2.1 Linear regression model

In the linear regression model, the predicted phrase pair quality score is defined as

$$Sco(e,f) = \sum_i \lambda_i f_i(e,f) \qquad (1)$$

where $f_i(e,f)$ is the feature for the phrase pair (*e,f*), as to be defined in section 3. These feature values can be binary (0/1), integers or real values. λ s are the feature weights to be learned from training data. The phrase pair quality score in the training data is defined as the sum of the target phrase's BLEU score (Papineni et. al. 2002) and the source phrase's BLEU score, where the reference translation is obtained from phrase pairs extracted from human alignment. Details about the training data are given in section 4. The linear regression model is trained using a statistical package R[1]. After training, the learned feature weights are applied on a held-out set of phrase pairs with known quality scores to evaluate the model's regression accuracy.

2.2 Neural Network model

A feed-forward back-propagation network (Bryson and Ho, 1969) is created with one hidden layer and 20 nodes. During training, the phrase pair features are fed into the network with their quality scores as expected outputs. After certain iterations of training, the neural net's weights are stable and its mean square error on the training set has been significantly reduced. Then the learned network weights are fixed, and are applied to the test phrase pairs for regression accuracy evaluation. We use MatLab™'s neural net toolkit for training and test.

We will compare both models' prediction accuracy in section 6. We would like to know whether the non-linear regression model outperforms linear regression model in terms of score prediction error, and if fewer regression errors correspond to better translation quality.

3 Feature Description

In this section we will describe the features we use to model the equivalence of a bilingual phrase pair (*e,f*). These features are defined on the phrase pair, its compositional units (words and characters), attributes (POS tags, numbers), co-occurrence frequency, length ratio, coverage ratio and alignment pattern.

- Phrase : $P_p(f \mid e)$, $P_p(e \mid f)$

$$P_p(e \mid f) = \frac{C(e,f)}{C(f)} \qquad (2)$$

where $C(e,f)$ is the co-occurrence frequency of the phrase pair (*e,f*), and C(*f*) is the occurrence frequency of the source phrase *f*. $P_p(f \mid e)$ is defined similarly.

- Word : $P_w(f \mid e)$, $P_w(e \mid f)$

$$P_w(e \mid f) = \prod_i \max_j t(e_i \mid f_j) \qquad (3)$$

where $t(e_i \mid f_j)$ is the lexical translation probability. This is similar to the word-level phrase

[1] http://www.r-project.org/

translation probability, as typically calculated in SMT systems (Brown et. al. 1993). Here we use max instead of sum. $P_w(f \mid e)$ is calculated similarly.

- Character: $P_c(f \mid e), P_c(e \mid f)$

When the source or target words are composed of smaller units, such as characters for Chinese words, or prefix/stem/suffix for Arabic words, we can calculate their translation probability on the sub-unit level. This is helpful for languages where the meaning of a word is closely related to its compositional units, such as Chinese and Arabic.

$$P_c(e \mid f) = \prod_i \max_n t(e_i \mid c_n) \qquad (4)$$

where c_n is the n-th character in the source phrase f (n=1,…,N).

- POS tag: $P_t(f \mid e), P_t(e \mid f)$

In addition to the probabilities estimated at the character, word and phrase levels based on the surface forms, we also compute the POS-based phrase translation probabilities. For each source and target word in a phrase pair, we automatically label their POS tags. Then POS-based probabilities are computed in a way similar to the calculation of the word-level phrase translation probability (formula 3). It is believed that such syntactic information can help to distinguish good phrase pairs from bad ones (for example, when a verb is aligned to a noun, its POS translation probability should be low).

- Length ratio

This feature computes the ratio of the number of content words in the source and target phrases. It is designed to penalize phrases where content words in the source phrase are dropped in the target phrase (or vice versa). The ratio is defined to be 10 if the target phrase has zero content word while the source phrase has non-zero content words. If neither phrase contains a content word, the ratio is defined to be 1.

- Log frequency

This feature takes the logarithm of the co-occurrence frequency of the phrase pair. High frequency phrase pairs are more likely to be correct translations if they are not due to systematic alignment errors.

- Coverage ratio

We propose this novel feature based on the observation that if a phrase pair is a correct translation, it often includes correct sub-phrase pair translations (*decomposition*). Similarly a correct phrase pair will also appear in correct longer phrase pair translations (*composition*) unless it is a very long phrase pair itself. Formally we define the coverage ratio of a phrase pair (*e,f*) as:

$$Cov(e,f) = Cov_d(e,f) + Cov_c(e,f). \quad (5)$$

Here $Cov_d(e,f)$ is the decomposition coverage:

$$Cov_d(e,f) = \sum_{f_i \subseteq f} \frac{\sum_{(e_i,f_i)\in P_L} \Delta(e_i, e)}{\sum_{(*,f_i)\in P_L} 1} \qquad (6)$$

where f_i is a sub-phrase of f, and (e_i, f_i) is a phrase pair in the MT system's bilingual phrase library P_L. $\Delta(e_1, e_2)$ is defined to be 1 if $e_1 \subseteq e_2$, otherwise it is 0. For each source sub-phrase f_i, this formula calculates the ratio that its target translation e_i is also a sub-phrase of the target phrase *e*, then the ratio is summed over all the source sub-phrases.

Similarly the composition coverage is defined as

$$Cov_c(e,f) = \sum_{f \subseteq f^j} \frac{\sum_{(e^j,f^j)\in P_L} \Delta(e, e^j)}{\sum_{(*,f^j)\in P_L} 1} \qquad (7)$$

where f^j is any source phrase containing f and e^j is one of f^j's translations in P_L. We call f^j a super-phrase of *f*. For each source super-phrase f^j, this formula calculates the ratio that its target translation e^j is also a super-phrase of the target phrase *e*, then the ratio is summed over all the source super-phrases.

Short phrase pairs (such as a phrase pair with one source word translating into one target word) have less sub-phrases but more super-phrases (for long phrase pairs, it is the other way around).

Combining the two coverage factors produces balanced coverage ratio, not penalizing too short or too long phrases.

- Number match

During preprocessing of the training data, numbers are mapped into a special token ($num) for better generalization. Typically one number corresponds to one special token. During translation numbers should not be arbitrarily dropped or inserted. Therefore we can check whether the source and target phrases have the right number of $num to be matched. If they are the same the number match feature has value 1, otherwise it is 0.

- Alignment pattern

This feature calculates the number of *unaligned* content words in a given phrase pair, where word alignment is obtained simply based on the maximum lexical translation probability of the source (target) word given all the target (source) words in the phrase pair.

Among the above 13 features, the number match feature is a binary feature, the alignment pattern feature is an integer-value feature, and the rest are real-value features. Also note that most features are positively correlated with the phrase translation quality (the greater the feature value, the more likely it is a correct phrase translation) except the alignment pattern feature, where more unaligned content words corresponds to bad phrase translations.

4 Training Data

The training data for both the linear regression and neural network models are bilingual phrase pairs with the above 13 feature values as well as their expected phrase quality scores. The feature values can be computed according to the description in section 3. The expected translation quality score for the phrase pair (*e*,*f*) is defined as

$$B(e,f)=Bleu(e,e^{*}\mid f)+Bleu(f,f^{*}\mid e) \quad (8)$$

where e^{*} is the human translation of the source phrase *f*, and f^{*} is the human translation of the target phrase *e*. These human translations are obtained from hand alignment of some parallel sentences.

1. Given hand alignment of some bilingual sentence pairs, extract gold phrase translation pairs.
2. Apply automatic word alignment on the same bilingual sentences, and extract phrase pairs. Note that due to the word alignment errors, the extracted phrase pairs are noisy.
3. For each phrase pair (*e*, *f*) in the noisy phrase table, find whether the source phrase *f* also appears in the gold phrase table as (*e**, *f*). If so, use the corresponding target phrase(s) *e** as reference translation(s) to evaluate the BLEU score of the target phrase *e* in the noisy phrase table.
4. Similarly, for each *e* in (*e*, *f*), identify (*e*, *f**) in the gold phrase table and compute the BLEU score of *f* using *f** as the reference.
5. The sum of the above two BLEU scores is the phrase pair's translation quality score.

5 Phrase Rescoring

Given the bilingual phrase pairs' quality score, there are several ways to use them for statistical machine translation.

5.1 Quality score as a decoder feature

A straightforward way is to use the quality scores as an additional feature in the SMT system, combined with other features (phrase scores, word scores, distortion scores, LM scores etc.) for MT hypotheses scoring. The feature weight can be empirically learned using manual tuning or automatic tuning such as MERT (Och 2003). In this situation, all the phrase pairs and their quality scores are stored in the MT system, which is different from the following approach where incorrect phrase translations are pruned.

