homeless?"). Therefore, we are working towards developing a system for question answering from clusters of complex stories published over time. As can be seen at the bottom of Figure 1, we plan to add a component to our current system that allows users to ask questions as they read a story. They may then choose to receive either a precise answer or a question-focused summary.

Currently, we address the question-focused sentence retrieval task. While passage retrieval (PR) is clearly not a new problem (e.g. (Robertson et al., 1992; Salton et al., 1993)), it remains important and yet often overlooked. As noted by (Gaizauskas et al., 2004), while PR is the crucial first step for question answering, Q&A research has typically not empha-



Hurricane Isabel's outer bands moving onshore

produced on 09/18, 6:18 AM

2% Summary

The North Carolina coast braced for a weakened but still potent Hurricane Isabel while already rain-soaked areas as far away as Pennsylvania prepared for possibly ruinous flooding. (2:3) A hurricane warning was in effect from Cape Fear in southern North Carolina to the Virginia-Maryland line, and tropical storm warnings extended from South Carolina to New Jersey. (2:14)

While the outer edge of the hurricane approached the North Carolina coast Wednesday, the center of the storm was still 400 miles south-southeast of Cape Hatteras, N.C., late Wednesday morning. (3:10) BBC NEWS World Americas Hurricane Isabel prompts US shutdown (4:1)

Ask us:

What states have been affected by the hurricane so far?

Around 200,000 people in coastal areas of North Carolina and Virginia were ordered to evacuate or risk getting trapped by flooding from storm surges up to 11 feet. (5:8) The storm was expected to hit with its full fury today, slamming into the North Carolina coast with 105-mph winds and 45-foot wave crests, before moving through Virginia and bashing the capital with gusts of about 60 mph. (7:6)

Figure 1: Question tracking interface to a summarization system.

sized it. The specific problem we consider differs from the classic task of PR for a Q&A system in interesting ways, due to the time-sensitive nature of the stories in our corpus. For example, one challenge is that the answer to a user's question may be updated and reworded over time by journalists in order to keep a running story fresh, or because the facts themselves change. Therefore, there is often more than one correct answer to a question.

We aim to develop a method for sentence retrieval that goes beyond finding sentences that are similar to a single query. To this end, we propose to use a stochastic, graph-based method. Recently, graph-based methods have proved useful for a number of NLP and IR tasks such as document re-ranking in ad hoc IR (Kurland and Lee, 2005) and analyzing sentiments in text (Pang and Lee, 2004). In (Erkan and Radev, 2004), we introduced the LexRank method and successfully applied it to generic, multi-document summarization. Presently, we introduce topic-sensitive LexRank in creating a sentence retrieval system. We evaluate its performance against a competitive baseline, which considers the similarity between each sentence and the question (using IDF-weighed word overlap). We demonstrate that LexRank significantly improves question-focused sentence selection over the baseline.

2 Formal description of the problem

Our goal is to build a question-focused sentence retrieval mechanism using a topic-sensitive version of the LexRank method. In contrast to previous PR systems such as Okapi (Robertson et al., 1992), which ranks documents for relevancy and then proceeds to find paragraphs related to a question, we address the finer-grained problem of finding sentences containing answers. In addition, the input to our system is a set of documents relevant to the topic of the query that the user has already identified (e.g. via a search engine). Our system does not rank the input documents, nor is it restricted in terms of the number of sentences that may be selected from the same document.

The output of our system, a ranked list of sentences relevant to the user's question, can be subsequently used as input to an answer selection system in order to find specific answers from the extracted sentences. Alternatively, the sentences can be returned to the user as a question-focused summary. This is similar to "snippet retrieval" (Wu et al., 2004). However, in our system answers are extracted from a set of multiple documents rather than on a document-by-document basis.

3 Our approach: topic-sensitive LexRank

3.1 The LexRank method

In (Erkan and Radev, 2004), the concept of graph-based centrality was used to rank a set of sentences, in producing generic multi-document summaries. To apply LexRank, a similarity graph is produced for the sentences in an input document set. In the graph, each node represents a sentence. There are edges between nodes for which the cosine similarity between the respective pair of sentences exceeds a given threshold. The degree of a given node is an indication of how much information the respective sentence has in common with other sentences. Therefore, sentences that contain the most salient information in the document set should be very central within the graph.

Figure 2 shows an example of a similarity graph for a set of five input sentences, using a cosine similarity threshold of 0.15. Once the similarity graph is constructed, the sentences are then ranked according to their eigenvector centrality. As previously mentioned, the original LexRank method performed well in the context of generic summarization. Below, we describe a topic-sensitive version of LexRank, which is more appropriate for the question-focused sentence retrieval problem. In the new approach, the score of a sentence is determined by a mixture model of the relevance of the sentence to the query and the similarity of the sentence to other high-scoring sentences.

3.2 Relevance to the question

In topic-sensitive LexRank, we first stem all of the sentences in a set of articles and compute word IDFs by the following formula:

$$\text{idf}_w = \log\left(\frac{N+1}{0.5 + sf_w}\right) \tag{1}$$

where N is the total number of sentences in the cluster, and sf_w is the number of sentences that the word w appears in.

We also stem the question and remove the stop words from it. Then the relevance of a sentence s to the question q is computed by:

$$\text{rel}(s|q) = \sum_{w \in q} \log(tf_{w,s} + 1) \times \log(tf_{w,q} + 1) \times \text{idf}_w \tag{2}$$

where $tf_{w,s}$ and $tf_{w,q}$ are the number of times w appears in s and q, respectively. This model has proven to be successful in query-based sentence retrieval (Allan et al., 2003), and is used as our competitive baseline in this study (e.g. Tables 4, 5 and 7).

3.3 The mixture model

The baseline system explained above does not make use of any inter-sentence information in a cluster. We hypothesize that a sentence that is similar to the high scoring sentences in the cluster should also have a high score. For instance, if a sentence that gets a high score in our baseline model is likely to contain an answer to the question, then a related sentence, which may not be similar to the question itself, is also likely to contain an answer.

This idea is captured by the following mixture model, where $p(s|q)$, the score of a sentence s given a question q, is determined as the sum of its relevance to the question (using the same measure as the baseline described above) and the similarity to the other sentences in the document cluster:

$$p(s|q) = d\frac{\text{rel}(s|q)}{\sum_{z \in C}\text{rel}(z|q)} + (1-d)\sum_{v \in C}\frac{\text{sim}(s,v)}{\sum_{z \in C} sim(z,v)}p(v|q) \tag{3}$$

where C is the set of all sentences in the cluster. The value of d, which we will also refer to as the "question bias," is a trade-off between two terms in the

Figure 2: LexRank example: sentence similarity graph with a cosine threshold of 0.15.

equation and is determined empirically. For higher values of d, we give more importance to the relevance to the question compared to the similarity to the other sentences in the cluster. The denominators in both terms are for normalization, which are described below. We use the cosine measure weighted by word IDFs as the similarity between two sentences in a cluster:

$$\text{sim}(x,y) = \frac{\sum_{w \in x,y} \text{tf}_{w,x}\text{tf}_{w,y}(\text{idf}_w)^2}{\sqrt{\sum_{x_i \in x}(\text{tf}_{x_i,x}\text{idf}_{x_i})^2} \times \sqrt{\sum_{y_i \in y}(\text{tf}_{y_i,y}\text{idf}_{y_i})^2}} \tag{4}$$

Equation 3 can be written in matrix notation as follows:

$$\mathbf{p} = [d\mathbf{A} + (1-d)\mathbf{B}]^{\text{T}}\mathbf{p} \tag{5}$$

$\mathbf{A}$ is the square matrix such that for a given index i, all the elements in the i^{th} column are proportional to $\text{rel}(i|q)$. $\mathbf{B}$ is also a square matrix such that each entry $\mathbf{B}(i,j)$ is proportional to $sim(i,j)$. Both matrices are normalized so that row sums add up to 1. Note that as a result of this normalization, all rows of the resulting square matrix $\mathbf{Q} = [d\mathbf{A} + (1-d)\mathbf{B}]$ also add up to 1. Such a matrix is called *stochastic* and defines a Markov chain. If we view each sentence as a state in a Markov chain, then $\mathbf{Q}(i,j)$ specifies the transition probability from state i to state j in the corresponding Markov chain. The vector $\mathbf{p}$ we are looking for in Equation 5 is the stationary distribution of the Markov chain. An intuitive interpretation of the stationary distribution can be understood by the concept of a random walk on the graph representation of the Markov chain.

With probability d, a transition is made from the current node (sentence) to the nodes that are similar to the query. With probability (1-d), a transition is made to the nodes that are lexically similar to the current node. Every transition is weighted according to the similarity distributions. Each element of the vector $\mathbf{p}$ gives the asymptotic probability of ending up at the corresponding state in the long run regardless of the starting state. The stationary distribution of a Markov chain can be computed by a simple iterative algorithm, called power method.[1]

A simpler version of Equation 5, where $\mathbf{A}$ is a uniform matrix and $\mathbf{B}$ is a normalized binary matrix, is known as PageRank (Brin and Page, 1998; Page et al., 1998) and used to rank the web pages by the Google search engine. It was also the model used to rank sentences in (Erkan and Radev, 2004).

3.4 Experiments with topic-sensitive LexRank

We experimented with different values of d on our training data. We also considered several threshold values for inter-sentence cosine similarities, where we ignored the similarities between the sentences that are below the threshold. In the training phase of the experiment, we evaluated all combinations of LexRank with d in the range of $[0, 1]$ (in increments of 0.10) and with a similarity threshold ranging from $[0, 0.9]$ (in increments of 0.05). We then found all configurations that outperformed the baseline. These configurations were then applied to our development/test set. Finally, our best sentence retrieval system was applied to our test data set and evaluated against the baseline. The remainder of the paper will explain this process and the results in detail.

4 Experimental setup

4.1 Corpus

We built a corpus of 20 multi-document clusters of complex news stories, such as plane crashes, political controversies and natural disasters. The data clusters and their characteristics are shown in Table 1. The news articles were collected from various sources. "Newstracker" clusters were collected automatically by our Web-based news summarization system. The number of clusters randomly assigned to the training, development/test and test data sets were 11, 3 and 6, respectively.

Next, we assigned each cluster of articles to an annotator, who was asked to read all articles in the cluster. He or she then generated a list of factual questions key to understanding the story. Once we collected the questions for each cluster, two judges independently annotated nine of the training clusters. For each sentence and question pair in a given cluster, the judges were asked to indicate whether or not the sentence contained a complete answer to the question. Once an acceptable rate of interjudge agreement was verified on the first nine clusters (Kappa (Carletta, 1996) of 0.68), the remaining 11 clusters were annotated by one judge each.

In some cases, the judges did not find any sentences containing the answer for a given question. Such questions were removed from the corpus. The final number of questions annotated for answers over the entire corpus was 341, and the distributions of questions per cluster can be found in Table 1.

4.2 Evaluation metrics and methods

To evaluate our sentence retrieval mechanism, we produced extract files, which contain a list of sentences deemed to be relevant to the question, for the system and from human judgment. To compare different configurations of our system to the baseline system, we produced extracts at a fixed length of 20 sentences. While evaluations of question answering systems are often based on a shorter list of ranked sentences, we chose to generate longer lists for several reasons. One is that we are developing a PR system, of which the output can then be input to an answer extraction system for further processing. In such a setting, we would most likely want to generate a relatively longer list of candidate sentences. As previously mentioned, in our corpus the questions often have more than one relevant answer, so ideally, our PR system would find many of the relevant sentences, sending them on to the answer component to decide which answer(s) should be returned to the user. Each system's extract file lists the document

[1]The stationary distribution is unique and the power method is guaranteed to converge provided that the Markov chain is ergodic (Seneta, 1981). A non-ergodic Markov chain can be made ergodic by reserving a small probability for jumping to any other state from the current state (Page et al., 1998).

Cluster	Sources	Articles	Questions	Data set	Sample question
Algerian terror threat	AFP, UPI	2	12	train	What is the condition under which GIA will take its action?
Milan plane crash	MSNBC, CNN, ABC, Fox, USAToday	9	15	train	How many people were in the building at the time of the crash?
Turkish plane crash	BBC, ABC, FoxNews, Yahoo	10	12	train	To where was the plane headed?
Moscow terror attack	UPI, AFP, AP	7	7	train	How many people were killed in the most recent explosion?
Rhode Island club fire	MSNBC, CNN, ABC, Lycos, Fox, BBC, Ananova	10	8	train	Who was to blame for the fire?
FBI most wanted	AFP, UPI	3	14	train	How much is the State Department offering for information leading to bin Laden's arrest?
Russia bombing	AP, AFP	2	11	train	What was the cause of the blast?
Bali terror attack	CNN, FoxNews, ABC, BBC, Ananova	10	30	train	What were the motivations of the attackers?
Washington DC sniper	FoxNews, Ha'aretz, BBC, BBC, Washington Times, CBS	8	28	train	What kinds of equipment or weapons were used in the killings?
GSPC terror group	Newstracker	8	29	train	What are the charges against the GSPC suspects?
China earthquake	Novelty 43	25	18	train	What was the magnitude of the earthquake in Zhangjiakou?
Gulfair	ABC, BBC, CNN, USAToday, FoxNews, Washington Post	11	29	dev/test	How many people were on board?
David Beckham trade	AFP	20	28	dev/test	How long had Beckham been playing for MU before he moved to RM?
Miami airport evacuation	Newstracker	12	15	dev/test	How many concourses does the airport have?
US hurricane	DUC d04a	14	14	test	In which places had the hurricane landed?
EgyptAir crash	Novelty 4	25	29	test	How many people were killed?
Kursk submarine	Novelty 33	25	30	test	When did the Kursk sink?
Hebrew University bombing	Newstracker	11	27	test	How many people were injured?
Finland mall bombing	Newstracker	9	15	test	How many people were in the mall at the time of the bombing?
Putin visits England	Newstracker	12	20	test	What issue concerned British human rights groups?

Table 1: Corpus of complex news stories.

and sentence numbers of the top 20 sentences. The "gold standard" extracts list the sentences judged as containing answers to a given question by the annotators (and therefore have variable sizes) in no particular order.[2]

We evaluated the performance of the systems using two metrics - Mean Reciprocal Rank (MRR) (Voorhees and Tice, 2000) and Total Reciprocal Document Rank (TRDR) (Radev et al., 2005). MRR, used in the TREC Q&A evaluations, is the reciprocal rank of the first correct answer (or sentence, in our case) to a given question. This measure gives us an idea of how far down we must look in the ranked list in order to find a correct answer. To contrast, TRDR is the total of the reciprocal ranks of all answers found by the system. In the context of answering questions from complex stories, where there is often more than one correct answer to a question, and where answers are typically time-dependent, we should focus on maximizing TRDR, which gives us a measure of how many of the relevant sentences were identified by the system. However, we report both the average MRR and TRDR over all questions in a given data set.

5 LexRank versus the baseline system

In the training phase, we searched the parameter space for the values of d (the question bias) and the similarity threshold in order to optimize the resulting TRDR scores. For our problem, we expected that a relatively low similarity threshold pair with a high question bias would achieve the best results. Table 2 shows the effect of varying the similarity threshold.[3] The notation $LR[a, d]$ is used, where a is the similarity threshold and d is the question bias. The optimal range for the parameter a was between 0.14 and 0.20. This is intuitive because if the threshold is too high, such that only the most lexically similar sentences are represented in the graph, the method does not find sentences that are related but are more lex-

[2]For clusters annotated by two judges, all sentences chosen by at least one judge were included.

[3]A threshold of -1 means that no threshold was used such that all sentences were included in the graph.

System	Ave. MRR	Ave. TRDR
LR[-1.0,0.65]	0.5270	0.8117
LR[0.02,0.65]	0.5261	0.7950
LR[0.16,0.65]	0.5131	0.8134
LR[0.18,0.65]	0.5062	0.8020
LR[0.20,0.65]	0.5091	0.7944
LR[-1.0,0.80]	0.5288	0.8152
LR[0.02,0.80]	0.5324	0.8043
LR[0.16,0.80]	0.5184	0.8160
LR[0.18,0.80]	0.5199	0.8154
LR[0.20,0.80]	0.5282	0.8152

LR[0.20,0.85]	0.5317	0.8203
LR[0.20,0.90]	0.5368	0.8265

Table 3: Training phase: effect of question bias (d) on Ave. MRR and TRDR.

ically diverse (e.g. paraphrases). Table 3 shows the effect of varying the question bias at two different similarity thresholds (0.02 and 0.20). It is clear that a high question bias is needed. However, a small probability for jumping to a node that is lexically similar to the given sentence (rather than the question itself) is needed. Table 4 shows the configurations of LexRank that performed better than the baseline system on the training data, based on mean TRDR scores over the 184 training questions. We applied all four of these configurations to our unseen development/test data, in order to see if we could further differentiate their performances.

5.1 Development/testing phase

The scores for the four LexRank systems and the baseline on the development/test data are shown in

System	Ave. MRR	Ave. TRDR
Baseline	0.5518	0.8297
LR[0.14,0.95]	0.5267	0.8305
LR[0.18,0.90]	0.5376	0.8382
LR[0.18,0.95]	0.5421	0.8382
LR[0.20,0.95]	0.5404	0.8311

Table 4: Training phase: systems outperforming the baseline in terms of TRDR score.

System	Ave. MRR	Ave. TRDR
Baseline	0.5709	1.0002
LR[0.14,0.95]	0.5882	1.0469
LR[0.18,0.90]	0.5820	1.0288
LR[0.18,0.95]	0.5956	1.0411
LR[0.20,0.95]	0.6068	1.0601

Table 5: Development testing evaluation.

Cluster	B-MRR	LR-MRR	B-TRDR	LR-TRDR
Gulfair	0.5446	0.5461	0.9116	0.9797
David Beckham trade	0.5074	0.5919	0.7088	0.7991
Miami airport evacuation	0.7401	0.7517	1.7157	1.7028

Table 6: Average scores by cluster: baseline versus LR[0.20,0.95].

Table 5. This time, all four LexRank systems outperformed the baseline, both in terms of average MRR and TRDR scores. An analysis of the average scores over the 72 questions within each of the three clusters for the best system, LR[0.20,0.95], is shown in Table 6. While LexRank outperforms the baseline system on the first two clusters both in terms of MRR and TRDR, their performances are not substantially different on the third cluster. Therefore, we examined properties of the questions within each cluster in order to see what effect they might have on system performance.

We hypothesized that the baseline system, which compares the similarity of each sentence to the question using IDF-weighted word overlap, should perform well on questions that provide many content words. To contrast, LexRank might perform better when the question provides fewer content words, since it considers both similarity to the query and inter-sentence similarity. Out of the 72 questions in the development/test set, the baseline system outperformed LexRank on 22 of the questions. In fact, the average number of content words among these 22 questions was slightly, but not significantly, higher than the average on the remaining questions (3.63 words per question versus 3.46). Given this observation, we experimented with two mixed strategies, in which the number of content words in a question determined whether LexRank or the baseline system was used for sentence retrieval. We tried threshold values of 4 and 6 content words, however, this did not improve the performance over the pure strategy of system LR[0.20,0.95]. Therefore, we applied this

	Ave. MRR	**Ave. TRDR**
Baseline	0.5780	0.8673
LR[0.20,0.95]	0.6189	0.9906
p-value	na	0.0619

Table 7: Testing phase: baseline vs. LR[0.20,0.95].

system versus the baseline to our unseen test set of 134 questions.

5.2 Testing phase

As shown in Table 7, LR[0.20,0.95] outperformed the baseline system on the test data both in terms of average MRR and TRDR scores. The improvement in average TRDR score was statistically significant with a p-value of 0.0619. Since we are interested in a passage retrieval mechanism that finds sentences relevant to a given question, providing input to the question answering component of our system, the improvement in average TRDR score is very promising. While we saw in Section 5.1 that LR[0.20,0.95] may perform better on some question or cluster types than others, we conclude that it beats the competitive baseline when one is looking to optimize mean TRDR scores over a large set of questions. However, in future work, we will continue to improve the performance, perhaps by developing mixed strategies using different configurations of LexRank.

6 Discussion

The idea behind using LexRank for sentence retrieval is that a system that considers only the similarity between candidate sentences and the input query, and not the similarity between the candidate sentences themselves, is likely to miss some important sentences. When using any metric to compare sentences and a query, there is always likely to be a tie between multiple sentences (or, similarly, there may be cases where fewer than the number of desired sentences have similarity scores above zero). LexRank effectively provides a means to break such ties. An example of such a scenario is illustrated in Tables 8 and 9, which show the top ranked sentences by the baseline and LexRank, respectively for the question “What caused the Kursk to sink?” from the Kursk submarine cluster. It can be seen that all top five sentences chosen by the baseline system have

Rank	**Sentence**	**Score**	**Relevant?**
1	The Russian governmental commission on the accident of the submarine Kursk sinking in the Barents Sea on August 12 has rejected 11 original explanations for the disaster, but still cannot conclude what caused the tragedy indeed, Russian Deputy Premier Ilya Klebanov said here Friday.	4.2282	N
2	There has been no final word on what caused the submarine to sink while participating in a major naval exercise, but Defense Minister Igor Sergeyev said the theory that Kursk may have collided with another object is receiving increasingly concrete confirmation.	4.2282	N
3	Russian Deputy Prime Minister Ilya Klebanov said Thursday that collision with a big object caused the Kursk nuclear submarine to sink to the bottom of the Barents Sea.	4.2282	Y
4	Russian Deputy Prime Minister Ilya Klebanov said Thursday that collision with a big object caused the Kursk nuclear submarine to sink to the bottom of the Barents Sea.	4.2282	Y
5	President Clinton’s national security adviser, Samuel Berger, has provided his Russian counterpart with a written summary of what U.S. naval and intelligence officials believe caused the nuclear-powered submarine Kursk to sink last month in the Barents Sea, officials said Wednesday.	4.2282	N

Table 8: Top ranked sentences using baseline system on the question “What caused the Kursk to sink?”.

the same sentence score (similarity to the query), yet the top ranking two sentences are not actually relevant according to the judges. To contrast, LexRank achieved a better ranking of the sentences since it is better able to differentiate between them. It should be noted that both for the LexRank and baseline systems, chronological ordering of the documents and sentences is preserved, such that in cases where two sentences have the same score, the one published earlier is ranked higher.

7 Conclusion

We presented topic-sensitive LexRank and applied it to the problem of sentence retrieval. In a Web-based news summarization setting, users of our system could choose to see the retrieved sentences (as in Table 9) as a question-focused summary. As indicated in Table 9, each of the top three sentences were judged by our annotators as providing a complete answer to the respective question. While the first two sentences provide the same answer (a collision caused the Kursk to sink), the third sentence provides a different answer (an explosion caused the disaster). While the last two sentences do not provide answers according to our judges, they do provide context information about the situation. Alternatively, the user might prefer to see the extracted

Rank	Sentence	Score	Relevant?
1	Russian Deputy Prime Minister Ilya Klebanov said Thursday that collision with a big object caused the Kursk nuclear submarine to sink to the bottom of the Barents Sea.	0.0133	Y
2	Russian Deputy Prime Minister Ilya Klebanov said Thursday that collision with a big object caused the Kursk nuclear submarine to sink to the bottom of the Barents Sea.	0.0133	Y
3	The Russian navy refused to confirm this, but officers have said an explosion in the torpedo compartment at the front of the submarine apparently caused the Kursk to sink.	0.0125	Y
4	President Clinton's national security adviser, Samuel Berger, has provided his Russian counterpart with a written summary of what U.S. naval and intelligence officials believe caused the nuclear-powered submarine Kursk to sink last month in the Barents Sea, officials said Wednesday.	0.0124	N
5	There has been no final word on what caused the submarine to sink while participating in a major naval exercise, but Defense Minister Igor Sergeyev said the theory that Kursk may have collided with another object is receiving increasingly concrete confirmation.	0.0123	N

Table 9: Top ranked sentences using the LR[0.20,0.95] system on the question "What caused the Kursk to sink?"

answers from the retrieved sentences. In this case, the sentences selected by our system would be sent to an answer identification component for further processing. As discussed in Section 2, our goal was to develop a topic-sensitive version of LexRank and to use it to improve a baseline system, which had previously been used successfully for query-based sentence retrieval (Allan et al., 2003). In terms of this task, we have shown that over a large set of unaltered questions written by our annotators, LexRank can, on average, outperform the baseline system, particularly in terms of TRDR scores.

8 Acknowledgments

We would like to thank the members of the CLAIR group at Michigan and in particular Siwei Shen and Yang Ye for their assistance with this project.

Abstract

We investigate techniques to support the answering of opinion-based questions. We first present the OpQA corpus of opinion questions and answers. Using the corpus, we compare and contrast the properties of fact and opinion questions and answers. Based on the disparate characteristics of opinion vs. fact answers, we argue that traditional fact-based QA approaches may have difficulty in an MPQA setting without modification. As an initial step towards the development of MPQA systems, we investigate the use of machine learning and rule-based subjectivity and opinion source filters and show that they can be used to guide MPQA systems.

1 Introduction

Much progress has been made in recent years in automatic, open-domain question answering (e.g., Voorhees (2001), Voorhees (2002), Voorhees and Buckland (2003)). The bulk of the research in this area, however, addresses fact-based questions like: "When did McDonald's open its first restaurant?" or "What is the Kyoto Protocol?". To date, however, relatively little research been done in the area of Multi-Perspective Question Answering (MPQA), which targets questions of the following sort:

- How is Bush's decision not to ratify the Kyoto Protocol looked upon by Japan and other US allies?
- How do the Chinese regard the human rights record of the United States?

In comparison to fact-based question answering (QA), researchers understand far less about the properties of questions and answers in MPQA, and have yet to develop techniques to exploit knowledge of those properties. As a result, it is unclear whether approaches that have been successful in the domain of fact-based QA will work well for MPQA.

We first present the *OpQA* corpus of opinion questions and answers. Using the corpus, we compare and contrast the properties of fact and opinion questions and answers. We find that text spans identified as answers to opinion questions: (1) are approximately twice as long as those of fact questions, (2) are much more likely (37% vs. 9%) to represent *partial* answers rather than complete answers, (3) vary much more widely with respect to syntactic category – covering clauses, verb phrases, prepositional phrases, and noun phrases; in contrast, fact answers are overwhelming associated with noun phrases, and (4) are roughly half as likely to correspond to a single syntactic constituent type (16-38% vs. 31-53%).

Based on the disparate characteristics of opinion vs. fact answers, we argue that traditional fact-based QA approaches may have difficulty in an MPQA setting without modification. As one such modification, we propose that MPQA systems should rely on natural language processing methods to identify information about opinions. In experiments in opinion question answering using the OpQA corpus, we find that filtering potential answers using machine learning and rule-based NLP opinion filters substantially improves the performance of an end-to-end MPQA system according to both a mean reciprocal rank (MRR) measure (0.59 vs. a baseline of 0.42) and a metric that determines the mean rank of the first correct answer (MRFA) (26.2 vs. a baseline of 61.3). Further, we find that requiring opinion answers to match the requested opinion source (e.g., does <source> approve of the Kyoto Protocol) dramatically improves the performance of the MPQA system on the hardest questions in the corpus.

The remainder of the paper is organized as follows. In the next section we summarize related work. Section 3 describes the OpQA corpus. Section 4 uses the OpQA corpus to identify potentially problematic issues for handling opinion vs. fact questions. Section 5 briefly describes an opinion annotation scheme used in the experiments. Sections 6 and 7 explore the use of opinion information in the design of MPQA systems.

2 Related Work

There is a growing interest in methods for the automatic identification and extraction of opinions, emotions, and sentiments in text. Much of the relevant research explores sentiment classification, a text categorization task in which the goal is to assign to a document either positive ("thumbs up") or negative ("thumbs down") polarity (e.g. Das and Chen (2001), Pang et al. (2002), Turney (2002), Dave et al. (2003), Pang and Lee (2004)). Other research has concentrated on analyzing opinions at, or below, the sentence level. Recent work, for example, indicates that systems can be trained to recognize opinions, their polarity, their source, and their strength to a reasonable degree of accuracy (e.g. Dave et al. (2003), Riloff and Wiebe (2003), Bethard et al. (2004), Pang and Lee (2004), Wilson et al. (2004), Yu and Hatzivassiloglou (2003), Wiebe and Riloff (2005)).

Related work in the area of corpus development includes Wiebe et al.'s (2005) opinion annotation scheme to identify *subjective expressions* — expressions used to express opinions, emotions, sentiments and other *private states* in text. Wiebe et al. have applied the annotation scheme to create the MPQA corpus consisting of 535 documents manually annotated for phrase-level expressions of opinion. In addition, the NIST-sponsored TREC evaluation has begun to develop data focusing on opinions — the 2003 Novelty Track features a task that requires systems to identify opinion-oriented documents w.r.t. a specific issue (Voorhees and Buckland, 2003).

While all of the above work begins to bridge the gap between text categorization and question answering, none of the approaches have been employed or evaluated in the context of MPQA.

3 OpQA Corpus

To support our research in MPQA, we created the OpQA corpus of opinion and fact questions and answers. Additional details on the construction of the corpus as well as results of an interannotator agreement study can be found in Stoyanov et al. (2004).

3.1 Documents and Questions

The OpQA corpus consists of 98 documents that appeared in the world press between June 2001 and May 2002. All documents were taken from the aforementioned MPQA corpus (Wilson and Wiebe, 2003)[1] and are manually annotated with phrase-level opinion information, following the annotation scheme of Wiebe et al. (2005), which is briefly summarized in Section 5. The documents cover four general (and controversial) topics: President Bush's alternative to the Kyoto protocol (*kyoto*); the US annual human rights report (*humanrights*); the 2002 coup d'etat in Venezuela (*venezuela*); and the 2002 elections in Zimbabwe and Mugabe's reelection (*mugabe*). Each topic is covered by between 19 and 33 documents that were identified automatically via IR methods.

Both fact and opinion questions for each topic were added to the OpQA corpus by a volunteer not associated with the current project. The volunteer was provided with a set of instructions for creating questions together with two documents on each topic selected at random. He created between six and eight questions on each topic, evenly split between fact and opinion. The 30 questions are given in Table 1 sorted by topic.

3.2 Answer annotations

Answer annotations were added to the corpus by two annotators according to a set of annotation instruc-

[1]The MPQA corpus is available at `http://nrrc.mitre.org/NRRC/publications.htm`. The OpQA corpus is available upon request.

tions.[2] Every text segment that *contributes* to an answer to any of the 30 questions is annotated as an answer. In particular, answer annotations include segments that constitute a *partial answer*. Partial answers either (1) lack the specificity needed to constitute a full answer (e.g., "before May 2004" partially answers the question *When was the Kyoto protocol ratified?* when a specific date is known) or (2) need to be combined with at least one additional answer segment to fully answer the question (e.g., the question *Are the Japanese unanimous in their opposition of Bush's position on the Kyoto protocol?* is answered only partially by a segment expressing a single opinion). In addition, annotators mark the minimum answer spans (e.g., "a Tokyo organization," vs. "a Tokyo organization representing about 150 Japanese groups").

4 Characteristics of opinion answers

Next, we use the OpQA corpus to analyze and compare the characteristics of fact vs. opinion questions. Based on our findings, we believe that QA systems based solely on traditional QA techniques are likely to be less effective at MPQA than they are at traditional fact-based QA.

4.1 Traditional QA architectures

Despite the wide variety of approaches implied by modern QA systems, almost all systems rely on the following two steps (subsystems), which have empirically proven to be effective:

- **IR module.** The QA system invokes an IR subsystem that employs traditional text similarity measures (e.g., tf/idf) to retrieve and rank document fragments (sentences or paragraphs) w.r.t. the question (query).

- **Linguistic filters.** QA systems employ a set of filters and text processing components to discard some document fragments. The following filters have empirically proven to be effective and are used universally:

  Semantic filters prefer an answer segment that matches the semantic class(es) associated with the question type (e.g., *date* or *time* for *when* questions; *person* or *organization* for *who* questions).

  Syntactic filters are also configured on the type of question. The most common and effective syntactic filters select a specific constituent (e.g., noun phrase) according to the question type (e.g., *who* question).

QA systems typically interleave the above two subsystems with a variety of different processing steps of both the question and the answer. The goal of the processing is to identify text fragments that contain an answer to the question. Typical QA systems do not perform any further text processing; they return the text fragment as it occurred in the text. [3]

4.2 Corpus-based analysis of opinion answers

We hypothesize that QA systems that conform to this traditional architecture will have difficulty handling opinion questions without non-trivial modification. In support of this hypothesis, we provide statistics from the OpQA corpus to illustrate some of the characteristics that distinguish answers to opinion vs. fact questions, and discuss their implications for a traditional QA system architecture.

Answer length. We see in Table 2 that the average length of opinion answers in the OpQA corpus

[2]The annotation instructions are available at `http://www.cs.cornell.edu/ ves/Publications/publications.htm`.

[3]This architecture is seen mainly in QA systems designed for TREC's "factoid" and "list" QA tracks. Systems competing in the relatively new "definition" or "other" tracks have begun to introduce new approaches. However, most such systems still rely on the IR step and return the text fragment as it occurred in the text.

	Number of answers	Length	Number of partials
fact	124	5.12	12 (9.68%)
opinion	415	9.24	154 (37.11%)

Table 2: Number of answers, average answer length (in tokens), and number of partial answers for fact/opinion questions.

is 9.24 tokens, almost double that of fact answers. Unfortunately, longer answers could present problems for some traditional QA systems. In particular, some of the more sophisticated algorithms that perform **additional processing** steps such as logical verifiers (Moldovan et al., 2002) may be less accurate or computationally infeasible for longer answers. More importantly, longer answers are likely to span more than a single syntactic constituent, rendering the syntactic filters, and very likely the semantic filters, less effective.

Partial answers. Table 2 also shows that over 37% of the opinion answers were marked as partial vs. 9.68% of the fact answers. The implications of partial answers for the traditional QA architecture are substantial: an MPQA system will require an **answer generator** to (1) distinguish between partial and full answers; (2) recognize redundant partial answers; (3) identify which subset of the partial answers, if any, constitutes a full answer; (4) determine whether additional documents need to be examined to find a complete answer; and (5) asemble the final answer from partial pieces of information.

Syntactic constituent of the answer. As discussed in Section 4.1, traditional QA systems rely heavily on the predicted syntactic and semantic class of the answer. Based on answer lengths, we speculated that opinion answers are unlikely to span a single constituent and/or semantic class. This speculation is confirmed by examining the phrase type associated with OpQA answers using Abney's (1996) CASS partial parser.[4] For each question, we count the number of times an answer segment for the question (in the manual annotations) matches each constituent type. We consider four constituent types – noun phrase (n), verb phrase (v), prepositional phrase (p), and clause (c) – and three matching criteria:

Fact						Opinion					
Question	# of answers	Matching Criteria			syn type	Question	# of answers	Matching Criteria			syn type
		ex	up	up/dn				ex	up	up/dn	
H 1	1	0	0	0		H 3	15	5	5	5	c
H 2	4	2	2	2	n	H 5	24	5	5	10	n
H 4	1	0	0	0		H 6	123	17	23	52	n
K 1	48	13	14	24	n	K 5	3	0	0	1	
K 2	38	13	13	19	n	K 6	34	6	5	12	c
K 3	1	1	1	1	c n	K 7	55	9	8	19	c
K 4	2	1	1	1	n	K 8	25	4	4	10	v
M 2	3	0	0	1		M 1	74	10	12	29	v
M 3	1	0	0	1		M 6	12	3	5	7	n
M 4	10	2	2	5	n	M 7	1	0	0	0	
M 5	3	1	1	2	c	M 8	3	0	0	1	
V 1	4	3	3	4	n	V 3	1	1	0	1	c
V 2	1	1	1	1	n	V 4	13	2	2	2	c
V 5	3	0	1	1		V 6	9	2	2	5	c n
V 8	4	2	4	4	n	V 7	23	3	1	5	
Coverage	124	39 31%	43 35%	66 53%		Coverage	415	67 16%	70 17%	159 38%	

Table 3: Syntactic Constituent Type for Answers in the OpQA Corpus

1. The **ex**act match criterion is satisfied only by answer segments whose spans exactly correspond to a constituent in the CASS output.

2. The **up** criterion considers an answer to match a CASS constituent if the constituent completely contains the answer and no more than three additional (non-answer) tokens.

3. The **up/dn** criterion considers an answer to match a CASS constituent if it matches according to the **up** criterion or if the answer completely contains the constituent and no more than three additional tokens.

The counts for the analysis of answer segment syntactic type for fact vs. opinion questions are summarized in Table 3. Results for the 15 fact questions are shown in the left half of the table, and for the 15 opinion questions in the right half. The leftmost column in each half provides the question topic and number, and the second column indicates the total number of answer segments annotated for the question. The next three columns show, for each of the **ex**, **up**, and **up/dn** matching criteria, respectively, the number of annotated answer segments that match the majority syntactic type among answer segments for that question/criterion pair. Using a traditional QA architecture, the MPQA system might filter answers based on this majority type. The *syn type* column indicates the majority syntactic type using the exact match criterion; two values in the column indicate a tie for majority syntactic type, and an empty syntactic type indicates that no answer exactly matched any of the four constituent types. With only a few exceptions, the **up** and **up/dn** matching criteria agreed in majority syntactic type.

Results in Table 3 show a significant disparity between fact and opinion questions. For fact ques-

[4]The parser is available from `http://www.vinartus.net/spa/`.

tions, the syntactic type filter would keep 31%, 35%, or 53% of the correct answers, depending on the matching criterion. For opinion questions, there is unfortunately a two-fold reduction in the percentage of correct answers that would remain after filtering — only 16%, 17% or 38%, depending on the matching criterion. More importantly, the majority syntactic type among answers for fact questions is almost always a noun phrase, while no single constituent type emerges as a useful syntactic filter for opinion questions (see the **syn phrase** columns in Table 3). Finally, because semantic class information is generally tied to a particular syntactic category, the effectiveness of traditional semantic filters in the MPQA setting is unclear.

In summary, identifying answers to questions in an MPQA setting within a traditional QA architecture will be difficult. First, the implicit and explicit assumptions inherent in standard linguistic filters are consistent with the characteristics of fact- rather than opinion-oriented QA. In addition, the presence of relatively long answers and partial answers will require a much more complex **answer generator** than is typically present in current QA systems.

In Sections 6 and 7, we propose initial steps towards modifying the traditional QA architecture for use in MPQA. In particular, we propose and evaluate two types of **opinion filters** for MPQA: **subjectivity filters** and **opinion source filters**. Both types of linguistic filters rely on phrase-level and sentence-level opinion information, which has been manually annotated for our corpus; the next section briefly describes the opinion annotation scheme.

5 Manual Opinion Annotations

Documents in our OpQA corpus come from the larger MPQA corpus, which contains manual opinion annotations. The annotation framework is described in detail in (Wiebe et al., 2005). Here we give a high-level overview.

The annotation framework provides a basis for *subjective expressions*: expressions used to express opinions, emotions, and sentiments. The framework allows for the annotation of both directly expressed private states (e.g., *afraid* in the sentence "John is afraid that Sue might fall,") and opinions expressed by the choice of words and style of language (e.g., *it is about time* and *oppression* in the sentence "It is about time that we end Saddam's oppression"). In addition, the annotations include several attributes, including the *intensity* (with possible values *low*, *medium*, *high*, and *extreme*) and the *source* of the private state. The *source* of a private state is the person or entity who holds or experiences it.

6 Subjectivity Filters for MPQA Systems

This section describes three **subjectivity filters** based on the above opinion annotation scheme. Below (in Section 6.3), the filters are used to remove fact sentences from consideration when answering opinion questions, and the OpQA corpus is used to evaluate their effectiveness.

6.1 Manual Subjectivity Filter

Much previous research on automatic extraction of opinion information performed classifications at the sentence level. Therefore, we define sentence-level opinion classifications in terms of the phrase-level annotations. For our gold standard of manual opinion classifications (dubbed MANUAL for the rest of the paper) we will follow Riloff and Wiebe's (2003) convention (also used by Wiebe and Riloff (2005)) and consider a sentence to be *opinion* if it contains at least one opinion of intensity *medium* or higher, and to be *fact* otherwise.