5.2 Discriminative phrase rescoring

Another approach is to select good and bad phrase pairs based on their predicted quality scores, then discriminatively rescore the phrase pairs in the baseline phrase library. We sort the phrase pairs based on their quality scores in a decreasing order. The bottom *N* phrase pairs are considered as incorrect translations and pruned from the phrase library. The top M phrase pairs P_M are considered as good phrases with correct translations. As identifying correct sub-phrase translation requires accurate word alignment within phrase pairs, which is not easy to obtain due to the lack of rich context information within the phrase pair, we only boost the good phrase pairs' super-phrases in the phrase library. Given a phrase pair (*e*,*f*) with phrase co-occurrence count *C*(*e*,*f*), the weighted co-occurrence count is defined as:

$$C'(e,f) = C(e,f) \prod_{(e_i,f_i)\in(e,f)} b_i \qquad (9)$$

where (e_i, f_i) is a *good* sub-phrase pair of (*e*,*f*) belonging to P_M, with quality score b_i. Note that if (*e*,*f*) contains multiple good sub-phrase pairs, its co-occurrence count will be boosted multiple times. Here the boost factor is defined as the product of quality scores of good sub-phrase pairs. Instead of product, one can also use sum, which did not perform as well in our experiments. The weighted co-occurrence count is used to calculate the new phrase translation scores:

$$P'(e \mid f) = \frac{C'(e,f)}{\sum C'(*,f)} \qquad (10)$$

$$P'(f \mid e) = \frac{C'(e,f)}{\sum C'(e,*)} \qquad (11)$$

which replace the original phrase translation scores in the SMT system. In addition to phrase co-occurrence count rescoring, the quality scores can also be used to rescore word translation lexicons by updating word co-occurrence counts accordingly.

6 Experiments

We conducted several experiments to evaluate the proposed phrase rescoring approach. First we evaluate the two regression models' quality score prediction accuracy. Secondly, we apply the predicted phrase scores on machine translation tasks. We will measure the improvement on translation quality as well as the reduction of model size. Our experiments are on English-Chinese translation.

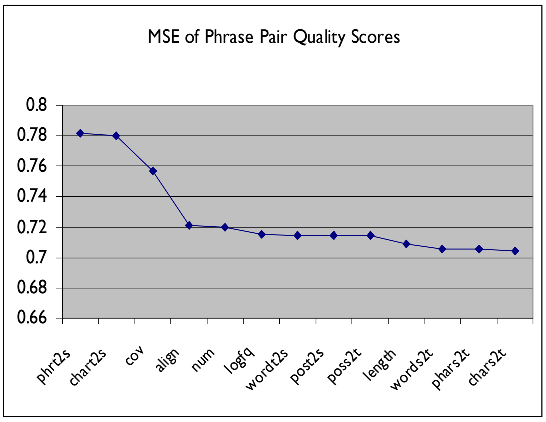

Figure 1. Linear regression model phrase pair prediction MSE curve. Errors are significantly reduced when more features are introduced (phrs2t /phrt2s: phrase source-to-target/target-to-source features; words2t/wordt2s: word-level; chars2t/chart2s: character-level; poss2t/post2s: POS-level; cov: coverage ratio; align: alignment pattern; logfq: log frequency; num: number match; length: length ratio).

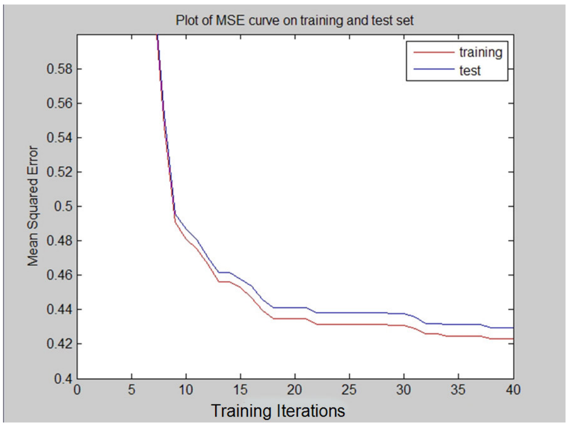

Figure 2. Neural network model phrase pair prediction MSE curve. Errors are significantly reduced with more training iterations.

6.1 Regression model evaluation

We select 10K English-Chinese sentence pairs with both hand alignment and automatic HMM alignment, and extract 106K phrase pairs with true phrase translation quality scores as computed according to formula 8. We choose 53K phrase pairs for regression model training and another 53K phrase pairs for model evaluation. There are 14 parameters to be learned (13 feature weights plus an intercept parameter) for the linear regression model, and 280 weights (13×20

Table 2. Examples of good and bad phrase pairs based on the linear regression model and neural network's predicted quality scores.

for the input weight matrix plus 20×1 for the output weight vector) for the neural network model. In both cases, the training data size is much more than the parameters size, so there is no data sparseness problem.

After the model parameters are learned from the training data, we apply the regression model to the evaluation data set, then compute the phrase quality score prediction mean squared error (MSE, also known as the average residual sum of squares):

$$MSE = \frac{1}{K}\sum_{k}\left[B_p(e_k, f_k) - B_t(e_k, f_k)\right]^2 \quad (12)$$

where B_p is the predicted quality score of the phrase pair (e_k, f_k), while B_t is the true score calculated based on human translations.

Figure 1 shows the reduction of the regression error in the linear regression model trained with different features. One may find that the MSE is significantly reduced (from 0.78 to 0.70) when additional features are added into the regression model.

Similarly, the neural network's MSE curve is shown in Figure 2. It can be seen that the MSE is significantly reduced with more iterations of training (from the initial error of 1.33 to 0.42 after 40 iterations).

Table 2 shows some phrase pairs with high/low quality scores predicted by the linear regression model and the neural network. One can see that both models assign high scores to good phrase translations and low scores to noisy phrase pairs. Although the values of these scores are beyond the range of [0, 2] as defined in formula 8, this is not a problem for our MT tasks, since they are only used as phrase boosting weights or pruning threshold.

6.2 Machine translation evaluation

We test the above phrase rescoring approach on English-Chinese machine translation. The SMT system is a phrase-based decoder similar to the description in (Tillman 2006), where various features are combined within the log-linear framework. These features include source-to-target phrase translation score based on relative frequency, source-to-target and target-to-source word-to-word translation scores, language model score, distortion model scores and word count. The training data for these features are 10M Chi-

Table 3. Translation quality improvements with rescored phrase tables. Best result (1.2 BLEU gain) is obtained with discriminative rescoring by boosting top 30K phrase pairs and pruning bottom 600K phrase pairs, with some weight tuning.

nese-English sentence pairs, mostly newswire and UN corpora released by LDC. The parallel sentences have word alignment automatically generated with HMM and MaxEnt word aligner. Bilingual phrase translations are extracted from these word-aligned parallel corpora. Due to the noise in the bilingual sentence pairs and automatic word alignment errors, the phrase translation library contains many incorrect phrase translations, which lead to inaccurate translations, as seen in Figure 3.

Our evaluation data is NIST MT08 English-Chinese evaluation testset, which includes 1859 sentences from 129 news documents. The automatic metrics are BLEU and NIST scores, as used in the NIST 2008 English-Chinese MT evaluation. Note that as there is no whitespace as Chinese word boundary, the Chinese translations are segmented into characters before scoring in order to reduce the variance and errors caused by automatic word segmentation, which is also done in the NIST MT evaluation.

Table 3 shows the automatic MT scores using the baseline phrase table and rescored phrase tables. When the phrase quality scores from the linear regression model are used as a separate feature in the SMT system (***LR-mtfeat*** as described in section 5.1), the improvement is 0.7 BLEU points (0.16 in terms of NIST scores). By boosting the good phrase pairs (top 30K[2] phrase pairs, ***LR-boost***) from linear regression model, the MT quality is improved by 0.7 BLEU points over the baseline system. Pruning the bad phrase pairs (tail 600K phrase pairs) without using the quality scores as features (***LR-prune***) also improves the MT by 0.4 BLEU points. Combining ***LR-boost*** and ***LR_prune***, a discriminatively rescored phrase table (***LR-disc***) improved the BLEU score by 1.1 BLEU points, and reduce the phrase table size by 16% (from 3.6M to 3.0M phrase pairs). Manually tuning the boosting weights of good phrase pairs leads to additional improvement. Discriminative rescoring using the neural net work scores (***NN-disc***) produced similar improvement**.**

We also experiment with phrase table pruning using Fisher significant test, as proposed in (Johnson et. al. 2007). We tuned the pruning threshold for the best result. It shows that the significance pruning improves over the baseline by 0.3 BLEU pts with 17.5% reduction in phrase table, but is not as good as our proposed phrase rescoring method. In addition, we also show the MT result using a count pruning phrase table (Count-Prune) where 600K phrase translation pairs are pruned based on their co-occurrence counts. The MT performance of such phrase table pruning is slightly worse than the baseline MT system, and significantly worse than the result using the proposed rescored phrase table.

When comparing the linear regression and neural network models, we find rescoring with both models lead to similar MT improvements, even though the neural network model has much fewer regression errors (0.44 vs. 0.7 in terms of MSE). This is due to the rich parameter space of the neural network.

Overall, the discriminative phrase rescoring improves the SMT quality by 1.2 BLEU points and reduces the phrase table size by 16%. With statistical significance test (Zhang and Vogel 2004), all the improvements are statistically significant with p-value < 0.0001.

Figure 3 presents some English sentences, with phrase translation pairs selected in the final translations (the top one is from the baseline MT system and the bottom one is from the LR-disc system).

[2] These thresholds are empirically chosen.

We find that incorrect phrase translations in the baseline system (as highlighted with blue bold font) are corrected and better translation results are obtained.

7 Conclusion

We introduced a discriminative phrase rescoring approach, which combined rich features with linear regression and neural network to predict phrase pair translation qualities. Based on these quality scores, we boost good phrase translations while pruning bad phrase translations. This led to statistically significant improvement (1.2 BLEU points) in MT and reduced phrase table size by 16%.

For the future work, we would like to explore other models for quality score prediction, such as SVM. We will want to try other approaches to utilize the phrase pair quality scores, in addition to rescoring the co-occurrence frequency. Finally, we will test this approach in other domain applications and language pairs.

FactRank: Random Walks on a Web of Facts

Microsoft Research
ppantel@microsoft.com

Abstract

Fact collections are mostly built using semi-supervised relation extraction techniques and wisdom of the crowds methods, rendering them inherently noisy. In this paper, we propose to validate the resulting facts by leveraging global constraints inherent in large fact collections, observing that correct facts will tend to match their arguments with other facts more often than with incorrect ones. We model this intuition as a graph-ranking problem over a fact graph and explore novel random walk algorithms. We present an empirical study, over a large set of facts extracted from a 500 million document webcrawl, validating the model and showing that it improves fact quality over state-of-the-art methods.

1 Introduction

Fact bases, such as those contained in *Freebase*, *DBpedia*, *KnowItAll*, and *TextRunner*, are increasingly burgeoning on the Internet, in government, in high tech companies and in academic laboratories. Bar the accurate manual curation typified by Cyc (Lenat, 1995), most fact bases are built using either semi-supervised techniques or wisdom of the crowds techniques, rendering them inherently noisy. This paper describes algorithms to validate and re-rank fact bases leveraging global constraints imposed by the semantic arguments predicated by the relations.

Facts are defined as instances of *n*-ary typed relations such as *acted-in*⟨*movie*, *actor*⟩, *director-of*⟨*movie*, *director*⟩, *born-in*⟨*person*, *date*⟩, and *buy*⟨*person*, *product*, *person*⟩. In all but very small fact bases, relations share an argument type, such as *movie* for the relations *acted-in* and *director-of* in the above example. The hypothesis explored in this paper is that when two fact instances from two relations share the same value for a shared argument type, then the validity of both facts should be increased. Conversely, we also hypothesize that an incorrect fact instance will tend to match a shared argument with other facts far less frequently. For example, consider the following four facts from the relations *acted-in*, *director-of*, and *is-actor*:

t_1: *acted-in*⟨Psycho, Anthony Perkins⟩
t_2: **acted-in*⟨Walt Disney Pictures, Johnny Depp⟩
t_3: *director-of*⟨Psycho, Alfred Hitchcock⟩
t_4: *is-actor*⟨Anthony Perkins⟩

Our confidence in the validity of t_1 increases with the knowledge of t_3 and t_4 since the argument *movie* is shared with t_3 and *actor* with t_4. Similarly, t_1 increases our confidence in the validity of t_3 and t_4. For t_2, we expect to find few facts that will match a *movie* argument with *Walt Disney Pictures*. Facts that share the *actor* argument *Johnny Depp* with t_2 will increase its validity, but the lack of matches on its *movie* argument will decrease its validity.

In this paper, we present *FactRank*, which formalizes the above intuitions by constructing a fact graph and running various random walk graph-ranking algorithms over it to re-rank and validate the facts. A collection of facts is modeled in the form of a graph where nodes are fact instances and edges connect nodes that have the same value for a shared argument type (e.g., t_1 would be linked by an edge to both t_3 and t_4.) Given a graph representation of facts, we explore various random walk algorithms to propagate our confidence in individual facts through the web of facts. We explore algorithms such as PageRank (Page et al., 1999) as well as propose novel algorithms that leverage several unique characteristics of fact graphs. Finally, we present an empirical analysis, over a large collection of facts extracted from a 500 mil-

lion document webcrawl, supporting our model and confirming that global constraints in a fact base can be leveraged to improve the quality of the facts. Our proposed algorithms are agnostic to the sources of a fact base, however our reported experiments were carried over a state-of-the-art semi-supervised extraction system. In summary, the main contributions of this paper are:

- We formalize the notion of ranking facts in a holistic manner by applying graph-based ranking algorithms (Section 2).
- We propose novel ranking algorithms using random walk models on facts (Section 3).
- We establish the effectiveness of our approach through an extensive experimental evaluation over a real-life dataset and show improvements over state-of-the-art ranking methods (Section 4).

2 Fact Validation Revisited

We denote an n-ary ***relation*** r with typed arguments $t_1, t_2, \cdots, t_n$ as $r\langle t_1, t_2, \cdots t_n\rangle$. In this paper, we limit our focus to unary and binary relations. A ***fact*** is an instance of a relation. For example, *acted-in*⟨*Psycho, Anthony Perkins*⟩ is a fact from the *acted-in*$\langle movie, actor\rangle$ relation.

Definition 2.1 [Fact base]: *A* fact base *is a collection of facts from several relations. Textrunner and Freebase are example fact bases (note that they also contain knowledge beyond facts such as entity lists and ontologies.)* □

Definition 2.2 [Fact farm]: *A* fact farm *is a subset of interconnected relations in a fact base that share arguments among them.* □

For example, consider a fact base consisting of facts for relations involving movies, organizations, products, etc., of which the relations *acted-in* and *director-of* could form a MOVIES fact farm.

Real-world fact bases are built in many ways. Semi-supervised relation extraction methods include *KnowItAll* (Etzioni et al., 2005), *TextRunner* (Banko and Etzioni, 2008), and many others such as (Riloff and Jones, 1999; Pantel and Pennacchiotti, 2006; Paşca et al., 2006; Mintz et al., 2009). Wisdom of the crowds methods include DBpedia (Auer et al., 2008) and Freebase which extracts facts from various open knowledge bases and allow users to add or edit its content.

Most semi-supervised relation extraction methods follow (Hearst, 1992). Starting with a relatively small set of seed facts, these extractors iteratively learn patterns that can be instantiated to identify new facts. To reflect their confidence in an extracted fact, extractors assign an *extraction score* with each fact. Methods differ widely in how they define the *extraction score*. Similarly, many extractors assign a *pattern score* to each discovered pattern. In each iteration, the highest scoring patterns and facts are saved, which are used to seed the next iteration. After a fixed number of iterations or when a termination condition is met, the instantiated facts are ranked by their *extraction score*.

Several methods have been proposed to generate such ranked lists (e.g., (Riloff and Jones, 1999; Banko and Etzioni, 2008; Matuszek et al., 2005; Pantel and Pennacchiotti, 2006; Paşca et al., 2006). In this paper, we re-implement the large-scale state-of-the-art method proposed by Paşca et al. (2006). This pattern learning method generates binary facts and computes the extraction scores of a fact based on (a) the scores of the patterns that generated it, and (b) the distributional similarity score between the fact and the seed facts. We computed the distributional similarity between arguments using (Pantel et al., 2009) over a large crawl of the Web (described in Section 4.1). Other implementation details follow (Paşca et al., 2006).

In our experiments, we observed some interesting ranking problems as illustrated by the following example facts for the *acted-in* relation:

id:	Facts (#Rank)
t_1:	*acted-in*⟨Psycho, Anthony Perkins⟩ (#26)
t_2:	**acted-in*⟨Walt Disney Pictures, Johnny Depp⟩ (#9)

Both t_1 and t_2 share similar contexts in documents (e.g., ⟨*movie*⟩ *film starring* ⟨*actor*⟩ *and* ⟨*movie*⟩ *starring* ⟨*actor*⟩), and this, in turn, boosts the pattern-based component of the extraction scores for t_1. Furthermore, due to the ambiguity of the term *psycho*, the distributional similarity-based component of the scores for fact t_2 is also lower than that for t_1.

Relations	id : Facts
acted-in	t_1 : ⟨Psycho, Anthony Perkins⟩
	t_2 : *⟨Walt Disney Pictures, Johnny Depp⟩
director-of	t_3 : ⟨Psycho, Alfred Hitchcock⟩
producer-of	t_4 : ⟨Psycho, Hilton Green⟩
is-actor	t_5 : ⟨Anthony Perkins⟩
	t_6 : ⟨Johnny Depp⟩
is-director	t_7 : ⟨Alfred Hitchcock⟩
is-movie	t_8 : ⟨Psycho⟩

Table 1: Facts share arguments across relations which can be exploited for validation.

Our work in this paper is motivated by the following observation: the ranked list generated by an individual extractor does not leverage any global information that may be available when considering a fact farm in concert. To understand the information available in a fact farm, consider a MOVIES fact farm consisting of relations, such as, *acted-in*, *director-of*, *producer-of*, *is-actor*, *is-movie*, and *is-director*. Table 1 lists sample facts that were generated in our experiments for these relations[1]. In this example, we observe that for t_1 there exist facts in foreign relations, namely, *director-of* and *producer-of* that share the same value for the *Movie* argument, and intuitively, facts t_3 and t_4 add to the validity of t_1. Furthermore, t_1 shares the same value for the *Actor* argument with t_5. Also, t_3, which is expected to boost the validity of t_1, itself shares values for its arguments with facts t_4 and t_7, which again intuitively adds to the validity of t_1. In contrast to this *web of facts* generated for t_1, the fact t_2 shares only one of its argument value with one other fact, i.e., t_6.

The above example underscores an important observation: *How does the web of facts generated by a fact farm impact the overall validity of a fact?* To address this question, we hypothesize that facts that share arguments with many facts are more reliable than those that share arguments with few facts. To capture this hypothesis, we model a web of facts for a farm using a graph-based representation. Then, using graph analysis algorithms, we propagate reliability to a fact using the scores of other facts that recursively connect to it.

Starting with a fact farm, to validate the facts in each consisting relation, we:

(1) Identify arguments common to relations in the farm.
(2) Run extraction methods to generate each relation.
(3) Construct a graph-based representation of the extracted facts using common arguments identified in Step (1) (see Section 3.1 for details on constructing this graph.)
(4) Perform link analysis using random walk algorithms over the generated graph, propagating scores to each fact through the interconnections (see Section 3.2 for details on various proposed random walk algorithms).
(5) Rank facts in each relation using the scores generated in Step (4) or by combining them with the original extraction scores.