6.2 Two Automatic Subjectivity Filters

As discussed in section 2, several research efforts have attempted to perform automatic opinion classification on the clause and sentence level. We investigate whether such information can be useful for MPQA by using the automatic sentence level opinion classifiers of Riloff and Wiebe (2003) and Wiebe and Riloff (2005).

Riloff and Wiebe (2003) use a bootstrapping algorithm to perform a sentence-based opinion classification on the MPQA corpus. They use a set of high precision subjectivity and objectivity clues to identify subjective and objective sentences. This data is then used in an algorithm similar to AutoSlog-TS (Riloff, 1996) to automatically identify a set of extraction patterns. The acquired patterns are then used iteratively to identify a larger set of subjective and objective sentences. In our experiments we use

		precision	recall	F
MPQA corpus	RULEBASED	90.4	34.2	46.6
	NAIVE BAYES	79.4	70.6	74.7

Table 4: Precision, recall, and F-measure for the two classifiers.

the classifier that was created by the reimplementation of this bootstrapping process in Wiebe and Riloff (2005). We will use RULEBASED to denote the opinion information output by this classifier.

In addition, Wiebe and Riloff used the RULEBASED classifier to produce a labeled data set for training. They trained a Naive Bayes subjectivity classifier on the labeled set. We will use NAIVE BAYES to refer to Wiebe and Riloff's naive Bayes classifier.[5] Table 4 shows the performance of the two classifiers on the MPQA corpus as reported by Wiebe and Riloff.

6.3 Experiments

We performed two types of experiments using the subjectivity filters.

6.3.1 Answer rank experiments

Our hypothesis motivating the first type of experiment is that subjectivity filters can improve the answer identification phase of an MPQA system. We implement the IR subsystem of a traditional QA system, and apply the subjectivity filters to the IR results. Specifically, for each opinion question in the corpus [6] , we do the following:

1. Split all documents in our corpus into sentences.
2. Run an information retrieval algorithm[7] on the set of all sentences using the question as the query to obtain a *ranked list* of sentences.
3. Apply a subjectivity filter to the *ranked list* to remove all fact sentences from the *ranked list*.

We test each of the MANUAL, RULEBASED, and NAIVE BAYES subjectivity filters. We compare the rank of the first answer to each question in the

Topic	Qnum	Baseline	Manual	NaiveBayes	Rulebased
Kyoto	5	1	1	1	1
	6	5	4	4	3
	7	1	1	1	1
	8	1	1	1	1
Human Rights	3	1	1	1	1
	5	10	6	7	5
	6	1	1	1	1
Venezuela	3	106	81	92	35
	4	3	2	3	1
	6	1	1	1	1
	7	3	3	3	2
Mugabe	1	2	2	2	2
	6	7	5	5	4
	7	447	291	317	153
	8	331	205	217	182
MRR :		0.4244	0.5189	0.5078	0.5856
MRFA:		61.3333	40.3333	43.7333	26.2

Table 5: Results for the subjectivity filters.

ranked list before the filter is applied, with the rank of the first answer to the question in the *ranked list* after the filter is applied.

Results. Results for the opinion filters are compared to a simple baseline, which performs the information retrieval step with no filtering. Table 5 gives the results on the 15 opinion questions for the baseline and each of the three *subjectivity filters*. The table shows two cumulative measures – the mean reciprocal rank (MRR) [8] and the mean rank of the first answer (MRFA). [9]

Table 5 shows that all three *subjectivity filters* outperform the baseline: for all three filters, the first answer in the filtered results for all 15 questions is ranked at least as high as in the baseline. As a result, the three subjectivity filters outperform the baseline in both MRR and MRFA. Surprisingly, the best performing subjectivity filter is RULEBASED, surpassing the gold standard MANUAL, both in MRR (0.59 vs. 0.52) and MRFA (40.3 vs. 26.2). Presumably, the improvement in performance comes from the fact that RULEBASED identifies subjective sentences with the highest precision (and lowest recall). Thus, the RULEBASED subjectivity filter discards non-subjective sentences most aggressively.

6.3.2 Answer probability experiments

The second experiment, *answer probability*, begins to explore whether opinion information can be

[5]Specifically, the one they label *Naive Bayes 1*.

[6]We do not evaluate the opinion filters on the 15 fact questions. Since opinion sentences are defined as containing at least one opinion of intensity medium or higher, opinion sentences can contain factual information and sentence-level opinion filters are not likely to be effective for fact-based QA.

[7]We use the Lemur toolkit's standard tf.idf implementation available from `http://www.lemurproject.org/`.

[8]The MRR is computed as the average of $1/r$, where r is the rank of the first answer.

[9]MRR has been accepted as the standard performance measure in QA, since MRFA can be strongly affected by outlier questions. However, the MRR score is dominated by the results in the high end of the ranking. Thus, MRFA may be more appropriate for our experiments because the filters are an intermediate step in the processing, the results of which other MPQA components may improve.

			sentence	
			fact	opinion
question	Manual	fact	56 (46.67%)	64 (53.33%)
		opinion	42 (10.14%)	372 (89.86%)
	Naive Bayes	fact	49 (40.83%)	71 (59.17%)
		opinion	57 (13.77%)	357 (86.23%)
	Rulebased	fact	96 (80.00%)	24 (20.00%)
		opinion	184 (44.44%)	230 (55.56%)

Table 6: Answer probability results.

used in an **answer generator**. This experiment considers correspondences between (1) the classes (i.e., opinion or fact) assigned by the subjectivity filters to the sentences containing answers, and (2) the classes of the questions the answers are responses to (according to the OpQA annotations). That is, we compute the probabilities (where *ans* = answer):
P(*ans* is in a *C1* sentence | *ans* is the answer to a *C2* question) for all four combinations of *C1*=opinion, fact and *C2*=opinion, fact.

Results. Results for the answer probability experiment are given in Table 6. The rows correspond to the classes of the questions the answers respond to, and the columns correspond to the classes assigned by the subjectivity filters to the sentences containing the answers. The first two rows, for instance, give the results for the MANUAL criterion. MANUAL placed 56 of the answers to fact questions in fact sentences (46.67% of all answers to fact questions) and 64 (53.33%) of the answers to fact questions in opinion sentences. Similarly, MANUAL placed 42 (10.14%) of the answers to opinion questions in fact sentences, and 372 (89.86%) of the answers to opinion questions in opinion sentences.

The answer probability experiment sheds some light on the subjectivity filter experiments. All three subjectivity filters place a larger percentage of answers to opinion questions in opinion sentences than they place in fact sentences. However, the different filters exhibit different degrees of discrimination. Answers to opinion questions are almost always placed in opinion sentences by MANUAL (89.86%) and NAIVE BAYES (86.23%). While that aspect of their performance is excellent, MANUAL and NAIVE BAYES place more answers to fact questions in opinion rather than fact sentences (though the percentages are in the 50s). This is to be expected, because MANUAL and NAIVE BAYES are more conservative and err on the side of classifying sentences as opinions: for MANUAL, the presence of any subjective expression makes the entire sentence opinion, even if parts of the sentence are factual; NAIVE BAYES shows high recall but lower precision in recognizing opinion sentences (see Table 4). Conversely, RULEBASED places 80% of the fact answers in fact sentences and only 56% of the opinion answers in opinion sentences. Again, the lower number of assignments to opinion sentences is to be expected, given the high precision and low recall of the classifier. But the net result is that, for RULEBASED, the off-diagonals are all less than 50%: it places more answers to fact questions in fact rather than opinion sentences (80%), and more answers to opinion questions in opinion rather than fact sentences (56%). This is consistent with its superior performance in the subjectivity filtering experiment.

In addition to explaining the performance of the subjectivity filters, the answer rank experiment shows that the automatic opinion classifiers can be used directly in an **answer generator** module. The two automatic classifiers rely on evidence in the sentence to predict the class (the information extraction patterns used by RULEBASED and the features used by NAIVE BAYES). In ongoing work we investigate ways to use this evidence to extract and summarize the opinions expressed in text, which is a task similar to that of an **answer generator** module.

7 Opinion Source Filters for MPQA Systems

In addition to subjectivity filters, we also define an opinion *source filter* based on the manual opinion annotations. This filter removes all sentences that do not have an opinion annotation with a source that matches the source of the question[10]. For this filter we only used the MANUAL source annotations since we did not have access to automatically extracted source information. We employ the same Answer Rank experiment as in 6.3.1, substituting the source filter for a subjectivity filter.

Results. Results for the source filter are mixed. The filter outperforms the baseline on some questions and performs worst on others. As a result the MRR for the source filter is worse than the base-

[10]We manually identified the sources of each of the 15 opinion questions.

line (0.4633 vs. 0.4244). However, the source filter exhibits by far the best results using the MRFA measure, a value of 11.267. The performance improvement is due to the filter's ability to recognize the answers to the hardest questions, for which the other filters have the most trouble (questions *mugabe* 7 and 8). For these questions, the rank of the first answer improves from 153 to 21, and from 182 to 11, respectively. With the exception of question *venezuela* 3, which does not contain a clear source (and is problematic altogether because there is only a single answer in the corpus and the question's qualification as opinion is not clear) the *source filter* always ranked an answer within the first 25 answers. Thus, *source filters* can be especially useful in systems that rely on the presence of an answer within the first few ranked answer segments and then invoke more sophisticated analysis in the **additional processing** phase.

8 Conclusions

We began by giving a high-level overview of the OpQA corpus. Using the corpus, we compared the characteristics of answers to fact and opinion questions. Based on the different characteristics, we surmise that traditional QA approaches may not be as effective for MPQA as they have been for fact-based QA. Finally, we investigated the use of machine learning and rule-based opinion filters and showed that they can be used to guide MPQA systems.

Acknowledgments We would like to thank Diane Litman for her work eliciting the questions for the OpQA corpus, and the anonymous reviewers for their helpful comments.This work was supported by the Advanced Research and Development Activity (ARDA), by NSF Grants IIS-0208028 and IIS-0208798, by the Xerox Foundation, and by a NSF Graduate Research Fellowship to the first author.

Abstract

Following recent developments in the automatic evaluation of machine translation and document summarization, we present a similar approach, implemented in a measure called POURPRE, for automatically evaluating answers to definition questions. Until now, the only way to assess the correctness of answers to such questions involves manual determination of whether an information nugget appears in a system's response. The lack of automatic methods for scoring system output is an impediment to progress in the field, which we address with this work. Experiments with the TREC 2003 and TREC 2004 QA tracks indicate that rankings produced by our metric correlate highly with official rankings, and that POURPRE outperforms direct application of existing metrics.

1 Introduction

Recent interest in question answering has shifted away from factoid questions such as "What city is the home to the Rock and Roll Hall of Fame?", which can typically be answered by a short noun phrase, to more complex and difficult questions. One interesting class of information needs concerns so-called definition questions such as "Who is Vlad the Impaler?", whose answers would include "nuggets" of information about the 16th century warrior prince's life, accomplishments, and legacy. Actually a misnomer, definition questions can be better paraphrased as "Tell me interesting things about *X*.", where *X* can be a person, an organization, a common noun, etc. Taken another way, definition questions might be viewed as simultaneously asking a whole series of factoid questions about the same entity (e.g., "When was he born?", "What was his occupation?", "Where did he live?", etc.), except that these questions are not known in advance; see Prager et al. (2004) for an implementation based on this view of definition questions.

Much progress in natural language processing and information retrieval has been driven by the creation of reusable test collections. A test collection consists of a corpus, a series of well-defined tasks, and a set of judgments indicating the "correct answers". To complete the picture, there must exist meaningful metrics to evaluate progress, and ideally, a machine should be able to compute these values automatically. Although "answers" to definition questions are known, there is no way to automatically and objectively determine if they are present in a given system's response (we will discuss why in Section 2). The experimental cycle is thus tortuously long; to accurately assess the performance of new techniques, one must essentially wait for expensive, large-scale evaluations that employ human assessors to judge the runs (e.g., the TREC QA track). This situation mirrors the state of machine translation and document summarization research a few years ago. Since then, however, automatic scoring metrics such as BLEU and ROUGE have been introduced as stopgap measures to facilitate experimentation.

Following these recent developments in evalua-

tion research, we propose POURPRE, a technique for automatically evaluating answers to definition questions. Like the abovementioned metrics, POURPRE is based on *n*-gram co-occurrences, but has been adapted for the unique characteristics of the question answering task. This paper will show that POURPRE can accurately assess the quality of answers to definition questions without human intervention, allowing experiments to be performed with rapid turnaround. We hope that this will enable faster exploration of the solution space and lead to accelerated advances in the state of the art.

This paper is organized as follows: In Section 2, we briefly describe how definition questions are currently evaluated, drawing attention to many of the intricacies involved. We discuss previous work in Section 3, relating POURPRE to evaluation metrics for other language applications. Section 4 discusses metrics for evaluating the quality of an automatic scoring algorithm. The POURPRE measure itself is outlined in Section 5; POURPRE scores are correlated with official human-generated scores in Section 6, and also compared to existing metrics. In Section 7, we explore the effect that judgment variability has on the stability of definition question evaluation, and its implications for automatic scoring algorithms.

2 Evaluating Definition Questions

To date, NIST has conducted two formal evaluations of definition questions, at TREC 2003 and TREC 2004.[1] In this section, we describe the setup of the task and the evaluation methodology.

Answers to definition questions are comprised of an unordered set of [document-id, answer string] pairs, where the strings are presumed to provide some relevant information about the entity being "defined", usually called the target. Although no explicit limit is placed on the length of the answer string, the final scoring metric penalizes verbosity (discussed below).

To evaluate system responses, NIST pools answer strings from all systems, removes their association with the runs that produced them, and presents them to a human assessor. Using these responses and research performed during the original development of the question, the assessor creates an "answer key"—a list of "information nuggets" about the target. An information nugget is defined as a fact for which the assessor could make a binary decision as to whether a response contained that nugget (Voorhees, 2003). The assessor also manually classifies each nugget as

[1]TREC 2004 questions were arranged around "topics"; definition questions were implicit in the "other" questions.

[XIE19971012.0112] The Cassini space probe, due to be launched from Cape Canaveral in Florida of the United States tomorrow, has a 32 kilogram plutonium fuel payload to power its seven year journey to Venus and Saturn.
Nuggets assigned: 1, 2

[NYT19990816.0266] Early in the Saturn visit, Cassini is to send a probe named Huygens into the smog-shrouded atmosphere of Titan, the planet's largest moon, and parachute instruments to its hidden surface to see if it holds oceans of ethane or other hydrocarbons over frozen layers of methane or water.
Nuggets assigned: 4, 5, 6

Figure 1: Examples of judging actual system responses.

either *vital* or *okay*. Vital nuggets represent concepts that must be present in a "good" definition; on the other hand, okay nuggets contribute worthwhile information about the target but are not essential; cf. (Hildebrandt et al., 2004). As an example, nuggets for the question "What is the Cassini space probe?" are shown in Table 1.

Once this answer key of vital/okay nuggets is created, the assessor then manually scores each run. For each system response, he or she decides whether or not each nugget is present. Assessors do not simply perform string matches in this decision process; rather, this matching occurs at the conceptual level, abstracting away from issues such as vocabulary differences, syntactic divergences, paraphrases, etc. Two examples of this matching process are shown in Figure 1: nuggets 1 and 2 were found in the top passage, while nuggets 4, 5, and 6 were found in the bottom passage. It is exactly this process of conceptually matching nuggets from the answer key with system responses that we attempt to capture with an automatic scoring algorithm.

The final F-score for an answer is calculated in the manner described in Figure 2, and the final score of a run is simply the average across the scores of all questions. The metric is a harmonic mean between nugget precision and nugget recall, where recall is heavily favored (controlled by the β parameter, set to five in 2003 and three in 2004). Nugget recall is calculated solely on vital nuggets, while nugget precision is approximated by a length allowance given based on the number of both vital and okay nuggets returned. Early on in a pilot study, researchers discovered that it was impossible for assessors to consistently enumerate the total set of nuggets contained

Let

r	# of *vital* nuggets returned in a response
a	# of *okay* nuggets returned in a response
R	# of *vital* nuggets in the answer key
l	# of non-whitespace characters in the entire answer string

Then

$$\text{recall } (\mathcal{R}) = r/R$$

$$\text{allowance } (\alpha) = 100 \times (r+a)$$

$$\text{precision } (\mathcal{P}) = \begin{cases} 1 & \text{if } l < \alpha \\ 1 - \frac{l-\alpha}{l} & \text{otherwise} \end{cases}$$

Finally, the $F(\beta) = \dfrac{(\beta^2+1) \times \mathcal{P} \times \mathcal{R}}{\beta^2 \times \mathcal{P} + \mathcal{R}}$

$\beta = 5$ in TREC 2003, $\beta = 3$ in TREC 2004.

Figure 2: Official definition of F-measure.

in a system response, given that they were usually extracted text fragments from documents (Voorhees, 2003). Thus, a penalty for verbosity serves as a surrogate for precision.

3 Previous Work

The idea of employing *n*-gram co-occurrence statistics to score the output of a computer system against one or more desired reference outputs was first successfully implemented in the BLEU metric for machine translation (Papineni et al., 2002). Since then, the basic method for scoring translation quality has been improved upon by others, e.g., (Babych and Hartley, 2004; Lin and Och, 2004). The basic idea has been extended to evaluating document summarization with ROUGE (Lin and Hovy, 2003).

Recently, Soricut and Brill (2004) employed *n*-gram co-occurrences to evaluate question answering in a FAQ domain; unfortunately, the task differs from definition question answering, making their results not directly applicable. Xu et al. (2004) applied ROUGE to automatically evaluate answers to definition questions, viewing the task as a variation of document summarization. Because TREC answer nuggets were terse phrases, the authors found it necessary to rephrase them—two humans were asked to manually create "reference answers" based on the assessors' nuggets and IR results, which was a labor-intensive process. Furthermore, Xu et al. did not perform a large-scale assessment of the reliability of ROUGE for evaluating definition answers.

4 Criteria for Success

Before proceeding to our description of POURPRE, it is important to first define the basis for assessing the quality of an automatic evaluation algorithm. Correlation between official scores and automatically-generated scores, as measured by the coefficient of determination R^2, seems like an obvious metric for quantifying the performance of a scoring algorithm. Indeed, this measure has been employed in the evaluation of BLEU, ROUGE, and other related metrics.

However, we believe that there are better measures of performance. In comparative evaluations, we ultimately want to determine if one technique is "better" than another. Thus, the system rankings produced by a particular scoring method are often more important than the actual scores themselves. Following the information retrieval literature, we employ Kendall's τ to capture this insight. Kendall's τ computes the "distance" between two rankings as the minimum number of pairwise adjacent swaps necessary to convert one ranking into the other. This value is normalized by the number of items being ranked such that two identical rankings produce a correlation of 1.0; the correlation between a ranking and its perfect inverse is -1.0; and the expected correlation of two rankings chosen at random is 0.0. Typically, a value of greater than 0.8 is considered "good", although 0.9 represents a threshold researchers generally aim for. In this study, we primarily focus on Kendall's τ, but also report R^2 values where appropriate.

5 POURPRE

Previously, it has been assumed that matching nuggets from the assessors' answer key with systems' responses must be performed manually because it involves semantics (Voorhees, 2003). We would like to challenge this assumption and hypothesize that term co-occurrence statistics can serve as a surrogate for this semantic matching process. Experience with the ROUGE metric has demonstrated the effectiveness of matching unigrams, an idea we employ in our POURPRE metric. We hypothesize that matching bigrams, trigrams, or any other longer *n*-grams will not be beneficial, because they primarily account for the fluency of a response, more relevant in a machine translation task. Since answers to definition questions are usually document extracts, fluency is less important a concern.

The idea behind POURPRE is relatively straightforward: match nuggets by summing the unigram co-occurrences between terms from each nugget and terms from the system response. We decided to start with the simplest possible approach: count the word overlap and divide by the total number of terms in the answer nugget. The only additional wrinkle is to ensure that all words appear within the same answer string. Since nuggets represent coherent concepts, they are unlikely to be spread across different answer strings (which are usually different extracts of source documents). As a simple example, let's say we're trying to determine if the nugget "A B C D" is contained in the following system response:

1. A
2. B C D
3. D
4. A D

The match score assigned to this nugget would be $3/4$, from answer string 2; no other answer string would get credit for this nugget. This provision reduces the impact of coincidental term matches.

Once we determine the match score for every nugget, the final F-score is calculated in the usual way, except that the automatically-derived match scores are substituted where appropriate. For example, nugget recall now becomes the sum of the match scores for all vital nuggets divided by the total number of vital nuggets. In the official F-score calcula-

Run	POURPRE				ROUGE

Table 2: Correlation (Kendall's τ) between rankings generated by POURPRE/ROUGE and official scores.

Run	POURPRE				ROUGE	
	micro, cnt	macro, cnt	micro, *idf*	macro, *idf*	+stop	−stop
TREC 2004 ($\beta = 3$)	0.837	**0.929**	0.904	0.914	0.854	0.871
TREC 2003 ($\beta = 3$)	0.919	**0.963**	0.941	0.957	0.876	0.887
TREC 2003 ($\beta = 5$)	0.954	**0.965**	0.957	0.964	0.919	0.929

Table 3: Correlation (R^2) between values generated by POURPRE/ROUGE and official scores.

tion, the length allowance—for the purposes of computing nugget precision—was 100 non-whitespace characters for every okay and vital nugget returned. Since nugget match scores are now fractional, this required some adjustment. We settled on an allowance of 100 non-whitespace characters for every nugget match that had non-zero score.

A major drawback of this basic unigram overlap approach is that all terms are considered equally important—surely, matching "year" in a system's response should count for less than matching "Huygens", in the example about the Cassini space probe. We decided to capture this intuition using inverse document frequency, a commonly-used measure in information retrieval; $idf(t_i)$ is defined as $log(N/c_i)$, where N is the number of documents in the collection, and c_i is the number of documents that contain the term t_i. With scoring based on *idf*, term counts are simply replaced with *idf* sums in computing the match score, i.e., the match score of a particular nugget is the sum of the *idf*s of matching terms in the system response divided by the sum of all term *idf*s from the answer nugget. Finally, we examined the effects of stemming, i.e., matching stemmed terms derived from the Porter stemmer.

In the next section, results of experiments with submissions to TREC 2003 and TREC 2004 are reported. We attempted two different methods for aggregating results: microaveraging and macroaveraging. For microaveraging, scores were calculated by computing the nugget match scores over all nuggets for all questions. For macroaveraging, scores for each question were first computed, and then averaged across all questions in the testset. With microaveraging, each nugget is given equal weight, while with macroaveraging, each question is given equal weight.

As a baseline, we revisited experiments by Xu et al. (2004) in using ROUGE to evaluate definition questions. What if we simply concatenated all the answer nuggets together and used the result as the "reference summary" (instead of using humans to create custom reference answers)?

6 Evaluation of POURPRE

We evaluated all definition question runs submitted to the TREC 2003[2] and TREC 2004 question answering tracks with different variants of our POURPRE metric, and then compared the results with the official F-scores generated by human assessors. The Kendall's τ correlations between rankings produced by POURPRE and the official rankings are shown in Table 2. The coefficients of determination (R^2) between the two sets of scores are shown in Table 3. We report four separate variants along two different parameters: scoring by term counts only vs. scoring by term *idf*, and microaveraging vs. macroaveraging. Interestingly, scoring based on macroaveraged term

[2]In TREC 2003, the value of β was arbitrarily set to five, which was later determined to favor recall too heavily. As a result, it was readjusted to three in TREC 2004. In our experiments with TREC 2003, we report figures for both values.

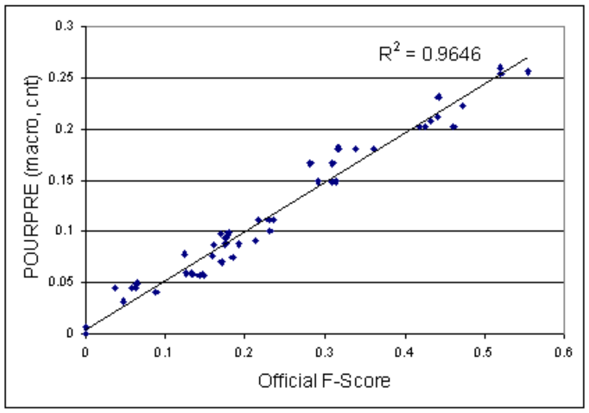

Figure 3: Scatter graph of official scores plotted against the POURPRE scores (macro, count) for TREC 2003 ($\beta = 5$).

counts outperformed any of the *idf* variants.

A scatter graph plotting official F-scores against POURPRE scores (macro, count) for TREC 2003 ($\beta = 5$) is shown in Figure 3. Corresponding graphs for other variants appear similar, and are not shown here. The effect of stemming on the Kendall's τ correlation between POURPRE (macro, count) and official scores in shown in Table 4. Results from the same stemming experiment on the other POURPRE variants are similarly inconclusive.

For TREC 2003 ($\beta = 5$), we performed an analysis of rank swaps between official and POURPRE scores. A rank swap is said to have occurred if the relative ranking of two runs is different under different conditions—they are significant because rank swaps might prevent researchers from confidently drawing conclusions about the relative effectiveness of different techniques. We observed 81 rank swaps (out of a total of 1431 pairwise comparisons for 54 runs). A histogram of these rank swaps, binned by the difference in official score, is shown in Figure 4. As can be seen, 48 rank swaps (59.3%) occurred when the difference in official score is less than 0.02; there were no rank swaps observed for runs in which the official scores differed by more than 0.061. Since measurement error is an inescapable fact of evaluation, we need not be concerned with rank swaps that can be attributed to this factor. For TREC 2003, Voorhees (2003) calculated this value to be approximately 0.1; that is, in order to conclude with 95% confidence that one run is better than another, an absolute F-score difference greater than 0.1 must be observed. As can be seen, all the rank swaps observed can be attributed to error inherent in the evaluation process.

Run	unstemmed	stemmed
TREC 2004 ($\beta = 3$)	0.833	0.825
TREC 2003 ($\beta = 3$)	0.886	0.897
TREC 2003 ($\beta = 5$)	0.878	0.895

Table 4: The effect of stemming on Kendall's τ; all runs with (macro, count) variant of POURPRE.

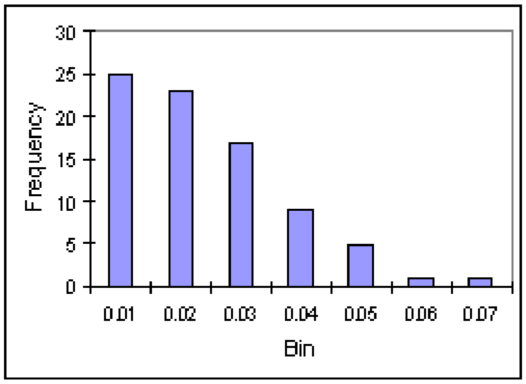

Figure 4: Histogram of rank swaps for TREC 2003 ($\beta = 5$), binned by difference in official score.

From these results, we can see that evaluation of definition questions is relatively coarse-grained. However, TREC 2003 was the first formal evaluation of definition questions; as methodologies are refined, the margin of error should go down. Although a similar error analysis for TREC 2004 has not been performed, we expect a similar result.

Given the simplicity of our POURPRE metric, the correlation between our automatically-derived scores and the official scores is remarkable. Starting from a set of questions and a list of relevant nuggets, POURPRE can accurately assess the performance of a definition question answering system without any human intervention.

6.1 Comparison Against ROUGE

We choose ROUGE over BLEU as a baseline for comparison because, conceptually, the task of answering definition questions is closer to summarization than it is to machine translation, in that both are recall-oriented. Since the majority of question answering systems employ extractive techniques, fluency (i.e., precision) is not usually an issue.

How does POURPRE stack up against using ROUGE[3] to directly evaluate definition questions? The Kendall's τ correlations between rankings produced by ROUGE (with and without stopword removal) and the official rankings are shown in Table 2; R^2 values are shown in Table 3. In all cases, ROUGE does not perform as well.

We believe that POURPRE better correlates with official scores because it takes into account special characteristics of the task: the distinction between vital and okay nuggets, the length penalty, etc. Other than a higher correlation, POURPRE offers an advantage over ROUGE in that it provides a better diagnostic than a coarse-grained score, i.e., it can reveal *why* an answer received a particular score. This allows researchers to conduct failure analyses to identify opportunities for improvement.

7 The Effect of Variability in Judgments

As with many other information retrieval tasks, legitimate differences in opinion about relevance are an inescapable fact of evaluating definition questions—systems are designed to satisfy real-world information needs, and users inevitably disagree on which nuggets are important or relevant. These disagreements manifest as scoring variations in an evaluation setting. The important issue, however, is the degree to which variations in judgments affect conclusions that can be drawn in a comparative evaluation, i.e., can we still confidently conclude that one system is "better" than another? For the *ad hoc* document retrieval task, research has shown that system rankings are stable with respect to disagreements about document relevance (Voorhees, 2000). In this section, we explore the effect of judgment variability on the stability and reliability of TREC definition question answering evaluations.

The vital/okay distinction on nuggets is one major source of differences in opinion, as has been pointed out previously (Hildebrandt et al., 2004). In the Cassini space probe example, we disagree with the assessors' assignment in many cases. More importantly, however, there does not appear to be any operationalizable rules for classifying nuggets as either vital or okay. Without any guiding principles, how can we expect our systems to automatically recognize this distinction?

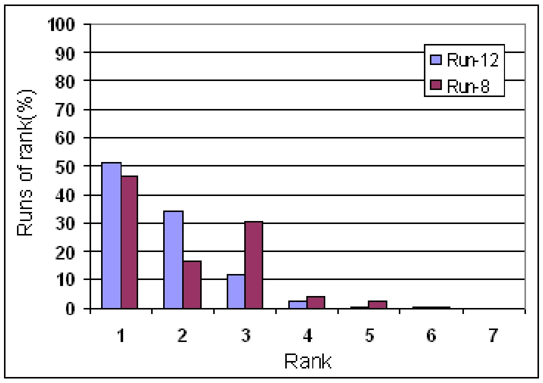

Figure 5: Distribution of rank placement using random judgments (for top two runs from TREC 2004).

How do differences in opinion about vital/okay nuggets impact the stability of system rankings? To answer this question, we measured the Kendall's τ correlation between the official rankings and rankings produced by different variations of the answer key. Three separate variants were considered:

- all nuggets considered vital
- vital/okay flipped (all vital nuggets become okay, and all okay nuggets become vital)
- randomly assigned vital/okay labels

Results are shown in Table 5. Note that this experiment was conducted with the manually-evaluated system responses, not our POURPRE metric. For the last condition, we conducted one thousand random trials, taking into consideration the original distribution of the vital and okay nuggets for each question using a simplified version of the Metropolis-Hastings algorithm (Chib and Greenberg, 1995); the standard deviations are reported.

These results suggest that system rankings are sensitive to assessors' opinion about what constitutes a vital or okay nugget. In general, the Kendall's τ values observed here are lower than values computed from corresponding experiments in *ad hoc* document retrieval (Voorhees, 2000). To illustrate, the distribution of ranks for the top two runs from

[3]We used ROUGE-1.4.2 with n set to 1, i.e. unigram matching, and maximum matching score rating.

Run	everything vital	vital/okay flipped	random judgments
TREC 2004 ($\beta = 3$)	0.919	0.859	0.841 $\pm$ 0.0195
TREC 2003 ($\beta = 3$)	0.927	0.802	0.822 $\pm$ 0.0215
TREC 2003 ($\beta = 5$)	0.920	0.796	0.808 $\pm$ 0.0219

Table 5: Correlation (Kendall's τ) between scores under different variations of judgments and the official scores. The 95% confidence interval is presented for the random judgments case.

TREC 2004 (RUN-12 and RUN-8) over the one thousand random trials is shown in Figure 5. In 511 trials, RUN-12 was ranked as the highest-scoring run; however, in 463 trials, RUN-8 was ranked as the highest-scoring run. Factoring in differences of opinion about the vital/okay distinction, one could not conclude with certainty which was the "best" run in the evaluation.

It appears that differences between POURPRE and the official scores are about the same as (or in some cases, smaller than) differences between the official scores and scores based on variant answer keys (with the exception of "everything vital"). This means that further refinement of the metric to increase correlation with human-generated scores may not be particularly meaningful; it might essentially amount to overtraining on the whims of a particular human assessor. We believe that sources of judgment variability and techniques for managing it represent important areas for future study.

8 Conclusion

We hope that POURPRE can accomplish for definition question answering what BLEU has done for machine translation, and ROUGE for document summarization: allow laboratory experiments to be conducted with rapid turnaround. A much shorter experimental cycle will allow researchers to explore different techniques and receive immediate feedback on their effectiveness. Hopefully, this will translate into rapid progress in the state of the art.[4]

Integrating linguistic knowledge in passage retrieval for question answering

Abstract

In this paper we investigate the use of linguistic knowledge in passage retrieval as part of an open-domain question answering system. We use annotation produced by a deep syntactic dependency parser for Dutch, Alpino, to extract various kinds of linguistic features and syntactic units to be included in a multi-layer index. Similar annotation is produced for natural language questions to be answered by the system. From this we extract query terms to be sent to the enriched retrieval index. We use a genetic algorithm to optimize the selection of features and syntactic units to be included in a query. This algorithm is also used to optimize further parameters such as keyword weights. The system is trained on questions from the competition on Dutch question answering within the Cross-Language Evaluation Forum (CLEF). We could show an improvement of about 15% in mean total reciprocal rank compared to traditional information retrieval using plain text keywords (including stemming and stop word removal).

1 Introduction

Improving information retrieval (IR) through natural language processing (NLP) has been the goal for many researchers. NLP techniques such as lemmatization and compound splitting have been used in several studies (Krovetz, 1993; Hollink et al., 2003). Linguistically motivated syntactic units such as noun phrases (Zhai, 1997), head-modifier pairs (Fagan, 1987; Strzalkowski et al., 1996) and subject-verb-object triples (Katz and Lin, 2003) have also been integrated in information retrieval. However, most of these studies resulted in only little success or even decreasing performance. It has been argued that NLP and especially deep syntactic analysis is still too brittle and ineffective (Katz and Lin, 2003).

Integrating NLP in information retrieval seems to be very hard because the task here is to match plain text keywords to natural language documents. In question answering (QA), however, the task is to match natural language questions to relevant answers within document collections. For this, we have to analyze the question in order to determine what kind of answer the user is expecting. Traditional information retrieval is used in QA systems to filter out relevant passages from the document collection which are then processed to extract possible answers. Hence, the performance of this *passage retrieval* component (especially in terms of recall) is crucial for the success of the entire system. NLP tools and linguistic resources are frequently used in QA systems, e.g. (Bernardi et al., 2003; Moldovan et al., 2002), although not very often for passage retrieval (some exceptions are (Strzalkowski et al., 1996; Katz and Lin, 2003; Neumann and Sacaleanu, 2004)).

Our goal is to utilize information that can be extracted from the analyzed question in order to match linguistic features and syntactic units in analyzed documents. The main research question is to find appropriate units and features that actually help to improve the retrieval component. Furthermore, we have to find an appropriate way of combining query terms to optimize IR performance. For this, we apply an iterative learning approach based on example questions annotated with their answers.

In the next section we will give a brief description of our question answering system with focus on the passage retrieval component. Thereafter we will discuss the query optimization algorithm followed by a section on experimental results. The final section contains our conclusions.

2 Question answering with dependency relations

Our Dutch question answering system, Joost (Bouma et al., 2005), consists of two streams: a table look-up strategy using off-line information extraction and an on-line strategy using passage retrieval and on-the-fly answer extraction. In both strategies we use syntactic information produced by a wide-coverage dependency parser for Dutch, Alpino (Bouma et al., 2001). In the off-line strategy we use syntactic patterns to extract information from unrestricted text to be stored in fact tables (Jijkoun et al., 2004). For the on-line strategy, we assume that there is a certain overlap between syntactic relations in the question and in passages containing the answers. Furthermore, we also use strategies for reasoning over dependency rules to capture semantic relationships that are expressed by different syntactic patterns (Bouma et al., 2005).

Our focus is set on open-domain question answering using data from the CLEF competition on Dutch QA. We have parsed the entire corpus provided by CLEF with about 4,000,000 sentences in about 190,000 documents. The dependency trees are stored in XML and are directly accessible from the QA system. Syntactic patterns for off-line information extraction are run on the entire corpus. For the on-line QA strategy we use traditional information retrieval to select relevant passages from the corpus to be processed by the answer extraction modules. This step is necessary to reduce the search space for the QA system to make it feasible to run on-line QA. As segmentation level we used paragraphs marked in the corpus (about 1.1 million).

Questions are parsed within the QA system using the same parser. Using their analysis, the system determines the question type and, hence, the expected answer type. According to the type, we try to find the answer first in the fact database (if an appropriate table exists) and then (as fallback) in the corpus using the on-line QA strategy.

2.1 Passage retrieval in Joost

Information retrieval is one of the bottle-necks in the on-line strategy of our QA system. The system relies on the passages retrieved by this component and fails if IR does not provide relevant documents. Traditional IR uses a bag-of-words approach using plain text keywords to be matched with word-vectors describing documents. The result is usually a ranked list of documents. Simple techniques such as stemming and stop word removal are used to improve the performance of such a system. This is also the base-line approach for passage retrieval in our QA system.

The passage retrieval component in Joost includes an interface to seven off-the shelf IR systems. One of the systems supported is Lucene from the Apache Jakarta project (Jakarta, 2004). Lucene is a widely-used open-source Java library with several extensions and useful features. This was the IR engine of our choice in the experiments described here. For the base-line we use standard settings and a public Dutch text analyzer for stemming and stop word removal. Now, the goal is to extend the base-line by incorporating linguistic information produced by the syntactic analyzer. Figure 1 shows a dependency tree produced for one of the sentences in the CLEF corpus. We like to include as much information from the parsed data as possible to find better matches between an analyzed question and passages that contain answers. From the parse trees, we extract various kinds of linguistic features and syntactic units to be stored in the index. Besides the dependency relations the parser also produces part-of-speech (POS) tags, named entity labels and linguistic root forms. It also recognizes compositional compounds and particle verbs. All this information might be useful for our passage retrieval component.

Lucene supports multiple index fields that can be filled with different types of data. This is a useful

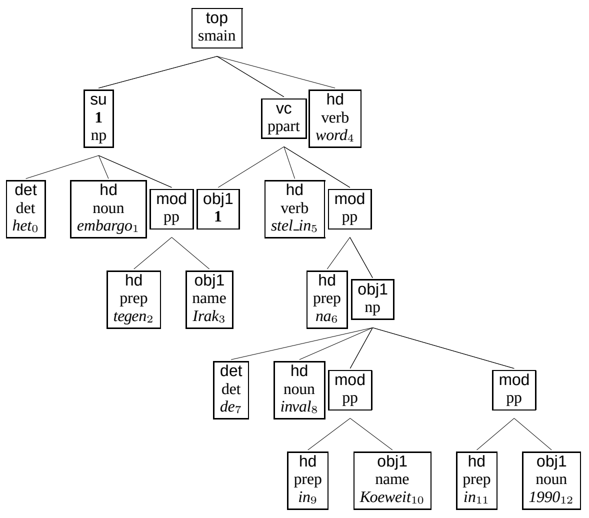

Figure 1: A dependency tree produced by Alpino: *Het embargo tegen Irak werd ingesteld na de inval in Koeweit in 1990.* (The embargo against Iraq has been declared after the invasion of Kuwait in 1990.)

feature since it allows one to store various kinds of information in different fields in the index. Henceforth, we will call these data fields *index layers* and, thus, the index will be called a *multi-layer index*. We distinguish between *token layers*, *type layers* and *annotation layers*. Token layers include one item per token in the corpus. Table 1 lists token layers defined in our index.