For the rest of the paper, we focus on generating better ranked lists than the original rankings proposed by a state-of-the-art extractor.

3 FactRank: Random Walk on Facts

Our approach considers a fact farm holistically, leveraging the global constraints imposed by the semantic arguments of the facts in the farm. We model this idea by constructing a graph representation of the facts in the farm (Section 3.1) over which we run graph-based ranking algorithms. We give a brief overview of one such ranking algorithm (Section 3.2) and present variations of it for fact re-ranking (Section 3.3). Finally, we incorporate the original ranking from the extractor into the ranking produced by our random walk models (Section 3.4).

3.1 Graph Representation of Facts

Definition 3.1 *We define a* fact graph *FG(V, E), with V nodes and E edges, for a fact farm, as a graph containing facts as nodes and a set of edges between these nodes. An edge between nodes v_i and v_j indicates that the facts share the same value for an argument that is common to the relations that v_i and v_j belong to.* □

Figure 1 shows the fact graph for the example in Table 1 centered around the fact t_1.

Note on the representation: The above graph representation is just one of many possible options. For instance, instead of representing facts by nodes, nodes could represent the arguments of facts (e.g., *Psycho*) and nodes could be connected by edges if they occur together in a fact. The task of studying a "best" representation remains a future work direction. However, we believe that our proposed methods can be easily adapted to other such graph representations.

[1] The *is-actor*⟨actor⟩, *is-director*⟨director⟩, and *is-movie*⟨movie⟩ relations are equivalent to the relation *is-a*⟨c-instance, class⟩ where $class \in \{actor, director, movie\}$.

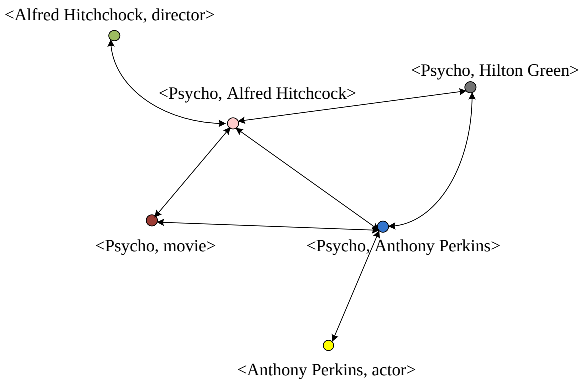

Figure 1: Fact graph centered around t_1 in Table 1.

3.2 The FactRank Hypothesis

We hypothesize that connected facts increase our confidence in those facts. We model this idea by propagating *extraction scores* through the fact graph similarly to how authority is propagated through a hyperlink graph of the Web (used to estimate the importance of a webpage). Several link structure analysis algorithms have been proposed for this goal, of which we explore a particular example, namely, PageRank (Page et al., 1999). The premise behind PageRank is that given the hyperlink structure of the Web, when a page v generates a link to page u, it confers some of its importance to u. Therefore, the importance of a webpage u depends on the number of pages that link to u and furthermore, on the importance of the pages that link to u. More formally, given a directed graph $G = (V, E)$ with V vertices and E edges, let $I(u)$ be the set of nodes that link to a node u and $O(v)$ be the set of nodes linked by v. Then, the importance of a node u is defined as:

$$p(u) = \sum_{v \in I(u)} \frac{p(v)}{|O(v)|} \tag{1}$$

The PageRank algorithm iteratively updates the scores for each node in G and terminates when a convergence threshold is met. To guarantee the algorithm's convergence, G must be irreducible and aperiodic (i.e., a connected graph). The first constraint can be easily met by converting the adjacency matrix for G into a stochastic matrix (i.e., all rows sum up to 1.) To address the issue of periodicity, Page et al. (1999) suggested the following modification to Equation 1:

$$p(u) = \frac{1-d}{|V|} + d \cdot \sum_{v \in I(u)} \frac{p(v)}{|O(v)|} \tag{2}$$

where d is a damping factor between 0 and 1, which is commonly set to 0.85. Intuitively, PageRank can be viewed as modeling a "random walker" on the nodes in G and the score of a node, i.e., PageRank, determines the probability of the walker arriving at this node.

While our method makes use of the PageRank algorithm, we can also use other graph analysis algorithms (e.g., HITS (Kleinberg, 1999)). A particularly important property of the PageRank algorithm is that the stationary scores can be computed for *undirected* graphs in the same manner described above, after replacing each undirected edge by a bi-directed edge. Recall that the edges in a fact graph are bi-directional (see Figure 1).

3.3 Random Walk Models

Below, we explore various random walk models to assign scores to each node in a fact graph *FG*.

3.3.1 Model Implementations

Pln: Our first method applies the traditional PageRank model to *FG* and computes the score of a node u using Equation 2.

Traditional PageRank, as is, does not make use of the *strength* of the links or the nodes connected by an edge. Based on this observation, researchers have proposed several variations of the PageRank algorithm in order to solve their problems. For instance, variations of random walk algorithms have been applied to the task of extracting important words from a document (Hassan et al., 2007), for summarizing documents (Erkan and Radev, 2004), and for ordering user preferences (Liu and Yang, 2008). Following the same idea, we build upon the discussion in Section 3.2 and present random walk models that incorporate the strength of an edge.

Dst: One improvement over ***Pln*** is to distinguish between nodes in *FG* using the extraction scores of the facts associated with them: extraction methods such as our reimplementation of (Paşca et al., 2006) assign scores to each output fact to reflect its confidence in it (see Section 3.2). Intuitively, a higher scoring node that connects to u should increase the importance of u more than a connection from a lower scoring node. Let $I(u)$ be the set of nodes that link to u and $O(v)$ be the set of nodes linked by v. Then, if $w(u)$ is the extraction score for the fact represented by node u, the score for node u is defined:

$$p(u) = \frac{1-d}{|V|} + d \cdot \sum_{v \in I(u)} \frac{w(v) \times p(v)}{|O(v)|} \quad (3)$$

where $w(v)$ is the confidence score for the fact represented by v. Naturally, other (externally derived) extraction scores can also be substituted for $w(v)$.

Avg: We can further extend the idea of determining the strength of an edge by combining the extraction scores of *both* nodes connected by an edge. Specifically,

$$p(u) = \frac{1-d}{|V|} + d \cdot \sum_{v \in I(u)} \frac{avg(u,v) \times p(v)}{|O(v)|} \quad (4)$$

where $avg(u,v)$ is the average of the extraction scores assigned to the facts associated with nodes u and v.

Nde: In addition to using extraction scores, we can also derive the strength of a node depending on the number of *distinct* relations it connects to. For instance, in Figure 1, t_1 is linked to four distinct relations, namely, *director-of*, *producer-of*, *is-actor*, *is-movie*, whereas, t_2 is linked to one relation, namely, *is-actor*. We compute $p(u)$ as:

$$p(u) = \frac{1-d}{|V|} + d \cdot \sum_{v \in I(u)} \frac{(\alpha \cdot w(v) + (1-\alpha) \cdot r(v)) \times p(v)}{|O(v)|} \quad (5)$$

where $w(v)$ is the confidence score for node v and $r(v)$ is the fraction of total number of relations in the farm that contain facts with edges to v.

3.3.2 Dangling nodes

In traditional hyperlink graphs for the Web, dangling nodes (i.e., nodes with no associated edges) are considered to be of low importance which is appropriately represented by the scores computed by the PageRank algorithm. However, an important distinction from this setting is that fact graphs are sparse causing them to have valid facts with no counterpart matching arguments in other relation, thus rendering them dangling. This may be due to several reasons, e.g., extractors often suffer from less than perfect recall and they may miss valid facts. In our experiments, about 10% and 40% of nodes from *acted-in* and *director-of*, respectively, were dangling nodes.

Handling dangling nodes in our extraction-based scenario is a particularly challenging issue: while demoting the validity of dangling nodes could critically hurt the quality of the facts, lack of global information prevents us from systematically introducing them into the re-ranked lists. We address this issue by maintaining the original rank positions when re-ranking dangling nodes.

3.4 Incorporating Extractor Ranks

Our proposed random walk ranking methods ignore the ranking information made available by the original relation extractor (e.g., (Paşca et al., 2006) in our implementation). Below, we propose two ways of combining the ranks suggested by the original ranked list O and the re-ranked list G, generated using the algorithms in Section 3.3.

R-Avg: The first combination method computes the average of the ranks obtained from the two lists. Formally, if $O(i)$ is the original rank for fact i and $G(i)$ is the rank for i in the re-ranked list, the combined rank $M(i)$ is computed as:

$$M(i) = \frac{O(i) + G(i)}{2} \quad (6)$$

R-Wgt: The second method uses a weighted average of the ranks from the individual lists:

$$M(i) = \frac{w_o \cdot O(i) + (1-w_o) \cdot G(i)}{2} \quad (7)$$

In practice, this linear combination can be learned; in our experiments, we set them to $w_o = 0.4$ based on our observations over an independent training set. Several other combination functions could also be applied to this task. For instance, we explored the *min and* max functions but observed little improvements.

4 Experimental Evaluation

4.1 Experimental Setup

Extraction method: For our extraction method, we reimplemented the method described in (Paşca et al., 2006) and further added a validation layer on top of it based on Wikipedia (we boosted the scores of a fact if there exists a Wikipedia page for either of the fact's arguments, which mentions the other argument.) This state-of-the-art method forms a *strong* baseline in our experiments.