Table 1: Token layers

text	plain text tokens
root	root forms
RootPOS	root form + POS tag
RootHead	root form + head
RootRel	root form + relation name
RootRelHead	root form + relation + head

We included various combinations of features derived from the dependency trees to make it possible to test their impact on IR. Features are simply concatenated (using special delimiting symbols between the various parts) to create individual items in the layer. For example, the *RootHead* layer contains concatenated dependent-head bigrams taken from the dependency relations in the tree. Tokens in the *text* layer and in the *root* layer have been split at hyphens and underscores to split compositional compounds and particle verbs (Alpino adds underscores

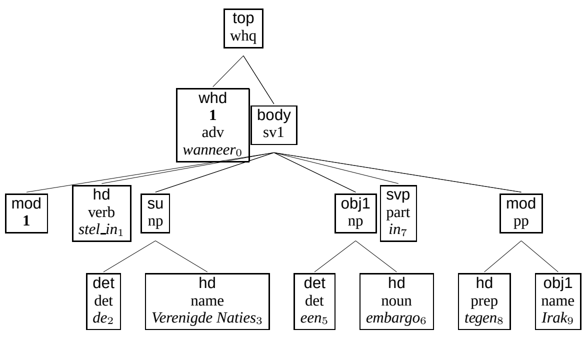

Figure 2: A dependency tree for a question: *Wanneer stelde de Verenigde Naties een embargo in tegen Irak?* (When did the United Nations declare the embargo against Iraq?)

between the compositional parts). Type layers include only specific types of tokens in the corpus, e.g. named entities or compounds (see table 2).

Table 2: Type layers

compound	compounds

nePER	person names
neORG	organization names

Annotation layers include only the labels of (certain) token types. So far, we defined only one annotation layer for named entity labels. This layer may contain the items 'ORG', 'PER' or 'LOC' if such a named entity occurs in the text passage.

3 Query formulation

Questions are analyzed in the same way as sentences in documents. Hence, we can extract appropriate units from analyzed questions to be matched with the various layers in the index. For example, we can extract root-head word pairs to be matched with the RootHead layer. In this way, each layer can be queried using keywords of the same type. Furthermore, we can also use linguistic labels to restrict our query terms in several ways. For example, we can use part-of-speech labels to exclude keywords of a certain word class. We can also use the syntactic relation name to define query constraints. Each token layer can be restricted in this way (even if the feature used for the restriction is not part of the layer). For example, we can limit our set of root keywords to *nouns* even though part-of-speech labels are not part of the root layer. We can also combine constraints, for example, RootPOS keywords can be restricted to *nouns* that are in an *object* relation within the question.

Another feature of Lucene is the support of keyword weights. Keywords can be "boosted" using so-called "boost factors". Furthermore, keywords can also be marked as "required". These two features can be applied to all kinds of keywords (token layer, type layer, annotation layer keywords, and restricted keywords).

The following list summarizes possible keyword types in our passage retrieval component:

basic: a keyword in one of the index layers

restricted: *token-layer* keywords can be restricted to a certain word class and/or a certain relation type. We use only the following word class restrictions: *noun, name, adjective, verb*; and the following relation type restrictions: *direct object, modifier, apposition* and *subject*

weighted: keywords can be weighted using a *boost factor*

required: keywords can be marked as required

Query keywords from all types can be combined into a single query. We connect them in a disjunctive way which is the default operation in Lucene. The query engine provides ranked query results and, therefore, each disjunction may contribute to the ranking of the retrieved documents but does not harm the query if it does not produce any matching results. We may, for example, form a query with the following elements: (1) all plain *text* tokens; (2) named entities (*ne*) boosted with factor 2; (3) *RootHead* bigrams where the root is in an object relation; (4) *RootRel* keywords for all nouns. Applying these parameters to the question in figure 2 we get the following query:[1]

```
text:(Irak embargo Verenigde Naties stelde)
ne:(Irak^2 Verenigde_Naties^2)
RootHead:(Irak/tegen embargo/stel_in)
RootRel:(embargo/obj1)
```

Now, query terms from various keyword types may refer to the same index layer. For example, we may use weighted plain text keywords restricted to nouns together with unrestricted plain text keywords. To combine them we use a preference mechanism to keep queries simple and to avoid disjunctions with conflicting keyword parameters: (a) Restricted keyword types are more specific than basic keywords; (b) Keywords restricted in relation type *and* POS are more specific than keywords with only one restriction; (c) Relation type restrictions are more specific than POS restrictions. Using these rules we define that weights of more specific keywords overwrite weights of less specific ones. Furthermore, we define that the "required-marker" ('+') overwrites keyword weights. Using these definitions we would get the following query if we add two elements to the query from above: (5) plain text keywords in an object relation with boost factor 3 and (6) plain text keywords labeled as names marked as required.

```
text:(Irak^3 embargo^3 +Verenigde +Naties
stelde)
ne:(Irak^2 Verenigde_Naties^2)
RootHead:(Irak/tegen embargo/stel_in)
RootRel:(embargo/obj1)
```

Finally, we can also use the question type determined by question analysis in the retrieval component. The question type corresponds to the expected answer type, i.e. we expect an entity of that type in the relevant text passages. In some cases, the question type can be mapped to one of the named entity labels assigned by the parser, e.g. a *name question* is looking for names of persons (ne = PER), a question for a *capital* is looking for a location (ne = LOC) and a question for organizations is looking for the name of an organization (ne = ORG). Hence, we can add another keyword type, the expected answer type to be matched with named entity labels in the *ne* layer, cf. (Prager et al., 2000).

There are many possible combinations of restrictions even with the small set of POS labels and relation types listed above. However, many of them are useless because they cannot be instantiated. For example, an adjective cannot appear in subject relation to its head. For simplicity we limit ourselves to the following eight combined restrictions (POS + relation type): names + {direct object, modifier, apposition, subject} and nouns + {direct object, modifier, apposition, subject}. These can be applied to all token layers in the same way as the other restrictions using single constraints.

Altogether we have 109 different keyword types

[1]Note that stop words have been removed.

using the layers and the restrictions defined above. Now the question is to select appropriate keyword types among them with the optimal parameters (weights) to maximize retrieval performance. The following section describes the optimization procedure used to adjust query parameters.

4 Optimization of query parameters

In the previous sections we have seen the internal structure of the multi-layer index and the queries we use in our passage retrieval component. Now we have to address the question of how to select layers and restrict keywords to optimize the performance of the system according to the QA task. For this we employ an automatic optimization procedure that learns appropriate parameter settings from example data. We use annotated training material that is described in the next section. Thereafter, the optimization procedure is introduced.

4.1 CLEF questions and evaluation

We used results from the CLEF competition on Dutch QA from the years 2003 and 2004 for training and evaluation. They contain natural language questions annotated with their answers found in the CLEF corpus (answer strings and IDs of documents in which the answer was found). Most of the questions are factoid questions such as 'Hoeveel inwoners heeft Zweden?' (How many inhabitants does Sweden have?). Altogether there are 631 questions with 851 answers.[2]

Standard measures for evaluating information retrieval results are precision and recall. However, for QA several other specialized measures have been proposed, e.g. mean reciprocal rank (MRR) (Vorhees, 1999), coverage and redundancy (Roberts and Gaizauskas, 2004). MRR accounts only for the first passage retrieved containing an answer and disregards the following passages. Coverage and redundancy on the other hand disregard the ranking completely and focus on the sets of passages retrieved. However, in our QA system, the IR score (on which the retrieval ranking is based) is one of the clues used by the answer identification modules. Therefore, we use the *mean of the total reciprocal ranks* (MTRR), cf. (Radev et al., 2002), to combine features of all three measures:

$$MTRR = \frac{1}{x}\sum_{i=1}^{x}\sum_{d\in A_i}\frac{1}{rank_{R_i}(d)}$$

A_i is the set of retrieved passages containing an answer to question number i (subset of R_i) and $rank_{R_i}(d)$ is the rank of document d in the list of retrieved passages R_i.

In our experiments we used the provided answer string rather than the document ID to judge if a retrieved passage was relevant or not. In this way, the IR engine may provide passages with correct answers from other documents than the ones marked in the test set. We do simple string matching between answer strings and words in the retrieved passages. Obviously, this introduces errors where the matching string does not correspond to a valid answer in the context. However, we believe that this does not influence the global evaluation figure significantly and therefore we use this approach as a reasonable compromise when doing automatic evaluation.

4.2 Learning query parameters

As discussed earlier, there is a large variety of possible keyword types that can be combined to query the multi-layer index. Furthermore, we have a number of parameters to be set when formulating a query, e.g. the keyword weights. Selecting the appropriate keywords and parameters is not straightforward. We like to carry out a systematic search for optimizing parameters rather than using our intuition. Here, we use the information retrieval engine as a black box with certain input parameters. We do not know how the ranking is done internally or how the output is influenced by parameter changes. However, we can inspect and evaluate the output of the system. Hence, we need an iterative approach for testing several settings to optimize query parameters. The output for each setting has to be evaluated according to a certain objective function. For this, we need an automatic procedure because we want to check many different settings in a batch run. The performance of the system can be measured in several ways, e.g. us-

[2]Each question may have multiple possible answers. We also added some obvious answers which were not in the original test set when encountering them in the corpus. For example, names and numbers can be spelled differently (*Kim Jong Il* vs. *Kim Jong-Il, Saoedi-Arabië* vs. *Saudi-Arabië, bijna vijftig jaar* vs. *bijna 50 jaar*)

ing the MTRR scores described in the previous section. We have chosen to use this measure and the annotated CLEF questions to evaluate the retrieval performance automatically.

We decided to use a simplified genetic algorithm to optimize query parameters. This algorithm is implemented as an iterative "trial-and-error beam search" through possible parameter settings. The optimization loop works as follows (using a sub-set of the CLEF questions):

1. Run initial queries (one keyword type per IR run) with default weights.

2. Produce a number of new settings by combining two previous ones (= *crossover*). For this, select two settings from an N-best list from the previous IR runs. Apply *mutation* operations (see next step) until the new settings are unique (among all settings we have tried so far).

3. Change some of the new settings at random (= *mutation*) using pre-defi ned mutation operations.

4. Run the queries using the new settings and evaluate the retrieval output (determine *fitness*).

5. Continue with 2 until some stop condition is satisfi ed.

This optimization algorithm is very simple but requires some additional parameters. First of all, we have to set the size of the *population*, i.e. the number of IR runs (*individuals*) to be kept for the next iteration. We decided to keep the population small with only 25 individuals. Then we have to decide how to evaluate fitness to rank retrieval results. This is done using the MTRR measure. *Natural selection* using these rankings is simplified to a top-N search without giving individuals with lower fitness values a chance to survive. This also means that we can update the population directly when a new IR run is finished. We also have to set a maximum number of new settings to be created. In our experiments we limit the process to a maximum of 50 settings that may be tried simultaneously. A new setting is created as soon as there is a spot available.

An important part of the algorithm is the combination of parameters. We simply merge the settings of two previous runs (*parents*) to produce a new setting (a *child*). That means that all keyword types (with their restrictions) from both parents are included in the child's setting. Parents are selected at random without any preference mechanism. We also use a very simple strategy in cases where both parents contain the same keyword type. In these cases we compute the arithmetic mean of the weight assigned to this type in the parents' settings (default weight is one). If the keyword type is marked as required in one of the parents, it will also be marked as required in the child's setting (which will overwrite the keyword weight if it is set in the other parent).

Another important principle in genetic optimization is mutation. It refers to a randomized modification of settings when new individuals are created. First, we apply mutation operations where new settings are not unique.[3] Secondly, mutation operations are applied with fixed probabilities to new settings.

In most genetic algorithms, settings are converted to genes consisting of bit strings. A mutation operation is then defined as flipping the value of one randomly chosen bit. In our approach, we do not use bit strings but define several mutation operations to modify parameters directly. The following operations have been defined:

- a new keyword type is added to new settings with a chance of 0.2

- a keyword type is removed from the settings with a chance of 0.1

- a keyword weight (boost factor) is modified by a random value between -5 and 5 with a chance of 0.2 (but only if the weight remains a positive value)

- a keyword type is marked as required with a chance of 0.01

All these parameters are intuitively chosen. We assigned rather high probabilities to the mutation operations to reduce the risk of local maximum traps. Note that there is no obvious condition for termination. In randomized approaches like this one the development of the fitness score is most likely not monotonic and therefore, it is hard to predict when we should stop the optimization process. However, we expect the scores to converge at some point and we may stop if a certain number of new settings does not improve the scores anymore.

[3]We require unique settings in our implementation because we want to avoid re-computation of fi tness values for settings that have been tried already. "Good" settings survive anyway using our top-N selection approach.

5 Experiments

We selected a random set of 420 questions from the CLEF data for training and used the remaining 150 questions for evaluation. We used the optimization algorithm with the settings as described above. IR was run in parallel on 3-7 Linux workstations on a local network. We retrieved a maximum of 20 passages per question. For each setting we computed the fitness scores for the training set and the evaluation set using MTRR. The top scores have been printed after each 10 runs and compared to the evaluation scores. Figure 3 shows a plot of the fitness score development throughout the optimization process in comparison with the evaluation scores.

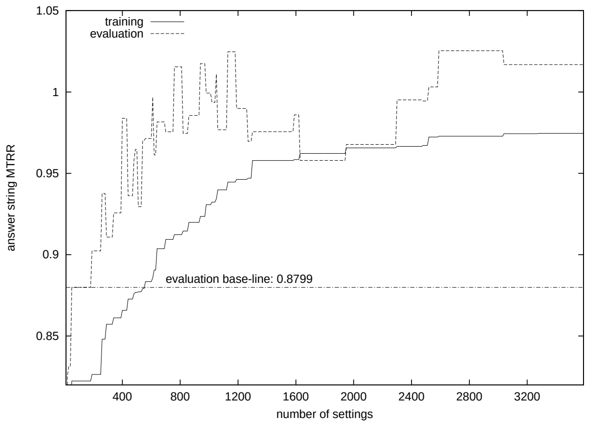

Figure 3: Parameter optimization

The base-line of 0.8799 refers to the retrieval result on evaluation data when using traditional IR with plain text keywords only (i.e. using the text layer, Dutch stemming and stop word removal). The base-line performance on training data is slightly worse with 0.8224 MTRR. After 1130 settings the MTRR scores increased to 0.9446 for training data and 1.0247 for evaluation data. Thereafter we can observe a surprising drop in evaluation scores to around 0.97 in MTRR. This might be due to overfitting although the drop seems to be rather radical. After that the curve of the evaluation scores goes back to about the same level as achieved before and the training curve seems to level out. The MTRR score after 3200 settings is at 1.0169 on evaluation data which is a statistically significant improvement of the baseline score (tested using the Wilcoxon matched-pairs signed-ranks test at $p < 0.01$). MTRR measured on document IDs and evaluation data did also increase from 0.5422 to 0.6215 which is statistically significant at p¡0.02. Coverage went up from 78.68% to 81.62% on evaluation data and the redundancy was improved from 3.824 to 4.272 (significance tests have not been carried out). Finally, the QA performance using Joost with only the IR based strategy was increased from 0.289 (using CLEF scores) to 0.331. This, however, is not statistically significant according to the Wilcoxon test and may be due to chance.

Table 3: Optimized parameters (3200 settings)

weighted keywords			required keywords	
layer	restriction	weight	layer	restriction
text		7.43	root	name
text	name	11.94

nePER		0.91		

Table 3 shows the features and weights selected in the training process. The largest weights are given to names in the text layer, to root forms of names in modifier relations and to plain text adjectives. Many keyword types use 'name' or 'noun' as POS restriction. A surprisingly large number of keyword types are marked as required. Some of them overlap with each other and are therefore redundant. For example, all RootPOS keywords are marked as required and therefore, the restrictions of RootPOS keywords are useless because they do not alter the query. However, in other cases overlapping keyword type definitions do influence the query. For example, RootRel keywords in general are marked as required. However, other type definitions replace some of them with weighted keywords, e.g., RootRel noun keywords. Finally, some of them may be changed back to required keywords, e.g., RootRel keywords of nouns in a modifier relation.

6 Conclusions

In this paper we describe an approach for integrating linguistic information derived from dependency analyses in passage retrieval for question answering. Our retrieval component uses a multi-layer index containing various combinations of linguistic features and syntactic units extracted from a fully analyzed corpus of unrestricted Dutch text. Natural language questions are parsed in the same way. Their analyses are used to build complex queries to our extended index. We demonstrated a genetic algorithm for optimizing query parameters to improve the retrieval performance. The system was trained on questions from the CLEF competition on open-domain question answering for Dutch which are annotated with corresponding answers in the corpus. We could show a significant improvement of about 15% in mean total reciprocal rank using extended queries with optimized parameters compared with the base-line of traditional information retrieval using plain text keywords.

Abstract

MIT's Audio Notebook added great value to the note-taking process by retaining audio recordings, e.g. during lectures or interviews. The key was to provide users ways to quickly and easily access portions of interest in a recording. Several non-speech-recognition based techniques were employed. In this paper we present a system to search directly the audio recordings by key phrases. We have identified the user requirements as accurate ranking of phrase matches, domain independence, and reasonable response time. We address these requirements by a hybrid word/phoneme search in lattices, and a supporting indexing scheme. We will introduce the ranking criterion, a unified hybrid posterior-lattice representation, and the indexing algorithm for hybrid lattices. We present results for five different recording sets, including meetings, telephone conversations, and interviews. Our results show an average search accuracy of 84%, which is dramatically better than a direct search in speech recognition transcripts (less than 40% search accuracy).

1 Introduction

Lisa Stifelman proposed in her thesis the idea of the "Audio Notebook," where audio recordings of lectures and interviews are retained along with the notes (Stifelman, 1997). She has shown that the audio recordings are valuable to users if portions of interest can be accessed quickly and easily.

Stifelman explored various techniques for this, including user-activity based techniques (most noteworthy time-stamping notes so they can serve as an index into the recording) and content-based ones (signal processing for accelerated playback, "snap-to-grid" (=phrase boundary) based on prosodic cues). The latter are intended for situations where the former fail, e.g. when the user has no time for taking notes, does not wish to pay attention to it, or cannot keep up with complex subject matter, and as a consequence the audio is left without index. In this paper, we investigate technologies for searching the *spoken content* of the audio recording.

Several approaches have been reported in the literature for the problem of indexing spoken words in audio recordings. The TREC (Text REtrieval Conference) Spoken-Document Retrieval (SDR) track has fostered research on audio-retrieval of broadcast-news clips. Most TREC benchmarking systems use broadcast-news recognizers to generate approximate transcripts, and apply text-based information retrieval to these. They achieve retrieval accuracy similar to using human reference transcripts, and ad-hoc retrieval for broadcast news is considered a "solved problem" (Garofolo, 2000). Noteworthy are the rather low word-error rates (20%) in the TREC evaluations, and that recognition errors did not lead to catastrophic failures due to redundancy of news segments and queries.

However, in our scenario, requirements are rather different. First, word-error rates are much higher (40-60%). Directly searching such inaccurate speech recognition transcripts suffers from a poor recall. Second, unlike broadcast-news material, user recordings of conversations will not be limited to a few specific domains. This not only poses difficulties for obtaining domain-specific training data, but also implies an unlimited vocabulary of query phrases users want to use. Third, audio recordings will accumulate. When the audio database grows to hundreds or even thousands of hours, a reasonable response time is still needed.

A successful way to deal with high word error rates is the use of recognition alternates (lattices). For example, (Seide and Yu, 2004; Yu and Seide, 2004) reports a substantial 50% improvement of FOM (Figure Of Merit) for a word-spotting task in voicemails. Improvements from using lattices were also reported by (Saraclar and Sproat, 2004) and (Chelba and Acero, 2005).

To address the problem of domain independence, a subword-based approach is needed. In (Logan, 2002) the authors address the problem by indexing phonetic or word-fragment based transcriptions. Similar approaches, e.g. using overlapping M-grams of phonemes, are discussed in (Schäuble, 1995) and (Ng, 2000). (James and Young, 1994) introduces the approach of searching phoneme lattices. (Clements, 2001) proposes a similar idea called "phonetic search track." In previous work (Seide and Yu, 2004), promising results were obtained with phonetic lattice search in voicemails. In (Yu and

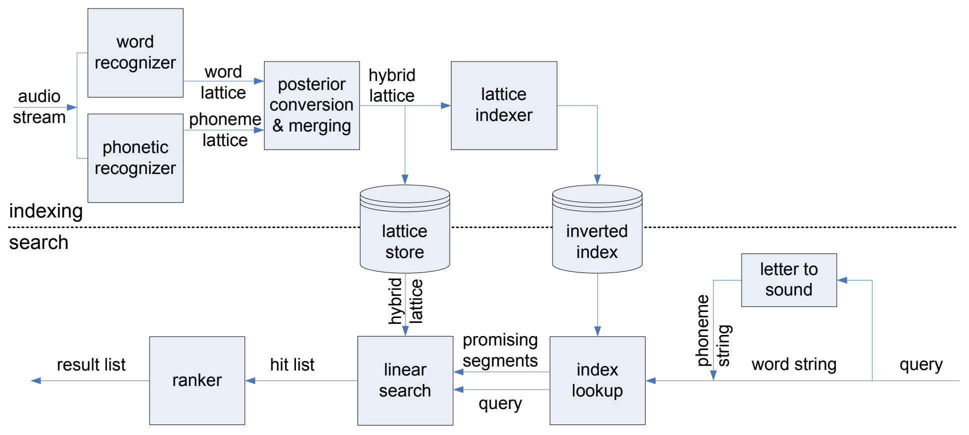

Figure 1: System architecture.

Seide, 2004), it was found that even better result can be achieved by combining a phonetic search with a word-level search.

For the third problem, quick response time is commonly achieved by indexing techniques. However, in the context of phonetic lattice search, the concept of "indexing" becomes a non-trivial problem, because due to the unknown-word nature, we need to deal with an open set of index keys. (Saraclar and Sproat, 2004) proposes to store the individual lattice arcs (inverting the lattice). (Allauzen *et al.*, 2004) introduces a general indexation framework by indexing expected term frequencies ("expected counts") instead of each individual keyword occurrence or lattice arcs. In (Yu *et al.*, 2005), a similar idea of indexing expected term frequencies is proposed, suggesting to approximate expected term frequencies by M-*gram phoneme language models* estimated on segments of audio.

In this paper, we combine previous work on phonetic lattice search, hybrid search and lattice indexing into a real system for searching recorded conversations that achieves high accuracy and can handle hundreds of hours of audio. The main contributions of this paper are: a real system for searching conversational speech, a novel method for combining phoneme and word lattices, and experimental results for searching recorded conversations.

The paper is organized as follows. Section 2 gives an overview of the system. Section 3 introduces the overall criterion, based on which the system is developed, Section 4 introduces our implementation for a hybrid word/phoneme search system, and Section 5 discusses the lattice indexing mechanism. Section 6 presents the experimental results, and Section 7 concludes.

2 A System For Searching Conversations

A system for searching the spoken content of recorded conversations has several distinct properties. Users are searching their own meetings, so most searches will be known-item searches with at most a few correct hits in the archive. Users will often search for specific phrases that they remember, possibly with boolean operators. Relevance weighting of individual query terms is less of an issue in this scenario.

We identified three user requirements:

- high recall and accurate ranking of phrase matches;
- domain independence – it should work for any topic, ideally without need to adapt vocabularies or language models;
- reasonable response time – a few seconds at most, independent of the size of the conversation archive.

We address them as follows. First, to increase recall we search *recognition alternates* based on *lattices*. Lattice oracle word-error rates[1] are significantly lower than word-error rates of the best path. For example, (Chelba and Acero, 2005) reports a lattice oracle error rate of 22% for lecture recordings at a top-1 word-error rate of 45%[2]. To utilize recognizer scores in the lattices, we formulating the ranking problem as one of risk minimization and derive that keyword hits should be ranked by their *word (phrase) posterior probabilities*.

Second, domain independence is achieved by combining large-vocabulary recognition with a phonetic search. This helps especially for proper names and specialized terminology, which are often either missing in the vocabulary or not well-predicted by the language model.

Third, to achieve quick response time, we use an M-gram based indexing approach. It has two stages, where the first stage is a fast index lookup to create a short-list of candidate lattices. In the second stage, a detailed lattice match is applied to the lattices in the short-list. We call the second stage *linear search* because search time grows linearly with the duration of the lattices searched.

[1]The "oracle word-error rate" of a lattice is the word error rate of the path through the lattice that has the least errors.

[2]Note that this comparison was for a reasonably well-tuned recognizer setup. Any arbitrary lattice oracle error rate can be obtained by adjusting the recognizer's pruning setup and investing enough computation time (plus possibly adapting the search-space organization).

The resulting system architecture is shown in Fig. 1. In the following three sections, we will discuss our solutions in these three aspects in details respectively.

3 Ranking Criterion

For ranking search results according to "relevance" to the user's query, several relevance measures have been proposed in the text-retrieval literature. The key element of these measures is weighting the contribution of individual keywords to the relevance-ranking score. Unfortunately, text ranking criteria are not directly applicable to retrieval of speech because recognition alternates and confidence scores are not considered.

Luckily, this is less of an issue in our known-item style search, because the simplest of relevance measures can be used: A search hit is assumed relevant if the query phrase was indeed said there (and fulfills optional boolean constraints), and it is not relevant otherwise.

This simple relevance measure, combined with a variant of the *probability ranking principle* (Robertson, 1977), leads to a system where phrase hits are ranked by their phrase posterior probability. This is derived through a Bayes-risk minimizing approach as follows:

1. Let the relevance be $R(Q, \mathrm{hit}^i)$ of a returned audio hit – hit^i to a user's query Q formally defined is 1 (match) if the hit is an occurrence of the query term with time boundaries $(t_s^{\mathrm{hit}^i}, t_e^{\mathrm{hit}^i})$, or 0 if not.

2. The user expects the system to return a list of audio hits, ranked such that the *accumulative relevance* of the top n hits $(\mathrm{hit}^1 ... \mathrm{hit}^n)$, averaged over a range of $n = 1...n_{\max}$, is maximal:
$$\frac{1}{n_{\max}} \sum_{n=1}^{n_{\max}} \sum_{i=1}^{n} R(Q, \mathrm{hit}^i) \quad \overset{!}{=} \quad \max . \qquad (1)$$
Note that this is closely related to popular word-spotting metrics, such as the NIST (National Institute of Standards & Technology) Figure Of Merit.

To the retrieval system, the true transcription of each audio file is unknown, so it must maximize Eq. (1) in the sense of an expected value

$$E_{WT|O}\left\{ \frac{1}{n_{\max}} \sum_{n=1}^{n_{\max}} \sum_{i=1}^{n} R_{WT}(Q, \mathrm{hit}^i) \right\} \quad \overset{!}{=} \quad \max,$$

where O denotes the totality of all audio files (O for observation), $W = (w_1, w_2, ..., w_N)$ a hypothesized transcription of the entire collection, and $T = (t_1, t_2, ..., t_{N+1})$ the associated time boundaries on a shared collection-wide time axis.

$R_{WT}(\cdot)$ shall be relevance w.r.t. the hypothesized transcription and alignment. The expected value is taken w.r.t. the posterior probability distribution $P(WT|O)$ provided by our speech recognizer in the form of scored lattices. It is easy to see that this expression is maximal if the hits are ranked by their expected relevance $E_{WT|O}\{R_{WT}(Q, \mathrm{hit}^i)\}$. In our definition of relevance, $R_{WT}(Q, \mathrm{hit}^i)$ is written as

$$R_{WT}(Q, \mathrm{hit}^i) \quad = \quad \begin{cases} 1 & \exists k, l : t_k = t_s^{\mathrm{hit}^i} \\ & \quad \wedge t_{k+l} = t_e^{\mathrm{hit}^i} \\ & \quad \wedge w_k, ..., w_{k+l-1} = Q \\ 0 & \text{otherwise} \end{cases}$$

and the expected relevance is computed as

$$\begin{aligned} E_{WT|O}\{R_{WT}(Q, \mathrm{hit}^i)\} &= \sum_{WT} R_{WT}(Q, \mathrm{hit}^i) P(WT|O) \\ &= P(*, t_s^{\mathrm{hit}^i}, Q, t_e^{\mathrm{hit}^i}, *|O) \end{aligned}$$

with

$$P(*, t_s, Q, t_e, *|O) \quad = \sum_{\substack{WT:\exists k,l:t_k=t_s \wedge t_{k+l}=t_e \\ \wedge w_k,...,w_{k+l-1}=Q}} P(WT|O). \qquad (2)$$

For single-word queries, this is the well-known *word posterior probability* (Wessel *et al.*, 2000; Evermann *et al.*, 2000). To cover multi-label phrase queries, we will call it *phrase posterior probability*.

The formalism in this section is applicable to all sorts of units, such as fragments, syllables, or words. The transcription W and its units w_k, as well as the query string Q, should be understood in this sense. For a regular word-level search, W and Q are just *strings of words* In the context of phonetic search, W and Q are *strings of phonemes*. For simplicity of notation, we have excluded the issue of multiple pronunciations of a word. Eq. (2) can be trivially extended by summing up over all alternative pronunciations of the query. And in a hybrid search, there would be multiple representations of the query, which are just as pronunciation variants.

4 Word/Phoneme Hybrid Search

For a combined word and phoneme based search, two problems need to be considered:

- Recognizer configuration. While established solutions exist for word-lattice generation, what needs to be done for generating high-quality phoneme lattices?
- How should word and phoneme lattices be jointly represented for the purpose of search, and how should they be searched?

4.1 Speech Recognition

4.1.1 Large-Vocabulary Recognition

Word lattices are generated by a common speaker-independent large-vocabulary recognizer. Because the speaking style of conversations is very different from, say, your average speech dictation system, specialized acoustic models are used. These are trained on conversational speech to match the speaking style. The vocabulary and the trigram language model are designed to cover a broad range of topics.

The drawback of large-vocabulary recognition is, of course, that it is infeasible to have the vocabulary cover all possible keywords that a user may use, particularly proper names and specialized terminology.

One way to address this *out-of-vocabulary problem* is to mine the user's documents or e-mails to adapt the recognizer's vocabulary. While this is workable for some scenarios, it is not a good solution e.g. when new words are frequently introduced in the conversations themselves rather than preceding written conversations, where the spelling of a new word is not obvious and thus inconsistent, or when documents with related documents are not easily available on the user's hard disk but would have to be specifically gathered by the user.

A second problem is that the performance of state-of-the-art speech recognition relies heavily on a well-trained domain-matched language model. Mining user data can only yield a comparably small amount of training data. Adapting a language model with it would barely yield a robust language model for newly learned words, and their usage style may differ in conversational speech.

For the above reasons, we decided not to attempt to adapt vocabulary and language model. Instead, we use a fixed broad-domain vocabulary and language model for large-vocabulary recognition, and augment this system with maintenance-free *phonetic search* to cover new words and mismatched domains.

4.1.2 Phonetic Recognition

The simplest phonetic recognizer is a regular recognizer with the vocabulary replaced by the list of phonemes of the language, and the language model replaced by a phoneme M-gram. However, such phonetic language model is much weaker than a word language model. This results in poor accuracy and inefficient search.

Instead, our recognizer uses "phonetic word fragments" (groups of phonemes similar to syllables or half-syllables) as its vocabulary and in the language model. This provides phonotactic constraints for efficient decoding and accurate phoneme-boundary decisions, while remaining independent of any specific vocabulary. A set of about 600 fragments was automatically derived from the language-model training set by a bottom-up grouping procedure (Klakow, 1998; Ng, 2000; Seide and Yu, 2004). Example fragments are /-k-ih-ng/ (the syllable -*king*), /ih-n-t-ax-r-/ (*inter-*), and /ih-z/ (the word *is*).

With this, lattices are generated using the common Viterbi decoder with word-pair approximation (Schwartz *et al.*, 1994; Ortmanns *et al.*, 1996). The decoder has been modified to keep track of individual phoneme boundaries and scores. These are recorded in the lattices, while fragment-boundary information is discarded. This way, phoneme lattices are generated.

In the results section we will see that, even with a well-trained domain-matching word-level language model, searching phoneme lattices can yield search accuracies comparable with word-level search, and that the best performance is achieved by combining both into a hybrid word/phoneme system.

4.2 Unified Hybrid Lattice Representation

Combining word and phonetic search is desirable because they are complementary: Word-based search yields better precision, but has a recall issue for unknown and rare words, while phonetic search has very good recall but suffers from poor precision especially for short words.

Combining the two is not trivial. Several strategies are discussed in (Yu and Seide, 2004), including using a hybrid recognizer, combining lattices from two separate recognizers, and combining the results of two separate systems. Both hybrid recognizer configuration and lattice combination turned out difficult because of the different dynamic range of scores in word and phonetic paths.

We found it beneficial to convert both lattices into posterior-based representations called *posterior lattices* first, which are then merged into a hybrid posterior lattice. Search is performed in a hybrid lattice in a unified manner using both phonetic and word representations as "alternative pronunciation" of the query, and summing up the resulting phrase posteriors.

Posterior lattices are like regular lattices, except that they do not store acoustic likelihoods, language model probabilities, and precomputed forward/backward probabilities, but *arc and node posteriors*. An arc's posterior is the probability that the arc (with its associated word or phoneme hypothesis) lies on the correct path, while a node posterior is the probability that the correct path connects two word/phoneme hypotheses through this node. In our actual system, a node is only associated with a point in time, and the node posterior is the probability of having a word or phoneme boundary at its associated time point.

The inclusion of node posteriors, which to our knowledge is a novel contribution of this paper, makes an exact computation of phrase posteriors from posterior lattices possible. In the following we will explain this in detail.

4.2.1 Arc and Node Posteriors

A lattice $\mathcal{L} = (\mathcal{N}, \mathcal{A}, n_{\text{start}}, n_{\text{end}})$ is a directed acyclic graph (DAG) with $\mathcal{N}$ being the set of nodes, $\mathcal{A}$ is the set of arcs, and n_{start}, $n_{\text{end}} \in \mathcal{N}$ being the unique initial and unique final node, respectively. Nodes represent times and possibly context conditions, while arcs represent word or phoneme hypotheses.[3]

Each node $n \in \mathcal{N}$ has an associated time $t[n]$ and possibly an acoustic or language-model context condition. Arcs are 4-tuples $a = (S[a], E[a], I[a], w[a])$. $S[a]$, $E[a]$

[3]Alternative definitions of lattices are possible, e.g. nodes representing words and arcs representing word transitions.

$\in \mathcal{N}$ denote the start and end node of the arc. $I[a]$ is the arc label[4], which is either a word (in word lattices) or a phoneme (in phonetic lattices). Last, $w[a]$ shall be a weight assigned to the arc by the recognizer. Specifically, $w[a] = p_{\text{ac}}(a)^{1/\lambda} \cdot P_{\text{LM}}(a)$ with acoustic likelihood $p_{\text{ac}}(a)$, language model probability P_{LM}, and language-model weight λ.

In addition, we define *paths* $\pi = (a_1, \cdots, a_K)$ as *sequences* of connected arcs. We use the symbols S, E, I, and w for paths as well to represent the respective properties for entire paths, i.e. the path start node $S[\pi] = S[a_1]$, path end node $E[\pi] = E[a_K]$, path label sequence $I[\pi] = (I[a_1], \cdots, I[a_K])$, and total path weight $w[\pi] = \prod_{k=1}^{K} w[a_k]$.

Finally, we define $\Pi(n_1, n_2)$ as the entirety of all paths that start at node n_1 and end in node n_2: $\Pi(n_1, n_2) = \{\pi | S[\pi] = n_1 \wedge E[\pi] = n_2\}$.

With this, the phrase posteriors defined in Eq. 2 can be written as follows.

In the simplest case, Q is a single word token. Then, the phrase posterior is just the word posterior and, as shown in e.g. (Wessel *et al.*, 2000) or (Evermann *et al.*, 2000), can be computed as

$$\begin{aligned} P(*, t_s, Q, t_e, *|O) &= \frac{\sum\limits_{\substack{\pi=(a_1,\cdots,a_K) \in \Pi(n_{\text{start}}, n_{\text{end}}): \\ \exists l: [S[a_l]] = t_s \wedge t[E[a_l]] = t_e \wedge I[a_l] = Q}} w[\pi]}{\sum\limits_{\pi \in \Pi(n_{\text{start}}, n_{\text{end}})} w[\pi]} \\ &= \sum_{\substack{a \in \mathcal{A}: t[S[a]] = t_s \\ \wedge t[E[a]] = t_e \wedge I[a] = Q}} P_{\text{arc}}[a] \qquad (3) \end{aligned}$$

with $P_{\text{arc}}[a]$ being the *arc posterior* defined as

$$P_{\text{arc}}[a] = \frac{\alpha_{S[a]} \cdot w[a] \cdot \beta_{E[a]}}{\alpha_{n_{\text{end}}}}$$

with the *forward/backward probabilities* α_n and β_n defined as:

$$\begin{aligned} \alpha_n &= \sum_{\pi \in \Pi(n_{\text{start}}, n)} w[\pi] \\ \beta_n &= \sum_{\pi \in \Pi(n, n_{\text{end}})} w[\pi]. \end{aligned}$$

α_n and β_n can conveniently be computed from the word lattices by the well-known forward/backward recursion:

$$\begin{aligned} \alpha_n &= \begin{cases} 1.0 & n = n_{\text{start}} \\ \sum\limits_{a: E[a] = n} \alpha_{S[a]} \cdot w[a] & \text{otherwise} \end{cases} \\ \beta_n &= \begin{cases} 1.0 & n = n_{\text{end}} \\ \sum\limits_{a: S[a] = n} w[a] \cdot \beta_{E[a]} & \text{otherwise.} \end{cases} \end{aligned}$$

[4]Lattices are often interpreted as weighted finite-state acceptors, where the arc labels are the *input symbols*, hence the symbol I.

Now, in the general case of multi-label queries, the phrase posterior can be computed as

$$\begin{aligned} &P(*, t_s, Q, t_e, *|O) \\ &= \sum_{\substack{\pi=(a_1,\cdots,a_K): \\ t[S[\pi]] = t_s \wedge t[E[\pi]] = t_e \wedge I[\pi] = Q}} \frac{P_{\text{arc}}[a_1] \cdots P_{\text{arc}}[a_K]}{P_{\text{node}}[S[a_2]] \cdots P_{\text{node}}[S[a_K]]} \end{aligned}$$

with $P_{\text{node}}[n]$, the *node posterior*[5], defined as

$$P_{\text{node}}[n] = \frac{\alpha_n \cdot \beta_n}{\alpha_{n_{\text{end}}}}. \qquad (4)$$

4.2.2 Advantages of Posterior Lattices

The posterior-lattice representation has several advantages over traditional lattices. First, lattice storage is reduced because only one value (node posterior) needs to be stored per node instead of two (α, β)[6]. Second, node and arc posteriors have a smaller and similar dynamic range than α_n, β_n, and $w[a]$, which is beneficial when the values should be stored with a small number of bits.

Further, for the case of word-based search, the summation in Eq. 3 can also be precomputed by merging all lattice nodes that carry the same time label, and merging the corresponding arcs by summing up their arc posteriors. In such a "pinched" lattice, word posteriors for single-label queries can now be looked up directly. However, posteriors for multi-label strings cannot be computed precisely anymore. Our experiments have shown that the impact on ranking accuracy caused by this approximation is neglectable. Unfortunately, we have also found that the same is not true for phonetic search.

The most important advantage of posterior lattices for our system is that they provide a way of combining the word and phoneme lattices into a single structure – by simply merging their start nodes and their end nodes. This allows to implement hybrid queries in a single unified search, treating the phonetic and the word-based representation of the query as alternative pronunciations.

5 Lattice Indexing

Searching lattices is time-consuming. It is not feasible to search large amounts of audio. To deal with hundreds or even thousands of hours of audio, we need some form of inverted indexing mechanism.

This is comparably straight-forward when indexing text. It is also not difficult for indexing word lattices. In both case, the set of words to index is known. However, indexing phoneme lattices is very different, because theoretically any phoneme string could be an indexing item.

[5]Again, mind that in our lattice formulation word/phoneme hypotheses are represented by arcs, while nodes just represent connection points. The node posterior is the probability that the correct path passes through a connection point.

[6]Note, however, that storage for the traditional lattice can also be reduced to a single number per node by weight pushing (Saraclar and Sproat, 2004), using an algorithm that is very similar to the forward/backward procedure.

We address this by our M-gram lattice-indexing scheme. It was originally designed for phoneme lattices, but can be – and is actually – used in our system for indexing word lattices.

First, audio files are clipped into homogeneous segments. For an audio segment i, we define the *expected term frequency* (ETF) of a query string Q as summation of phrase posteriors of all hits in this segment:

$$\begin{aligned}\mathrm{ETF}_i(Q) &= \sum_{\forall t_s, t_e} P(*, t_s, Q, t_e, * | O^i) \\ &= \sum_{\pi \in \Pi^i : I[\pi] = Q} p[\pi]\end{aligned}$$

with Π^i being the set of all paths of segment i.

At indexing time, ETFs of a list of M-grams for each segment are calculated. They are stored in an inverted structure that allows retrieval by M-gram.

In search time, the ETFs of the query string are estimated by the so-called "M-gram approximation". In order to explain this concept, we need to first introduce $P(Q|O^i)$ – the probability of observing query string Q at any word boundary in the recording O^i. $P(Q|O^i)$ has a relationship with ETF as

$$\mathrm{ETF}_i(Q) = \tilde{N}_i \cdot P(Q|O^i)$$

with $\tilde{N}_i$ being the expected number of words in the segment i. It can also be computed as

$$\tilde{N}_i = \sum_{n \in \mathcal{N}_i} p[n],$$

where $\mathcal{N}_i$ is the node set for segment i.

Like the M-gram approximation in language-model theory, we approximate $P(Q|O^i)$ as

$$\begin{aligned}P(Q|O^i) &\approx \tilde{P}(Q|O^i) \\ &= \prod_{k=1}^{l} \tilde{P}(q_k | q_{k-M+1}, \cdots, q_{k-1}, O^i),\end{aligned}$$

while the right-hand items can be calculated from M-gram ETFs:

$$\begin{aligned}&\tilde{P}(q_k | q_{k-M+1}, \cdots, q_{k-1}, O^i) \\ &\quad = \frac{\mathrm{ETF}_i(q_{k-M+1}, \cdots, q_k)}{\mathrm{ETF}_i(q_{k-M+1}, \cdots, q_{k-1})}.\end{aligned}$$

The actual implementation uses only M-grams extracted from a large background dictionary, with a simple backoff strategy for unseen M-grams, see (Yu *et al.*, 2005) for details.

The resulting index is used in a two stage-search manner: The index itself is only used as the first stage to determine a short-list of promising segments that may contain the query. The second stage involves a linear lattice search to get final results.

Table 1: Test corpus summary.

test set	duration	#segments	keyword set (incl. OOV)
ICSI meetings	2.0h	429	1878 (96)
SWBD eval2000	3.6h	742	2420 (215)
SWBD rt03s	6.3h	1298	2325 (236)
interviews (phone)	1.1h	267	1057 (49)
interviews (lapel)	1.0h	244	1629 (107)

6 Results

6.1 Setup

We have evaluated our system on five different corpora of recorded conversations:

- one meeting corpus (NIST "RT04S" development data set, ICSI portion, (NIST, 2000-2004))
- two eval sets from the switchboard (SWBD) data collection ("eval 2000" and "RT03S", (NIST, 2000-2004))
- two in-house sets of interview recordings of about one hour each, one recorded over the telephone, and one using a single microphone mounted in the interviewee's lapel.

For each data set, a keyword list was selected by an automatic procedure (Seide and Yu, 2004). Words and multi-word phrases were selected from the reference transcriptions if they occurred in at most two segments. Example keywords are *overseas*, *olympics*, and *"automated accounting system"*. For the purpose of evaluation, those data sets are cut into segments of about 15 seconds each. The size of the corpora, their number of segments, and the size of the selected keyword set are given in Table 1.

The acoustic model we used is trained on 309h of the Switchboard corpus (SWBD-1). The LVCSR language model was trained on the transcriptions of the Switchboard training set, the ICSI-meeting training set, and the LDC Broadcast News 96 and 97 training sets. No dedicated training data was available for the in-house interview recordings. The recognition dictionary has 51388 words. The phonetic language model was trained on the phonetic version of the transcriptions of SWBD-1 and Broadcast News 96 plus about 87000 background dictionary entries, a total of 11.8 million phoneme tokens.

To measure the search accuracy, we use the "Figure Of Merit" (FOM) metric defined by NIST for word-spotting evaluations. In its original form, it is the average of detection/false-alarm curve taken over the range [0..10] false alarms per hour per keyword. Because manual word-level alignments of our test sets were not available, we modified the FOM such that a correct hit is a 15-second segment that contains the key phrase.

Besides FOM, we use a second metric – "Top Hit Precision" (THP), defined as the correct rate of the best ranked hit. If no hit is returned for an existing query term, it is counted as an error. Both of these metrics are relevant measures in our known-item search.

Table 2: Baseline transcription word-error rates (WER) as well as precision (P), recall (R), FOM and THP for searching the transcript.

test set	WER [%]	P [%]	R [%]	FOM [%]	THP [%]
ICSI meetings	44.1	80.6	43.8	43.6	43.6
SWBD eval2000	39.0	79.6	41.1	41.1	41.1

Top Hit Precision (THP) [%]			
ICSI meetings	67.2	65.0	78.7
SWBD eval2000	67.1	63.6	77.9
SWBD rt03s	59.6	59.1	71.7
interviews (phone)	55.7	64.4	73.1
interviews (lapel)	55.6	59.7	71.2
average	61.0	62.4	74.5
INV words only	64.5	62.4	75.3
OOV words only	0	60.5	60.5

6.2 Word/Phoneme Hybrid Search

Table 2 gives the LVSCR transcription word-error rates for each set. Almost all sets have a word-error rates above 40%. Searching those speech recognition transcriptions results in FOM and THP values below 40%.

Table 3 gives results of searching in word, phoneme, and hybrid lattices. First, for all test sets, word-lattice search is drastically better than transcription-only search.

Second, comparing word-lattice and phoneme-lattice search, phoneme lattices outperforms word lattices on all tests in terms of FOM. This is because phoneme lattice has better recall rate. For THP, word lattice search is slightly better except on the interview sets for which the language model is not well matched. Hybrid search leads to a substantial improvement over each (27.6% average FOM improvement and 16.2% average THP improvement over word lattice search). This demonstrates the complementary nature of word and phoneme search.

We also show results separately for known words (in-vocabulary, INV) and out-of-vocabulary words (OOV). Interestingly, even for known words, hybrid search leads to a significant improvement (get 22.0% for FOM and 16.7% for THP) compared to using word lattices only.

6.3 Effect of Node Posterior

In Section 4.2, we have shown that phrase posteriors can be computed from posterior lattices if they include both arc and node posteriors (Eq. 4). However, posterior representations of lattices found in literature only include word (arc) posteriors, and some posterior-based systems simply ignore the node-posterior term, e.g. (Chelba and Acero, 2005). In Table 4, we evaluate the impact on accuracy when this term is ignored. (In this experiment, we bypassed the index-lookup step, thus the numbers are slightly different from Table 3.)

We found that for word-level search, the effect of node posterior compensation is indeed neglectable. However, for phonetic search it is not: We observe a 4% relative FOM loss.

6.4 Index Lookup and Linear Search

Section 5 introduced a two-stage search approach using an M-gram based indexing scheme. How much accuracy is lost from incorrectly eliminating correct hits in the first (index-based) stage? Table 5 compares three setups. The first column shows results for linear search only: no index lookup used at all, a complete linear search is performed on all lattices. This search is optimal but does not scale up to large database. The second column shows index lookup *only*. Segments are ranked by the approximate M-gram based ETF score obtained from the index. The third column shows the two-stage results.

The index-based two-stage search is indeed very close to a full linear search (average FOM loss of 1.2% and THP loss of 0.2% points). A two-stage search takes under two seconds and is mostly independent of the database size. In other work, we have applied this technique successfully to search a database of nearly 200 hours.

6.5 The System

Fig. 2 shows a screenshot of a research prototype for a search-enabled audio notebook. In addition to a note-taking area (bottom) and recording controls, it includes a rich audio browser showing speaker segmentation and automatically identified speaker labels (both not scope of this paper). Results of keyword searches are shown as color highlights, which are clickable to start playback at that position.

7 Conclusion

In this paper, we have presented a system for searching recordings of conversational speech, particularly meet-

Table 4: Effect of ignoring the node-posterior term in phrase-posterior computation (shown for ICSI meeting set only).

FOM	word	phoneme
exact computation	72.1	82.3
node posterior ignored	72.0	79.2
relative change [%]	-0.1	-3.8

Table 5: Comparing the effect of lattice indexing. Shown is unindexed "linear search," index lookup only (segments selected via the index without subsequent linear search), and the combination of both.

test set	linear search	index lookup	two-stage
Figure Of Merit (FOM) [%]			
ICSI meetings	88.6	86.4	88.2
SWBD eval2000	88.7	86.5	87.3

interviews (phone)	83.8	81.2	83.3
interviews (lapel)	78.3	76.1	77.7
average	85.3	83.1	84.1
Top Hit Precision (THP) [%]			
ICSI meetings	78.8	70.7	78.7
SWBD eval2000	78.0	71.4	77.9
SWBD rt03s	71.9	65.7	71.7
interviews (phone)	73.8	64.6	73.1
interviews (lapel)	70.8	65.9	71.2
average	74.7	67.7	74.5

ings and telephone conversations. We identified user requirements as accurate ranking of phrase matches, domain independence, and reasonable response time. We have addressed these by hybrid word/phoneme lattice search and a supporting indexing scheme. Unlike many other spoken-document retrieval systems, we search recognition alternates instead of only speech recognition transcripts. This yields a significant improvement of keyword spotting accuracy. We have combined word-level search with phonetic search, which not only enables the system to handle the open-vocabulary problem, but also substantially improves in-vocabulary accuracy. We have proposed a posterior-lattice representation that allows for unified word and phoneme indexing and search. To speed up the search process, we proposed M-gram based lattice indexing, which extends our open vocabulary search ability for large collection of audio. Tested on five different recording sets including meetings, conversations, and interviews, a search accuracy (FOM) of 84% has been achieved – dramatically better than searching speech recognition transcripts (under 40%).

Abstract

Applying the noisy channel model to search query spelling correction requires an error model and a language model. Typically, the error model relies on a weighted string edit distance measure. The weights can be learned from pairs of misspelled words and their corrections. This paper investigates using the Expectation Maximization algorithm to learn edit distance weights directly from search query logs, without relying on a corpus of paired words.

1 Introduction

There are several sources of error in written language. Typing errors can be divided into two groups (Kucich, 1992): typographic errors and cognitive errors. Typographic errors are the result of mistyped keys and can be described in terms of keyboard key proximity. Cognitive errors on the other hand, are caused by a misunderstanding of the correct spelling of a word. They include phonetic errors, in which similar sounding letter sequences are substituted for the correct sequence; and homonym errors, in which a word is substituted for another word with the same pronunciation but a different meaning. Spelling errors can also be grouped into errors that result in another valid word, such as homonym errors, versus those errors that result in a non-word. Generally non-word errors are easier to detect and correct. In addition to its traditional use in word processing, spelling correction also has applications in optical character recognition and handwriting recognition. Spelling errors in this context are caused by inaccurate character recognition.

Spelling correction is a well developed research problem in the field of computational linguistics. The first dictionary based approach to spelling correction (Damerau, 1964) considers all words that can not be found in a dictionary as misspellings. The correct word is found by making a single edit operation (insertion, deletion, or substitution) on the misspelled word and re-checking the dictionary for the inclusion of the altered version. This method works well for correcting most typos, but often misspelled words are off by more than one character. A method of quantifying string-to-string distance is introduced in (Wagner and Fischer, 1974), allowing the consideration of multiple edit operations when determining candidate corrections. Each edit operation is assigned a fixed cost. Edit operations, though, can be more accurately modelled by considering every possible insertion, deletion, and substitution operation individually instead of having a fixed cost for each operation. For example, the application of probabilistic models to spelling correction is explored in (Kernighan, Church, and Gale, 1990), in which a confusion matrix describes the probability of each letter being substituted for another. The Bayesian noisy channel model is used to determine the the error probabilities, with the simplifying assumption that each word has at most one spelling error. In (Ristad and Yianilos, 1997), a probabilistic model of edit distance is learned from pairs of misspelled words and their corrections. This extends Kernighan's approach by allowing multiple edit operations rather than assuming a single edit. The probability of edit operations is learned from a corpus of pairs of misspelled words and corrections.

Search query correction is an interesting branch of spelling correction. Due to the wide variety of search queries, dictionary based spelling correction is not adequate for correcting search terms. The concept of using query logs to aid in spelling correction is explored in (Brill and Cucerzan, 2004). It is noted that using traditional Levenshtein distance as an error model can lead to inappropriate corrections, so a weighted distance measure is used instead.

This paper focuses on deriving a language model and probabilistic error model directly from search query logs without requiring a corpus of misspelled words paired with their corrections. The task of search query spelling correction is analyzed, and an implementation of the Expectation Maximization (EM) algorithm to learn an error model is described, with reference to similar approaches. In Section 2, the make-up of search queries is analyzed in the context of spelling correction. Section 3 details the noisy channel model spelling correction framework and describes how the EM algorithm is applied to learn an error model. The learned error model is explored in Section 4. The derived model is tested in Section 5 by comparing its performance in the single word spelling correction task to popular spell checking applications. Finally, conclusions and directions for future work are presented in Section 6.

2 Analysis of Search Queries

Search queries present a difficult challenge for traditional spelling correction algorithms. As mentioned above, dictionary-based approaches cannot be used since many search terms include words and names that are not well established in the language. Furthermore, search queries typically consist of a few key words rather than grammatically correct sentences, making grammar-based approaches inappropriate. In addition, spelling errors are more common in search queries than in regular written text, as approximately 10-15 % of search queries contain a misspelling (Brill and Cucerzan, 2004). The suitability of query logs as a corpus for spelling correction is investigated in this section.

The metaspy website[1] displays search queries submitted to the popular metacrawler search engine in real time. Over a period of five days in the last week of March 2005, 580,000 queries were extracted from the site. Several interesting observations can be made from the analysis of the search queries.

[1]www.metaspy.com

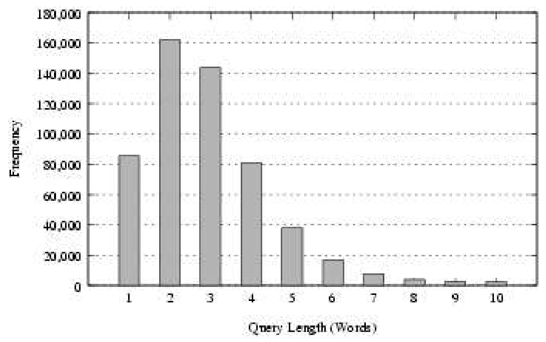

Figure 1: Query Length Frequency Histogram

2.1 Query Length

On average, each query consisted of approximately 3 words. Figure 1 shows the distribution of query lengths.

As illustrated in Figure 1, over 80% of queries include more than one search term. Thus word n-gram probabilities provide useful statistical knowledge that can be exploited to improve spelling correction. Although word cooccurrences are not used for spelling correction in this paper, the possibilities for n-gram analysis are explored in Section 3.2. The longer queries (>5 terms) often contain quotations, song lyric excerpts or very specific product names.

The frequency of words in written text has been shown to follow Zipf's law. That is, if the words are ordered in terms of frequency, the relationship between frequency and rank can be approximated with the following equation.

$$F \approx \frac{C}{r^m} \tag{1}$$

where F is the frequency, r is rank, C is a constant, and m is an exponent close to 1. In logarithmic form,

$$\log(F) = \log(C) - m * \log(r) \tag{2}$$

The frequency and rank of search query tokens approximately follow the same distribution, with some deviation at the high and low ends. Figure 2 shows the frequency distribution for dictionary and

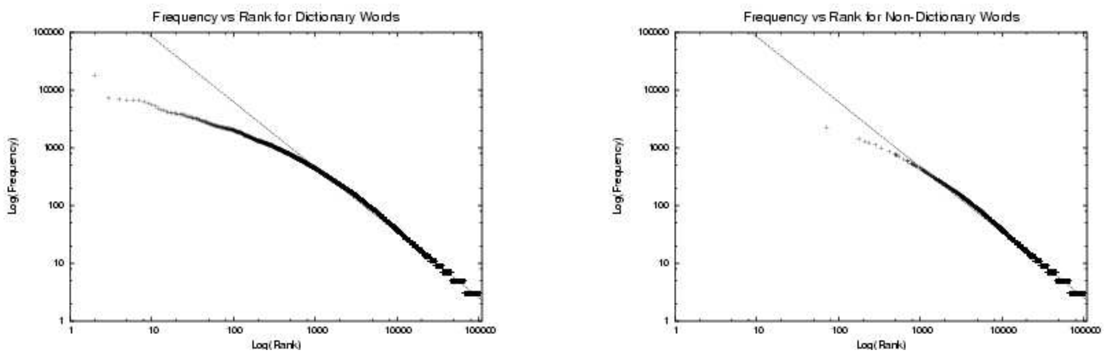

Figure 2: Token Frequency vs. Rank for Dictionary and Non-Dictionary Words

non-dictionary search query tokens. The word list available on most Unix systems */usr/dict/words* is a comprehensive list that contains 96,274 words, including names, plurals, verbs in several tenses, and colloquialisms. Following tokenization of the query logs, the tokens were divided into dictionary and non-dictionary words. The frequency-rank relationship is similar for both types of words, except that nearly all of the 100 most frequent query tokens are dictionary words. The exponent m, the (negative) slope of the linear best fit lines shown in Figure 2, was determined to be 1.11 for dictionary words, and 1.14 for non-dictionary words. As in (Baeza-Yates, 2005), the exponent is slightly higher than 1, partly due to the less frequent use of function words such as *the* in search queries relative to formal writing.

Although the majority of search tokens can be found in a standard dictionary, a large proportion of the less common queries are not dictionary words. In fact, 73% of unique word types were not found in the dictionary. Taking token frequency into consideration, these non-dictionary tokens account for approximately 20% of query search words, including correctly and incorrectly spelled words. However, the majority of the non-dictionary tokens are correctly spelled words, illustrating the unsuitability of traditional dictionary based spelling correction for search query correction.

What are these non-dictionary words? An analysis of the top two hundred non-dictionary words in the query logs allows categorization into a few main groups. The percentage of non-dictionary words belonging to each category, and some examples from each category are shown in Table 1. The first category, *e-speak*, includes words and abbreviations that are commonly used online, but have not crossed over into common language. This category includes words such as *pics, multiplayer*, and *clipart*. The second category is closely related to the first, and includes company and product names, such as *google, xbox*, and *hotmail*. Many of these terms refer to online entities or computer games. Incorrectly spelled words are another main class of non-dictionary tokens. Among the top 20 non-dictionary tokens are words with missing punctuation, such as *womens* and *childrens*, or with missing spaces, such as *realestate*. Names of people and locations are also common search queries, as well as medical terminology. Finally, foreign words make up another class of words that are not found in an (English) dictionary. The 20 highest frequency non-dictionary tokens from the extracted query logs are *pics, html, multiplayer, googletestad, google, xbox, childrens, ebay, angeles, hotmail, womens, ERBS, clipart, playstation, ratzinger, Ilios, lettre, realestate, tech* and *mallorca*.

	Word Class	**Percent**	**Examples**
1	E-speak & new words	45%	pics, html, multiplayer, clipart, mpeg, midi
2	Companies & Products	18%	google, xbox, ebay, hotmail , playstation
3	Proper Names	16%	(los) angeles, ratzinger, ilios, mallorca
4	Medical terms	5%	ERBS, mesothelioma, neuropsychological, alzheimers
5	Misspellings	9%	womens, realestate
6	Foreign Words	6%	lettre, para

Table 1: Classes of Non-Dictionary Words

3 Spelling Correction for Search Queries

The spelling correction problem can be considered in terms of the noisy channel model, which considers the misspelled word v to be a corrupted version of the correctly spelled word w.

$$P(w|v) = \frac{P(v|w)P(w)}{P(v)} \tag{3}$$

Finding the best candidate correction W involves maximizing the above probability.

$$W = argmax_w P(v|w)P(w) \tag{4}$$

The denominator $P(v)$ in Equation 3 is the same for all w and can be eliminated from the calculation. $P(v|w)$ models the errors that corrupt string w into string v, and $P(w)$ is the language model, or prior probability, of word w.

3.1 Error Model

Given two strings v and w, $P(v|w)$ is the probability that v is transmitted given that the desired word is w. One method of describing the noise model is to consider $P(v|w)$ to be proportional to the number of edit operations required to transform w into v. This gives

$$P(v|w) \propto ED(v, w) \tag{5}$$

where $ED(v, w)$ is the edit distance between v and w.

The traditional edit distance calculation assigns a fixed cost for each insertion, deletion, and substitution operation. For example, each insertion and deletion may be assigned a cost of 1, while substitutions are assigned a cost of 1.5. The edit distance calculation can be accomplished by dynamic programming.

The error model can be improved if each edit operation is considered separately, rather than assigning a fixed cost to each operation. For example, the substitution of the letter i for the letter e may be much more likely than k for e. Thus if a string S_1 differs from string S_2 by one $e \rightarrow i$ substitution, it should be considered more similar to S_2 than a string S_3 that differs from S_1 by an $e \rightarrow k$ substitution.

Generating an accurate error model that considers each edit operation individually requires learning edit distance weights. As described in (Ristad and Yianilos, 1997), character-to-character edit distance costs $ED(e)$ can be related to edit probability $P(e)$ by means of the equation:

$$ED(e) = -\log[P(e)] \tag{6}$$

where e is an edit operation consisting of a substitution of one alphanumeric character for another ($c_1 \rightarrow c_2$), an insertion ($\_ \rightarrow c_1$), or a deletion ($c_1 \rightarrow \_$).

Thus higher probability edits will have lower edit distances, and the string to string edit distance calculation proceeds in the same way as the traditional calculation. This convenient representation allows whole string-to-string edit probability to be expressed in terms of the edit distance of the edit sequence $[e_1 ... e_n]$:

$$\begin{aligned} P(w|v) &= \Pi P(e_i) \\ &= P(e_1) * P(e_2) * ... * P(e_n) \end{aligned} \tag{7}$$

Taking the log of both sides gives

$$\begin{aligned} \log[P(w|v)] =& \log[P(e_1)] + \log[P(e_2)] \\ & + ... + \log[P(e_n)] \end{aligned} \tag{8}$$

Finally, by combining 6 and 8 we can relate the probability of misspelling a string w as v to string-to-string edit distance.

$$\log[P(w|v)] = -ED(w, v) \tag{9}$$

The edit probabilities can be estimated using the expectation maximization (EM) algorithm as described in Section 3.3.

3.2 Language Model

Along with the error model, a language model is used to determine the most likely correction for every input query. Often, spelling correction programs use N-gram language models that use nearby words to help determine the most probable correction. For example, it is noted in (Brill and Cucerzan, 2004) that employing a trigram language model can substantially improve performance relative to a unigram model. However, if search query logs are not very large, bigram or trigram data may be too sparse to be helpful. Nevertheless, a word unigram model can be used for training the error model. The unigram model is determined by tokenizing the query logs and determining the frequency of each token. The language model $P(w)$ is the frequency of the word $C(w)$ divided by the total number of tokens N in the query log:

$$P(w) = \frac{C(w)}{N} \tag{10}$$

Add-One smoothing is used to account for words not present in query logs.

3.3 Determining Edit Probabilities with Expectation Maximization

The EM algorithm is used to determine the parameters of the probability distribution for a given a set of data. It can be considered to be a soft-clustering algorithm: given several data points, the task is to find the cluster parameters which best represent the data. The EM algorithm is applied iteratively to each data point in a two-step process; the expectation step determines the degree to which data agrees with each cluster/hypothesis, and the maximization step updates the parameters to reflect the inclusion of the new data.

Prior to running the EM algorithm, the edit distance table is seeded with initial values. The initialization stage assigns high probability (low edit distance) to characters being typed correctly, and a lower probability for character substitutions. For each character l, substitution distance is equally distributed over all other characters and the deletion operation ($l \rightarrow \_$). Specifically the initial probability for a character match was set to 90%, and the remaining 10% was equally distributed over the other 26 possible substitutions. Essentially, the first edit distance calculated in the EM algorithm will be equivalent to the fixed-weight Levenshtein distance. After this preprocessing stage, the edit probability matrix is iteratively improved with the E-Step and M-Step described below. The operation of the EM algorithm is illustrated in Figure 3.

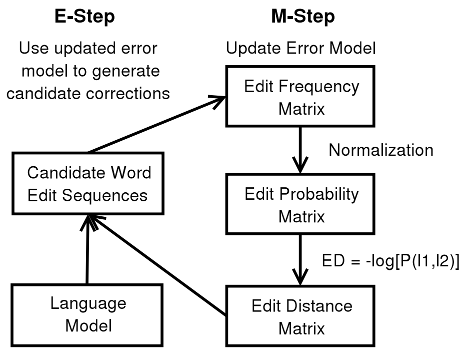

Figure 3: The EM process

For each query token, possible corrections are harvested from the query word list. The entire word list is searched, and any word within a threshold edit distance is considered as a candidate. Since the query logs can be quite large, determining the exact weighted edit distance between the input query and each logged query is quite computationally expensive. Instead, the candidate queries are first narrowed down using a fast approximate string matching algorithm (Wu and Manber, 1990) to determine all candidates within k unweighted edit operations. Then, the candidate queries that are within a second tighter threshold T, based on weighted edit distance, are kept.

$$Candidates(v) = \{w_i | ED(w_i, v) < T\}$$

Generally several words in the query logs will meet the above criteria. The threshold T is chosen to ensure the inclusion of all reasonable corrections, while maintaining a manageable computation time. If T were infinite, every query log token would need to be considered, taking too much time. On the other hand, if T is too small, some corrections may not be considered. In practice, K was set to 3 unweighted edits, and T was set as a constant proportion of word length.

The expectation of each candidate correction is the probability that the word w_i was desired given that the query was v:

$$P(w_i|v) = \frac{P(v|w_i)P(w_i)}{P(v)} \tag{11}$$

where $P(v|w)$ and $P(w)$ are determined using the error and language models described in Equations (9) and (10).

If the value of T is set high enough, it can be assumed that the correct word w is within the set of candidates. So, the sum of probabilities over all candidates is normalized to $P(v)$ in accordance with Bayes Rule of Total Probability.

$$P(v) = \Sigma_j P(v|w_j)P(w_j) \tag{12}$$

Correction	**Error Model**	**Language Model**	**Total Probability**	**Normalized**
equipment	0.0014	0.00078	1.1e-6	0.77
equpment	0.64	5.0e-7	3.4e-7	0.23
equipiment	0.0005	5.0e-7	1.0e-9	0.0005

Table 2: Candidate Corrections for *equpment*

This gives us the following formula for the expectation value

$$P(w_i|v) = \frac{P(v|w_i)P(w_i)}{\Sigma_j P(v|w_j)P(w_j)} \qquad (13)$$

The E-step is used to generate candidate corrections for input query tokens. For example, input query *"equpment"* returns the candidate corrections and their probabilities shown in Table 2.

Note that several incorrectly spelled words, including *"equpment"* itself, are given as candidate corrections. However, the language model derived from the query logs assigns a low probability to the incorrect candidates. In the case of a correctly spelled query, the most likely candidate correction is the word itself. However, occasionally there is a correctly spelled but infrequent word within a small edit distance of another more common word. In this case, the language model will bias the correction probability in favor of an incorrect edit. Nevertheless, overall these cases do not seem to cause a significant impact on the error model except in the case of plural nouns as discussed in Section 4.

The maximization step updates the edit distance probabilities and edit distance table to reflect the query considered in the E-Step. For each candidate correction, the required edits are added to the edit frequency table, weighted by the probability of the correction. Then, the probability of an edit for each character is normalized to 1 and the edit probabilities are stored in a table. Finally, Equation 6 is used to generate the edit probability table. For example, for the input query *"equpment"* in response to the first candidate correction ($equpment \rightarrow equipment$), the following substitution frequencies will each be incremented by 0.77: $e \rightarrow e, q \rightarrow q, u \rightarrow u, i \rightarrow \_, p \rightarrow p, m \rightarrow m, e \rightarrow e, n \rightarrow n, t \rightarrow t$. The ($i \rightarrow \_$) edit represents deletion of the letter i.

Letter	**Subs**	**Letter**	**Subs**
a	e_qo	n	_fkb
b	grnw	o	a_ei
c	_ksm	p	nfrm

j	blhm	w	prgk
k	vots	x	gtms
l	r_is	y	ioaje
m	nkvs	z	skmt

Table 3: Most Common Substitutions

4 The Learned Error Model

Approximately 580,000 queries were extracted from the metaspy site over a period of 5 days. After generating a language model by analyzing token frequencies, the EM algorithm was run on a subset of the queries to find the edit probability matrix.

After 15,000 iterations, several patterns can be observed in the edit distance table. The most common edit operations are shown in Table 3. As expected, vowels are most commonly substituted for other vowels. As can be seen in the table, vowel-to-vowel edits are more probable than vowel-to-consonant transitions. The letter e is most commonly mistyped as a, o, and i; the letter i is most often mistyped as a, u, and e. For the most part, vowel substitutions can be considered to be cognitive errors (except $o \rightarrow i$ may be a cognitive error or typographic error). The effect of keyboard key proximity is also evident; b is often typed as g; d as s; m as n; and so on. Other errors seem to be a result of phonetic similarity; c is misspelled as k and s; q as g and k; and v as w. In general, the edit probabilities roughly match those derived using a corpus of word pairs in (Kernighan, Church, and Gale, 1990).

The insertion probabilities for each letter are shown in Figure 4. Equation 6 is used to convert the edit distances to probabilities. Words in the plural form cause problems for the algorithm, as is illustrated by the high probability of s insertion in Fig-

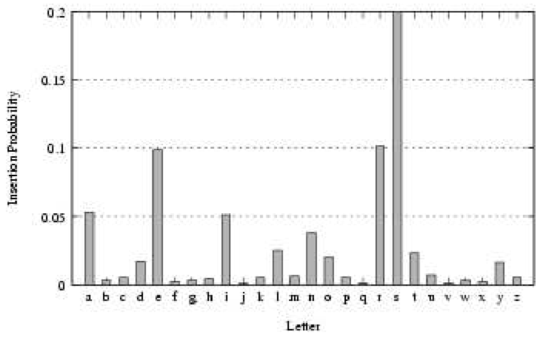

Figure 4: Letter Insertion Probabilities

Spell Checker	ISPELL 3.1.20	ASPELL 0.29	EMBED	Google
Total Tokens	508	508	508	508
Total Found	272 (53.5%)	480 (94.5%)	402 (79.1%)	-
Top 1 (%)	197 (38.8%)	302 (59.5%)	211 (41.5%)	291 (57%)
Top 5 (%)	260 (51.2%)	435 (85.6%)	331 (65.2%)	-
Top 25 (%)	272 (53.5%)	478 (94.1%)	386 (76.0%)	-

Table 4: Spelling Correction Accuracy

ure 4. That is because high frequency query words often appear in both singular and plural form. Every time the singular form is encountered, the plural is considered as a viable candidate correction, and the s insertion probability is increased. Complementarily, every time the plural form is seen, the singular form is considered, increasing the s deletion probability. Indeed, as can be seen in Table 3, deletion is the highest probability operation for the letter s.

5 Testing

To test the accuracy of the error model, the well-known Unix based spelling correction programs *Ispell*[2] and *Aspell*[3] spell checking programs were used for comparison. Ispell generates candidate corrections by considering all words within 1 edit of the misspelled word. *Aspell* uses the *metaphone* algorithm (Philips, 1990), which divides English words into phonetic segments, and generates alternate spellings by substituting similar sounding phones. The test data set[4] consists of 547 misspelled words paired with their best correction as determined by a human expert.Compound words were removed from the test set, leaving 508 misspellings. Several of the misspellings differ from the correction by multiple edit operations. Only the error model learned by the EM algorithm on the search engine queries was used; instead of using the probabilistic language model derived from the query logs and used for training, the word list in */usr/dict/words* was used, with equal probability assigned to each word. Since the test data is composed of single words of varying prevalence, a language model does not significantly aid correction. In practice, the language model would improve performance.

Table 4 compares the performance of the *Aspell* and *Ispell* spell checkers with the Expectation Maximization Based Edit Distance (EMBED) spelling correction system described in this paper. The percentages refer to the percentage of instances in which the correct correction was within the top N suggestions given by the algorithm. If only the top recommended correction is considered, EMBED fares better than *Ispell*, but worse than *Aspell*. For the top 5 and 25 corrections, the rankings of the algorithms are the same.

As Table 4 shows, in several cases the EMBED algorithm did not find the correction within the top 25 suggestions. Typically, the misspellings that could not be found had large edit distances from their corrections. For example, suggestions for the misspelling ”extions” included ”actions” and ”motions” but not the desired correction ”extensions”. In general, by using a phonetic model to compress English words, *Aspell* can find misspellings that have larger edit distances from their correction. However, it relies on a language specific pronunciation model that is manually derived. EM based spelling correction, on the other hand, can be learned from a unlabeled corpus and can be applied to other languages without modification. Although the test data set was comprised of misspelled dictionary words for the purposes of comparison, the spelling correction system described here can handle a continuously evolving vocabulary. Also, the approach described here can be used to train more general error models.

[2]International Ispell Version 3.1.20. http://www.lasr.cs.ucla.edu/geoff/ispell.html

[3]Kevin Atkinson. Aspell Version 0.29. http://aspell.sourceforge.net/

[4]Kevin Atkinson. http://aspell.net/test/

Comparison to online spelling suggestion systems such as provided by the *Google* search engine is difficult since search results are returned for nearly every query on account of the large lexicon. Consequently, many suggestions provided by *Google* are reasonable, but do not correspond to the golden standard in the test data. For example, ”cimplicity” and ”hallo” are not considered misspellings since several online companies and products contain these terms, and ”verison” is corrected to ”verizon” rather than ”version.” While *Google* returns 291 corrections in agreement with the data set (57%), another 44 were judged to be acceptable corrections, giving an accuracy of 66%. In addition, several of the apparently misspelled test strings are new words, proper names, or commonly accepted alternate spellings that are common on the web, so no suggestions were given. Taking these words into account would further improve the accuracy rating.

6 Conclusions and Future Work

The EM algorithm is able to learn an accurate error model without relying on a corpus of paired strings. The edit probabilities determined using the EM algorithm are similar to error models previously generated using other approaches. In addition, the generated error model can be used to find the correct spelling of misspelled words as described in Section 5. However, there are several improvements that can be made to improve spelling error correction. One step is increasing the size of the corpus. While the corpus included nearly 580,000 queries, several thousand of those queries were correctly spelled words without any misspelled versions in the corpus, or misspelled words without the correctly spelled version available. This results in the misidentification of candidate spelling corrections. Another improvement that can improve candidate correction identification is the use of better language models, as discussed in Section 3.2. Since a large proportion of queries contain more than one word, word n-gram statistics can be used to provide context sensitive spelling correction. Finally, a large proportion of typos involve letter transpositions, and other operations that can not be captured by a single-letter substitution model. In (Brill and Moore, 2000), a more general model allowing generic string to string edits is used, allowing many-to-one and one-to-many character substitution edits. Pronunciation modeling in (Toutanova and Moore, 2002) further improves spelling correction performance.

Abstract

Query expansion techniques generally select new query terms from a set of top ranked documents. Although a user's manual judgment of those documents would much help to select good expansion terms, it is difficult to get enough feedback from users in practical situations. In this paper we propose a query expansion technique which performs well even if a user notifies just a relevant document and a non-relevant document. In order to tackle this specific condition, we introduce two refinements to a well-known query expansion technique. One is application of a transductive learning technique in order to increase relevant documents. The other is a modified parameter estimation method which laps the predictions by multiple learning trials and try to differentiate the importance of candidate terms for expansion in relevant documents. Experimental results show that our technique outperforms some traditional query expansion methods in several evaluation measures.

1 Introduction

Query expansion is a simple but very useful technique to improve search performance by adding some terms to an initial query. While many query expansion techniques have been proposed so far, a standard method of performing is to use relevance information from a user (Ruthven, 2003). If we can use more relevant documents in query expansion, the likelihood of selecting query terms achieving high search improvement increases. However it is impractical to expect enough relevance information. Some researchers said that a user usually notifies few relevance feedback or nothing (Dumais and et al., 2003).

In this paper we investigate the potential performance of query expansion under the condition that we can utilize little relevance information, especially we only know a relevant document and a non-relevant document. To overcome the lack of relevance information, we tentatively increase the number of relevant documents by a machine learning technique called *Transductive Learning*. Compared with ordinal inductive learning approach, this learning technique works even if there is few training examples. In our case, we can use many documents in a hit-list, however we know the relevancy of few documents. When applying query expansion, we use those increased documents as if they were true relevant ones. When applying the learning, there occurs some difficult problems of parameter settings. We also try to provide a reasonable resolution for the problems and show the effectiveness of our proposed method in experiments.

The point of our query expansion method is that we focus on the availability of relevance information in practical situations. There are several researches which deal with this problem. Pseudo relevance feedback which assumes top n documents as relevant ones is one example. This method is simple and relatively effective if a search engine returns a hit-list which contains a certain number of relative documents in the upper part. However, unless this assumption holds, it usually gives a worse ranking than the initial search. Thus several researchers propose some specific procedure to make pseudo feedback be effective (Yu and et al, 2003; Lam-Adesina and Jones, 2001). In another way, Onoda (Onoda et al., 2004) tried to apply one-class SVM (Support Vector Machine) to relevance feedback. Their purpose is to improve search performance by using only non-relevant documents. Though their motivation is similar to ours in terms of applying a machine learning method to complement the lack of relevance information, the assumption is somewhat different. Our assumption is to utilizes manual but the minimum relevance judgment.

Transductive leaning has already been applied in the field of image retrieval (He and et al., 2004). In this research, they proposed a transductive method called the manifold-ranking algorithm and showed its effectiveness by comparing with active learning based Support Vector Machine. However, their setting of relevance judgment is not different from many other traditional researches. They fix the total number of images that are marked by a user to 20. As we have already claimed, this setting is not practical because most users feel that 20 is too much for judgment. We think none of research has not yet answered the question. For relevance judgment, most of the researches have adopted either of the following settings. One is the setting of "Enough relevant documents are available", and the other is "No relevant document is available". In contrast to them, we adopt the setting of "Only one relevant document is available". Our aim is to achieve performance improvement with the minimum effort of judging relevancy of documents.

The reminder of this paper is structured as follows. Section 2 describes two fundamental techniques for our query expansion method. Section 3 explains a technique to complement the smallness of manual relevance judgment. Section 4 introduces a whole procedure of our query expansion method step by step. Section 5 shows empirical evidence of the effectiveness of our method compared with two traditional query expansion methods. Section 6 investigates the experimental results more in detail. Finally, Section 7 summarizes our findings.

2 Basic Methods

2.1 Query Expansion

So far, many query expansion techniques have been proposed. While some techniques focus on the domain specific search which prepares expansion terms in advance using some domain specific training documents (Flake and et al, 2002; Oyama and et al, 2001), most of techniques are based on relevance feedback which is given automatically or manually.

In this technique, expansion terms are selected from relevant documents by a scoring function. The Robertson's *wpq* method (Ruthven, 2003) is often used as such a scoring function in many researches (Yu and et al, 2003; Lam-Adesina and Jones, 2001). We also use it as our basic scoring function. It calculates the score of each term by the following formula.

$$wpq_t = \left(\frac{r_t}{R} - \frac{n_t - r_t}{N - R}\right) * \log \frac{r_t/(R - r_t)}{(n_t - r_t)/(N - n_t - R + r_t)} \quad (1)$$

where r_t is the number of seen relevant documents containing term t. n_t is the number of documents containing t. R is the number of seen relevant documents for a query. N is the number of documents in the collection. The second term of this formula is called the Robertson/Spark Jones weight (Robertson, 1990) which is the core of the term weighting function in the Okapi system (Robertson, 1997).

This formula is originated in the following formula.

$$wpq_t = (p_t - q_t) \log \frac{p_t(1 - q_t)}{q_t(1 - p_t)} \quad (2)$$

where p_t is the probability that a term t appears in relevant documents. q_t is the probability that a term t appears in non-relevant documents. We can easily notice that it is very important how the two probability of p_t and q_t should be estimated. The first formula estimates p_t with $\frac{r_t}{R}$ and q_t with $\frac{N_t - R_t}{N - R}$. For the good estimation of p_t and q_t, plenty of relevant document is necessary. Although pseudo feedback which automatically assumes top n documents as relevant is one method and is often used, its performance heavily depends on the quality of an initial search. As we show later, pseudo feedback has limited performance.