Corpus and farms: We ran our extractor over a large Web crawl consisting of 500 million English

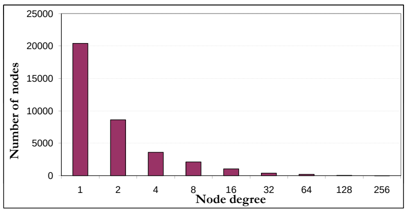

Figure 2: Degree distribution for MOVIES.

webpages crawled by the Yahoo! search engine. We removed paragraphs containing fewer than 50 tokens and then removed all duplicate sentences. The resulting corpus consists of over 5 million sentences. We defined a farm, MOVIES, with relations, *acted-in*, *director-of*, *is-movie*, *is-actor*, and *is-director*.

Evaluation methodology: Using our extraction method over the Web corpus, we generate over 100,000 facts for the above relations. However, to keep our evaluation manageable, we draw a random sample from these facts. Specifically, we first generate a ranked list using the extraction scores output by our extractor. We will refer to this method as ***Org*** (original). We then generate a fact graph over which we will run our methods from Section 3.3 (each of which will re-rank the facts). Figure 2 shows the degree, i.e., number of edges, distribution of the fact graph generated for MOVIES. We ran ***Avg***, ***Dst***, ***Nde***, ***R-Avg***, and ***R-Wgt*** on this fact graph and using the scores we re-rank the facts for each of the relations. In Section 4.2, we will discuss our results for the *acted-in* and *director-of* relations.

Fact Verification: To verify whether a fact is valid or not, we recruit human annotators using the paid service Mechanical Turk. For each fact, two annotations were requested (keeping the total cost under \$100). The annotators were instructed to mark incorrect facts as well as disallow any values that were not "well-behaved." For instance, *acted-in*$\langle$*Godfather, Pacino*$\rangle$ is correct, but *acted-in*$\langle$*The, Al Pacino*$\rangle$ is incorrect. We manually adjudicated 32% of the facts where the judges disagreed.

Evaluation metrics: Using the annotated facts, we construct a goldset S of facts and compute the precision of a list L as: $\frac{|L \cap S|}{|S|}$. To compare the effectiveness of the ranked lists, we use average precision, a standard measure in information retrieval for evaluating ranking algorithms, defined as: $A_p(L) = \frac{\sum_{i=1}^{|L|} P(i) \cdot isrel(i)}{\sum_{i=1}^{|L|} isrel(i)}$, where $P(i)$ is the precision of L at rank i, and *isrel(i)* is 1 if the fact at rank i is in S, and 0 otherwise. We also study the precision values at varying ranks in the list. For robustness, we report the results using 10-fold cross validation.

Method	Average precision		
	30%	50%	100%
Org	0.51	0.39	0.38
Pln	0.44	0.35	0.32
Avg	0.55	0.44	0.42

Table 3: Average precision for *director-of* for varying proportion of fact graph of MOVIES.

4.2 Experimental Results

Effectiveness of graph-based ranking: Our first experiment studies the overall quality of the ranked lists generated by each method. Table 2 compares the average precision for *acted-in*, with the maximum scores highlighted for each column. We list results for varying proportions of the original fact graph (30%, 50%, and 100%). Due to our small goldset sizes, these results are not statistically significant over ***Org***, however we consistently observed a positive trend similar to those reported in Table 2 over a variety of evaluation sets generated by randomly building 10-folds of all the facts.

Overall, the ***Avg*** method offers a competitive alternative to the original ranked list generated by the extractor ***Org***: not only are the average precision values for ***Avg*** higher than ***Org***, but as we will see later, the rankings generated by our graph-based methods exhibits some positive unique characteristics. These experiments also

R	*Org*	*Pln*	*Avg*	*Dst*	*Nde*	*R-Avg*	*R-Wgt*

25	**0.60**	0.54	0.56	0.57	0.56	0.57	0.57
30	0.57	0.57	0.57	0.57	0.57	0.58	**0.59**
33	0.56	0.56	0.56	0.56	0.56	0.56	0.56

Table 5: Precision at varying ranks for the *director-of* relation (R stands for Ranks).

confirm our initial observations: using traditional PageRank (***Pln***) is not desirable for the task of re-ranking facts (see Section 3.3). Our modifications to the PageRank algorithm (e.g., ***Avg***, ***Dst***, ***Nde***) consistently outperform the traditional PageRank algorithm (***Pln***). The results also underscore the benefit of combining the original extractor ranks with those generated by our graph-based ranking algorithms with ***R-Wgt*** consistently leading to highest or close to the highest average precision scores.

In Table 3, we show the average precision values for *director-of.* In this case, the summary statistic, average precision, does not show many differences between the methods. To take a finer look into the quality of these rankings, we investigated the precision scores at varying ranks across the methods. Table 4 and Table 5 show the precision at varying ranks for *acted-in* and *director-of* respectively. The maximum precision values for each rank are highlighted.

For *acted-in* again we see that ***Avg***, ***R-Avg***, ***R-Wgt*** outperform ***Org*** and ***Pln*** at *all* ranks, and ***Dst*** outperforms ***Org*** at two ranks. While the method ***Nde*** outperforms ***Org*** for a few cases, we expected it to perform better. Error analysis revealed that the sparsity of our fact graph was the problem. In our MOVIES fact graph, we observed very few nodes that are linked to *all* possible relation types, and the scores used by ***Nde*** rely on being able to identify nodes that link to numerous relation types. This problem can be alleviated by reducing the sparsity of the fact graphs (e.g., by allowing edges between nodes that are "similar enough"), which we plan to explore as future work. For *director-of,* Table 5 now shows that for small ranks (less than 15), a small (but consistent in our 10-folds) improvement is observed when comparing our random walk algorithms over ***Org***.

#Relation	*Avg*	*Dst*	*Nde*
2	0.35	0.34	0.33
3	0.35	0.35	0.34
4	0.37	0.36	0.35
5	0.38	0.38	0.37
6	0.42	0.41	0.41

Table 6: Average precision for *acted-in* for varying number of relations in the MOVIES fact farm.

While our proposed algorithms show a consistent improvement for *acted-in*, the case of *director-of* needs further discussion. For both average precision and precision vs. rank values, ***Avg***, ***R-Avg***, and ***R-Wgt*** are similar or slightly better than ***Org***. We observed that the graph-based algorithms tend to bring together "clusters" of noisy facts that may be spread out in the original ranked list of facts. To illustrate this point, we show the ten lowest scoring facts for the *director-of* relation. Table 7 shows these ten facts for ***Org*** as well as ***Avg***. These examples highlight the ability of our graph-based algorithms to demote noisy facts.

Effect of number of relations: To understand the effect of the number of relations in a farm (and hence connectivity in a fact graph), we verified the re-ranking quality of our proposed methods on various subsets of the MOVIES fact farm. We generated five different subsets, one with 2 relations, another with 3 relations, and three more with four, five, and six relations (note that although we have 5 relations in the farm, *is-movie* can be used in combination with both *acted-in* and *director-of,* thus yielding six relations to ablate.) Table 6 shows the results for *acted-in.* Overall, performance improves as we introduce more relations (i.e., more connectivity). Once again, we observe that the performance deteriorates for sparse graphs: using very few relations results in degenerating the average precision of the original ranked list. The issue of identifying the "right" characteristics of the fact graph (e.g., number of relations, degree distribution, etc.) remains future work.

Table 7: Sample facts for *director-of* at the bottom of the ranked list generated by (a) ***Org*** and (b) ***Avg***.

Evaluation conclusion: We demonstrated the effectiveness of our graph-based algorithms for reranking facts. In general, ***Avg*** outperforms ***Org*** and ***Pln***, and we can further improve the performance by using a combination-based ranking algorithm such as ***R-Wgt***. We also studied the impact of the size of the fact graphs on the quality of the ranked lists and showed that increasing the density of the fact farms improves the ranking using our methods.

5 Related Work

Information extraction from text has received significant attention in the recent years (Cohen and McCallum, 2003). Earlier approaches relied on hand-crafted extraction rules such as (Hearst, 1992), but recent efforts have developed supervised and semi-supervised extraction techniques (Riloff and Jones, 1999; Agichtein and Gravano, 2000; Matuszek et al., 2005; Pantel and Pennacchiotti, 2006; Paşca et al., 2006; Yan et al., 2009) as well as unsupervised techniques (Davidov and Rappoport, 2008; Mintz et al., 2009). Most common methods today use semi-supervised pattern-based learning approaches that follow (Hearst, 1992), as discussed in Section 2. Recent work has also explored extraction-related issues such as, *scalability* (Paşca et al., 2006; Ravichandran and Hovy, 2002; Pantel et al., 2004; Etzioni et al., 2004), *learning extraction schemas* (Cafarella et al., 2007a; Banko et al., 2007), and *organizing extracted facts* (Cafarella et al., 2007b). There is also a lot of work on deriving extraction scores for facts (Agichtein and Gravano, 2000; Downey et al., 2005; Etzioni et al., 2004; Pantel and Pennacchiotti, 2006).

These extraction methods are complementary to our general task of fact re-ranking. Since our proposd re-ranking algorithms are agnostic to the methods of generating the initial facts and since they do not rely on having available corpus statistics, we can use any of the available extractors in combination with any of the scoring methods. In this paper, we used Paşca et al.'s (2006) state-of-the-art extractor to learn a large set of ranked facts.