We here consider a query expansion technique which uses manual feedback. It is no wonder manual feedback shows excellent and stable performance if enough relevant documents are available, hence the challenge is how it keeps high performance with less amount of manual relevance judgment. In particular, we restrict the manual judgment to the minimum amount, namely only **a relevant document and a non-relevant document**. In this assumption, the problem is how to find more relevant documents based on a relevant document and a non-relevant document. We use transductive learning technique which is suitable for the learning problem where there is small training examples.

2.2 Transductive Learning

Transductive learning is a machine learning technique based on the transduction which directly derives the classification labels of test data without making any approximating function from training data (Vapnik, 1998). Because it does not need to make approximating function, it works well even if the number of training data is small.

The learning task is defined on a data set X of n points. X consists of training data set $L = (\vec{x}_1, \vec{x}_2, ..., \vec{x}_l)$ and test data set $U = (\vec{x}_{l+1}, \vec{x}_{l+2}, ..., \vec{x}_{l+u})$; typically $l \ll u$. The purpose of the learning is to assign a label to each data point in U under the condition that the label of each data point in L are given.

Recently, transductive learning or semi-supervised learning is becoming an attractive subject in the machine learning field. Several algorithms have been proposed so far (Joachims, 1999; Zhu and et al., 2003; Blum and et al., 2004) and they show the advantage of this approach in various learning tasks. In order to apply transductive learning to our query expansion, we select an algorithm called "*Spectral Graph Transducer* (SGT)" (Joachims, 2003), which is one of the state of the art and the best transductive learning algorithms. SGT formalizes the problem of assigning labels to U with an optimization problem of the constrained ratiocut. By solving the relaxed problem, it produces an approximation to the original solution.

When applying SGT to query expansion, X corresponds to a set of top n ranked documents in a hit-list. X does not corresponds to a whole document collection because the number of documents in a collection is too huge[1] for any learning system to process. L corresponds to two documents with manual judgments, a relevant document and a non-relevant document. Furthermore, U corresponds to the documents of $X \cap \overline{L}$ whose relevancy is unknown. SGT is used to produce the relevancy of documents in U. SGT actually assigns values around $\gamma_+ - \theta$ for documents possibly being relevant and $\gamma_- - \theta$ for documents possibly being non-relevant. $\gamma_+ = +\sqrt{\frac{1-f_p}{f_p}}$, $\gamma_- = -\sqrt{\frac{f_p}{1-f_p}}$, $\theta = \frac{1}{2}(\gamma_+ + \gamma_-)$, and f_p is the fraction of relevant documents in X. We cannot know the true value of f_p in advance, thus we have to estimate its approximation value before applying SGT.

According to Joachims, parameter k (the number of k-nearest points of a data $\vec{x}$) and d (the number of eigen values to ...) give large influence to SGT's learning performance. Of course those two parameters should be set carefully. However, besides them, f_p is much more important for our task because it controls the learning performance. Since extremely small L (actually $|L| = 2$ is our setting) give no information to estimate the true value of f_p, we do not strain to estimate its single approximation value but propose a new method to utilize the results of learning with some promising f_p. We describe the method in the next section.

3 Parameter Estimations based on Multiple SGT Predictions

3.1 Sampling for Fraction of Positive Examples

SGT prepares 2 estimation methods to set f_p automatically. One is to estimate from the fraction of positive examples in training examples. This method is not suitable for our task because f_p is always fixed to 0.5 by this method if the number of training examples changes despite the number of relevant documents is small in many practical situations. The other is to estimate with a heuristic that the difference between a setting of f_p and the fraction of positive examples actually assigned by SGT should be as small as possible. The procedure provided by SGT starts from $f_p = 0.5$ and the next f_p is set to the fraction of documents assigned as relevant in the previous SGT trial. It repeats until f_p changes

[1]Normally it is more than ten thousand.

```
Input
  $N_{tr}$   // the number of training examples
Output
  $S$        // a set of sampling points

$piv = \ln(N_{tr})$;  // sampling interval
$nsp = 0$;            // the number of sampling points
for($i = piv$; $i \leq N_{tr} - 1$; $i+ = piv$){
    add $i$ to ;
    nsp++;
    if(nsp == 10){ exit; }
}
```

Figure 1: Pseudo code of sampling procedure for f_p

five times or the difference converges less than 0.01. This method is neither works well because the convergence is not guaranteed at all.

Presetting of f_p is primarily very difficult problem and consequently we take another approach which laps the predictions of multiple SGT trials with some sampled f_p instead of setting a single f_p. This approach leads to represent a relevant document by not a binary value but a real value between 0 and 1. The sampling procedure for f_p is illustrated in Figure 1. In this procedure, sampling interval changes according to the number of training examples. In our preliminary test, the number of sampling points should be around 10. However this number is adhoc one, thus we may need another value for another corpus.

3.2 Modified estimations for p_t and q_t

Once we get a set of sampling points $S = \{f_p^i : i = 1 \sim 10\}$, we run SGT with each f_p^i and laps each resultant of prediction to calculate p_t and q_t as follows.

$$p_t = \frac{\sum_i r_t^i}{\sum_i R_i} \tag{3}$$

$$q_t = \frac{\sum_i n_t - r_t^i}{\sum_i N - R_i} \tag{4}$$

Here, R_i is the number of documents which SGT predicts as relevant with ith value of f_p^i, and r_t^i is the number of documents in R_i where a term t appears. In each trial, SGT predicts the relevancy of documents by binary value of 1 (for relevant) and 0 (for non-relevant), yet by lapping multiple resultant of predictions, the binary prediction value changes to a real value which can represents the relevancy of documents in more detail. The main merit of this approach in comparison with fixing f_p to a single value, it can differentiate a value of p_t if N_{tr} is small.

4 Expansion Procedures

We here explain a whole procedure of our query expansion method step by step.

1. **Initial Search**: A retrieval starts by inputting a query for a topic to an IR system.

2. **Relevance Judgment for Documents in a Hit-List**: The IR system returns a hit-list for the initial query. Then the hit-list is scanned to check whether each document is relevant or non-relevant in descending order of the ranking. In our assumption, this reviewing process terminates when a relevant document and a non-relevant one are found.

3. **Finding more relevant documents by transductive learning**: Because only two judged documents are too few to estimate p_t and q_t correctly, our query expansion tries to increase the number of relevant documents for the *wpq* formula using the SGT transductive learning algorithm. As shown in Figure2, SGT assigns a value of the possibility to be relevant for the topic to each document with no relevance judgment (documents under the dashed line in the Fig) based on two judged documents (documents above the dashed line in the Figure).

2. Document 0
3. Document ?
4. Document ?
:
i. Document ?
:
Manually assigned
Assigned by Transductive Learning
Labels
"1" means a positive label
"0" means a negative label
"?" means an unknown label

Figure 2: A method to find tentative relevant documents

4. **Selecting terms to expand the initial query**: Our query expansion method calculates the score of each term appearing in relevant documents (including documents judged as relevant by SGT) using *wpq* formula, and then selects a certain number of expansion terms according to the ranking of the score. Selected terms are added to the initial query. Thus an expanded query consists of the initial terms and added terms.

5. **The Next Search with an expanded query**: The expanded query is inputted to the IR system and a new hit-list will be returned. One cycle of query expansion finishes at this step.

   In the above procedures, we naturally introduced transductive learning into query expansion as the effective way in order to automatically find some relevant documents. Thus we do not need to modify a basic query expansion procedure and can fully utilize the potential power of the basic query expansion.

   The computational cost of transductive learning is not so much. Actually transductive learning takes a few seconds to label 100 unlabeled documents and query expansion with all the labeled documents also takes a few seconds. Thus our system can expand queries sufficiently quick in practical applications.

5 Experiments

This section provides empirical evidence on how our query expansion method can improve the performance of information retrieval. We compare our method with other traditional methods.

5.1 Environmental Settings

5.1.1 Data set

We use the TREC-8 data set (Voorhees and Harman, 1999) for our experiment. The document corpus contains about 520,000 news articles. Each document is preprocessed by removing stopwords and stemming. We also use fifty topics (No.401-450) and relevance judgments which are prepared for adhoc task in the TREC-8. Queries for an initial search are nouns extracted from the **title** tag in each topic.

5.1.2 Retrieval Models

We use two representative retrieval models which are bases of the Okapi (Robertson, 1997) and SMART systems. They showed highest performance in the TREC-8 competition.

Okapi : The weight function in Okapi is BM25. It calculates each document's score by the following formula.

$$score(d) = \sum_{T \in Q} w^{(1)} \cdot \frac{(k_1+1)tf(k_3+1)qtf}{(K+tf)(k_3+qtf)} \quad (5)$$

$$w^{(1)} = \log \frac{(r_t+0.5)/(R-r_t+0.5)}{(n_t-r_t+0.5)/(N-n_t-R+r_t+0.5)} \quad (6)$$

$$K = k_1\left((1-b)+b\frac{dl}{avdl}\right) \quad (7)$$

where Q is a query containing terms T, tf is the term's frequency in a document, qtf is the term's frequency in a text from which Q was derived. r_t and n_t are described in section 2. K is calculated by (7), where dl and $avdl$ denote the document length and the average document length. In our experiments, we set $k_1 = 1.2, k_3 = 1000, b = 0.75$, and $avdl = 135.6$. Terms for query expansion are ranked in decreasing order of $r_t \times w^{(1)}$ for the following Okapi's retrieval tests without SGT (**Okapi_manual** and **Okapi_pseudo**) to make conditions the same as of TREC-8.

SMART : The SMART's weighting function is as follows[2].

$$score(d) = \sum_{T \in Q} \{1+\ln(1+\ln(tf))\} * \log(\frac{N+1}{df}) * pivot \quad (8)$$

$$pivot = \frac{1}{0.8+0.2 \times \frac{dl}{avdl}} \quad (9)$$

df is the term's document frequency. tf, dl and $avdl$ are the same as Okapi. When doing relevance feedback, a query vector is modified by the following Rocchio's method (with parameters $\alpha = 3$, $\beta = 2$, $\gamma = 2$).

$$\vec{Q}_{new} = \alpha\vec{Q}_{old} + \frac{\beta}{|D_{rel}|}\sum_{D_{rel}}\vec{d} - \frac{\gamma}{|D_{nrel}|}\sum_{D_{nrel}}\vec{d} \quad (10)$$

[2]In this paper, we use AT&T's method (Singhal et al., 1999) applied in TREC-8

Table 1: Results of Initial Search

	P10	P30	RPREC	MAP	R05P
Okapi_ini	0.466	0.345	0.286	0.239	0.195
SMART_ini	0.460	0.336	0.271	0.229	0.187

D_{rel} and D_{nrel} are sets of seen relevant and non-relevant documents respectively. Terms for query expansion are ranked in decreasing order of the above Rocchio's formula.

Table 1 shows their initial search results of Okapi (**Okapi_ini**) and SMART (**SMART_ini**). We adopt five evaluation measures. Their meanings are as follows (Voorhees and Harman, 1999).

P10 : The precision after the first 10 documents are retrieved.

P30 : The precision after the first 30 documents are retrieved.

R-Prec : The precision after the first R documents are retrieved, where R is the number of relevant documents for the current topic.

MAP : Mean average precision (MAP) is the average precision for a single topic is the mean of the precision obtained after each relevant document is retrieved (using zero as the precision for relevant documents that are not retrieved).

R05P : Recall at the rank where precision first dips below 0.5 (after at least 10 documents have been retrieved).

The performance of query expansion or relevance feedback is usually evaluated on a residual collection where seen documents are removed. However we compare our method with pseudo feedback based ones, thus we do not use residual collection in the following experiments.

5.1.3 Settings of Manual Feedback

For manual feedback, we set an assumption that a user tries to find relevant and non-relevant documents within only top 10 documents in the result of an initial search. If a topic has no relevant document or no non-relevant document in the top 10 documents, we do not apply manual feedback, instead we consider the result of the initial search for

100	0.498	0.369	0.272	0.255	0.188

such topics. There are 8 topics [3] which we do not apply manual feedback methods.

5.2 Basic Performance

Firstly, we evaluate the basic performance of our query expansion method by changing the number of training examples. Since our method is based on Okapi model, we represent it as **Okapi_sgt** (with parameters $k = 0.5 * N_{tr}$, $d = 0.8 * N_{tr}$. k is the number of nearest neighbors, d is the number of eigen values to use and N_{tr} is the number of training examples).

Table 2-5 shows five evaluation measures of **Okapi_sgt** when the number of expansion terms changes. We test 20, 50 and 100 as the number of training examples and 5, 10 15 and 20 for the number of expansion terms. As for the number of training examples, performance of 20 and 50 does not differ so much in all the number of expansion terms. However performance of 100 is clearly worse than of 20 and 50. The number of expansion terms does not effect so much in every evaluation measures. In the following experiments, we compare the results of **Okapi_sgt** when the number of training examples is 50 with other query expansion methods.

[3]Topic numbers are 409, 410, 424, 425, 431, 432, 437 and 450

SMART_pse	0.466	0.359	0.272	0.243	0.187

5.3 Comparison with other Manual Feedback Methods

We next compare our query expansion method with the following manual feedback methods.

Okapi_man : This method simply uses only one relevant document judged by hand. This is called *incremental relevance feedback* (Aalbersberg, 1992; Allan, 1996; Iwayama, 2000).

SMART_man : This method is SMART's manual relevance feedback (with parameters $\alpha = 3$, $\beta = 2$, $\gamma = 0$). γ is set to 0 because the performance is terrible if γ is set to 2.

Table 6 shows the mean average precision of three methods when the number of expansion terms changes. Since the number of feedback documents is extremely small, two methods except for **Okapi_sgt** get worse than their initial searches. **Okapi_man** slightly decreases as the number of expansion terms increases. Contrary, **SMART_man** do not change so much as the number of expansion terms increases. Table 7 shows another evaluation measures with 10 terms expanded. It is clear that **Okapi_sgt** outperforms the other two methods.

5.4 Comparison with Pseudo Feedback Methods

We finally compare our query expansion method with the following pseudo feedback methods.

Okapi_pse : This is a pseudo version of Okapi which assumes top 10 documents in the initial search as relevant ones as well as TREC-8 settings.

SMART_pse : This is a pseudo version of SMART. It also assumes top 10 documents as relevant ones. In addition, it assumes top 500-1000 documents as non-relevant ones.

In TREC-8, above two methods uses TREC1-5 disks for query expansion and a phase extraction technique. However we do not adopt these methods in our experiments[4]. Since these methods showed the highest performance in the TREC-8 adhoc task, it is reasonable to compare our method with them as competitors.

Table 8 shows the mean average precision of three methods when the number of expansion terms changes. Performance does not differ so much if the number of expansion terms changes. **Okapi_sgt** outperforms at any number of expansion. Table 9 shows the results in other evaluation measures. **Okapi_sgt** also outperforms except for **R05P**. In particular, performance in **P10** is quite well. It is preferable behavior for the use in practical situations.

6 Discussion

In the experiments, the feedback documents for **Okapi_sgt** is top ranked ones. However some users do not select such documents. They may choose another relevant and non-relevant documents which rank in top 10. Thus we test an another experiment where relevant and non-relevant documents are selected randomly from top 10 rank. Table 10 shows the result. Compared with table 2, the performance seems to become slightly worse. This shows that a

[4]Thus the performance in our experiments is a bit worse than the result of TREC-8

Table 10: Results of **Okapi_sgt** with random feedback (5 terms expanded)

	P10	P30	RPREC	MAP	R05P
20	0.498	0.372	0.288	0.265	0.222
50	0.456	0.359	0.294	0.268	0.200
100	0.452	0.335	0.270	0.246	0.186

user should select higher ranked documents for relevance feedback.

7 Conclusion

In this paper we proposed a novel query expansion method which only use the minimum manual judgment. To complement the lack of relevant documents, this method utilizes the SGT transductive learning algorithm to predict the relevancy of unjudged documents. Since the performance of SGT much depends on an estimation of the fraction of relevant documents, we propose a method to sample some good fraction values. We also propose a method to laps the predictions of multiple SGT trials with above sampled fraction values and try to differentiate the importance of candidate terms for expansion in relevant documents. The experimental results showed our method outperforms other query expansion methods in the evaluations of several criteria.

Abstract

This paper explores the segmentation of tutorial dialogue into cohesive topics. A latent semantic space was created using conversations from human to human tutoring transcripts, allowing cohesion between utterances to be measured using vector similarity. Previous cohesion-based segmentation methods that focus on expository monologue are reapplied to these dialogues to create benchmarks for performance. A novel moving window technique using orthonormal bases of semantic vectors significantly outperforms these benchmarks on this dialogue segmentation task.

1 Introduction

Ever since Morris and Hirst (1991)'s groundbreaking paper, topic segmentation has been a steadily growing research area in computational linguistics, with applications in summarization (Barzilay and Elhadad, 1997), information retrieval (Salton and Allan, 1994), and text understanding (Kozima, 1993). Topic segmentation likewise has multiple educational applications, such as question answering, detecting student initiative, and assessing student answers.

There have been essentially two approaches to topic segmentation in the past. The first of these, lexical cohesion, may be used for either linear segmentation (Morris and Hirst, 1991; Hearst, 1997) or hierarchical segmentation (Yarri, 1997; Choi, 2000). The essential idea behind the lexical cohesion approaches is that different topics will have different vocabularies. Therefore the lexical cohesion within topics will be higher than the lexical cohesion between topics, and gaps in cohesion may mark topic boundaries. The second major approach to topic segmentation looks for distinctive textual or acoustic markers of topic boundaries, e.g. referential noun phrases or pauses (Passonneau and Litman, 1993; Passonneau and Litman, 1997). By using multiple markers and machine learning methods, topic segmentation algorithms may be developed using this second approach that have a higher accuracy than methods using a single marker alone (Passonneau and Litman, 1997).

The primary technique used in previous studies, lexical cohesion, is no stranger to the educational NLP community. Lexical cohesion measured by latent semantic analysis (LSA) (Landauer and Dumais, 1997; Dumais, 1993; Manning and Schütze, 1999) has been used in automated essay grading (Landauer, Foltz, and Laham, 1998) and in understanding student input during tutorial dialogue (Graesser et al., 2001). The present paper investigates an orthonormal basis of LSA vectors, currently used by the AutoTutor ITS to assess student answers (Hu et al., 2003), and how it may be used to segment tutorial dialogue.

The focus on dialogue distinguishes our work from virtually all previous work on topic segmentation: prior studies have focused on monologue rather than dialogue. Without dialogue, previous approaches have only limited relevance to interactive educational applications such as intelligent tutoring systems (ITS). The only existing work on topic segmentation in dialogue, Galley et al. (2003), segments recorded speech between multiple persons using both lexical cohesion and distinctive textual and acoustic markers. The present work differs from Galley et al. (2003) in two respects, viz. we focus solely on textual information and we directly address the problem of tutorial dialogue.

In this study we apply the methods of Foltz et al. (1998), Hearst (1994, 1997), and a new technique utilizing an orthonormal basis to topic segmentation of tutorial dialogue. All three are vector space methods that measure lexical cohesion to determine topic shifts. Our results show that the new using an orthonormal basis significantly outperforms the other methods.

Section 2 reviews previous work, and Section 3 reviews the vector space model. Section 4 introduces an extension of the vector space model which uses an orthonormal basis. Section 5 outlines the task domain of tutorial dialogue, and Section 6 presents the results of previous and the current method on this task domain. A discussion and comparison of these results takes place in Section 7. Section 8 concludes.

2 Previous work

Though the idea of using lexical cohesion to segment text has the advantages of simplicity and intuitive appeal, it lacks a unique implementation. An implementation must define how to represent units of text, compare the cohesion between units, and determine whether the results of comparison indicate a new text segment. Both Hearst (1994, 1997) and Foltz et al. (1998) use vector space methods discussed below to represent and compare units of text. The comparisons can be characterized by a moving window, where successive overlapping comparisons are advanced by one unit of text. However, Hearst (1994, 1997) and Foltz et al. (1998) differ on how text units are defined and on how to interpret the results of a comparison.

The text unit's definition in Hearst (1994, 1997) and Foltz et al. (1998) is generally task dependent, depending on what size gives the best results. For example, when measuring comprehension, Foltz et al. (1998) use the unit of the sentence, as opposed to the more standard unit of the proposition, because LSA is most correlated with comprehension at that level. However, when using LSA to segment text, Foltz et al. (1998) use the paragraph as the unit, to "smooth out" the local changes in cohesion and become more sensitive to more global changes of cohesion. Hearst likewise chooses a large unit, 6 token-sequences of 20 tokens (Hearst, 1994), but varies these parameters dependent on the characteristics of the text to be segmented, e.g. paragraph size.

Under a vector space model, comparisons are performed by calculating the cosine of vectors representing text. As stated previously, these comparisons reflect the cohesion between units of text. In order to use these comparisons to segment text, however, one must have a criterion in place. Foltz et al. (1998), noting mean cosines of .16 for boundaries and .43 for non-boundaries, choose a threshold criterion of .15, which is two standard deviations below the boundary mean of .43. Using LSA and this criterion, Foltz et al. (1998) detected chapter boundaries with an F-measure of .33 (see Manning and Schütze (1999) for a definition of F-measure). Hearst (1994, 1997) in contrast uses a relative comparison of cohesion, by recasting vector comparisons as depth scores. A depth score is computed as the difference between a given vector comparison and its surrounding peaks, i.e. the local maxima of vector comparisons on either side of the given vector comparison. The greater the difference between a given comparison and its surrounding peaks, the higher the depth score. Once all the depth scores are calculated for a text, those that are higher than one standard deviation below the mean are taken as topic boundaries. Using a vector space method without singular value decomposition, Hearst (1997) reports an F-measure of .70 when detecting topic shifts between paragraphs. Thus previous work suggests that the Hearst (1997) method is superior to that of Foltz et al. (1998), having roughly twice the accuracy indicated by F-measure. Although these two results used different data sets and are therefore not directly comparable, one would predict based on this limited evidence that the Hearst algorithm would outperform the Foltz algorithm on other topic segmentation tasks.

3 The vector space model

The vector space model is a statistical technique that represents the similarity between collections of words as a cosine between vectors (Manning and Schütze, 1999). The process begins by collecting text into a corpus. A matrix is created from the corpus, having one row for each unique word in the corpus and one column for each document or paragraph. The cells of the matrix consist of a simple count of the number of times word *i* appeared in document *j*. Since many words do not appear in any given document, the matrix is often sparse. Weightings are applied to the cells that take into account the frequency of word *i* in document *j* and the frequency of word *i* across all documents, such that distinctive words that appear infrequently are given the most weight. Two collections of words of arbitrary size are compared by creating two vectors. Each word is associated with a row vector in the matrix, and the vector of a collection is simply the sum of all the row vectors of words in that collection. Vectors are compared geometrically by the cosine of the angle between them.

LSA (Landauer and Dumais, 1997; Dumais 1993) is an extension of the vector space model that uses singular value decomposition (SVD). SVD is a technique that creates an approximation of the original word by document matrix. After SVD, the original matrix is equal to the product of three matrices, word by singular value, singular value by singular value, and singular value by document. The size of each singular value corresponds to the amount of variance captured by a particular dimension of the matrix. Because the singular values are ordered in decreasing size, it is possible to remove the smaller dimensions and still account for most of the variance. The approximation to the original matrix is optimal, in the least squares sense, for any number of dimensions one would choose. In addition, the removal of smaller dimensions introduces linear dependencies between words that are distinct only in dimensions that account for the least variance. Consequently, two words that were distant in the original space can be near in the compressed space, causing the inductive machine learning and knowledge acquisition effects reported in the literature (Landauer and Dumais, 1997).

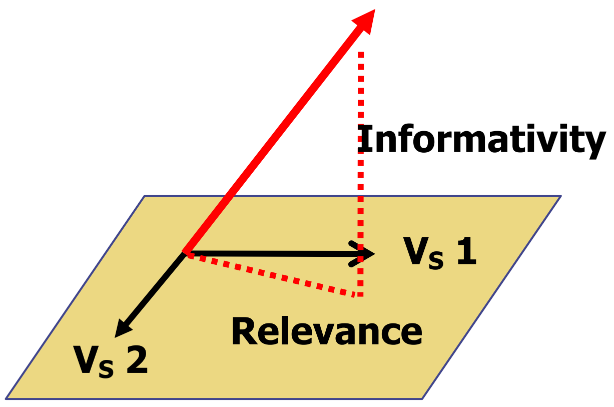

Figure 1. Projecting a new utterance to the basis

4 An orthonormal basis

Cohesion can be measured by comparing the cosines of two successive sentences or paragraphs (Foltz, Kintsch, and Landauer, 1998). However, cohesion is a crude measure: repetitions of a single sentence will be highly cohesive (cosine of 1) even though no new information is introduced. A variation of the LSA algorithm using orthonormalized vectors provides two new measures, "informativity" and "relevance", which can detect how much new information is added and how relevant it is in a context (Hu et al., 2003). The essential idea is to represent context by an orthonormalized basis of vectors, one vector for each utterance. The basis is a subspace of the higher dimensional LSA space, in the same way as a plane or line is a subspace of 3D space. The basis is created by projecting each utterance vector onto the basis of previous utterance vectors using a method known as the Gram-Schmidt process (Anton, 2000). Each projected utterance vector has two components, a component parallel to the basis and a component perpendicular to the basis. These two components represent "informativity" and "relevance", respectively. Let us first consider "relevance". Since each vector in the basis is orthogonal, the basis represents all linear combinations of what has been previously said. Therefore the component of a new utterance vector that is parallel to the basis is already represented by a linear combination of the existing vectors. "Informativity" follows similarly: it is the perpendicular component of a new utterance vector that can not be represented by the existing basis vectors. For example, in Figure 1, a new utterance creates a new vector that can be projected to the basis, forming a triangle. The leg of the triangle that lies along the basis indicates the "relevance" of the recent utterance to the basis; the perpendicular leg indicates new information. Accordingly, a repeated utterance would have complete "relevance" but zero new information.

5 Procedure

The task domain is a subset of conversations from human-human computer mediated tutoring sessions on Newton's Three Laws of Motion, in which tutor and tutee engaged in a chat room-style conversation. The benefits of this task domain are twofold. Firstly, the conversations are already transcribed. Additionally, tutors were instructed to introduce problems using a fixed set of scripted problem statements. Therefore each topic shift corresponds to a distinct problem introduced by the tutor. Clearly this problem would be trivial for a cue phrase based approach, which could learn the finite set of problem introductions. However, the current lexical approach does not have this luxury: words in the problem statements recur throughout the following dialogue.

Human to human computer mediated physics tutoring transcripts first were removed of all markup, translated to lower case, and each utterance was broken into a separate paragraph. An LSA space was made with these paragraphs alone, approximately one megabyte of text. The conversations were then randomly assigned to training (21 conversations) and testing (22 conversations). The average number of utterances per topic, 16 utterances, and the average number of words per utterance, 32 words, were calculated to determine the parameters of the segmentation methods. For example, a moving window size greater than 16 utterances implies that, in the majority of occurrences, the moving window straddles three topics as opposed to the desired two.

To replicate Foltz et al. (1998), software was written in Java that created a moving window of varying sizes on the input text, and the software retrieved the LSA vector and calculated the cosine of each window. Hearst (1994, 1997) was replicated using the JTextTile (Choi, 1999) Java software. A variant of Hearst (1994, 1997) was created by using LSA instead of the standard vector space method. The orthonormal basis method also used a moving window; however, in contrast to the previous methods, the window is not treated just as a large block of text. Instead, the window consists of two orthonormal bases, one on either side of an utterance. That is, a region of utterances above the test utterance is projected, utterance by utterance, into an orthonormal basis, and likewise a region of utterances below the test utterance is projected into another orthonormal basis. Then the test utterance is projected into each orthonormal basis, yielding measures of "relevance" and "informativity" with respect to each. Next the elements that make up each orthonormal basis are aggregated into a block, and a cosine is calculated between the test utterance and the blocks on either side, producing a total of six measures.

Each tutoring session consists of the same 10 problems, discussed between one of a set of 4 tutors and one of 18 subjects. The redundancy provides a variety of speaking and interaction styles on the same topic.

```
Tutor: A clown is riding a
unicycle in a straight line.
She accidentally drops an egg
beside her as she continues
to move with constant veloc-
ity. Where will the egg land
relative to the point where
the unicycle touches the
ground? Explain.
Student: The egg should land
right next to the unicycle.
The egg has a constant hori-
zontal velocity.  The verti-
cal velocity changes and
decreases as gravity pulls
the egg downward at a rate of
9.8m/s^2.  The egg should
therefore land right next to
the unicycle.
Tutor: Good! There is only
one thing I would like to
know. What can you say about
the horizontal velocity of
the egg compared to the hori-
zontal velocity of the clown?
Student: Aren't they the
same?
```

All of the 10 problems are designed to require application of Newton's Laws to be solved, and therefore conversations share many terms such as force, velocity, acceleration, gravity, etc.

6 Results

For each method, the development set was first used to establish the parameters such as text unit size and classification criterion. The methods, tuned to these parameters, were then applied to the testing data.

6.1 Foltz et al. (1998)

In order to replicate Foltz et al.'s results, a text unit size and window size needed to be chosen. The utterance was chosen as the text unit size, which included single word utterances, full sentences, and multi-sentence utterances. To determine the most appropriate window size, results from all sizes between 1 and 16 (the average number of utterances between topic shifts) were gathered. The greatest difference between the means for utterances that introduce a topic shift versus non-shift utterances occurs when the window contains four utterances. The standard deviation is uniformly low for windows containing more than two utterances and therefore can be disregarded in choosing a window size.

The optimal cosine threshold for classification was found using logistic regression (Garson, 2003) which establishes a relationship between the cosine threshold and the log odds of classification. The optimal cutoff was found to be shift odds = .17 with associated F-measure of .49. The logistic equation of best fit is:

$$\ln(\text{shift odds}) = 1.887 + (-13.345 \cdot \text{cosine})$$

F-measure of .49 is 48% higher than the F-measure reported by Foltz et al. (1998) for segmenting monologue. On the testing corpus the F-measure is .52, which demonstrates good generalization for the logistic equation given. Compared the F-measure of .33 reported by Foltz et al. (1998), the current result is 58% higher.

6.2 Hearst (1994, 1997)

The JTextTile software was used to implement Hearst (1994) on dialogue. As with Foltz et al. (1998), a text unit and window size had to be determined for dialogue. Hearst (1994) recommends using the average paragraph size as the window size. Using the development corpus's average topic length of 16 utterances as a reference point, F-measures were calculated for the combinations of window size and text unit size in Table 1.

The optimal combination of parameters (F-measure = .17) is a unit size of 16 words and a window size of 16 units. This combination matches Hearst (1994)'s heuristic of choosing the window size to be the average paragraph length.

		Window size				
		2	**4**	**8**	**16**	**32**
Unit size	**8**	.134	.129	.130	.146	.144
	16	.142	.133	.130	.171	.140
	32	.138	.132	.130	.151	.143

Table 1. Unit vs. window size for Hearst method

On the test set, this combination of parameters yielded an F-measure of .14 as opposed to the F-measure for monologue reported by Hearst (1997), .70. For dialogue, the algorithm is 20% as effective as it is for monologue. It is unclear, however, exactly what part of the algorithm contributes to this poor performance. The two most obvious possibilities are the segmentation criterion, i.e. depth scores, or the standard vector space method.

To further explore these possibilities, the Hearst method was augmented with LSA. Again, the unit size and window size had to be calculated. As with Foltz, the unit size was taken to be the utterance. The window size was determined by computing F-measures on the development corpus for all sizes between 1 and 16. The optimal window size is 9, F-measure = .22. Given the smaller number of test cases, 22, this F-measure of .22 is not significantly different from .17. However, the Foltz method is significantly higher than both of these, $p < .10$.

6.3 Orthonormal basis

The text unit used in the orthonormal basis is the single utterance. The optimal window size, i.e. the orthonormal basis size, was determined by creating a logistic regression to calculate the maximum F-measure for several orthonormal basis sizes. The findings of this procedure are listed in Table 2.

Size	*3*	*4*	*5*	*6*	*8*	*10*	*15*
F	.59	.63	.65	.72	.73	.72	.73

Table 2. F-measure for orthonormal basis sizes

F-measure monotonically increases until the orthonormal basis holds six elements and holds relatively steady for larger orthonormal basis sizes. Since F-measure does not increase much over .72 for greater orthonormal basis sizes, 6 was chosen as the most computationally efficient size for the strength of the effect. The logistic equation of best fit is:

$$\ln(\text{shift odds}) = \begin{aligned} & 20.027 \\ & + (16.703 \cdot \text{cosine}_2) \\ & + (\text{-}30.843 \cdot \text{relevance}_1) \\ & + (\text{-}23.567 \cdot \text{informativity}_1) \\ & + (\text{-}2.698 \cdot \text{relevance}_2) \\ & + (2.771 \cdot \text{informativity}_2) \end{aligned}$$

Where the index of 1 indicates a measure on the window preceding the utterance, and an index of 2 indicates a measure on the window following the utterance. In the regression, the cosine between the utterance and the preceding window was not significant, $p = .86$. This finding reflects the intuition that the cosine to the following window varies according to whether the following window is on a new topic, whereas the cosine to the preceding window is always high. Additionally, measures of “relevance” and “informativity” correspond to vector length; all other measures did not contribute significantly to the model and so were not included.

The sign of the metrics illuminates their role in the model. The negative sign on the coefficients for relevance$_1$, informativity$_1$, and relevance$_2$ indicates that they are inversely correlated with an utterance signaling the start of a new topic. The only surprising feature is that informativity$_1$ is negatively correlated instead of positively correlated: one would expect a topic shift to introduce new information. There is possibly some edge effect here, since the last move of a topic is often a summarizing move that shares many of the physics terms present in the introduction of a new topic. On the other hand, the positive sign on cosine$_2$ and informativity$_2$ indicates that the start of a new topic should have elements in common with the following material and add new information to that material, as an overview would. Beyond the sign, the exponentials of these values indicate how the two basis metrics are weighted. For example, when informativity$_2$ is raised by one unit, a topic shift is 16 times more likely.

On the testing corpus the F-measure of the orthonormal basis method is .67, which is significantly different from the performance of all three methods mentioned above, $p < .05$. Table 3 compares this result with the previous results in the current study for segmenting dialogue.

Method	*Hearst*	*Hearst + LSA*	*Foltz*	*Orth. basis*
F	.14	.22	.52	.67

Table 3. Comparison of dialogue segmentation methods

7 Discussion

The relative ranking of these results is not altogether surprising given the relationships between inferencing and LSA and between inferencing and dialogue. Foltz et al. (1998) found that LSA makes simple bridging inferences in addition to detecting lexical cohesion. These bridging inferences are a kind of collocational cohesion (Halliday and Hassan, 1976) whereby words that cooccur in similar contexts become highly related in the LSA space. Therefore in applications where this kind of inferencing is required, one might expect an LSA based method to excel.

Similarly to van Dijk and Kintsch's model of comprehension (van Dijk and Kintsch, 1983), dialogue can require inferences to maintain coherence. According to Grice's Co-operative Principle, utterances lacking semantic coherence flout the Maxim of Relevance and license an inference (Grice, 1975):

```
S1: Let’s go dancing.
S2: I have an exam tomorrow.
```

The "inference" in the sense of Foltz, Kintsch, and Landauer (1998) would be represented by a high cosine between these utterances, even though they don't share any of the same words. Dialogue generally tends to be less lexically cohesive and require more inferencing than expository monologue, so one might predict that LSA would excel in dialogue applications.

However, LSA has a weakness: the cosine measure between two vectors does not change monotonically as new word vectors are added to either of the two vectors. Accordingly, the addition of a word vector can cause the cosine between two text units to dramatically increase or decrease. Therefore the distinctive properties of individual words can be lost with the addition of more words to a text unit. This problem can be addressed by using an orthonormal basis (Hu et al., 2003). By using a basis, each utterance is kept independent, so "inferencing" can extend over both the entire set of utterances and the linear combination of any of its subsets. Accordingly, when "inferencing" over the entire text unit is required, one would expect a basis method using LSA vectors to outperform a standard LSA method. This expectation has been put to the test recently by Olney & Cai (2005), who find that an orthonormal basis can significantly predict entailment on test data supplied by the PASCAL Textual Entailment Challenge (PASCAL, 2004).

Beyond relative performance rankings, more support for the above reasoning can be found in the difference between Hearst and Hearst + LSA. Recall that in monologue, Hearst (1997) reports a much larger F-measure than Foltz et al. (1998), .70 vs. .33, albeit on different data sets. In the present dialogue corpus, these roles are reversed, .14 vs. .52. Possible reasons for this reversal are the segmentation criterion, the vector space method, or the fact that Foltz has been trained on similar data via regression and Hearst has not. However, comparing the Hearst algorithm with the Hearst + LSA algorithm indicates that a 57% improvement stems from the addition of LSA, keeping all other factors constant. While this result is not statistically significant, the direction of the result supports the use of an "inferencing" vector space method for segmenting dialogue.

Unfortunately, the large difference in F-measure between the Foltz algorithm and the Hearst + LSA algorithm is more difficult to explain. These two methods differ by their segmentation criterion and by their training (Foltz is a regression model and Hearst is not). It may be that Hearst (1994, 1997)'s segmentation criterion, i.e. depth scores, do not translate well to dialogue. Perhaps the assignment of segment boundaries based on the relative difference between a candidate score and its surrounding peaks is highly sensitive to cohesion gaps created by conversational implicatures. On the other hand the differences between these two methods may be entirely attributable to the amount of training they received. One way to separate the contributions of the segmentation criterion and training would be to create a logistic model using the Hearst + LSA method and to compare this to Foltz.

The increased effectiveness of the orthonormal basis method over the Foltz algorithm can also be explained in terms of "inferencing". Since "inferencing" is overwhelmed by lexical cohesion (Foltz et al., 1998), the increase in window size for the Foltz algorithm deteriorates performance for a window size greater than 4. In contrast, the orthonormal basis method becomes most effective as the orthonormal basis size increases past 4. This dichotomy illustrates that the Foltz algorithm is not complementary to an "inferencing" approach in general. Use of an orthonormal basis, on the other hand, increases sensitivity to collocational cohesion without sacrificing lexical cohesion.

8 Conclusion

This study explored the segmentation of tutorial dialogue using techniques that have previously been applied to expository monologue and using a new orthonormal basis technique. The techniques previously applied to monologue reversed their roles of effectiveness when applied to dialogue. This role reversal suggests the predominance of collocational cohesion, requiring "inferencing", present in this tutorial dialogue. The orthonormal basis method, which we suggest has an increased capacity for "inferencing", outperformed both of the techniques previously applied to monologue, and demonstrates that segmentation of these tutorial dialogues most benefits from a method sensitive to lexical and collocational cohesion over large text units.

Abstract

This work addresses the task of identifying thematic correspondences across sub-corpora focused on different topics. We introduce an unsupervised algorithmic framework based on distributional data clustering, which generalizes previous initial works on this task. The empirical results reveal interesting commonalities of different religions. We evaluate the results through measuring the overlap of our clusters with clusters compiled manually by experts. The tested variants of our framework are shown to outperform alternative methods applicable to the task.

1 Introduction

The ability to identify analogies and correspondences is one of the fascinating aspects of intelligence. Research in cognitive science has acknowledged the significance of this ability of human thinking, particularly in learning across different situations or domains where the common base to learning is not straightforward. Several previous computational models of analogy making (e.g. Falkenhainer et al., 1989) suggested symbolic computational mechanisms for constructing detailed mappings that connect corresponding ingredients across analogized systems.

This work explores the identification of thematic correspondences in texts through an extension of the well known data clustering problem. Previous works aimed at identifying – through clusters of words – concepts, sub-topics or themes that are prominent within a corpus of texts (e.g., Pereira et al., 1993; Li, 2002; Lin and Pantel, 2002). The current work deals with extending this line of research to identify corresponding themes across a corpus pre-divided to several sub-corpora, which are focused on different, yet related, topics.

This research task has been defined quite recently (Dagan et al., 2002), and has not been explored extensively yet. One could think, however, of many potential applications for drawing correspondences across textual resources: comparison of related firms or products, identifying equivalencies in news published in different countries, and so on. The experimental part of our work deals with revealing correspondences between different religions: Buddhism, Christianity, Hinduism, Islam and Judaism. Given a pre-partition of the corpus to sub-corpora, one for each religion, our method exposes common aspects for all religions, such as *sacred writings*, *festival*s and *suffering*.

The mechanism we employ directs corresponding key terms in the different sub-corpora, such as names of festivals of different religions, to be included in the same cluster. Term clustering methods in general, and in this work in particular, rely on word co-occurrence statistics: terms sharing similar words co-occurrence statistics are clustered together. Different topics, however, are characterized by distinctive terminology and typical word co-locations. Therefore, given a pre-divided corpus, similar co-occurrence patterns would typically be extracted from the same topical sub-corpus. When the terminology and typical phrases employed by each topic differ greatly (even if the topics are essentially related, e.g. different religions), the tendency to form topic-specific clusters intensifies regardless of factors that otherwise could have impact this tendency, such as the co-occurrence window size. Consequently, corresponding key terms of different topics may not be assigned by a standard method to the same cluster, in contrast to our goal. The method described in this paper aims precisely at this problem: it is designed to neutralize salient co-occurrence patterns within each topical sub-corpus and to promote less salient patterns that are shared across the sub-corpora.

In an earlier line of research we have formulated the above problem and addressed it within a probabilistic vector-based setting, presenting two related heuristic algorithms (Dagan et al., 2002; Marx et al., 2004). Here, we devise a general principled distributional clustering paradigm for this problem, termed *cross-partition clustering*, and show that the earlier algorithms are special cases of the new framework.

This paper proceeds as follows: Section 2 describes in more detail the cross-partition clustering problem. Section 3 reviews distributional data clustering methods, which form the basis to our algorithmic framework described in Section 4. Section 5 presents experimental results that reveal interesting themes common to different religions and demonstrates, through an evaluation based on human expert data, that the different variants of our framework outperform alternative methods.

2 The cross-partition clustering problem

The *cross-partition* clustering problem is an extension of the standard (single-set) data clustering problem. In the cross-partition setting, the dataset is pre-partitioned into several distinct *subsets* of elements to be clustered. For example, in our experiments each of these subsets consisted of topical key terms to be clustered. Each such subset was extracted automatically from a sub-corpus corresponding to a different religion (see Section 5).

As in the standard clustering problem, our goal is to cluster the data such that each term cluster would capture a particular theme in the data. However, the generated clusters are expected to identify themes that cut *across* all the given subsets. For example, one cluster consists of names of festivals of different religions, such as *Easter*, *Christmas*, *Sunday* (Christianity) *Ramadan*, *Friday*, *Id-al-fitr* (Islam) and *Sukoth*, *Shavuot*, *Passover* (Judaism; see Figure 4 for more examples).

3 Distributional clustering

Our algorithmic framework elaborates on Pereira et al.'s (1993) *distributional clustering* method. Distributional clustering probabilistically clusters data elements according to the distribution of a given set of features associated with the data. Each data element x is represented as a probability distribution $p(y|x)$ over all features y. In our data $p(y|x)$ is the empirical co-occurrence frequency of a feature word y with a key term x, normalized over all feature word co-occurrences with x.

The distributional clustering algorithmic scheme (Figure 1) is a probabilistic (soft) version of the well-known *K-means* algorithm. It iteratively alternates between:

(1) ***Calculating assignments to clusters***: calculate an assignment probability $p(c|x)$ for each data elements x into each one of the clusters c. This soft assignment is proportional to an information theoretic distance (KL divergence) between the element's $p(y|x)$ representation, and the centroid of c, represented by a distribution $p(y|c)$. The marginal cluster probability $p(c)$ may optionally be set as a prior in this calculation, as in Tishby et al. (1999; in Figure 1 we mark it with dotted underline, to denote it is optional).

Set t = 0, and repeatedly iterate the two update-steps below, till convergence (at time step t = 0, initialize $p_t(c|x)$ randomly or arbitrarily and skip step 1):

(1) $$p_t(c|x) = \underline{p_{t-1}(c)}\frac{e^{-\beta KL[p(y|x)\,||\,p_{t-1}(y|c)]}}{z_t(x,\beta)}$$

where $z_t(x,\beta) = \sum_{c'} \underline{p_{t-1}(c')}e^{-\beta KL[p(y|x)\,||\,p_{t-1}(y|c')]}$

(2) $$p_t(y|c) = \frac{1}{p_t(c)}\sum_x p(x)p_t(c|x)p(y|x)$$

where $p_t(c) = \sum_x p(x)p_t(c|x)$

(3) $$t = t+1$$

Figure 1: A general formulation of the iterative distributional clustering algorithm (with a fixed β value and a fixed number of clusters). The underlined $\underline{p_{t-1}(c)}$ term is optional.

(2) ***Calculating cluster centroids***: calculate a probability distribution $p(y|c)$ over all features y given each cluster c, based on the feature distribution of cluster elements, weighed by the $p(c|x)$ assignment probability calculated in step (1) above. This step imposes the independence of the clusters c of the features y given the data x (similarly to the *naïve Bayes* supervised framework).

Subsequent works (Tishby et al., 1999; Gedeon et al., 2003) have studied and motivated further the earlier distributional clustering method. Particularly, it can be shown that the algorithm of Figure 1 locally minimizes the following *cost function*:

$$F^{dist\text{-}clust} \equiv \underline{H(C)} - H(C|X) + \beta H(Y|C), \qquad (1)$$

where H denotes entropy[1] and X, Y and C are formal variables whose values range over all data elements, features and clusters, respectively.

Tishby et al.'s (1999) *information bottleneck* method (IB) includes the marginal cluster entropy $\underline{H(C)}$ in the cost term[2] (it is marked with dotted underline to denote its inclusion is optional, so that Eq. (1) encapsulates two different cost terms). The addition of $\underline{H(C)}$ corresponds to including the optional prior term $\underline{p_{t-1}(c)}$ in step (1) of the algorithm.

The parameter β that appears in the cost term and in step (1) of the algorithm can have any positive real value. It counterbalances the relative impact of the considerations of maximizing feature information conveyed by the partition to clusters, i.e. minimizing $H(Y|C)$, versus applying the *maximum entropy principle* to the cluster assignment probabilities (see Gedeon et al., 2004), i.e., maximizing $H(C|X)$. The higher β is, the more "determined" the algorithm becomes in assigning each element into the most appropriate cluster. In subsequent runs of the algorithm β can be increased, yielding more separable clusters (clusters with noticeably different centroids) upon convergence. The runs can repeat until, for some β, the desired number of separate clusters is obtained.

4 The cross-partition clustering method

In the cross-partition framework, the pre-partition of the data to subsets is captured through an additional formal variable W, whose values range over the subsets. In our data, each religion corresponds to a different W value, w. Each religion-related key term x is associated with one religion w, with $p(w|x) = 1$ (and $p(w'|x) = 0$ for any $w' \neq w$). Formally, our framework allows probabilistic pre-partition, i.e., $p(w|x)$ values between 0 and 1 but this option was not examined empirically.

The Cross-Partition (CP) clustering method (Figure 2) is an extended version of the probabilistic K-means scheme, introducing additional steps in the iterative loop that incorporate the added pre-partition variable W:

(1) ***Calculating assignments to clusters***, i.e. probabilistic $p(c|x)$ values, is based on current values of cluster *centroids*, as in distributional clustering.

(2) ***Calculating subset-projected cluster centroids***. Given the current element assignments, centroids are computed separately for each combination of

---

Set $t = 0$ and repeatedly iterate the following update steps sequence, till convergence (in the first iteration, when $t = 0$ randomly or arbitrarily initialize $p_t(c|x)$ and skip step CP1):

(1) $p_t(c|x) = \underline{p_{t-1}(c)} \dfrac{e^{-\beta KL[p(y|x) \| p^*_{t-1}(y|c)]}}{z_t(x,\beta)}$

where $z_t(x,\beta) = \sum_{c'} \underline{p_{t-1}(c')} e^{-\beta KL[p(y|x) \| p^*_{t-1}(y|c')]}$

(2) $p_t(y|c,w) = \dfrac{1}{p_t(c,w)} \sum_x p(x) p_t(c|x) p(y|x) p(w|x)$

where $p_t(c,w) = \sum_x p(x) p_t(c|x) p(w|x)$

(3) $p^*_t(c|y) = \underline{p^*_{t-1}(c)} \dfrac{\prod_w p_t(y|c,w)^{\eta p(w)}}{z^*_t(y,\eta)}$

where $z^*_t(y,\eta) = \sum_{c'} \underline{p_{t-1}(c')} \prod_w p_t(y|c',w)^{\eta p(w)}$

(4) $p^*_t(y|c) = \dfrac{1}{p^*_t(c)} \sum_y p(y) p^*_t(c|y)$

where $p^*_t(c) = \sum_y p(y) p^*_t(c|y)$

(5) $t = t + 1$

Figure 2: The cross partition clustering iterative algorithm (with fixed β and η values and a fixed number of clusters). The terms marked by dotted underline, $\underline{p_{t-1}(c)}$ and $\underline{p^*_t(c)}$, are optional.

[1] The entropy of a random variable A is $H(A) = \sum_{a,b} p(a) \log p(a)$, where a ranges over all values of A; the entropy of A conditioned on another variable B is $H(A|B) = \sum_{a,b} p(a,b) \log p(a|b)$, with a and b range over all values of A and B.

[2] The IB cost function was originally formulated as $F^{IB} \equiv I(C;X) - \beta I(C;Y)$. This formulation is equivalent to ours, as $I(C;X) = H(C) - H(C|X)$ and $I(C;Y) = H(Y) - H(Y|C)$, while $H(Y)$ is a constant term depending only on the data.

a cluster c projected on a pre-given subset w. Each such subset-projected centroid is given by a probability distribution $p(y|c,w)$ over the features y, for each c and w separately (instead of $p(y|c)$.

(3) ***Re-evaluating cluster-feature association***. Based on the subset projected centroids, the associations between features and clusters are re-evaluated: features that are commonly prominent across all subsets are promoted relatively to features with varying prominence. A weighted geometric mean scheme achieves this effect: the value of $\prod_w p(y|c,w)^{\eta p(w)}$ is larger as the different $p(y|c,w)$ values are distributed more uniformly over the different w's, for any given c and y. η is a positive valued free parameter, which controls the impact of uniformity versus variability of the averaged values. The re-evaluated associations resulting from this stage are probability distributions over the clusters denoted $p^*(c|y)$. We add an asterisk to distinguish this conditioned probability distribution from other $p(c|y)$ values that can be calculated directly from the output of the previous steps.

(4) ***Calculating cross-partition "global" centroids***: based on the probability distributions $p^*(c|y)$, we calculate a probability distribution $p^*(y|c)$ for every cluster c through a straightforward application of Bayes rule, obtaining the cross partition cluster centroids.

The novelty of the CP algorithm lies in step (3): rather than deriving cluster centroids directly, as in the standard k-means scheme, cluster-feature associations are biased by their prominence *across* the cluster projections over the different subsets. This way, only features that are prominent in the cluster across most subsets end up prominent in the eventual cluster centroid (computed in step 4). By incorporating for every c–y pair a product over all w's, independence of the feature-cluster associations from specific w values is ensured. This conforms to our target of capturing themes that cut across the pre-given partition and are not correlated with specific subsets.

Employing a separate update step in order to accomplish the above direction implies deviation from the familiar cost-based scheme. Indeed, the CP method is not directed by a single cost function that globally quantifies the cross partition clustering task on the whole. Rather, there are four different "local" cost-terms, each articulating a different aspect of the task. As shown in the appendix, each of the update steps (1)–(4) reduces one of these four cost terms, under the assumption that values not modified by that step are held constant. This assumption of course does not hold as values that are not modified by a given step are modified by another. Hence, downward convergence (of any of the cost terms) is not guaranteed.

However, empirical experimentation shows that the dynamics of the CP algorithm tend to stabilize on an equilibrial steady state, where the four different distributions produced by the algorithm balance each other, as illustrated in Figure 3. In fact, convergence occurred in all our text-based experiments (as well as in experiments with synthetic data; Marx et al., 2004).

Manipulating the value of the β parameter works in practice for the CP method as it works for distributional clustering: increasing β along subsequent runs enables the formation of configurations of growing numbers of clusters. The CP framework introduces an additional parameter, η. Intuitively, step (3). As said, the geometric mean scheme promotes those c–y associations for which the $p(y|c,w)$ values are distributed evenly across the w's (for any fixed c and y). A low η would imply a relatively low penalty to those c–y combinations that are not distributed evenly across the w's, but it

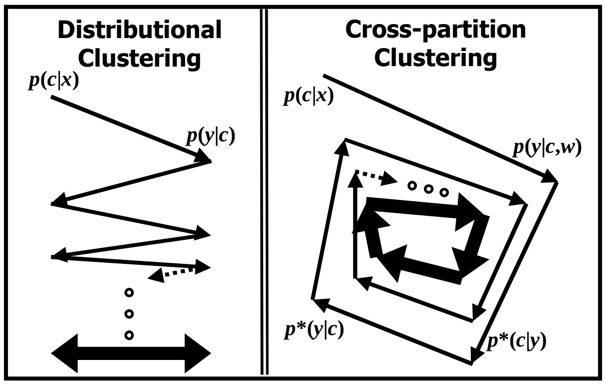

Figure 3: A schematic illustration of the dynamics of the CP framework versus that of distributional clustering. In distributional clustering convergence is onto a configuration where the two systems of distributions complementarily balance one another, bringing a cost term to a locally minimal value. In CP, stable configurations maintain balanced inter-dependencies (*equilibrium*) of four systems of probability distributions.

entails also loss of more information compared to high η. We experimented with η values that are fixed during a whole sequence of runs, while only β is gradually incremented (see Section 5).

Likewise the optional incorporation of priors in the distributional clustering scheme (Figure 1), the CP framework detailed in Figure 2 encapsulates four different algorithmic variants: the prior terms (marked in Figure 2 with dotted underline) can be optionally added in steps (1) and/or (3) of the algorithm. As in the distributional clustering case, the inclusion of these terms corresponds to inclusion of cluster entropy in the corresponding cost terms (see Appendix). It is interesting to note that we introduced previously, on intuitive accounts, some of these variants separately. Here we term the three variations involving priors CP_{I} (prior added in step (1) only, which is the same as the method described in Dagan et al., 2002), CP_{II} (prior added in step (3) only) and CP_{III} (prior added in both steps; as the method in Marx et al., 2004). The version with no priors is denoted CP. Our formulation reveals that these are all special cases of the general CP framework described above.

5 Experimental Results

The data elements that we used for our experiments – religion related key terms – were automatically extracted from a pre-divided corpus addressing five religions: Buddhism, Christianity, Hinduism, Islam and Judaism. The clustered key-term set was pre-partitioned, correspondingly, to five disjoint subsets, one per religion w.[3] In our experimental setting, the key term subsets for the different religions were considered disjoint, i.e., occurrences of the same word in different subsets were considered distinct elements. The set of features y consisted of words that co-occurred with key terms within ±5 word window, truncated by sentence boundaries. About 7000 features, each occurring in all five sub-corpora, were selected.

We survey below some results, which were produced by the plain (unprioired) CP algorithm with $\eta = 0.48$ applied to all five religions together. First, we describe our findings qualitatively and afterwards we provide quantitative evaluation.

[3] We use the dataset of Marx et al. (2004) – five sub-corpora, of roughly one million words each, consisting of introductory web pages, electronic journal papers and encyclopedic entries about the five religions; about 200 key terms were extracted from each sub-corpus to form the clustered subsets.

5.1 Cross-religion Themes

We have found that even the coarsest partition of the data to two clusters was informative and illuminating. It revealed two major aspects that seem to be equally fundamental in the religion domain. We termed them the “spiritual aspect” and “establishment aspect” of Religion. The “spiritual” cluster incorporated terms related with theology, underlying concepts and personal religious experience. Many of the terms assigned to this cluster with highest probability, such as *heaven*, *hell*, *soul*, *god* and *existence*, were in common use of several religions, but it included also religion-specific words such as *atman*, *liberation* and *rebirth* (key concepts of Hinduism). The “establishment” cluster contained names of schools, sects, clergical positions and other terms connected to religious institutions, geo-political entities and so on. Terms assigned to this cluster with high probability were mainly religion specific: *protestant*, *vatican*, *university*, *council* in Christianity; *conservative*, *reconstructionism*, *sephardim*, *ashkenazim* in Judaism and so on (few terms though were common to several religions, for instance *east* and *west*). This two-theme partition was obtained persistently (also when the CP method was applied to pairs of religions rather than to all five). Hence, these aspects appear to be the two universal constituents of religion-related texts in general, to the level the data reflect faithfully this domain.

Clusters of finer granularity still seem to capture fundamental, though more focused, themes. For example, the partition into seven clusters revealed the following topics (our titles): “schools”, “divinity”, “religious experience”, “writings”, “festivals and rite”, “material existence, sin, and suffering” and “family and education”. Figure 4 details the members of highest $p(c|x)$ values within each religion in each of the seven clusters.

The relation between the seven clusters to the coarser two-cluster configuration can be described in soft-hierarchy terms: the “schools” cluster and, to some lesser extent “festivals” and “family”, are related with the “establishment aspect” reflected in the partition to two, while “divinity”, “religious experience” and “suffering” are clearly associated with the “spiritual aspect”. The remaining topic, “writings”, is equally associated with both. The probabilistic framework enabled the CP method to

CCLUSTER 1 “Schools”
Buddhism: america asia japan west east korea india china tibet
Christianity: orthodox protestant catholic west orthodoxy organization rome council america
Hinduism: west christian religious civilization buddhism aryan social founder shaiva
Islam: africa asia west east sunni shiah christian country civilization philosophy
Judaism: reform conservative reconstructionism zionism orthodox america europe sephardim ashkenazim

CLUSTER 2 “Divinity”
Buddhism: god brahma
Christianity: holy-spirit jesus-christ god father savior jesus baptize salvation reign
Hinduism: god brahma
Islam: god allah peace messenger jesus worship believing tawhid command
Judaism: god hashem bless commandment abraham

CLUSTER 3 “Religious Experience”
Buddhism: phenomenon perception consciousness human concentration mindfulness physical liberation
Christianity: moral human humanity spiritual relationship experience expression incarnation divinity
Hinduism: consciousness atman human existence liberation jnana purity sense moksha
Islam: spiritual human physical moral consciousness humanity exist justice life
Judaism: spiritual human existence physical expression humanity experience moral connect

CLUSTER 4 “Writings”
Buddhism: pali-canon sanskrit sutra pitaka english translate chapter abhidhamma book
Christianity: chapter hebrew translate greek new-testament book text old-testament luke
Hinduism: rigveda gita sanskrit upanishad sutra smriti brahma-sutra scripture mahabharata
Islam: chapter surah bible write translate hadith book language scripture
Judaism: tanakh scripture mishnah book oral talmud bible write letter

CLUSTER 5 “Festivals and Rite”
Buddhism: full-moon celebration stupa ceremony sakya abbot ajahn robe retreat
Christianity: easter tabernacle christmas sunday sabbath jerusalem pentecost city season
Hinduism: puja ganesh festival ceremony durga rama pilgrimage rite temple
Islam: kaabah id ramadan friday id-al-fitr haj mecah mosque salah
Judaism: sukoth festival shavuot temple passover jerusalem rosh-hashanah temple-mount rosh-hodesh

CLUSTER 6 “Sin, Suffering, Material Existence”
Buddhism: lamentation water grief kill eat hell animal death heaven
Christianity: fire punishment eat water animal lost hell perish lamb
Hinduism: animal heaven earth death water kill demon birth sun
Islam: water animal hell punishment paradise food pain sin earth
Judaism: animal water eat kosher sin heaven death food forbid

CLUSTER 7 “Family and Education”
Buddhism: child friend son people family question learn hear teacher
Christianity: friend family mother boy question woman problem learn child
Hinduism: child question son mother family learn people teacher teach
Islam: sister husband wife child family marriage mother woman brother
Judaism: child marriage wife mother father women question family people

Figure 4: A sample from a seven-cluster CP configuration of the religion data, including the first members – up to nine – of highest $p(c|x)$ within each religion in each cluster. Cluster titles were assigned by the authors for reference.

cope with these composite relationships between the coarse partition and the finer one.

It is interesting to have a notion of those features y with high $p^*(c|y)$, within each cluster c. We exemplify those typical features, for each one of the seven clusters, through four of the highest $p^*(c|y)$ features (excluding those terms that function as both features and clustered terms):

- “schools” cluster:
  central, *dominant*, *mainstream*, *affiliate*;
- “divinity” cluster:
  omnipotent, *almighty*, *mercy*, *infinite*;
- “religious experience” cluster:
  intrinsic, *mental*, *realm*, *mature*;
- “writings” cluster:
  commentary, *manuscript*, *dictionary*, *grammar*;
- “festivals and rite” cluster:
  annual, *funeral*, *rebuild*, *feast*;
- “material existence, sin, and suffering” cluster:
  vegetable, *insect*, *penalty*, *quench*;
- “community and family” cluster:
  parent, *nursing*, *spouse*, *elderly*.

We demonstratively focus on the two-cluster and seven-cluster, as these numbers are small enough to allow review of all clusters. Configurations of more clusters revealed additional subtopics, such as *education*, *prayer* and so on.

There are some prominent points of correspondence between our findings to Ninian Smart’s comparative religion classics *Dimensions of the Sacred* (1996). For instance, Smart’s *ritual* dimension corresponds to our “festivals and rite” cluster and his *experiential and emotional* dimension corresponds to our “religious experience” cluster.

5.2 Evaluation with Expert Data

We evaluated the performance of our method against cross-religion key term clusters constructed manually by a team of three experts of comparative religion studies. Each manually produced clustering configuration referred to two of the five religions rather than to all five jointly, as in our qualitative review. We examined eight of the ten religion pairs that can be chosen from the total of five. Each religion pair was addressed independently by two different experts using the same set of key terms (so the total number of contributed configurations was 16). Thus, we could also asses the level of agreement between experts.

As an overlap measure we employed the Jaccard coefficient, which is the ratio $n_{11} / (n_{11} + n_{10} + n_{01})$, where:

n_{11} is the number of term pairs assigned to the same cluster by both our method and the expert;

n_{10} is the number of term pairs co-assigned by our method but not by the expert;

n_{01} is the number of term pairs co-assigned by the expert but not by our method.

As the Jaccard score relies on counts of individual term pairs, no assumption with regard to the suitable number of clusters is required. Hence, for each religion pair we produced with our method configurations of two to 16 clusters and calculated for each Jaccard scores based on the overlap with the relevant expert configurations. The scores obtained were averaged over the 15 configurations. The means, over all 16 experimental cases, of those average values are displayed in Table 1.

We tested all four CP method variants, with different fixed values of the η parameter. In addition, we evaluated results obtained by the priored version of distributional clustering (the IB method, Tishby et al., 1999; see Figure 1). Marx et al. (2004) mentioned Information Bottleneck with Side Information (IB-SI, Chechik & Tishby, 2003) as a method capable – unlike standard distributional clustering – of capturing information regarding pre-partition to subsets, which makes this method a seemingly sensible alternative to the CP method. Therefore, we tested the IB-SI method as well, following the adaptation scheme to the CP setting described by Marx et al, with a fixed value of its parameter, $\gamma = 0.07$ (with higher values convergence did not take place in all experiments). As Table 1 shows, the different CP variants performed better than the alternatives. The CP_{III} varinat, with both prior types, was less robust to changes in η value and seemed to be more sensitive to noise.

The experimental part of this work demonstrates that the task of drawing thematic correspondences is challenging. In the particular domain that we have examined the level of agreement between experts seems to make it evident that the task is inherently subjective and just partly consensual. It is remarkable therefore that most variations of our method approximate rather closely the upper bound of the level of agreement between the experts. Further, we have shown the merit of promoting shared cross-subset patterns and neutralizing topic-specific regularities in a newly introduced dedicated computational step. Methods that do not consider this direction (IB) or that incorporate it within a more conventional cost based search (IB-SI) yield notably poorer performance.

Table 1: Mean Jaccard scores for several methods, examined over of the 16 religion-pair evaluation cases (incorporating mean Jaccard scores over 2–16 clustering configurations, see text). The differences between most CP variants and cross-expert agreement are not statistically significant. The differences between IB, IB-SI and CP_{III} with $\eta = 0.83$ and expert agreement are significant (two-tailed t-test, $df = 15$, $p < 0.01$).

	$\eta = 0.48$	$\eta = 0.56$	$\eta = 0.67$	$\eta = 0.83$
CP	0.405	0.383	0.400	0.394
CP_I	0.416	0.400	0.415	0.399
CP_{II}	0. 410	0.387	0.409	0.417
CP_{III}	0. 405	0.420	0.370	0.293
IB: 0.1734	IB-SI ($\gamma = 0.07$): 0.1995			
Agreement between the experts: 0.462				

6 Disscussion

In this paper, we studied and demonstrated the cross partition method, a computational framework that addresses the task of identifying analogies and correspondences in texts. Our approach to this problem bridges between cognitive observations regarding analogy making, which have inspired it, and unsupervised learning techniques.

While previous cognitively-motivated computational frameworks required structured input (e.g. Falkenhainer et al., 1989), the CP method adapts distributional clustering (Pereira et al., 1993), a standard approach applicable to unstructured data. Unlike standard clustering, the CP method considers an additional source of information: pre-partition of the clustered data to several topical subsets (originated in different sub-corpora) between which a correspondence is drawn.

The innovative aspect of the cross-partition method lies in distinguishing feature information that cuts across the given pre-partition to subsets versus subset-specific information. In order to incorporate this aspect within distributional clustering, the CP method interleaves several update steps, each locally optimizing a different cost term.

Our experiments demonstrate that the CP method is capable of revealing interesting and non-trivial corresponding themes in texts. The results obtained with most variants of the CP method, with suitable tuning of the parameters, outperform comparable methods – standard distributional clustering and the IB-SI method – and are rather close to the level of agreement between experts.

The CP method revealed, along various resolution levels, meaningful themes that to our understanding can be considered prominent constituents of Religion. It would be an interesting challenge to apply the CP framework further for other tasks, possibly with more practical flavor, such as comparing and detecting commonalities between commercial products and firms, identifying equivalencies and precedents in legal cases and so on.

Appendix

This appendix specifies the four "local" cost terms mentioned in Section 4 and describes how the CP algorithmic framework (Fig. 2) modifies them.

Step (1) of the CP framework computes $p(c|x)$ values that reduce the value of the following term:

$$F^{CP1} \equiv \underline{H(C)} - H(C|X) + \beta \hat{H}^*(Y|C),$$

where $\hat{H}^*(Y|C) \equiv -\sum_x p(x) \sum_c p(c|x) \sum_y p(y|x) \log p^*(y|c)$. The $p^*(y|c)$ values are considered as if they are constant.

Step (2) computes $p(c|x)$ values reducing the value of

$$F^{CP2} \equiv -\sum_x p(x) \sum_c p(c|x) \sum_y p(y|x) \sum_w p(w|x) \log p(y|c,w),$$

which is equal to $H(Y|C,W)$, subject to an independence assumption extending the assumption explicated in footnote 4, namely for each feature y, cluster c, and pre-given subset w: $p(c,y,w) = \sum_x p(x)\, p(c|x)\, p(y|x)\, p(w|x)$.

Step (3) finds $p^*(c|y)$ values that reduce the value of

$$F^{CP3} \equiv \underline{H^*(C)} - H^*(C|Y) + \eta \hat{H}(Y|C,W),$$

where $H^*(C|Y) = -\sum_y p(y) \sum_c p^*(c|y) \log p^*(c|y)$ and $\hat{H}(Y|C,W) \equiv -\sum_w p(w) \sum_y p(y) \sum_c p^*(c|y) \log p(y|c,w)$, which is equal to the conditioned entropy $H(Y|C,W)$ under an assumption that W is independent of C and Y. The $p(y|c,w)$ values in this term are considered as if they are held constant.

Step (4) finds $p^*(y|c)$ values that reduce the value of

$$F^{CP4} = -\sum_y p(y) \sum_c p^*(c|y) \log p^*(y|c),$$

which can be denoted $H^*(Y|C)$. The $p^*(c|y)$ values are considered as if they are constant.

The underlined $\underline{H(C)}$ and $\underline{H^*(C)}$ terms in F^{CP1} and F^{CP3} are optional; there inclusion implies the inclusion of the prior terms in steps (1) and (3) of the algorithm (see Figure 2).

Flexible Text Segmentation with Structured Multilabel Classification

Abstract

Many language processing tasks can be reduced to breaking the text into segments with prescribed properties. Such tasks include sentence splitting, tokenization, named-entity extraction, and chunking. We present a new model of text segmentation based on ideas from multilabel classification. Using this model, we can naturally represent segmentation problems involving overlapping and non-contiguous segments. We evaluate the model on entity extraction and noun-phrase chunking and show that it is more accurate for overlapping and non-contiguous segments, but it still performs well on simpler data sets for which sequential tagging has been the best method.

1 Introduction

Text segmentation is a basic task in language processing, with applications such as tokenization, sentence splitting, named-entity extraction, and chunking. Many parsers, translation systems, and extraction systems rely on such segmentations to accurately process the data. Depending on the application, segments may be tokens, phrases, or sentences. However, in this paper we primarily focus on segmenting sentences into tokens.

The most common approach to text segmentation is to use finite-state sequence tagging models, in which each atomic text element (character or token) is labeled with a tag representing its role in a segmentation. Models of that form include hidden Markov models (Rabiner, 1989; Bikel et al., 1999) as well as discriminative tagging models based on maximum entropy classification (Ratnaparkhi, 1996; McCallum et al., 2000), conditional random fields (Lafferty et al., 2001; Sha and Pereira, 2003), and large-margin techniques (Kudo and Matsumoto, 2001; Taskar et al., 2003). Tagging models are the best previous methods for text segmentation. However, their purely sequential form limits their ability to naturally handle overlapping or non-contiguous segments.

We present here an alternative view of segmentation as *structured multilabel classification*. In this view, a segmentation of a text is a set of *segments*, each of which is defined by the set of text positions that belong to the segment. Thus, a particular segment may not be a set of consecutive positions in the text, and segments may overlap. Given a text $\boldsymbol{x} = x_1 \cdots x_n$, the set of possible segments, which corresponds to the set of possible classification *labels*, is $\text{seg}(\boldsymbol{x}) = \{\texttt{O}, \texttt{I}\}^n$; for $\boldsymbol{y} \in \text{seg}(\boldsymbol{x})$, $y_i = \texttt{I}$ iff x_i belongs to the segment. Then, our segmentation task is to determine which labels are correct segments in a given text. We have thus a structured multilabel classification problem: each instance, a text, may have multiple structured labels, representing each of its segments. These labels are structured in that they do not come from a predefined set, but instead are built from sets of choices associated to the elements of arbitrarily long instances.

More generally, we may be interested in *typed* segments, e.g. segments naming different types of entities. In that case, the set of segment labels is $\mathrm{seg}(\boldsymbol{x}) = T \times \{\mathtt{O}, \mathtt{I}\}^n$, where T is the set of segment types. Since the extension is straightforward, we frame the discussion in terms of untyped segments, and only discuss segment types as needed.

At first sight, it might appear that we have made the segmentation problem intractably harder by turning it into a classification problem with a number of labels exponential on the length of the instance. However, we can bound the number of labels under consideration and take advantage of the structure of labels to find the k most likely labels efficiently. This will allow us to exploit recent advances in online discriminative methods for multilabel classification and ranking (Crammer and Singer, 2002).

Though multilabel classification has been well studied (Schapire and Singer, 1999; Elisseeff and Weston, 2001), as far as we are aware, this is the first study involving structured labels.

2 Segmentation as Tagging

The standard approach to text segmentation is to use tagging techniques with a BIO tag set. Elements in the input text are tagged with one of `B` for the beginning of a contiguous segment, `I` for the inside of a contiguous segment, or `O` for outside a segment. Thus, segments must be contiguous and non-overlapping. For instance, consider the sentence *Estimated volume was a light 2.4 million ounces*. Figure 1a shows how this sentence would be labeled using the BIO tag set for the problem of identifying base NPs in text. Given a particular tagging for a sentence, it is trivial to find all the segments, those whose tag sequences are longest matches for the regular expression $\mathtt{BI}^*$. For typed segments, the BIO tag set is easily augmented to indicate not only segment boundaries, but also the type of each segment. Figure 1b exemplifies the tags for the task of finding people and organizations in text.

Sequential tagging with the BIO tag set has proven quite accurate for shallow parsing and named entity extraction tasks (Kudo and Matsumoto, 2001; Sha and Pereira, 2003; Tjong Kim Sang and De Meulder, 2003). However, this approach can only identify non-overlapping, contiguous segments. This is sufficient for some applications, and in any case, most training data sets are annotated without concern for overlapping or non-contiguous segments. However, there are instances in which sequential labeling techniques using the BIO label set will encounter problems.

Figure 2 shows two simple examples of segmentations involving overlapping, non-contiguous segments. In both cases, it is difficult to see how a sequential tagger could extract the segments correctly. It would be possible to grow the tag set to represent a bounded number of overlapping, non-contiguous segments by representing all possible combinations of segment membership over k overlapping segments, but this would require an arbitrary upper bound on k and would lead to models that generalize poorly and are expensive to train.

Dickinson and Meurers (2005) point out that, as language processing begins to tackle problems in free-word order languages and discourse analysis, annotating and extracting non-contiguous segmentations of text will become increasingly important. Though we focus primarily on entity extraction and NP chunking in this paper, there is no reason why ideas presented here could not be extended to managing other non-contiguous phenomena.

3 Structured Multilabel Classification

As outlined in Section 1, we represent segmentation as multilabel classification, assigning to each text the set of segments it contains. Figure 3 shows the segments for the examples of Figure 2. Each segment is given by a `O`/`I` assignment to its words, indicating which words belong to the segment.

By representing the segmentation problems as multilabel classification, we have fundamentally changed the objective of our learning and inference algorithms. The sequential tagging formulation is aimed to learn and find the best possible tagging of a text. In multilabel classification, we train model parameters so that correct labels — that is, correct segments – receive higher score than all incorrect ones. Likewise, inference becomes the problem of finding the set of correct labels for a text, that is, the set of correct segments.

We now describe the learning problem using the decision-theoretic multilabel classification and ranking framework of Crammer and Singer (2002) and Crammer (2005) as our starting point. In Sec-

tion 3.2, we describe a polynomial-time inference algorithm for finding up to k correct segments.

3.1 Training Multilabel Classifiers

Our model is based on a linear score $s(\boldsymbol{x}, \boldsymbol{y}; \mathbf{w})$ for each segment $\boldsymbol{y}$ of text $\boldsymbol{x}$, defined as

$$s(\boldsymbol{x}, \boldsymbol{y}; \mathbf{w}) = \mathbf{w} \cdot \mathbf{f}(\boldsymbol{x}, \boldsymbol{y})$$

where $\mathbf{f}(\boldsymbol{x}, \boldsymbol{y})$ is a feature vector representation of the sentence-segment pair, and $\mathbf{w}$ is a vector of feature weights. For a given text $\boldsymbol{x}$, $\text{act}(\boldsymbol{x}) \subseteq \text{seg}(\boldsymbol{x})$ denotes the set of correct segments for $\boldsymbol{x}$, and $\text{best}_k(\boldsymbol{x}; \mathbf{w})$ denotes the set of k segments with highest score relative to the weight vector $\mathbf{w}$. For learning, we use a training set $\mathcal{T} = \{(\boldsymbol{x}_t, \text{act}(\boldsymbol{x}_t))\}_{t=1}^{|\mathcal{T}|}$ of texts labeled with the correct segmentation.

We will discuss later the design of $\mathbf{f}(\boldsymbol{x}, \boldsymbol{y})$ and an efficient algorithm for finding the k highest scoring segments (where k is sufficiently large to include all correct segments). In this section, we present a method for learning a weight vector $\mathbf{w}$ that seeks to score correct segments above all incorrect segments.

Crammer and Singer (2002), extended by Crammer (2005), provide online learning algorithms for multilabel classification and ranking that take one instance at a time, construct a set of scoring constraints for the instance, and adjust the weight vector to satisfy the constraints. The constraints enforce a *margin* between the scores of correct labels and those of incorrect labels. The benefits of large-margin learning are best known from SVMs (Cristianini and Shawe-Taylor, 2000; Schölkopf and Smola, 2002), and are analyzed in detail by Crammer (2005) for online multilabel classification.

```

3.     for $t : 1..|\mathcal{T}|$
4.         $\mathbf{w}^{(i+1)} = \arg\min_{\mathbf{w}} \left\| \mathbf{w} - \mathbf{w}^{(i)} \right\|^2$
           s.t. $s(\boldsymbol{x}_t, \boldsymbol{y}; \mathbf{w}) \geq s(\boldsymbol{x}_t, \boldsymbol{y}'; \mathbf{w}) + 1$
               $\forall \boldsymbol{y} \in \text{act}(\boldsymbol{x}_t), \forall \boldsymbol{y}' \in \text{best}_k(\boldsymbol{x}_t; \mathbf{w}^{(i)}) - \text{act}(\boldsymbol{x}_t)$
6.         $i = i + 1$
7. $\mathbf{w} = \mathbf{w}^{(N*|\mathcal{T}|)}$
```

Figure 4: A simplified version of the multilabel learning algorithm of Crammer and Singer (2002).