Graph-based ranking algorithms have been explored for a variety of text-centric tasks. Random walk models have been built for document summarization (Erkan and Radev, 2004), keyword extraction (Hassan et al., 2007), and collaborative filtering (Liu and Yang, 2008). Closest to our work is that of Talukdar et al. (2008) who proposed random walk algorithms for learning instances of semantic classes from unstructured and structured text. The focus of our work is on random walk models over fact graphs in order to rerank collections of facts.

6 Conclusion

In this paper, we show how information available in a farm of facts can be exploited for reranking facts. As a key contribution of the paper, we modeled fact ranking as a graph ranking problem. We proposed random walk models that determine the validity of a fact based on (a) the number of facts that "vote" for it, (b) the validity of the voting facts, and (c) the extractor's confidence in these voting facts. Our experimental results demonstrated the effectiveness of our algorithms, thus establishing a stepping stone towards exploring graph-based frameworks for fact validation. While this paper forms the basis of employing random walk models for fact re-ranking, it also suggests several interesting directions for future work. We use and build upon PageRank, however, several alternative algorithms from the link analysis literature could be adapted for ranking facts. Similarly, we employ a single (simple) graph-based representation that treats all edges the same and exploring richer graphs that distinguish between edges supporting different arguments of a fact remains future work.

Open Entity Extraction from Web Search Query Logs

Abstract

In this paper we propose a completely unsupervised method for open-domain entity extraction and clustering over query logs. The underlying hypothesis is that classes defined by mining search user activity may significantly differ from those typically considered over web documents, in that they better model the *user space*, i.e. users' perception and interests. We show that our method outperforms state of the art (semi-)supervised systems based either on web documents or on query logs (16% gain on the clustering task). We also report evidence that our method successfully supports a real world application, namely keyword generation for sponsored search.

1 Introduction

Search engines are increasingly moving beyond the traditional keyword-in document-out paradigm, and are improving user experience by focusing on user-oriented tasks such as query suggestions and search personalization. A fundamental building block of these applications is recognizing structured information, such as, *entities* (e.g., mentions of people, organizations, or locations) or relations among entities (Cao et al., 2008; Hu et al., 2009). For this, search engines typically rely on large collections of entities and relations built using information extraction (IE) techniques (Chaudhuri et al., 2009).

Commonly used IE techniques follow two main assumptions: (1) IE focuses on extracting information from syntactically and semantically "well-formed" pieces of texts, such as, news corpora and web documents (Pennacchiotti and Pantel, 2009); (2) extraction processes are bootstrapped with some pre-existing knowledge of the target domain (e.g entities are typically extracted for pre-defined categories, such as Actors, Manufacturers, Persons, Locations (Grishman and Sundheim, 1996)). Prior work (Banko et al., 2007), has looked into relaxing the second assumption and proposed open information extraction (OIE), a domain-independent and scalable extraction paradigm, which however focuses mostly on web corpora.

In this paper, we argue that for user-oriented applications discussed earlier, IE techniques should go beyond the traditional approach of using "well-formed" text documents. With this in mind, we explore the utility of search query logs, a rich source of user behaviors and perception, and build techniques for open entity extraction and clustering over query logs. We hypothesize that web documents and query logs model two different spaces: web documents model the *web space*, i.e. general knowledge about entities and concepts in an objective and generic way; search query logs model the *user space*, i.e. the users' view and perception of the world in a more specific fashion, where available information directly expresses users' needs and intents. For example, in a web space, 'britney spears' will tend to be similar and be clustered with other singers, such as 'celine dion' and 'bruce springsteen'. On the contrary, in the users' space, she is highly similar and clustered with other gossiped celebrities like 'paris hilton' and 'serena williams': the users' space better models the users' perception of that person; such a space is then highly valuable for all those applications where users' perceptions matters.

To computationally model our hypothesis for OIE over search query logs, we present a two phase approach to OIE for search query logs. The first phase (*entity extraction*) extracts entities from the search query logs using an unsupervised approach, by applying pattern-based heuristics and statistical measures. The second phase (*entity clustering*) induces classes over these entities by applying clustering techniques. In summary, our main contribu-

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 510–518,
Beijing, August 2010

tions are: (1) We propose and instantiate a novel model for open information extraction over web search query logs; and we apply it to the task of entity extraction and clustering. (2) We show how we characterize each extracted entity to capture the 'user space', and induce classes over the entities. (3) We present an extensive evaluation over real-life datasets showing that query logs is a rich source for domain-independent user-oriented extraction tasks (Section 3). We also show the practicality of our approach by incorporating it into a real-world application, namely keyword suggestions for sponsored search (Section 4).

2 Open Entity Extraction on Query Log

In this section, we present our method for open entity extraction from query logs. We first describe our heuristic method for extracting entities (Section 2.1), and then three different feature 'user spaces' to cluster the entities (Section 2.2).

2.1 Entity Extraction

In our setting, entities correspond to Named Entities. i.e. they are defined using the standard named entity types described in (Sekine et al., 2002)[1]. In this paper, we use a set of entities extracted from query log, obtained by applying a simple algorithm (any other query log entity extraction method would apply here, e.g. (Pasca, 2007b)). The algorithm is based on the observation that oftentimes users construct their search query by copy-pasting phrases from existing texts. Due to this phenomenon, user queries often carry over surface-level properties such as capitalization and tokenization information. Our approach realizes this observation by identifying contiguous capitalized words from a user query. (In our experiments, we observed that 42% of the queries had at least one upper-case character.) Specifically, given a query $Q = q_1\ q_2\ q_3 \cdots\ q_n$, we define a candidate entity $E = e_1\ e_2\ \cdots\ e_m$ as the maximal sequence of words (i.e., alpha-numeric characters) in the query such that each word e_i in the entity begins with an uppercase character. The set of candidate entities is then cleaned by applying a set of heuristics, thus producing the final set of entities. In particular, for each extracted entity, we assign two confidence scores: a Web-based *representation score* and a query-log-based *standalone score*. The representation score checks if the case-sensitive representation observed for E in Q, is the most likely representation for E, as observed on a Web corpus (e.g., 'DOor HANGing TIps' is assigned a low representation score). The standalone score is based on the observation that a candidate E should often occur in a standalone form among the search query logs, in order to get the status of a proper named entity as defined in (Sekine et al., 2002; Grishman and Sundheim, 1996). In practice, among the query logs we must find queries of the form $Q == E$, capturing the fact that users are looking to learn more about the given entity[2].

2.2 Entity Clustering

The clustering phase takes as input any of the feature spaces presented in the rest of this section, and groups the entities according to the similarity of their vectors in the space. The desiderata for a clustering algorithm for the task of open-domain information extraction are the following: (1) The algorithm must be highly scalable, efficient, and able to handle high dimensionality, since the number of queries and the size of the feature vectors can be large; (2) We do not know in advance the number of clusters; therefore, the algorithm needs not to require a pre-defined number of clusters.

Any clustering algorithm fulfilling the above requirements would fit here. In our experiments, we adopt a highly scalable Map-Reduce implementation of the hard-clustering version of Clustering by Committee (CBC), a state-of-the-art clustering algorithm presented in (Pantel and Lin, 2002).

Context Feature Space. The basic hypothesis for the *context feature space*, is that an entity can be effectively represented by the set of contexts in which it appears in queries. This allows to capture the users' view of the entity, i.e. what people query, and want to know about the entity. This is similar to that proposed by Pasca (2007b; 2007a), i.e. that queries provide good semantics cues for modeling named entities.

Our query log feature space may significantly differ from a classical contextual feature space com-

[1] We exclude 'Time' and 'Numerical Expressions', which are out of the scope of our study.

[2] We refer the readers to (Jain and Pennacchiotti, 2010) for details on the entity extraction algorithms.

puted over a Web corpus, since the same entity can be differently perceived and described in the two corpora (query log and Web). Consider for example the entity 'galapagos islands'. Typical contexts on the Web and query log for this entity are:

web:	`endemic birds`
web:	`big turtles`
web:	`charles darwin foundation`
web:	`sensitive water`
qlog:	`trip to`
qlog:	`diving`
qlog:	`where are the`
qlog:	`travel package`

The difference between the two representations implies that entities that are similar on the Web, are not necessarily similar on query logs. For example, on the Web 'galapagos islands' is very similar to other countries such as 'tasmania', 'guinea' and 'luxemburg'; while on query log is similar to other sea-side travel destination and related concepts, such as 'greek isle', 'kauai snorkeling' and 'south america cruise'. Our new similarity computed over query log, is potentially useful for those applications in which is more important to represent users' intents, than an objective description of entities (e.g. in query suggestion and intent modeling).

To obtain our contextual representation we proceed as follows. For each entity e, we identify all queries in the query log, in which e appears. Then, we collect the set of all suffixes and postfixes of the entity in those queries. For example, given the entity 'galapagos islands' and the query 'summer 2008 galapagos islands tour', the contexts are: 'summer 2008' and 'tour'.