For segmentation, the number of possible labels (segments) is exponential on the length of the text. We make the problem tractable by including only the margin constraints between correct segments and at most k highest scoring incorrect segments. Figure 4 sketches an online learning algorithm for multilabel classification based on the work of Crammer (2005). In the algorithm, $\mathbf{w}^{(i+1)}$ is the projection of $\mathbf{w}^{(i)}$ onto the set of weight vectors such that the scores of correct segments are separated by a margin of at least 1 from the scores of incorrect segments among the k top-scoring segments. This update is *conservative* in that there is no weight change if the constraint set is already satisfied or empty; if some constraints are not satisfied, we make the smallest weight change that satisfies the constraints. Since, the objective is quadratic in $\mathbf{w}$ and the constraints are linear, the optimization problem can be solved by Hildreth's al-

```

Figure 3: Correct segments for two examples.

gorithm (Censor and Zenios, 1997).

Using standard arguments for linear classifiers (add constant feature, rescale weights) and the fact that all the correct scores in line 4 of Figure 4 are required to be above all the incorrect scores in the top k, that line can be replaced by

$$\begin{array}{l} \mathbf{w}^{(i+1)} = \arg\min_{\mathbf{w}} \left\|\mathbf{w} - \mathbf{w}^{(i)}\right\|^2 \\ \text{s.t. } s(\boldsymbol{x}_t, \boldsymbol{y}; \mathbf{w}) \geq 1 \text{ and } s(\boldsymbol{x}_t, \boldsymbol{y}'; \mathbf{w}) \leq -1 \\ \forall \boldsymbol{y} \in \text{act}(\boldsymbol{x}_t), \forall \boldsymbol{y}' \in \text{best}_k(\boldsymbol{x}_t; \mathbf{w}^{(i)}) - \text{act}(\boldsymbol{x}_t) \end{array}$$

If v is the number of correct segments for $\boldsymbol{x}$, this transformation replaces $O(kv)$ constraints with $O(k+v)$ constraints: segment scores are compared to a single positive or negative threshold rather then to each other. At test time, we find the segments with positive score by finding the k highest scoring segments and discarding those with a negative score.

3.2 Inference

During learning and at test time we require a method for finding the k highest scoring segments. At test time, we predict as correct all the segments with positive score in the top k. In this section we give an algorithm that calculates this precisely.

For inference, tagging models typically use the Viterbi algorithm (Rabiner, 1989). The algorithm is given by the following standard recurrences:

$$\begin{array}{rcl} S[i,t] & = & \max_{t'} s(t',t,i) + S[i-1,t'] \\ B[i,t] & = & \arg\max_{t'} s(t',t,i) + S[i-1,t'] \end{array}$$

with appropriate initial conditions, where $s(t',t,i)$ is the score for going from tag t' at $i-1$ to tag t at i. The dynamic programming table $S[i,t]$ stores the score of the best tag sequence ending at position i with tag t, and $B[i,t]$ is a back-pointer to the previous tag in the best sequence ending at i with t, which allows us to reconstruct the best sequence. The Viterbi algorithm has easy k-best extensions.

We could find the k highest scoring segments using Viterbi. However, for the case of non-contiguous segments, we would like to represent higher-order dependencies that are difficult to model in Viterbi. In particular, in Figure 3b we definitely want a feature bridging the gap between *Bill* and *Clinton*, which could not be captured with a standard first-order model. But moving to higher-order models would require adding dimensions to the dynamic programming tables S and B, with corresponding multipliers to the complexity of inference.

To represent dependencies between non-contiguous text positions, for any given segment $\boldsymbol{y} = y_1 \cdots y_n$, let $i(\boldsymbol{y}) = 0 i_1 \cdots i_m (n+1)$ be the increasing sequence of indices i_j such that $y_{i_j} = \mathtt{I}$, padded for convenience with the dummy first index 0 and last index $n+1$. Also for convenience, set $x_0 = $ `-s-` and $x_{n+1} = $ `-e-` for fixed start and end markers. Then, we restrict ourselves to feature functions $\mathbf{f}(\boldsymbol{x}, \boldsymbol{y})$ that factor relative to the input as

$$\mathbf{f}(\boldsymbol{x}, \boldsymbol{y}) = \sum_{j=1}^{|i(\boldsymbol{y})|} \mathbf{g}(i(\boldsymbol{y})_{j-1}, i(\boldsymbol{y})_j) \qquad (1)$$

where $i(\boldsymbol{y})_j$ is the j^{th} integer in $i(\boldsymbol{y})$ and $\mathbf{g}$ is a feature function depending on arbitrary properties of the input relative to the indices $i(\boldsymbol{y})_{j-1}$ and $i(\boldsymbol{y})_j$.

Applying (1) to the segment *Bill Clinton* in Figure 3, its score would be

$$\mathbf{w} \cdot [\mathbf{g}(0,3) + \mathbf{g}(3,6) + \mathbf{g}(6,11)]$$

This feature representation allows us to include dependencies between non-contiguous segment positions, as well as dependencies on any properties of the input, including properties of skipped positions.

We now define the following dynamic program

$$\begin{array}{rcl} S[i] & = & \max_{j<i} S[j] + \mathbf{w} \cdot \mathbf{g}(j,i) \\ B[i] & = & \arg\max_{j<i} S[j] + \mathbf{w} \cdot \mathbf{g}(j,i) \end{array}$$

These recurrences compute the score $S[i]$ of the best partial segment ending at i as the sum of the maximum score of a partial segment ending at position $j < i$, and the score of skipping from j to i. The back-pointer table B allows us to reconstruct the sequence of positions included in the segment.

Clearly, this program requires $O(n^2)$ time for a text of length n. Furthermore we can easily augment this algorithm in the standard fashion to find the k best segments, and multiple segment types, resulting in a runtime of $O(n^2kT)$, where T is the number of types. $O(n^2kT)$ is not ideal, but is still practical since in this work we are segmenting sentences. If we can bound the largest gap in any non-contiguous segment by a constant $g \ll n$, then the runtime can be improved to $O(ngkT)$. This runtime does not compare favorably to the standard Viterbi algorithm that runs in $O(nT^2)$, especially for large k. However, we found that for even large k we could still train large models in a matter of hours and test on unseen data in a few minutes.

3.2.1 Restrictions

Often a segmentation task or data set will restrict particular kinds of segments. For instance, it may be the case that a data set does not have any overlapping or non-contiguous segments. Embedded segmentations – those in which one segment's tokens are a subset of another's – is also a phenomenon that sometimes does not occur.

It is easy to restrict the inference algorithm to disallow such segments if they are unnecessary. For example, if two segments overlap or are embedded, the inference algorithm can just return the highest scoring one. Or it can simply ignore all non-contiguous segments if it is known that they do not occur in the data. In Section 4 we will augment the inference algorithm accordingly for each data set.

3.3 Feature Representation

We now discuss the design of the feature function for two consecutive segment positions $\mathbf{g}(j, i)$, where $j < i$. We build individual binary-valued features from predicates over the input, for instance, the identities of words in the sentence at particular positions relative to i and j. The selection of predicates varies by task, and we provide specific predicate sets in Section 4 for various data sets. In this section, we use for illustration word-pair identity predicates such as $x_j = \texttt{Bill}\ \&\ x_i = \texttt{Clinton}$.

For sequential tagging models, predicates are combined with the set of states (or tags) to create a feature representation. For our model, we define the following possible states:

$$\begin{array}{rcl} \text{start} & \equiv & j = 0 \\ \text{end} & \equiv & i = n + 1 \\ \text{next} & \equiv & j = i - 1 \\ \text{skip} & \equiv & j < i - 1 \end{array}$$

For example, the following features would be on for $\mathbf{g}(0, 3)$[1] and $\mathbf{g}(3, 6)$, respectively, in Figure 3a:

$$x_j = \texttt{-s-}\ \&\ x_i = \texttt{Bill}\ \&\ \text{start}$$
$$x_j = \texttt{Bill}\ \&\ x_i = \texttt{Clinton}\ \&\ \text{skip}$$

These features indicate a predicate's role in the segment: at the beginning, at the end, over contiguous segment words or skipping over some words. All features can be augmented to indicate specific segment types for multi-type segmentation tasks. No matter what the task, we always add predicates that represent ranges of the distance $i - j$, as well as what words or part-of-speech tags occur between the two words. For instance, $\mathbf{g}(3, 6)$ might contain

$$\texttt{word-in-between} = \texttt{and}\ \&\ \text{skip}$$

These features are designed to identify common characteristics of non-contiguous segments such as the presence of conjunctions or punctuation in skipped portions. Although we have considered only binary features here, the model in principle allows arbitrary real-valued feature.

3.4 Summary

We presented a method for text segmentation that equates the problem to structured multilabel classification where each label corresponds to a segment. We showed that learning and inference can be managed tractably in the formulation by efficiently finding the k highest scoring segments through a dynamic programming algorithm that factors the structure of each segment. The only concern is that k must be large enough to include all correct segments,

[1]Note that "skip" is not on for $\mathbf{g}(0, 3)$ even though $j < i-1$. Start and end states override other states.

which we will discuss further in Section 4. This method naturally models all possible segmentations including those with overlapping or non-contiguous segments. Out approach can be seen as multilabel variant of the work of McDonald et al. (2004), which creates a set of constraints to separate the score of the single correct output from the k highest scoring outputs with an appropriate large margin.

4 Experiments

We now describe a set of experiments on named entity and base NP segmentation. For these experiments, we set $k = n$, where n is the length of the sentence. This represents a reasonable upper bound on the number of entities or chunks in a sentence and results in a time complexity of $O(n^3T)$.

We compare our methods with both the averaged perceptron (Collins, 2002) and conditional random fields (Lafferty et al., 2001) using identical predicate sets. Though all systems use identical predicates, the actual features of the systems are different due to the fundamental differences between the multilabel classification and sequential tagging models.

4.1 Standard data sets

Our first experiments are standard named entity and base NP data sets with no overlapping, embedded or non-contiguous segments. These experiments will show that, for simple segmentations, our model is competitive with sequential tagging models.

For the named entity experiments we used the CoNLL 2003 (Tjong Kim Sang and De Meulder, 2003) data with people, organizations, locations and miscellaneous entities. We used standard predicates based on word, POS and orthographic information over a previous to next word window. For the NP chunking experiments we used the standard CoNLL 2000 data set (Kudo and Matsumoto, 2001; Sha and Pereira, 2003) using the predicate set defined by Sha and Pereira (2003).

The first three rows of Table 1 compare the multilabel classification approach to standard sequential classifiers. As one might expect, the performance of the multilabel classification method is below that of the sequential tagging methods. This is because those methods model contiguous segments well without the need for thresholds or k-best inference. In addition, the multilabel method shows significantly higher precision then recall. One possible reason for this is that during the course of learning, the model will see many segments that are *nearly* correct, e.g., segments that overlap correct segments and differ by a single token. As a result, the model learns to score all segments containing even a small amount of negative evidence as invalid in order to ensure that these nearly correct segments have a sufficiently low score.

One way to alleviate this problem is to restrict the inference algorithm to not return any overlapping, non-contiguous or embedded segmentations as discussed in Section 3.2.1, since this data set does not contain segments of this kind. This way, the learning stage only updates the parameters when a *nearly* correct segment actually out scores the correct one. The results of this system are shown in row 4 of Table 1. We can see that this change did lead to a more balanced precision/recall, however it is clear that more investigation is required.

4.2 Chemical substance extraction

The second set of experiments involves extracting chemical substance names from MEDLINE abstracts that relevant to the inhibition of the enzyme CYP450 (PennBioIE, 2005). We focus on abstracts that have at least one overlapping or non-contiguous annotation. This data set contains 6164 annotated chemical substances, including 6% that are both overlapping and non-contiguous. Figure 3b is an example from the corpus. We use identical predicates to the named entity experiments in Section 4.1. Though the data does contain overlapping and non-contiguous segments, it does not contain embedded segments. Results are shown in Table 2 using 10-fold cross validation. The sequential tagging models were trained using only sentences with no overlapping or non-contiguous entities. We found this provided the best performance. Row 4 of Table 2 shows the multilabel approach with the inference algorithm restricted to not allow embedded segments.

We can see that our method does significantly better on this data set (up to a 26% reduction in error). It is also apparent that the model is picking up some overlapping and non-contiguous entities (see Table 2). However, the models performance on these kinds of entities is lower than overall performance.

4.3 Tuning Precision and Recall

The learning algorithm in Section 3.1 seeks a separator through the origin, though, our experimental results suggest that this tends to favor precision at the expense of recall. However, at test time we can use a separation threshold different from zero. This parameter allows us to trade off precision against recall, and could be tuned on held-out data.

Figure 5 plots precision, recall and f-measure against the threshold for the basic multilabel model on the chemical substance, NP chunking and person entity extraction data sets. These plots clearly show what is expected: higher thresholds give higher precision, and lower thresholds give higher recall. In these data sets at least, a zero threshold is almost always near optimal, though sometimes we would benefit from a slightly lower threshold.

5 Discussion

We have presented a method for text segmentation that is base on discriminatively learning structured multilabel classifications. The benefits include

- Competitive performance with sequential tagging models.
- Flexible modeling of complex segmentations, including overlapping, embedded and non-contiguous segments.
- Adjustable precision-recall trade off.

However, there is a computation cost for our models. For a text of length n, training and testing require $O(n^3 T)$ time, where T is the number of segment types. Fortunately, this still results in training times on the order of hours.

Our approach is related to the work of Bockhorst and Craven (2004). In this work, a conditional random field model is trained to allow for overlapping segments with an $O(n^2)$ inference algorithm. The model is applied to biological sequence modeling with promising results. However, our approaches differ in two major respects. First, their model is probabilistic, and trained to maximize segmentation likelihood, while our model is trained to maximize margin. Second, our method allows for non-contiguous segments, at the cost of a slower $O(n^3)$ inference algorithm.

In further work, the classification threshold should also be learned to achieve the desired balance between precision and recall. It would also be useful to investigate methods for combining these models with standard sequential tagging models to get top performance on simple segmentations as well as on overlapping or non-contiguous ones.

A broader area of investigation are other problems in language processing that can benefit from structured multilabel classification, e.g., ambiguities in language often result in multiple acceptable parses for sentences. It may be possible to extend the algorithms presented here to learn to distinguish all acceptable parses from unacceptable ones instead of just finding a single parse when many are valid.

Abstract

We present a novel voice-based human-computer interface designed to enable individuals with motor impairments to use vocal parameters for continuous control tasks. Since discrete spoken commands are ill-suited to such tasks, our interface exploits a large set of continuous acoustic-phonetic parameters like pitch, loudness, vowel quality, etc. Their selection is optimized with respect to automatic recognizability, communication bandwidth, learnability, suitability, and ease of use. Parameters are extracted in real time, transformed via adaptation and acceleration, and converted into continuous control signals. This paper describes the basic engine, prototype applications (in particular, voice-based web browsing and a controlled trajectory-following task), and initial user studies confirming the feasibility of this technology.

1 Introduction

Many existing human-computer interfaces (e.g., mouse and keyboard, touch screens, pen tablets, etc.) are ill-suited to individuals with motor impairments. Specialized (and often expensive) human-computer interfaces that have been developed specifically for this target group include sip and puff switches, head mice, eye-gaze devices, chin joysticks and tongue switches. While many individuals with motor impairments have complete use of their vocal system, these devices make little use of it. Sip and puff switches, for example, have low communication bandwidth, making it impossible to achieve more complex control tasks.

Natural spoken language is often regarded as the obvious choice for a human-computer interface. However, despite significant research efforts in automatic speech recognition (ASR) (Huang et al., 2001), existing ASR systems are still not sufficiently robust to a wide variety of speaking conditions, noise, accented speakers, etc. ASR-based interfaces are therefore often abandoned by users after a short initial trial period. In addition, natural speech is optimal for communication between humans but sub-optimal for manipulating computers, windows-icons-mouse-pointer (WIMP) interfaces, or other electro-mechanical devices (such as a prosthetic robotic arm). Standard spoken language commands are useful for discrete but not for continuous operations. For example, in order to move a cursor from the bottom-left to the upper-right of a screen, the user might have to repeatedly utter “up” and “right” or “stop” and “go” after setting an initial trajectory and rate, which is quite inefficient. For these reasons, we are developing alternative and reusable voice-based assistive technology termed the “Vocal Joystick” (VJ).

2 The Vocal Joystick

The VJ approach has three main characteristics:
1) Continuous control parameters: Unlike standard speech recognition, the VJ engine exploits continuous vocal characteristics that go beyond simple sequences of discrete speech sounds (such as syllables or words) and include e.g., pitch, vowel quality, and loudness, which are then mapped to continuous con-

[*]This material is based on work supported by the National Science Foundation under grant IIS-0326382.

trol parameters.

2) Discrete vocal commands: Unlike natural speech, the VJ discrete input language is based on a pre-designed set of sounds. These sounds are selected with respect to acoustic discriminability (maximizing recognizer accuracy), pronounceability (reducing potential vocal strain), mnemonic characteristics (reducing cognitive load), robustness to environmental noise, and application appropriateness.

3) Reusable infrastructure: Our goal is not to create a single application but to provide a modular library that can be incorporated by developers into a variety of applications that can be controlled by voice. The VJ technology is not meant to replace standard ASR but to enhance and be compatible with it.

2.1 Vocal Characteristics

Three continuous vocal characteristics are extracted by the VJ engine: *energy*, *pitch*, and *vowel quality*, yielding four specifiable continuous degrees of freedom. The first of these, localized acoustic *energy*, is used for voice activity detection. In addition, it is normalized relative to the current vowel detected (see Section 3.3), and is used by our current VJ-WIMP application (Section 4) to control the velocity of cursor movements. For example, a loud voice causes a faster movement than does a quiet voice. The second parameter, *pitch*, is also extracted but is currently not mapped to any control dimension in the VJ-WIMP application but will be in the future. The third parameter is *vowel quality*. Unlike consonants, which are characterized by a greater degree of constriction in the vocal tract, vowels have much inherent signal energy and are therefore well-suited to environments where both high accuracy and noise-robustness are crucial. Vowels can be characterized using a 2-D space parameterized by F1 and F2, the first and second vocal-tract formants (resonant frequencies). We initially experimented with directly extracting F1/F2 and using them for directly specifying 2-D continuous control. While we have not ruled out the use of F1/F2 in the future, we have so far found that even the best F1/F2 detection algorithms available are not yet accurate enough for precise real-time specification of movement. Therefore, we classify vowels directly and map them onto the 2-D vowel space characterized by degree of constriction (i.e., tongue height) and tongue body position (Figure 1). In our VJ-WIMP application, we use

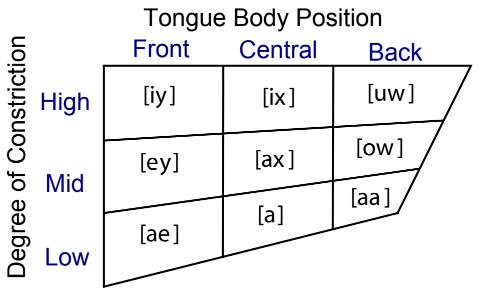

Figure 1: Vowel configurations as a function of their dominant articulatory configurations.

the four corners of this chart to map to the 4 principle directions of up, down, left, and right as shown in Figure 2 (note that the two figures are flipped and rotated with respect to each other). We have four different VJ systems running: A) a *4-class system* allowing only the specification of the 4 principle directions; B) a *5-class system* that also includes the phone [ax] to act as a carrier when wishing to vary only pitch and loudness; C) a *8-class* system that includes the four diagonal directions; and D) a *9-class* system that includes all phones and directions. Most of the discussion in this paper refers to the 4-class system.

A fourth vocal characteristic is also extracted by the VJ engine, namely *discrete sounds*. These sounds may correspond to button presses as on a mouse or joystick. The choice of sounds depends on the application and are chosen according to characteristic 2 above.

3 The VJ Engine

Our system-level design goals are modularity, low latency, and maximal computational efficiency. For this reason, we share common signal processing operations in multiple signal extraction modules, which yields real-time performance but leaves considerable computational headroom for the back-end applications being driven by the VJ engine.

Figure 3 shows the VJ engine architecture having three modules: signal processing, pattern recognition, and motion control.

3.1 Signal Processing

The goal of the signal processing module is to extract low-level acoustic features that can be used in

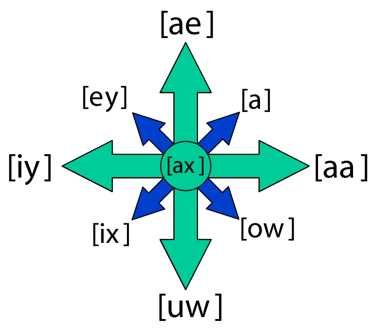

Figure 2: Vowel-direction mapping: vowels corresponding to directions.

estimating the vocal characteristics. The features we use are energy, normalized cross-correlation coefficients (NCCC), formant estimates, Mel-frequency cepstral coefficients (MFCCs), and formant estimates. To extract features, the speech signal is PCM sampled at a rate of F_s =16,000Hz. Energy is measured on a frame-by-frame basis with a frame size of 25ms and a frame step of 10ms. Pitch is extracted with a frame size of 40ms and a frame step of 10ms. Multiple pattern recognition tasks may share the same acoustic features: for example, energy and NCCCs are used for pitch tracking, and energy and MFCCs can be used in vowel classification and discrete sound recognition. Therefore, it is more efficient to decouple feature extraction from pattern recognition, as is shown in Figure 3.

3.2 Pattern Recognition

The pattern recognition module uses the acoustic features to extract desired parameters. The estimation and classification system must simultaneously perform *energy* computation (available from the input), *pitch tracking*, *vowel classification*, and *discrete sound recognition*.

Many state-of-the-art *pitch trackers* are based on dynamic programming (DP). This, however, often requires the meticulous design of local DP cost functions. The forms of these cost functions are usually empirically determined and/or their parameters are tuned by algorithms such as gradient descent (D.Talkin, 1995). Since different languages and applications may follow very different pitch transition patterns, the cost functions optimized for certain languages and applications may not be the most appropriate for others. Our VJ system utilizes a graphical model mechanism to automatically optimize the parameters of these cost functions, and has been shown to yield state-of-the-art performance (X.Li et al., 2004; J.Malkin et al., 2005).

For frame-by-frame *vowel classification*, our design constraints are the need for extremely low latency and low computational cost. Probability estimates for vowel classes thus need to be obtained as soon as possible after the vowel has been uttered or after any small change in voice quality has occurred. It is well known that models of vowel classification that incorporate temporal dynamics such as hidden Markov models (HMMs) can be quite accurate. However, the frame-by-frame latency requirements of VJ make HMMs unsuitable for vowel classification since HMMs estimate the likelihood of a model based on the entire utterance. An alternative is to utilize causal “HMM-filtering”, which computes likelihoods at every frame based on all frames seen so far. We have empirically found, however, that slightly non-causal and quite localized estimates of the vowel category probability is sufficient to achieve user satisfaction. Specifically, we obtain probability estimates of the form $p(V_t|X_{t-\tau},\ldots,X_{t+\tau})$, where V is a vowel class, and $X_{t-\tau},\ldots,X_{t+\tau}$ are feature frames within a length $2\tau+1$ window of features centered at time t. After several empirical trials, we decided on neural networks for vowel classification because of the availability of efficient discriminative training algorithms and their computational simplicity. Specifically we use a simple 2-layer multi-layer perceptron (Bishop, 1995) whose input layer consists of $26 * 7 = 182$ nodes, where 26 is the dimension of X_t, the MFCC feature vector, and $2\tau + 1 = 7$ is the number of consecutive frames, and that has 50 hidden nodes (the numbers 7 and 50 were determined empirically). The output layer has 4 output nodes representing 4 vowel probabilities. During training, the network is optimized to minimize the Kullback-Leibler (K-L) divergence between the output and the true label distribution, thus achieving the aforementioned probabilistic interpretation.

The VJ engine needs not only to detect that the user is specifying a vowel (for continuous control) but also a consonant-vowel-consonant (CVC) pattern (for discrete control) quickly and with a low probability of confusion (a VJ system also uses C and CV patterns for discrete commands). Requiring an initial consonant will phonetically distinguish these sounds from the pure vowel segments used for continuous control — the VJ system constantly monitors for changes that indicate the beginning of one of the discrete control commands. The vowel within the CV and CVC patterns, moreover, can help prevent background noise from being mis-classified as a discrete sound. Lastly, each such pattern currently requires an ending silence, so that the next command (a new discrete sound or continuous control vowel) can be accurately initiated. In all cases, a simple threshold-based rejection mechanism is used to reduce false positives.

To recognize the discrete control signals, HMMs are employed since, as in standard speech recognition, time warping is necessary to normalize for different signal durations corresponding to the same class. Specifically, we embed phone HMMs into "word" (C, CV, or CVC) HMMs. In this way, it is possible to train phone models using a training set that covers all possible phones, and then construct an application-specific discrete command vocabulary without retraining by recombining existing phone HMMs into new word HMMs. Therefore, each VJ-driven application can have its own appropriate discrete sound set.

3.3 Motion Control: Direction and Velocity

The VJ motion control module receives several pattern recognition parameters and processes them to produce output more appropriate for determining 2-D movement in the VJ-WIMP application.

Initial experiments suggested that using pitch to affect cursor velocity (Igarashi and Hughes, 2001) would be heavily constrained by an individual's vocal range. Giving priority to a more universal user-independent VJ system, we instead focused on relative energy. Our observation that users often became quiet when trying to move small amounts confirmed energy as a natural choice. Drastically different intrinsic average energy levels for each vowel, however, meant that comparing all sounds to a global average energy would create a large vowel-dependent bias. To overcome this, we distribute the energy per frame among the different vowels, in proportion to the probabilities output by the neural network, and track the average energy for each vowel independently. By splitting the power in this way, there is no effect when probabilities are close to 1, and we smooth out changes during vowel transitions when probabilities are more evenly distributed.

There are many possible options for determining velocity (a vector capturing both direction and speed magnitude) and "acceleration" (a function determining how the control-to-display ratio changes based on input parameters), and the different schemes have a large impact on user satisfaction. Unlike a standard mouse cursor, where the mapping is from 2-D hand movement to a 2-D screen, the VJ system maps from vocal-tract articulatory movement to a 2-D screen, and the transformation is not as straightforward. All values are for the current time frame t unless indicated otherwise. First, a raw direction value is calculated for each axis $j \in \{\text{x}, \text{y}\}$ as

$$d_j = \sum_i p_i \cdot \langle \mathbf{v}_i, \mathbf{e}_j \rangle \qquad (1)$$

in which $p_i = p(V_t = i | X_{t-\tau,\ldots,t+\tau})$ is the probability for vowel i at time t, $\mathbf{v}_i$ is a unit vector in the direction of vowel i, $\mathbf{e}_j$ is the unit-length positive directional basis vector along the j axis, and $\langle \mathbf{v}, \mathbf{e} \rangle$ is the projection of vector $\mathbf{v}$ onto unit vector $\mathbf{e}$. To determine movement speed, we first calculate a scalar for each axis j as

$$s_j = \sum_i \max \left[0, g_i \left(p_i \cdot f(\frac{E}{\mu_i}) \right) \right] \cdot |\langle \mathbf{v}_i, \mathbf{e}_j \rangle|$$

where E is the energy in the current frame, μ_i is the average energy for vowel i, and $f(\cdot)$ and $g_i(\cdot)$ are functions used for energy normalization and perceptual scaling (such as logs and/or cube-roots). This therefore allocates frame energy to direction based on the vowel probabilities. Lastly, we calculate the velocity for axis j at the current frame as

$$V_j = \beta \cdot s_j^{\alpha} \cdot \exp(\gamma s_j). \qquad (2)$$

where β represents the overall system sensitivity and the other values (α and γ) are warping constants, allowing the user to control the shape of the acceleration curve. Typically only one of α and γ is nonzero. Setting both to zero results in constant-speed movement along each axis, while $\alpha = 1$ and $\gamma = 0$ gives a linear mapping that will scale motion with energy but have no acceleration. The current user-independent system uses $\beta = 0.6$, $\gamma = 1.0$ and sets $\alpha = 0$. Lastly, the final velocity along axis j is $V_j d_j$. Future publications will report on systematic evaluations of different $f(\cdot)$ and $g_i(\cdot)$ functions.

3.4 Motion Control: User Adaptation

Since vowel quality is used for continuous control, inaccuracies can arise due to speaker variability owing to different speech loudness levels, vocal tract lengths, etc. Moreover, a vowel class articulated by one user might partially overlap in acoustic space with a different vowel class from another user. This imposes limitations on a purely user-independent vowel classifier. Differences in speaker loudness alone could cause significant unpredictability. To mitigate these problems, we have designed an adaptation procedure where each user is asked to pronounce four pre-defined vowel sounds, each lasting 2-3 seconds, at the beginning of a VJ session. We have investigated several novel adaptation strategies utilizing both neural networks and support vector machines (SVM). The fundamental idea behind them both is that an initial speaker-independent transformation of the space is learned using training data, and is represented by the first layer of a neural network. Adaptation data then is used to transform various parameters of the classifier (e.g., all or sub-portions of the neural network, or the parameters of the SVM). Further details of some of these novel adaptation strategies appear in (X.Li et al., 2005), and the remainder will appear in forthcoming publications. Also, the average energy values of each vowel for each user are recorded and used to normalize the speed control rate mentioned above. Preliminary evaluations on the data so far collected show very good results, with adaptation reducing the vowel classification error rate by 18% for the 4-class case, and 35% for the 8-class case. Moreover, informal studies have shown that users greatly prefer the VJ system after adaptation than before.

4 Applications and Videos

Our overall intent is for VJ to interface with a variety of applications, and our primary application so far has been to drive a standard WIMP interface with VJ controls, what we call the *VJ-WIMP* application. The current VJ version allows left button clicks (press and release, using the consonant [k]) as well as left button toggles (using consonant [ch]) to allow dragging. Since WIMP interfaces are so general, this allows us to indirectly control a plethora of different applications. Video demonstrations are available at the URL: `http://ssli.ee.washington.edu/vj`.

One of our key VJ applications is vocal web browsing. The video (dated 6/2005) shows examples of two web browsing tasks, one as an example of navigating the New York Times web site, the other using Google Maps to select and zoom in on a target area. Section 5 describes a preliminary evaluation on these tasks. We have also started using the VJ engine to control video games (third video example), have interfaced VJ with the Dasher system (Ward et al., 2000) (we call it the "Vocal Dasher"), and have also used VJ for figure drawing.

Several additional direct VJ-applications have also been developed. Specifically, we have directly interfaced the VJ system into a simple blocks world environment, where more precise object movement is possible than via the mouse driver. Specifically, this environment can draw arbitrary trajectories, and can precisely measure user fidelity when moving an object along a trajectory. Fidelity depends both on positional accuracy and task duration. One use of this environment shows the spatial direction corresponding to vocal effort (useful for training, forth video example). Another shows a simple robotic arm being controlled by VJ. We plan to use this environment to perform formal and precise user-performance studies in future work.

5 Preliminary User Study

We conducted a preliminary user study[1] to evaluate the feasibility of VJ and to obtain feedback regarding specific difficulties in using the VJ-WIMP system. While this study is not accurate in that: 1) it does not yet involve the intended target population

[1]The user study presented here used an earlier version of VJ than the current improved one described in the preceding pages.

of individuals with motor impairments, and: 2) the users had only a small amount of time to practice and become adept at using VJ, the study is still indicative of the VJ approach's overall viability as a novel voice-based human-computer interface method. The study quantitatively compares VJ performance with a standard desktop mouse, and provides qualitative measurement of the user's perception of the system.

5.1 Experiment Setup

We recruited seven participants ranging from age 22 to 26, none of whom had any motor impairment. Of the seven participants, two were female and five were male. All of them were graduate students in Computer Science, although none of them had previously heard of or used VJ. Four of the participants were native English speakers; the other three had an Asian language as their mother tongue.

We used a Dell Inspiron 9100 laptop with a 3.2 GHz Intel Pentium IV processor running the Fedora Core 2 operating system, with a 1280 x 800 24-bit color display. The laptop was equipped with an external Microsoft IntelliMouse connected through the USB port which was used for all of the tasks involving the mouse. A head-mounted Amanda NC-61 microphone was used as the audio input device, while the audio feedback from the laptop was output through the laptop speakers. The Firefox browser was used for all of the tasks, with the browser screen maximized such that the only portion of the screen which was not displaying the contents of the web page was the top navigation toolbar which was 30 pixels high.

5.2 Quantitative and Qualitative Evaluation

At the beginning of the quantitative evaluation, each participant was given a brief description of the VJ operations and was shown a demonstration of the system by a practiced experimenter. The participant was then guided through an adaptation process during which she/he was asked to pronounce the four directional vowels (Section 3.4). After adaptation, the participant was given several minutes to practice using a simple target clicking application. The quantitative portion of our evaluation followed a within-participant design. We exposed each participant to two experimental conditions which we refer to as input modalities: the *mouse* and the *VJ*. Each participant completed two tasks on each modality, with one trial per task.

The first task was a link navigation task (*Link*), in which the participants were asked to start from a specific web page and follow a particular set of links to reach a destination. Before the trial, the experimenter demonstrated the specified sequence of links to the participant by using the mouse and clicking at the appropriate links. The participant was also provided with a sheet of paper for their reference that listed the sequence of links that would lead them to the target. The web site we used was a Computer Science Department student guide and the task involved following six links with the space between each successive link including both horizontal and vertical components.

The second task was map navigation (*Map*), in which the participant was asked to navigate an online map application from a starting view (showing the entire USA) to get to a view showing a particular campus. The size of the map was 400x400 pixels, and the set of available navigation controls surrounding the map included ten discrete zoom level buttons, eight directional panning arrows, and a click inside the map causing the map to be centered and zoomed in by one level. Before the trial, a practiced experimenter demonstrated how to locate the campus map starting from the USA view to ensure they were familiar with the geography.

For each task, the participants performed one trial using the mouse, and one trial using a 4-class VJ. The trials were presented to the participants in a counterbalanced order. We recorded the completion time for each trial, as well as the number of *false positives* (system interprets a click when the user did not make a click sound), *missed recognitions* (the user makes a click sound but the system fails to recognize it as a click), and *user errors* (whenever the user clicks on an incorrect link). The recorded trial times include the time used by all of the above errors including recovery time.

After the completion of the quantitative evaluation, the participants were given a questionnaire which consisted of 14 questions related to the participants' perception of their experience using VJ such as the degree of satisfaction, frustration, and embarrassment. The answers were encoded on a 7-point Likert scale. We also included a space where the participants could write in any comments, and an in-

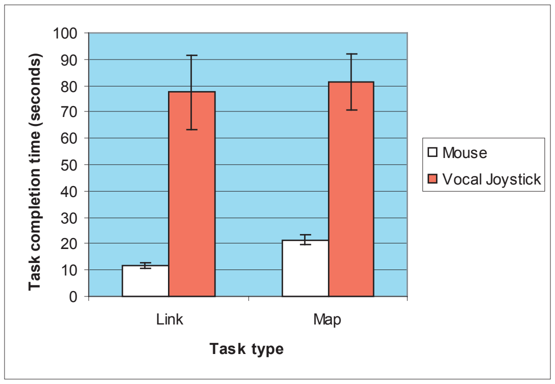

Figure 4: Task complement times

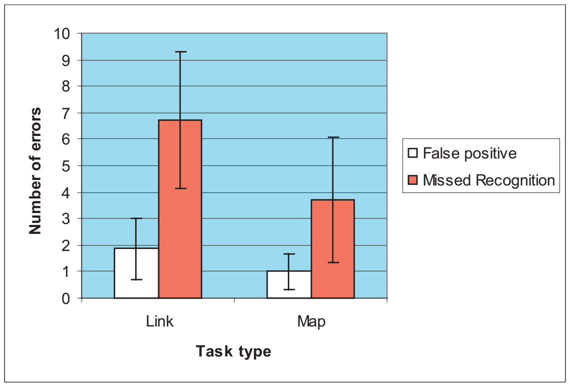

Figure 6: Average number of click errors per task

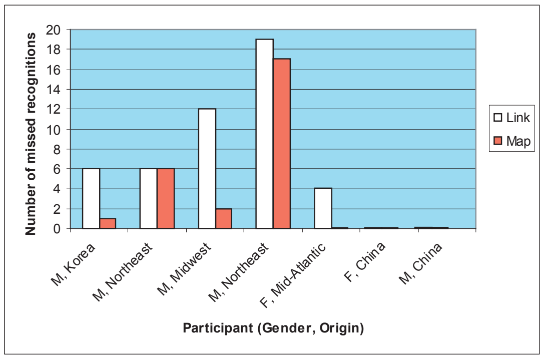

Figure 5: Missed recognitions by participant

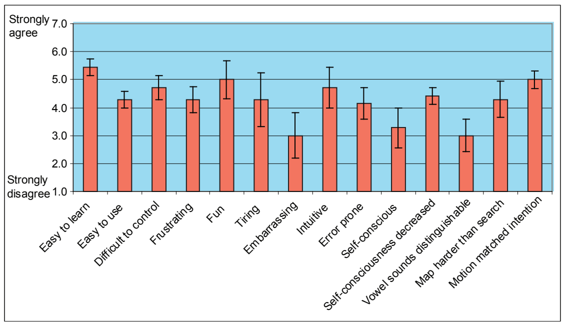

Figure 7: Questionnaire results

formal post-experiment interview was performed to solicit further feedback.

5.3 Results

Figure 4 shows the task completion times for Link and Map tasks, Figure 5 shows the breakdown of click errors by individual participants, Figure 6 shows the average number of false positive and missed recognition errors for each of the tasks. There was no instance of user error in any trial. Figure 7 shows the median of the responses to each of the fourteen questionnaire questions (error bars in each plot show ± standard error). In our measurement of the task completion times, we considered the VJ's recognition error rate as a fixed factor, and thus did not subtract the time spent during those errors from the task completion time.

There were several other interesting observations that were made throughout the study. We noticed that the participants who had the least trouble with missed recognitions for the clicking sound were either female or with an Asian language background, as shown in Figure 5. Our hypothesis regarding the better performance by female participants is that the original click sound was trained on one of our female researcher's voice. We plan also in future work to determine how the characteristics of different native language speakers influence VJ, and ultimately to correct for any bias.

All but one user explicitly expressed their confusion in distinguishing between the [ae] and [aa] vowels. Four of the seven participants independently stated that their performance would probably have been better if they had been able to practice longer, and did not attribute their perceived suboptimal performance to the quality of the VJ's recognition system. Several participants reported that they felt their vocal cords were strained due to having to produce a loud sound in order to get the cursor to move at the desired speed. We suspect this is due either to analog gain problems or to their adapted voice being too loud, and therefore the system calibrating the normal speed to correspond to the loud voice. We have since removed this problem by adjusting our adaptation strategy to express preference for a quiet voice.

In summary, the results from our study suggest that users without any prior experience were able to perform basic mouse based tasks using the Vocal Joystick system with relative slowdown of four to nine times compared to a conventional mouse. We anticipate that future planned improvements in the algorithms underlying the VJ engine (to improve accuracy, user-independence, adaptation, and speed) will further increase the VJ system's viability, and combined with practice could improve VJ enough so that it becomes a reasonable alternative compared to a standard mouse's performance.

6 Related Work

Related voice-based interface studies include (Igarashi and Hughes, 2001; Olwal and Feiner, 2005). Igarashi & Hughes presented a system where non-verbal voice features control a mouse system — their system requires a command-like discrete sound to determine direction before initiating a movement command, where pitch is used to control velocity. We have empirically found an energy-based mapping for velocity (as used in our VJ system) both more reliable (no pitch-tracking errors) and intuitive. Olwal & Feiner's system moves the mouse only after recognizing entire words. de Mauro's "voice mouse" `http://www.dii.unisi.it/~maggini/research/voice_mouse.html` focuses on continuous cursor movements similar to the VJ scenario; however, the voice mouse only starts moving after the vocalization has been completed leading to long latencies, and it is not easily portable to other applications. Lastly, the commercial dictation program Dragon by ScanSoft includes MouseGrid$^{\mathrm{TM}}$(Dra, 2004) which allows discrete vocal commands to recursively 9-partition the screen, thus achieving log-command access to a particular screen point. A VJ system, by contrast, uses continuous aspects of the voice, has change latency (about 60ms) not much greater than reaction time, and allows the user to make instantaneous directional change using one's voice (e.g., a user can draw a "U" shape in one breath).

7 Conclusions

We have presented new voice-based assistive technology for continuous control tasks and have demonstrated an initial system implementation of this concept. An initial user study using a group of individuals from the non-target population confirmed the feasibility of this technology. We plan next to further improve our system by evaluating a number of novel pattern classification techniques to increase accuracy and user-independence, and to introduce additional vocal characteristics (possibilities include vibrato, degree of nasality, rate of change of any of the above as an independent parameter) to increase the available simultaneous degrees of freedom controllable via the voice. Moreover, we plan to develop algorithms to decouple unintended user correlations of these parameters, and to further advance both our adaptation and acceleration algorithms.

Speech-based Information Retrieval System with Clarification Dialogue Strategy

Abstract

This paper addresses a dialogue strategy to clarify and constrain the queries for speech-driven document retrieval systems. In spoken dialogue interfaces, users often make utterances before the query is completely generated in their mind; thus input queries are often vague or fragmental. As a result, usually many items are matched. We propose an efficient dialogue framework, where the system dynamically selects an optimal question based on information gain (IG), which represents reduction of matched items. A set of possible questions is prepared using various knowledge sources. As a bottom-up knowledge source, we extract a list of words that can take a number of objects and potentially causes ambiguity, using a dependency structure analysis of the document texts. This is complemented by top-down knowledge sources of metadata and hand-crafted questions. An experimental evaluation showed that the method significantly improved the success rate of retrieval, and all categories of the prepared questions contributed to the improvement.

1 Introduction

The target of spoken dialogue systems is being extended from simple databases such as flight information (Levin et al., 2000; Potamianos et al., 2000) to general documents (Fujii and Itou, 2003) including newspaper articles (Chang et al., 2002; Hori et al., 2003). In such systems, the automatic speech recognition (ASR) result of the user utterance is matched against a set of target documents using the vector space model, and documents with high matching scores are presented to the user.

In this kind of document retrieval systems, user queries must include sufficient information to identify the desired documents. In conventional document query tasks with typed-text input, such as TREC QA Track (NIST and DARPA, 2003), queries are (supposed to be) definite and specific. However, this is not the case when speech input is adopted. The speech interface makes input easier. However, this also means that users can start utterances before queries are thoroughly formed in their mind. Therefore, input queries are often vague or fragmental, and sentences may be ill-formed or ungrammatical. Moreover, important information may be lost due to ASR errors. In such cases, an enormous list of possible relevant documents is usually obtained because there is very limited information that can be used as clues for retrieval. Therefore, it is necessary to narrow down the documents by clarifying the user's intention through a dialogue.

There have been several studies on the follow-up dialogue, and most of these studies assume that the target knowledge base has a well-defined structure. For example, Denecke (Denecke and Waibel, 1997) addressed a method to generate guiding questions based on a tree structure constructed by unifying pre-defined keywords and semantic slots. However, these approaches are not applicable to general docu-

ment sets without such structures.