Once the set of all contexts of all entities has been collected, we discard contexts appearing less than τ-times in the query log, so to avoid statistical biases due to data sparseness (in the reported experiments we set $\tau = 200$). We then compute the corrected pointwise mutual information (*cpmi*) (Pantel and Ravichandran, 2004) between each instance and each context c as:

$$cpmi(e,c) = log_2 \frac{f(e,c) \cdot f(*,*)}{f(e) \cdot f(c)} \cdot M \qquad (1)$$

where $f(e,c)$ is the number of times e and c occur in the same query; $f(e)$ and $f(c)$ is the count of the entity and the context in the query log; $f(*,*)$ the overall count of all co-occurrences between contexts and entities; and M is the correction factor presented in (Pantel and Ravichandran, 2004), that eases the pmi's bias towards infrequent entities/features. Each instance is then represented in the feature space of all contexts, by the computed pmi values. Note that our method does not use any NLP parsing, since queries rarely present syntactic structure. This guarantees the method to be computationally inexpensive and easily adaptable to languages other than English.

Clickthrough Feature Space. During a search session, users issue a search query for which the search engine presents a list of result urls. Of the search results, users choose those urls that are representative of their intent. This interaction is captured by means of a click, which is logged by most search engines as *click-through data*. For instance, a search log may contain the following clicked urls for a query 'flv converter', for different users:

$user_1$:	`www.flv-converter.com`
$user_2$:	`www.videoconverterdownload.com/flv/`
$user_3$:	`www.ripzor.com/flv.html`

Our main motivation behind clustering entities based on past user click behavior is that non-identical queries that generate clicks on the same urls capture similar user intent. Thus, grouping entities that were issued as a query and generated user clicks on the same url may be considered similar. For instance, the query 'convert flv' may also generate clicks on one of the above urls, thus hinting that the two entities are similar. We observed that websites tend to dedicate a url per entity. Therefore, grouping by click urls can lead to clusters with synonyms (i.e., different ways of representing the same entity) or variants (e.g., spelling errors). To get more relevant clusters, instead of grouping entities by the click urls, we use the base urls. For instance, the url `www.ripzor.com/flv.html` is generalized to `www.ripzor.com`.

With the advent of encyclopedic websites such as, `www.wikipedia.org` and `wwww.youtube.com`, naively clustering entities by the clickthrough data can led to non-similar entities to be placed in the same cluster. For instance, we observed the most frequently clicked base url for both 'gold retriever' and 'abraham lincoln' is `www.wikipedia.org`. To address this issue, in our experiments we employed a stop-list by eliminating top-5 urls based on their inverse document frequency, where an entity is intended as the 'document'.

In practice, each extracted entity e is represented by a feature vector of size equal to the number of distinct base urls in the click-through data, across all users. Each dimension in the vector represents a url in the click-through information. The value f of an entity e for the dimension associated with url j is computed as:

$$f(e,j) = \begin{cases} \frac{w(e,j)}{\sqrt{\sum_i^{|\mathcal{U}|} w(e,i)^2}} & \text{if url } j \text{ clicked for query } e; \\ 0 & \text{otherwise.} \end{cases}$$

where $\mathcal{U}$ is the set of base urls found in click-through data when entity e was issued as a query; and $w(e,i)$ is the number of time the base url i was clicked when e was a query.

Hybrid Feature Space. We also experiment a hybrid feature space, which is composed by the normalized union of the two feature spaces above (i.e. context and clickthrough). Though more complex hybrid models could be applied, such as one based on ensemble clustering, we here opt for a simple solution which allows to better read and compare to other methods.

3 Experimental Evaluation

In this section, we report experiments on our clustering method. The goal of the experiment is two-fold: (1) evaluate the intrinsic quality of the clustering methods, i.e. if two entities in the same cluster are similar or related from a web user's perspective; (2) verify if our initial hypothesis holds, i.e. if query log based features spaces capture different properties than Web based feature spaces (i.e. the 'user space'). In Section 3.1 we describe our experimental setup; and, in 3.2 we provide the results. We couple this intrinsic evaluation with an extrinsic application-driven one in Section 4.

3.1 Experimental Settings

In the experiments we use the following datasets:

Query log: A random sample of 100 million, fully anonymized queries collected by the Yahoo! search engine in the first 3 months of 2009, along with their frequency. This dataset is used to generate both the context and the clickthrough feature spaces for the clustering step.

Web documents: A collection of 500 million web pages crawled by a Yahoo! search engine crawl. This data set is used to implement a web-based feature space that we will compare to in Section 3.2.

Entity set: A collection of 2,067,385 entities, extracted with the method described in 2.1, which shows a precision of 0.705 ± 0.044. Details on the evaluation of such method are available in (Jain and Pennacchiotti, 2010), where a full comparison with state-of-the-art systems such as (Pasca, 2007b) and (Banko et al., 2007) are also reported.

Evaluation methodology: Many clustering evaluation metrics have been proposed, ranging from Purity to Rand-statistics and F-Measure. We first select from the original 2M entity set, a random set of n entities biased by their frequency in query logs, so to keep the experiment more realistic (more frequent entities have more chances to be picked in the sample). For each entity e in the sample set, we derived a random list of k entities that are clustered with e. In our experiments, we set $n = 10$ and $k = 20$. We then present to a pool of paid editors, each entity e along with the list of co-clustered entities. Editors are requested to classify each co-clustered entity e_i as *correct* or *incorrect*. An entity e_i is deemed as correct, if it is similar or related to e from a web user's perspective: to capture this intuition, the editor is asked the question: 'If you were interested in e, would you be also interested in e_i in any intent?'.[3] Annotators' agreement over a random set of 30 entities is $kappa = 0.64$ (Marques De Sá, 2003), corresponding to substantial agreement. Additionally, we ask editors to indicate the *relation type* between e and e_i (synonyms, siblings, parent-child, topically related).

Compared methods:

CL-CTX: A CBC run, based on the query log context feature space (Section 2.2).

CL-CLK: A CBC run, based on the clickthrough feature space (Section 2.2).

[3] For example, if someone is interested in 'hasbro', he could be probably also be interested in 'lego', when the intent is buying a toy. The complete set of annotation guidelines is reported in (Jain and Pennacchiotti, 2010).

method	# cluster	avg cluster size
CL-Web	1,601	240
CL-CTX	875	1,182
CL-CLK	4,385	173
CL-HYB	1,580	478

Table 1: Statistics on the clustering results.

CL-HYB: A CBC run, based on the hybrid space that combines CL-CTXand CL-CLK(Section 2.2).
CL-Web: A state-of-the-art open domain method based on features extracted from the Web documents data set (Pantel et al., 2009). This method runs CBC over a space where features are the contexts in which an entity appears (noun chunks preceding and following the target entity); and feature value is the *pmi* between the entity and the chunks.

Evaluation metrics: We evaluate each method using **accuracy**, intended as the percentage of correct judgments.

3.2 Experimental Results

Table 3 reports accuracy results. CL-HYB is the best performing method, achieving 0.85 accuracy, respectively +4% and +11% above CL-CLK and CL-Web. CL-CTX shows the lowest performance. Our results suggest that query log spaces are more suitable to model the 'user space' wrt web features. Specifically, clickthrough information are most useful confirming our hypothesis that queries that generate clicks on the same urls capture similar user intents.

To have an anecdotal and practical intuition on the results, in Table 2 we report some entities and examples of other entities from the same clusters, as obtained from the CL-HYB and CL-Web methods. The examples show that CL-HYB builds clusters according to a variety of relations, while CL-Web mostly capture sibling-like relations.

One relevant of such relations is topicality. For example, for 'aaa insurance' the CL-HYB cluster mostly contains entities that are topically related to the American Automobile Association, while the CL-Web cluster contains generic business companies. In this case, the CL-HYB approach simply chose to group together entities having clicks to 'aaa.com' and appearing in contexts as 'auto club'. On the contrary, CL-Web grouped according to contexts such as 'selling' and 'company'. The entity 'hip osteoarthritis' shows a similar behavior: CL-HYB groups entities topically related to orthopedic issues, since most of the entities are sharing contexts such as 'treatment' and 'recovery' and, at the same time, clicks to urls such as 'orthoinfo.aaos.org' and 'arthirtis.about.com'.

entity	CL-HYB	CL-Web
aaa insurance	roadside assistance personal liability insurance international driving permits aaa minnesota travelers checks	loanmax pilot car service localnet fibermark country companies insurance
paris hilton	brenda costa adriana sklenarikova kelly clarkson anja rubik federica ridolfi	julia roberts brad pitt nicole kidman al pacino tom hanks

hip osteoarthritis	atherosclerosis pneumonia hip fracture breast cancer anorexia nervosa	wrist arthritis disc replacement rotator cuff tears shoulder replacement american orthopedic society
acer america	acer aspire accessories aspireone acer monitors acer customer service acer usa	microsoft casio computer borland software sony nortel networks

Table 2: Sample of the generated entity clusters.

Another interesting observation regards entities referring to people. The 'paris hilton' and 'goldie hawn' examples show that the CL-Web approach groups famous people according to their category – i.e. profession in most cases. On the contrary, query log approaches tend to group people according to their social attitude, when this prevails over the profession. In the example, CL-HYB clusters the actress 'goldie hawn' with other actors, while 'paris hilton' is grouped with an heterogeneous set of celebrities that web users tend to query and click in a same manner: In this case, the social persona of 'paris hilton' prevails over its profession (actress/singer). This aspect is important in many applications, e.g. in query suggestion, where one wants to propose to the user entities that have been similarly queried and clicked.