In this paper, we propose a dialogue strategy to clarify the user's query and constrain the retrieval for a large-scale text knowledge base, which does not have a structure nor any semantic slots. In the proposed scheme, the system dynamically selects an optimal question, which can reduce the number of matched items most efficiently. As a criterion of efficiency of the questions, information gain (IG) is defined. A set of possible questions is prepared using bottom-up and top-down knowledge sources. As a bottom-up knowledge source, we conduct dependency structure analysis of the document texts, and extract a list of words that can take a number of objects, thus potentially causing ambiguity. This is combined with top-down knowledge sources of metadata and hand-crafted questions. The system then updates the query sentence using the user's reply to the question, so as to generate a confirmation to the user.

2 Document retrieval system for large-scale knowledge base

2.1 System overview

We have studied a dialogue framework to overcome the problems in speech-based document retrieval systems. In the framework, the system can handle three types of problems caused by speech input: ASR errors, redundancy in spoken language expression, and vagueness of queries. First, the system realizes robust retrieval against ASR errors and redundancies by detecting and confirming them. Then, the system makes questions to clarify the user's query and narrow down the retrieved documents.

The system flow of these processes is summarized below and also shown in Figure 1.

1. Recognize the user's query utterance.
2. Make confirmation for phrases which may include critical ASR errors.
3. Retrieve from knowledge base (KB).
4. Ask possible questions to the user and narrow down the matched documents.
5. Output the retrieval results.

In this paper, we focus on the latter stage of the proposed framework, and present a clarification dialogue strategy to narrow down documents.

Table 1: Document set (Knowledge Base: KB)

Text collection	# documents	text size (byte)
glossary	4,707	1.4M
FAQ	11,306	12M
DB of support articles	23,323	44M

2.2 Task and back-end retrieval system

Our task involves text retrieval from a large-scale knowledge base. For the target domain, we adopt a software support knowledge base (KB) provided by Microsoft Corporation. The knowledge base consists of the following three kinds: glossary, frequently asked questions (FAQ), and support articles. The specification is listed in Table 1, and there are about 40K documents in total. An example of support article is shown in Figure 2.

Dialog Navigator (Kiyota et al., 2002) has been developed at University of Tokyo as a retrieval system for this KB. The system accepts a typed-text input from users and outputs a result of the retrieval. The system interprets an input sentence by taking syntactic dependency and synonymous expression into consideration for matching it with the KB. The target of the matching is the summaries and detail information in the support articles, and the titles of the Glossary and FAQ. The retrieved result is displayed to the user as the list of documents like Web

search engines. Since the user has to read detail information of the retrieved documents by clicking their icons one by one, the number of items in the final result is restricted to about 15.

In this work, we adopt Dialog Navigator as a back-end system and construct a spoken dialogue interface.

3 Dialogue strategy to clarify user's vague queries

3.1 Dialogue strategy based on information gain (IG)

In the proposed clarification dialogue strategy, the system asks optimal questions to constrain the given retrieval results and help users find the intended ones. Questions are dynamically generated by selecting from a pool of possible candidates that satisfy the precondition. The information gain (IG) is defined as a criterion for the selection. The IG represents a reduction of entropy, or how many retrieved documents can be eliminated by incorporating additional information (a reply to a question in this case). Its computation is straightforward if the question classifies the document set in a completely disjointed manner. However, the retrieved documents may belong to two or more categories for some questions, or may not belong to any category. For example, some documents in our KB are related with multiple versions of MS-Office, but others may be irrelevant to any of them. Moreover, the matching score of the retrieved documents should be taken into account in this computation. Therefore, we define IG $H(S)$ for a candidate question S by the following equations.

$$H(S) = -\sum_{i=0}^{n} P(i) \cdot \log P(i)$$

$$P(i) = \frac{|C_i|}{\sum_{i=0}^{n} |C_i|}$$

$$|C_i| = \sum_{D_k \in i} CM(D_k)$$

Here, D_k denotes the k-th retrieved document by matching the query to the KB, and $CM(D)$ denotes the matching score of document D. Thus, C_i represents the number of documents classified into category i by candidate question S, which is weighted with the matching score. The documents that are not related to any category are classified as category 0.

The system flow incorporating this strategy is summarized below and also shown in Figure 3.

1. For a query sentence, retrieve from KB.
2. Calculate IG for all possible candidate questions which satisfy precondition.
3. Select the question with the largest IG (larger than a threshold), and ask the question to the user. Otherwise, output the current retrieval result.
4. Update the query sentence using the user's reply to the question.
5. Return to 1.

This procedure is explained in detail in the following sections.

3.2 Question generation based on bottom-up and top-down knowledge sources

We prepare a pool of questions using three methods based on bottom-up knowledge together with top-down knowledge of KB. For a bottom-up knowledge

Table 2: Examples of candidate questions (Dependency structure analysis: method 1)

Question	Precondition	Ratio of applicable doc.	IG
What did you <u>delete</u>?	Query sentence includes “delete”	2.15 (%)	7.44
What did you <u>install</u>?	Query sentence includes “install”	3.17 (%)	6.00
What did you <u>insert</u>?	Query sentence includes “insert”	1.12 (%)	7.12
What did you <u>save</u>?	Query sentence includes “save”	1.81 (%)	6.89
What is the <u>file</u> type?	Query sentence includes “file”	0.94 (%)	6.00
What did you <u>setup</u>?	Query sentence includes “setup”	0.69 (%)	6.45

source, we conducted a dependency structure analysis on KB. As for top-down knowledge, we make use of metadata included in KB and human knowledge.

3.2.1 Questions based on dependency structure analysis (method 1)

This type of question is intended to clarify the modifier or object of some words, based on dependency structure analysis, when they are uncertain. For instance, the verb “delete” can have various objects such as “application program” or “address book”. Therefore, the query can be clarified by identifying such objects if they are missing. However, not all words need to be confirmed because the modifier or object can be identified almost uniquely for some words. For instance, the object of the word “shutdown” is “computer” in most cases in this task domain. It is tedious to identify the object of such words. We therefore determine the words to be confirmed by calculating entropy for modifier-head pairs from the text corpus. The procedure is as follows.

1. Extract all modifier-head pairs from the text of KB and query sentences (typed input) to another retrieval system[1] provided by Microsoft Japan.
2. Calculate entropy $H(m)$ for every word based on probability $P(i)$. This $P(i)$ is calculated with the occurrence count $N(m)$ of word m that appears in the text corpus and the count $N(i, m)$ of word m whose modifier is i.

$$H(m) = -\sum_i P(i) * \log P(i)$$

$$P(i) = \frac{N(i, m)}{N(m)}$$

[1]http://www.microsoft.com/japan/enable/nlsearch/

Table 3: Examples of candidate questions (Metadata: method 2)

Question	Precondition	Ratio of applicable doc.	IG
What is the version of your Windows?	None	30.03 (%)	2.63
What is your application?	None	30.28 (%)	2.31
What is the version of your Word?	Query sentence includes “Word”	3.76 (%)	2.71
What is the version of your Excel?	Query sentence includes “Excel”	4.13 (%)	2.44

Table 4: List of candidate questions (Human knowledge: method 3)

Question	Precondition	Ratio of applicable doc.	IG
When did the symptom occur?	None	15.40 (%)	8.08
Tell me the error message.	Query sentence includes “error”	2.63 (%)	8.61
What do you concretely want to do?	None	6.98 (%)	8.04

As a result, we selected 40 words that have a large value of entropy. Question sentences for these words were generated with a template of “What did you ...?” and unnatural ones were corrected manually. Categories for IG calculation are defined by objects of these words included in matched documents. The system can make question using this method when these words are included in the user’s query. Table 2 lists examples of candidate questions using this method. In this table, ratio of applicable document corresponds to the ratio of documents that include the words selected above, and IG is calculated using applicable documents.

3.2.2 Questions based on metadata included in KB (method 2)

We also prepare candidate questions using the metadata attached to the KB. In general large-scale KBs, metadata is usually attached to manage them efficiently. For example, category information is attached to newspaper articles and books in libraries. In our target KB, a number of documents include metadata of product names to which the document applies. The system can generate question to which the user’s query corresponds using this metadata. However, some documents are related with multiple versions, or may not belong to any category. Therefore, the performance of these questions greatly depends on the characteristics of the metadata.

Fourteen candidate questions are prepared using this method. Example of candidate questions are listed in Table 3. Ratio of applicable document corresponds to the ratio of documents that have metadata of target products.

3.2.3 Questions based on human knowledge (method 3)

Software support is conventionally provided by operators at call centers. We therefore prepare candidate questions based on the human knowledge that has been accumulated there. This time, three kinds of questions are hand-crafted. For instance, the question “When did the symptom occur?” tries to capture key information to identify relevant documents. The categories for IG caluclation are defined using hand-crafted rules by focusing on key-phrases such as “after ...” or “during ...”. Candidate questions are listed in Table 4.

An example dialogue where the system asks questions based on IG is in Figure 4.

3.3 Update of retrieval query sentence

Through the dialogue to clarify the user’s query, the system updates the query sentence using the user’s reply to the question. Our backend information retrieval system does not adopt simple “bag-

S1:	What is your problem?
U1:	Too garbled to read.
(Retrieval results):	1. Close button and maximize button are garbled. 2. Characters are garbled in Outlook Today. 3. Characters are garbled while inserting Japanese text. 4. VB application is garbled to read. . . .
	(Calculate IG) · Candidate question 1: What is garbled to read? – IG 5.27 · Candidate question 2: What is the version of your Windows? – IG 1.43 · Candidate question 3: When did the symptom occur? – IG 2.47 . . .
S2:	**(Select question with largest IG)** What is garbled to read?
U2:	Characters on window button.
S3:	**(Update query sentence)** Retrieving with "Characters on window button are too garbled to read".

Figure 4: Example dialogue

of-words" model, but conducts a more precise dependency structure analysis for matching; therefore forming an appropriate query sentence is desirable rather than simply adding keywords. Moreover, it is more comprehensible to the user to present the updated query sentence than to show the sequence of ASR results. Here, the update rules of the query sentence are prepared as follows.

1. Questions based on dependency structure analysis
   The user's reply is added immediately before of after the word that is the reply's modifying head. For instance, the reply to the question "What did you delete?" is inserted right after the word "delete" in the query sentence.

2. Questions based on metadata of KB
   Phrases "In {Product name} {version name}" are added to the query sentence.

3. Questions based on human knowledge
   The position where the user's reply is inserted is specified beforehand for each question candidate. For instance, the reply to the question "Tell me the error message." is inserted right after the word "error" in the query sentence.

A dialogue example where the system updates the user's query is shown in Figure 5. In the example, the system makes confirmation "Retrieving with 'When I try to open it in explorer, I cannot open Excel 2002 file' " at the end of the dialogue before presenting the actual retrieval result.

3.4 Experimental evaluation

We implemented and evaluated the proposed method. We collected a test data by 14 subjects who had not used our system Each subject was requested to retrieve support articles for 14 tasks, which consisted of prepared scenarios (query sentences were not given). The subjects were allowed to utter a query again up to twice per task if they thought an adequate retrieval result was not obtained. As a result, we collected 238 utterances for 196 (=14 $\times$ 14) tasks in total. An example of scenario and user utterances are shown in Figure 6. The average word accuracy of ASR was 82.9%. The threshold value in IG that the system makes a question is set to 1.0 ini-

S1:	What is your problem?
U1:	I cannot open the file.
S2:	What is the file type? (method 1)
U2:	Excel file.
(Update query sentence):	“I cannot open Excel file.”
S3:	What is the version of your Excel? (method 2)
U3:	My Excel is version 2002.
(Update query sentence):	“I cannot open Excel 2002 file.”
S4:	When did the symptom occur? (method 3)
U4:	Tried to open it in explorer.
S5:	Retrieving with “When I try to open it in explorer, I cannot open Excel 2002 file”.

Figure 5: Query sentence update using user’s reply

- **An example of scenario**
  You are looking for restaurant in Kyoto using WWW. You have found a nice restaurant and tried to print out an image of the map showing the restaurant. However, it is not printed out. (Your browser is IE 6.0)
- **Examples of users’ utterance**
  - I want to print an image of map.
  - I can’t print out.
  - I failed to print a picture in homepage using IE.
  - Please tell me how to print out an image.

Figure 6: Example of scenario and user utterances

tially, and incremented by 0.3 every time the system generates a question through a dialogue session.

First, we evaluated the success rate of retrieval. We regarded a retrieval as successful when the retrieval result contained a correct document entry for the scenario. We compared the following cases.

1. Transcript: A correct transcript of the user utterance, prepared manually, was used as an input.

2. ASR result (baseline): The ASR result was used as an input.

3. Proposed method (log data): The system generated questions based on the proposed method, and the user replied to them as he/she thought appropriate.

We also evaluated the proposed method by simulation in order to confirm its theoretical effect. Various factors of the entire system might influence the performance in real dialogue which is evaluated by the log data. Specifically, the users might not have answered the questions appropriately, or the replies might not have been correctly recognized. Therefore, we also evaluated with the following condition.

4. Proposed method (simulation): The system generated questions based on the proposed method, and appropriate answers were given manually.

Table 5 lists the retrieval success rate and the rank of the correct document in the retrieval result, by these cases. The proposed method achieved a better success rate than when the ASR result was used. An improvement of 12.6% was achieved in the simulation case, and 7.7% by the log data. These figures demonstrate the effectiveness of the proposed approach. The success rate of the retrieval was about 5% higher in the simulation case than the log data. This difference is considered to be caused by following factors.

1. ASR errors in user’s uttered replies
   In the proposed strategy, the retrieval sentence is updated using the user’s reply to the question regardless of ASR errors. Even when the user notices the ASR errors, he/she cannot correct them. Although it is possible to confirm them using ASR confidence measures, it makes dialogue more complicated. Hence, it was not implemented this time.

2. User’s misunderstanding of the system’s questions
   Users sometimes misunderstood the system’s questions. For instance, to the system question “When did the symptom occur?”, some user

Table 5: Success rate and average rank of correct document in retrieval

	Success rate	Rank of correct doc.
Transcript	76.1%	7.20
ASR result (baseline)	70.7%	7.45
Proposed method (log data)	78.4%	4.40
Proposed method (simulation)	83.3%	3.85

Table 6: Comparison of question methods

	Success rate	# generated questions (per dialogue)
ASR result (baseline)	70.7%	—
Dependency structure analysis (method 1)	74.5%	0.38
Metadata (method 2)	75.7%	0.89
Human knowledge (method 3)	74.5%	0.97
All methods (method 1-3)	83.3%	2.24

replied simply “just now” instead of key information for the retrieval. To this problem, it may be necessary to make more specific questions or to display reply examples.

We also evaluated the efficiency of the individual methods. In this experiment, each of the three methods was used to generate questions. The results are in Table 6. The improvement rate by the three methods did not differ very much, and most significant improvement was obtained by using the three methods together. While the questions based on human knowledge are rather general and were used more often, the questions based on the dependency structure analysis are specific, and thus more effective when applicable. Hence, the questions based on the dependency structure analysis (method 1) obtained a relatively high improvement rate per question.

4 Conclusion

We proposed a dialogue strategy to clarify user' queries for document retrieval tasks. Candidate questions are prepared based on the dependency structure analysis of the KB together with KB metadata and human knowledge. The system selects an optimal question based on information gain (IG). Then, the query sentence is updated using the user's reply. An experimental evaluation showed that the proposed method significantly improved the success rate of retrieval, and all categories of the prepared questions contributed to the improvement.

The proposed approach is intended for restricted domains, where all KB documents and several knowledge sources are available, and it is not applicable to open-domain information retrieval such as Web search. We believe, however, that there are many targets of information retrieval in restricted domains, for example, manuals of electric appliances and medical documents for expert systems. The methodology proposed here is not so dependent on the domains, thus applicable to many other tasks of this category.

Abstract

This paper describes an application of reinforcement learning to determine a dialog policy for a complex collaborative task where policies for both the system and a proxy for a user of the system are learned simultaneously. With this approach a useful dialog policy is learned without the drawbacks of other approaches that require significant human interaction. The specific task that the agents were trained on was chosen for its complexity and requirement that both conversants bring task knowledge to the interaction, thus ensuring its collaborative nature. The results of our experiment show that you can use reinforcement learning to create an effective dialog policy, which employs a mixed initiative strategy, without the drawbacks of large amounts of data or significant human input.

1 Introduction

The problem of developing a dialog manager can be expressed as the task of building a specific dialog policy for the dialog system to follow as it interacts with the user. A dialog policy can be thought of as an enumeration of all of the states a dialog system can be in, and the corresponding action to take from each of those states. Thus a policy completely specifies the behavior of a dialog manager.

Most conventional approaches to accomplishing this task seek to directly model human interactions in some manner. These techniques include hand-crafting a policy, using a Wizard-of-Oz approach in an iterative manner and inducing a policy from a human-human dialog corpus. All three approaches have shortcomings that make them less than ideal for developing dialog systems. The approach of hand-crafting of a dialog policy is problematic as it is difficult to predict how a user with interact with it, making it difficult to craft an optimal policy. To get around this, an iterative approach can be used, with a Wizard taking the place of the system. However, it is still difficult to train a wizard, and it is difficult to explore many different strategies in order to find the optimal one. Human-human dialog can be used for policy generation, as this should represent optimal behavior to accomplish a task. However, computers are not capable of behaving exactly as a human. In addition, humans might not interact with a computer as they would another person.

Recently a number of researchers have proposed using reinforcement learning to alleviating the problems encountered with more conventional methods of developing dialog policies. With the development of a good policy evaluation function, reinforcement learning can effectively and quickly explore a large policy space. There is the additional benefit that it will learn a policy that is optimal for the capabilities of the system.

The main drawback of reinforcement learning approaches is that they require some form of conversational partner to train the system against. Conventionally, these partners have taken the form of a human (Walker, 2000; Singh et al., 2002) or a simulated user (Levin et al., 2000; Scheffler and Young, 2002; Georgila et al., 2005). These two types of conversational partners limit the complexity and diversity of policies that can be generated by reinforcement learning. These two approaches to training partners limit the whole system to the abilities of the partners themselves. For a human partner we run into the significant time and effort problems that were present in Wizard-of-Oz and handcrafting policy development. With a simulated user the system is limited by the complexity and flexibility of the simulated user, which itself can require a large degree of handcrafting by its creator.

In this paper, we propose a solution to the conversational partner problem of generating a dialog policy with reinforcement learning. We have taken a complex collaborative task and used reinforcement learning, applied to both participants, to develop a dialog policy for the task. By training both agents simultaneously we are able to avoid the uncertainties of creating a user to train against, as well as the time and data limitations of training directly against humans. Our training approach allows us to avoid these conventional drawbacks even while applying reinforcement learning to complex tasks.

Section 2 provides a brief overview of previous work in using reinforcement learning for dialog systems. Sections 3 and 4 describe the dialog task and its specification as a reinforcement-learning problem. Section 5 and 6 present the results of this experiment and a discussion of them.

2 Related Work

A number of researchers have explored using reinforcement learning to create a policy for a dialog system. Walker (2000) trained a dialog system, ELVIS, to learn a dialog strategy for supporting spoken language access to a user's email. The main function of ELVIS is to provide verbal summaries of email folders. This summary could consist of simple statements about the number of messages or a more detailed description of current emails.

Reinforcement learning is used to determine the best settings for a variety of properties of the system. For example, the system must learn to choose between email reading styles of reading back the full email first, reading a summary of the email first, or prompting the user with the two choices of reading styles. The system also learns whether it is better to take a mixed initiative or a system initiative strategy when interacting with the user.

To enable the learning process, ELVIS utilized human users as its conversational partner. Users performed a set of tasks with ELVIS, with each run using different state-property values, which were randomly chosen for that dialog. In order to support humans as a training partner Walker restricted the policy space so that it would only contain policies that were capable of accomplishing the available system tasks. Thus, during training the users would not be faced with a system that simply could not perform the tasks asked of it.

ELVIS was trained with a Q-learning approach that sought to determine the expected utility at each state, where utility was a subjective function involving such variables as task completion and user satisfaction. The state variables utilized in the training process were (a) whether the user's name is known, (b) what the initiative style is, (c) the task progress, and (d) what the user's current goal is. Given these state variables, ELVIS was able to learn the best style to adopt in responding to the user's requests at various points in the dialog. One major shortcoming of the conversational partner used with ELVIS is its reliance upon human interaction for training. This shortcoming is somewhat mitigated by the fact that the learning problem was one of fitting together preexisting policy components, but would be severely limiting if the goal was to learn a complete dialog policy. The amount of data necessary for learning a complete policy makes direct human interaction in the learning process unrealistic.

Levin et al. (2000) tackles a slightly different reinforcement-learning task. She is learning a policy to use in a dialog system built from a small set of atomic actions. This system is trained to provide a verbal interface to an airline flight database. This system is able to provide users with a way to find flights that meet a dynamic set of criteria. The dialog agent's state consists of information regarding the departure city, destination city, flight date, etc. Levin takes a useful approach in reducing the size of true state space by simply tracking when a particular state variable has a value rather than including the specific value in the state. For instance during a dialog when the system determines that the departure city is New York it does not distinguish this from when it has determined that the departure city is Chicago.

To converse with the dialog agent during reinforcement learning, Levin uses a "simulated user." The simulated user is created from a corpus of human dialogs with a prior airline system. In developing this user Levin makes the simplifying assumption that a user's response is based solely on the previous prompt. Then the specific probabilities for each user response are determined by examining the corpus for exchanges that match the possible prompts for the new dialog agent as well as hand crafting some of the probabilities. During the actual learning the agent used Monte Carlo training with exploring starts in order to fully explore the state space.

The "simulated user" method of supplying the conversational partner seems difficult and not particularly applicable to tasks where a dialog corpus does not already exist, but Kearns and Singh (1998) indicates that the accuracy of the transition probabilities for the probabilistic user is not critical for the dialog agent to learn an optimal strategy. While this experiment does allow for the dialog agent to learn a complex strategy, the notion of learning against a simulated user limits the space of policies that will be considered during training. Training against a conversational partner that is a model of a human automatically prejudices the system towards policies that we would be inclined towards building by hand and precludes the sincere exploration of all possible policies.

3 Task Specification

For our experiment we use the task presented in Yang and Heeman (2004), which is a modification of the DesignWorld task of Walker (1995). The task requires 2 conversants to agree on 5 pieces of furniture to place in a room. Both conversants know all of the furniture items that can be chosen, which differ by color, type and point value. Each conversant also has private preferences about which furniture items it wants in the room; such as 'if there is a red couch in the room, I also want a lamp in the room'. Each preference has a score. As this is a collaborative task, the conversants have the goal of finding the 5 furniture items that have the highest score, where the score is the sum of the point value of each of the 5 chosen furniture items less the scores for any violated preferences of either conversant.

The conversational agents work to achieve their goal by performing the following actions: **propose**, **accept**, **reject**, **inform**, and **release turn**. If there is not a current proposal, either agent can **propose** an item, which makes that item into the current proposal. If there is a current proposal, the other conversant can **accept** it or **reject** it. Accepting an item results in that item being included in the task solution and removes it as the current proposal. Rejecting a proposed item removes it as the current proposal. When an item has been rejected it remains a valid choice for future proposals. In addition to accepting or rejecting a proposal, either conversant may **inform** the other conversant of preferences that are violated by the current proposal. A preference is violated by the current proposal if the addition of that proposed item to the solution set would cause the solution set to violate the preference. When a conversant informs of a violated preference, that preference becomes mutually known and so affects future decisions by both participants. Only preferences that are not known by the other conversant are communicated. For turn taking, we include the action **release turn**, which the conversant that currently has the turn can perform to signal that it is relinquishing the turn (cf. Traum and Hinkelman, 1992). Note that after a release turn, the other agent must make the next move, which could itself be a release turn. The inclusion of this action allows conversants to perform multiple actions in a row, such as a reject, an inform, and a propose. Our approach to turn taking differs slightly from Yang and Heeman, as they make it an implicit part of other actions.

In order to successfully utilize these actions in a dialog, some reasoning effort is required of the conversants. Conversants must be able to determine what preferences are violated by a pending proposal and which of the remaining items makes the best proposal. In order to keep the reasoning effort manageable, we follow Yang and Heeman and use a greedy algorithm to pick the item that results in the best score for the item plus the set of items already accepted. The conversants do not consider interactions with the items that will be subsequently added to the plan. Conversants using this greedy approach can construct a plan that is very close to optimal.

4 Learning Specification

4.1 Agent Specification

In order to apply reinforcement learning to this task we must formalize the conversants as reinforcement learning agents, specifying their state and actions, as well as the environment they will interact in. In order to reduce the size of the state space for this task we simplified the representation of the state in a manner similar to that done by Levin (2004). We formulated the state of the dialog agents with many of the more specific details of the actual state of the task removed. For instance the agent state does not include specific information about the furniture item that is the pending proposal, rather the agent's state only indicates that there is a pending proposal.

The state specification for each agent includes the following binary variables: **Pending-Proposal**, **I-Proposed**, **Violated-Preference**, **Prior-Violated-Preferences**, and **Better-Alternative**. **Pending-Proposal** indicates whether an item has been proposed but not accepted or rejected. **I-Proposed** indicates if the agent made the most recent proposal. **Violated-Preference** indicates that the pending proposal has caused one or more violations of the conversant's private preferences. **Prior-Violated-Preferences** indicates whether the conversant had one or more violated preferences when the pending proposal was made. This variable allows the agent to remember what its original response to a proposal was, even after it may have shared all of its preferences that were violated (thus creating a state where it no longer has any violated personal preferences). **Better-Alternative** indicates that the agent thinks it knows an item that would achieve a better score than the item currently proposed.

The actions from Section 3 can be sequenced in a number of different orders, leading to different policies. Unlike Yang and Heeman, who compared handcrafted policies, we use reinforcement learning to learn policy pairs, one part of the pair for the system, and the other for the simulated user. We have restricted the space of policies that can be learned. First, we reduce the space by only considering legal sequences of actions. For example, if there is a pending proposal, another item cannot be proposed. Second, after 5 items have been accepted, the dialog is automatically ended. Third, to keep the space of dialog policies small, we force an inform to inform of all violated preferences at once.

The Reinforcement Learning states and actions of our dialog agents capture a subset of the true state of the dialog. Our agents do not have the ability to distinguish between, or develop distinct policies in response to, the proposal of a blue chair versus a red desk. Since our formulation of the dialog agents do not encode specific information about items or preferences, the dialog environment must maintain these details. This extra information that must include the currently proposed item, what each agent's private and currently violated preferences are, what preferences are shared between each agent, what items have been accepted as part of the task solution, and what items are still available for selection. This technique of generalizing the state space is the same as the one used by Levin (2000), and allows us to keep the state space at a manageable size for our task.

4.2 Reinforcement Learning

For our Reinforcement Learning algorithm we chose to use an on-policy Monte Carlo method (Sutton and Barto, 1998). Our chosen task is naturally episodic since the two agents agreeing upon five items indicates task completion and thus the end of the dialog, which constitutes one learning episode. We also imposed a limit of 500 interactions per dialog in order to ensure that each learning episode was finite even if the task was not successfully completed. For some state-action pairs our task does not allow the accurate specification of the resulting state. In fact, due to the way that our state representation simplifies the true task environment an action choice for many states will necessarily lead to different states depending upon the task environment. For instance, proposing an item will sometimes lead to that items acceptance and sometimes it will be rejected. Given this uncertainty our learning approach necessarily had to learn the expected rewards of actions instead of states.

At the end of each dialog the interaction is given a score based on the evaluation function and that score is used to update the dialog policy of both agents. The state-action history for each agent is iterated over separately and the score from the recent dialog is averaged in with the expected return from the existing policy. We chose not to include any discounting factor to the dialog score as we progressed back through the dialog history. The decision to equally weight each state-action pair in the dialog history was made because an action's contribution to the dialog score is not dependent upon its proximity to the end of the task. An action that accepts a proposed item at the beginning of the dialog should be rewarded as much as an action that accepts a proposed item later in the same dialog.

In order for the learning agents to obtain a large enough variety of experiences to fully explore the state space some exploration technique must be used. We chose to use e-greedy action selection in order to achieve this goal. With this approach the dialog agent makes an on policy action choice with probability 1-e and a random valid action choice the rest of the time.

Training both agents simultaneously causes each agent to learn its policy as an optimal response to the opposing agent. This can create problems in the initial stages of training as each agent has an immature policy that is based on little experience. In this situation each of the agents will associate weights with state action pairs based on action choices of the opposing agent that are themselves not well developed. As training progresses the eccentricities of the initial immature policies are perpetuated and the learning process does not converge on an effective dialog policy for either agent.

In order to combat the problem of converging to an effective policy we divided up the agent training process into multiple epochs. Each epoch is composed of a number of training episodes. The initial epsilon value is set to a large value and for each successive epoch the epsilon value for action selection is decreased. With an initially high epsilon value the agents are able to develop a policy that is initially weighted more heavily towards a response to random action selection than the immature policy of the other agent. As the epsilon value decreases, each agent slowly adjusts its learning to be weighted more heavily towards a response to the other agent's policy. This approach allows the agents to develop a minimally coherent dialog policy before beginning to rely too heavily upon the response of the opposing agent.

Utilizing this strategy of continuously decreasing epsilon values we were able to get both agents to converge to an effective and coherent dialog policy. The initial epsilon value was set to 80

4.3 Objective Function

In the reinforcement learning process the objective function provides the dialog agents with feed-back on the success of each dialog. The specification of this function requires input from a human. For our learning specification we crafted a simple function that attempted to model a human perception of a dialog's quality. Our objective function is linear combination of the solution quality (S) and the dialog length (L), taking the form:

$$o(S, I) = w_1 S - w_2 L$$

where w_1 and w_2 are positive constants. As higher values for S and lower values for L indicate better dialogs, we subtract $w_2 L$ from $w_1 S$. Instead of attempting to hand pick the constants in the objective function, we explored the effects of different values, which we report in Section 5.2.

For our experiment we trained the dialog agents for 200 epochs, where each epoch consisted of 200 training episodes. After the training the agents, we then had them perform 5000 dialogs with 100% on-policy action selection (i.e. strictly following the learned policy). The results of these 5000 dialogs were then combined to obtain an average plan score and average number of interactions for the policy of the agents. These two values are then combined according to the objective function to obtain a numeric score for the learned policy.

5 Results

In this section, we present the results of the dialog policies that we learned. We first present 3 baseline policies to which we will compare the performance of our learned policies. We will then present results varying the weights in the objective function in comparison to the baseline policies. As we are learning a pair of policies—one for the system and one representing the user—we explore how well the system policy does against handcrafted ones, that will represent what a user might do, rather than test it against its learned counter-part.

5.1 Baseline Policies

In order to provide comparative data to evaluate the effectiveness of our approach, we will compare the performance of the policies learned for the system and user against several pairs of handcrafted policies. The first pair implement the **unrestricted** initiative strategy of Yang and Heeman. Here, one conversant, A, proposes an item and then the other, B, informs A of any violated preferences. B then proposes an alternative and A informs B of any violated preferences. The process repeats until an item is proposed that does not violate any of the other agent's preferences. The second pair of policies implement the **restricted** initiative policy of Yang and Heeman, in which A proposes an item and B informs A of any violated preferences. However, the conversants do not switch roles: it is always A who proposes items and B that informs of preferences and accepts. These two policies represent successful handcrafted pairs of dialog policies. The third pair represents a minimum performance: A proposes an item and B simply accepts it. This is repeated for all 5 items, with A making all of the proposals. This policy is an **un-collaborative** approach, which represents how well A can do on its own.

5.2 Impact of Weights on Learned Policy

We first explore the ability of the reinforcement learning algorithm to learn a dialog policy pair that is optimal with respect to the objective function. The only important aspect of the weights is the ratio between the two: w_2/w_1. We varied the ratio from 0.1 to 0.5 in increments of 0.02. For each weight setting, we learned 66 policy pairs, and tested each policy pair on 1000 different task configurations. We compared the average objective function score of the learned policy pairs with the baseline restricted policy pair (cf. Scheffler and Young, 2002). Figure 1 shows the percentage of the learned policies that perform at least as well as the unrestricted policy pair

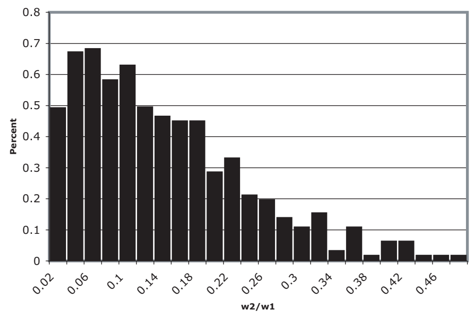

Figure 1: Percentage of learned policies performing better than unrestricted baseline pair.

at each weight setting. Interestingly, it is clear that there is a lack of convergence in the learning process, no weight ratio learns a good policy 100% of the time. Additionally, we see that as the weight ratio increases (putting more emphasis on shorter dialogs), the ability of the algorithm to learn good policies decreases. As the objective function gives this aspect more weight, it is more difficult for the objective function to learn the importance of solution quality. We think this lack of convergence is due to learning both the system and a simulated user at the same time, which is a more difficult reinforcement learning problem than just learning the policy for the system against a fixed user.

5.3 Lack of Convergence

To better understand the lack of convergence, we explore when a single weight is chosen for the objective function. For this analysis, we restricted ourselves to the objective function having a ratio for w_2/w_1 of 0.1, one of the best performing weights from section 5.2. For this setting, we learned a number of policy pairs, each learned from a different sequence of task configurations. We then tested each policy pair on 1000 task configurations, in which actions are selected strictly according to the learned policy. This gives us 1000 dialogs for each policy pair. We then computed the average objective function score for each policy pair and plotted them as a histogram in Figure 2. As can be seen, at this weight setting, 63% of the learned policies achieved an objective function score around 44.8. However, the rest achieved a performance substantially less than this. Hence, the reinforcement learning procedure does not always converge on an optimal solution.

To better understand why reinforcement learning is not always converging, we examined the components of the objective function score: solution quality and dialog length. Figure 3 uses the same x-axis as Figure 2: average objective function score. The y-axis plots the average solution quality and average dialog length. We see that at this weight ratio, all learned dialogue pairs are very consistent in solution quality, but that the difference in objective function scores is mainly due to differences in dialog length. This is consistent with our earlier observation that the reinforcement learning strategy sometimes disproportionately favors shorter dialog length.

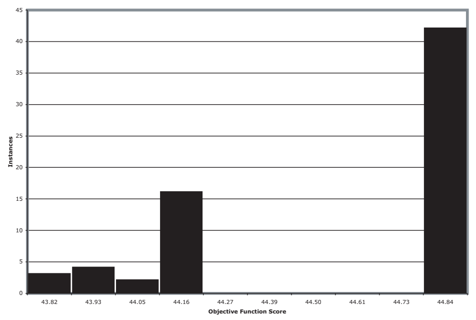

Figure 2: Average objective function scores for policies learned with w_2/w_1 = 0.1.

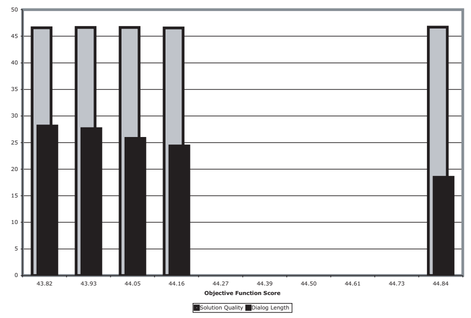

Figure 3: Variation of solution quality and dialogue length versus objective function score for policies learned with w_2/w_1 = 0.1.

5.4 Consistency of Policies

For the weight ratio of 0.1, the reinforcement learning algorithm usually finds a good policy pair. To further improve the likelihood of this happening, we could learn multiple policy pairs, and then pick the best performing one. In this section, we compare learned policies chosen in this way against the restricted baseline pairs. We learned 10 sets of 10 dialogue pairs. We then ran each on 1000 task configurations and chose the best performing policy pair in each set. We then ran the resulting 10 policy pairs on another set of 1000 task configurations. Table 1 gives the average objective function score for each of the 10 learned policy pairs and the 3 baseline pairs. From the table, we see that the learned policy pair performs almost as well as the restricted policy pair, for both solution quality and dialog length.

5.5 Robustness of Learned Policies

All of the results so far have used the learned policy for the system interacting with the corresponding policy that was learned for the user. However, there

	Objective Function	Solution Quality	Dialog Length
Learned Policies	44.90	46.71	18.17
Restricted	45.04	46.89	18.44
Unrestricted	44.40	46.80	24.07
Uncollaborative	32.52	33.62	11.00

Table 1: Comparison of Learned Policies

is no guarantee that a real user will behave like the learned policy. Thus, the true test of our approach is to run the learned system policy against actual users. The problem with testing our policies against actual users is that there are a number of aspects of dialog that we have not modeled, such as non-understandings, misunderstandings, and even parsing sentences into the action specification and generating sentences from the action specification. Thus, as a simplification we tested our learned system policy on the handcrafted baseline policies.

For the weight ratio of 0.1, we learned 10 sets of 10 pairs of policies and choose the best policy pair from each set. For each of the 10 policy pairs, we ran the system policy against the 6 individual policies from the 3 baseline policy pairs. We changed the hand-crafted policies slightly from Yang and Heeman so that the policies would not fail if they encountered unexpected input. For example, for the restricted policy for A (the conversant who proposes but never informs), if the learned policy proposes an item, A always rejects it. For the restricted policy for B (the conversant who informs but never proposes), if the learned policy releases the turn when there is not an item proposed, B simply releases the turn back to the learned policy.

Figure 4 shows the resulting average objective function scores on 1000 dialog runs. For each baseline policy, we show the performance with the policy pair, and then with each side of the baseline policy interacting with the learned policy. We see that although the performance of the learned policy is not as good as with the handcrafted pair, the performance is close, with the major shortcoming being a general increase in dialog length. Thus, the policies that we have learned our robust against different strategies a user might want to use.

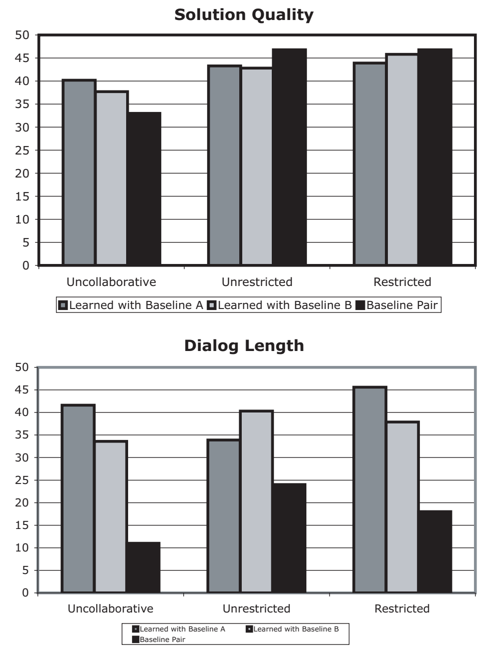

Figure 4: Learned dialogue policies interacting with baseline policies.

6 Conclusion

In this paper, we proposed using reinforcement for learning a dialog strategy for the system. Our approach differs from past research in that we learn the system policy in conjunction with learning a user policy. This approach of learning the user policy allows us to minimize human involvement, as neither a training corpus must be collected nor a simulated user built. Thus, the only human input required for this approach was to define the domain task and to define success in that domain. While our training approach did not always find an effective policy, we overcame this obstacle by carefully choosing a ratio for the weights in the objective function and by running the learning algorithm multiple times. Our approach resulted in learned system and user dialog policies that achieved comparable performance with handcrafted system and user policy pairs. Furthermore, the learned system policies were robust. When the learned system policies ‘conversed’ with the handcrafted user policies, the resulting dialogs had comparable solution quality to what the handcrafted system and user policies achieved together.

Even with the lack of convergence our approach could be applied to more complicated domains in order to learn an effective dialog policy. Our approach would be especially useful in situations where there are no existing corpora of human-human interactions for the domain or as a way to provide a check against a policy based on human intuition. In most situations where the domain requires significant collaboration between the dialog system and the user, training both the system and a user simultaneously will prove to be much less costly and labor intensive approach.