In order to check if the above observations are not anecdotal, we studied the *relation type* annotation provided by the editors (Table 4). Table shows

method	Precision
CL-Web	0.735
CL-CTX	0.460
CL-CLK	0.815 †
CL-HYB	**0.850** †

Table 3: Precision of various clustering methods († indicates statistical-significant better than the CL-Web method, using t-test).

class	**method**			
	CL-Web	CL-CTX	CL-CLK	CL-HYB
topic	0.27	0.46	0.46	0.40
sibling	0.72	0.43	0.29	0.32
parent	-	0.09	0.13	0.09
child	0.01	-	0.01	0.02
synonym	0.01	0.03	0.12	0.16

Table 4: Fraction of entities that have been classified by editors in the different relation types.

method	**labelled clusters**			
	CL-CTX	CL-CLK	CL-HYB	CL-Web
CL-CTX	-	0.2	0.53	0.29
CL-CLK	0.21	-	0.54	0.34
CL-HYB	0.53	0.51	-	0.31
CL-Web	0.33	0.35	0.41	-

Table 5: Purity of clusters for each method using clusters from other methods as “labelled” data.

that query log based methods are more varied in the type of clusters they build. Table 5 shows the difference between the clustering obtained using the different methods and the overlap between the produced clusters. For example, 40% of the relations for the CL-HYB system are topical, while 32% are sibiling ones. On the contrary, the CL-Web method is highly biased towards sibling relations.

As regard a more attentive analysis of the different query log based methods, CL-CTX has the lowest performance. This is mainly due to the fact that contextual data are sometimes too sparse and generic. For example ‘mozilla firefox’ is clustered with ‘movie program’ and ‘astro reading’ because they share only some very generic contexts such as ‘free downloads’. In order to get more data, one option is to relax the τ threshold (see Section 2) so to include more contexts in the semantic space. Unfortunately, this would have a strong drawback, in that low-frequency context tend to be idiosyncratic and spurious. A typical case regards recurring queries submitted by robots for research purposes, such as ‘who is X’, ‘biography of X’, or ‘how to X’. These queries tend to build too generic clusters containing people or objects. Another relevant problem of the CL-CTX method is that even when using a high τ cut, clusters still tend to be too big and generic, as statistics in Table 4 shows.

CL-CTX, despite the low performance, is very useful when combined with CL-CLK. Indeed the CL-HYB system improves +4% over the CL-CLK system alone. This is because the CL-HYB method is able to recover some misleading or incomplete evidence coming from the CL-CLK using features provided by CL-CLK. For example, editors judged as incorrect 11 out of 20 entities co-clustered with the entity ‘goldie hawn’ by CL-CLK. Most of these errors are movies (e.g. ‘beverly hills cops’) soap operas (e.g. ‘sortilegio’) and directors, because all have clicks to ‘imdb.com’ and ‘movies.yahoo.com’. CL-HYB recovers these errors by including features coming from CL-CTX such as ‘actress’.

In summary, query log spaces group together entities that are similar by web users (this being topical similarity or social attitude), thus constituting a practical model of the ‘user space’ to be leveraged by web applications.

4 Keywords for Sponsored Search

In this section we explore the use of our methods for keyword generation for sponsored search. In sponsored search, a search company opens an auction, where on-line advertisers bid on specific keywords (called *bidterms*). The winner is allowed to put its ad and link on the search result page of the search company, when the bidterm is queried. Companies such as Google and Yahoo are investing efforts for improving their bidding platforms, so to attract more advertisers in the auctions. Bidterm suggestion tools (adWords, 2009; yahooTool, 2009) are used to help advertiser in selecting bidterms: the advertisers enters a seed keyword (*seed*) expressing the intent of its ad, and the tool returns a list of suggested keywords (*suggestions*) that it can use for bidding – e.g for the seed ‘mp3 player’, a suggestion could be ‘ipod nano’. The task of generating bid suggestions (i.e. *keyword generation*) is typically automatic, and has received a growing attention in the search community for its impact on search company revenue. The main problem of existing methods for suggestion (adWords, 2009; yahooTool, 2009; wordTracker, 2009) is that they produce only suggestions that contain the initial seed (e.g. ‘belkin mp3 player’ for the seed ‘mp3 player’), while nonobvious (and potentially less expensive) suggestions not containing the seed are neglected (e.g. ‘ipod nano’ for ‘mp3 player’). For example for ‘galapagos islands’, a typical production system suggests ‘galapagos islands tour’ which cost almost 5$ per click; while the less obvious ‘isla santa cruz’ would cost only 0.35$. Below we show our method to discover such nonobvious suggestions, by retrieving entities in the same cluster of a given seed.

4.1 Experimental Setting

We evaluate the quality of the suggestions proposed by different methods for a set of seed bidterms., adopting the evaluation schema in (Joshi and Motwani, 2006)

Dataset Creation. To create the set of seeds, we use Google skTool[4]. The tool provides a list of popular bid terms, organized in a taxonomy of advertisement topics. We select 3 common topics: tourism, vehicles and consumer-electronics. For each topic, we randomly pick 5 seeds among the 800 most popular bid terms, which also appear in our entity set described in Section 3.1.[5]. We evaluate a system by collecting all its suggestions for the 15 seeds, and then extracting a random sample of 20 suggestions per seed.

Evaluation and Metrics. We use precision and Nonobviousness. **Precision** is computed by asking two experienced human experts to classify each suggestion of a given seed, as *relevant* or *irrelevant*. A suggestion is deemed as relevant if any advertiser would likely choose to bid for the suggestion, having as intent the seed. Annotator agreement, evaluated on a subset of 120 suggestions is $kappa = 0.72$ (substantial agreement). Precision is computed as the percentage of suggestions judged as relevant. **Nonobviousness** is a metric introduced in (Joshi and Motwani, 2006), capturing how nonobvious the suggestions are. It simply counts how many suggestions for a given seed do not contain the seed itself (or any of its variants): this metric is computed automatically using string matching and a simple stemmer.

Comparisons. We compare the suggestions proposed by `CL-CTX`, `CL-CLK`, and `CL-HYB`, against `Web` and two reference state-of-the-art production systems: Google AdWords (`GOO`) and Yahoo Search Marketing Tool (`YAH`). As concerns our methods, we extract as suggestions the entities that occur in the same cluster of a given seed. For the production systems, we rely on the suggestions proposed on the website of the tools.

4.2 Experimental Results

Precision results are reported in the second column of Table 6. Both `CL-CLK` and `CL-HYB` outperform `Web` in precision, `CL-HYB` being close to the upper-bound of the two production systems. As expected, production systems show a very high precision but their suggestions are very obvious. Our results are fairly in line with those obtained on a similar dataset, by Joshi and Motwani (2006).

A closer look at the results shows that most of the errors for `CL-CTX` are caused by the same problem outlined in Section 3.2: Some entities are wrongly assigned to a cluster, because they have some high *cpmi* context feature which is shared with the cluster centroid, but which is not very characteristic for the entity itself. This is particularly evident for some of the low frequency entities, where *cpmi* values could not reflect the actual semantics of the entity. For example the entity ‘nickelodeon’ (a kids tv channel in UK) is assigned to the cluster of ‘galapagos islands’, because of the feature ‘cruise’: indeed, some people query about ‘nickelodeon cruise’ because the tv channel organizes some kids cruises. Other mistakes are due to feature ambiguity. For example, the entity ’centurion boats’ is assigned to the cluster of ‘obertauern’ (a ski resort in Austria), because they share the ambiguous feature ‘ski’ (meaning either winter-ski or water-ski). As for the `CL-CLK` system, some of the errors are caused by the fact that some base url can refer to very different types of entities. For example the entity ‘color copier’ is suggested for the the camera ‘canon rebel xti’, since they both share clicks to the Canon website. The `CL-HYB` system achieves a higher preci-

[4] http://www.google.com/sktool

[5] The final set of 15 bid terms is: *tourism:*galapagos islands,holiday insurance,hotel booking,obertauern,wagrain; *vehicles:*audi q7,bmw z4,bmw dealers,suzuki grand vitara,yamaha banshee; *consumer electr:*canon rebel xti,divx converter,gtalk,pdf reader,flv converter.

method	Precision	Nonobviousness
GOO	0.982	0.174
YAH	0.966	0.195
Web	0.814	0.827
CL-CTX	0.547	0.963
CL-CLK	0.827	0.630
CL-HYB	0.946	0.567

Table 6: Results for keyword generation.

sion wrt CL-CTX and CL-CLK: the combination of the two spaces decreases the impact of misleading features –e.g. for 'yamaha bunshee', all CL-HYB 's suggestions are correct, while almost all CL-CLK 's suggestions are incorrect: the hybrid system recovered the negative effect of the misleading feature ebay.com, by backing up on features from the contextual subspace (e.g. 'custom', 'specs', 'used parts').

Nonobviousness results are reported in column three of Table 6. All our systems return a high number of nonobvious suggestions (all above 50%).[6] On the contrary, GOO and YAH show low performance, as both systems are heavily based on the substring matching technique. This strongly motivates the use of semantic approaches as those we propose, that guarantee at the same time both a higher linguistic variety and an equally high precision wrt the production systems. For example, for the seeds 'galapagos islands', GOO returns simple suggestions such as 'galapagos islands vacations' and 'galapagos islands map'; while CL-HYB returns 'caribbean mexico' and 'pacific dawn', two terms that are semantically related but dissimilar from the seed. Remember that these letter terms are related to the seed because they are similar in the user space, i.e. users looking at 'galapagos islands' tend to similarly look for 'caribbean mexico' and 'pacific dawn'. These suggestions would then be very valuable for tourism advertisers willing to improve their visibility through a non-trivial and possibly less expensive set of bid terms.

5 Related Work

While literature abounds with works on entity extraction from web documents (e.g. (Banko et al., 2007; Chaudhuri et al., 2009; Pennacchiotti and Pantel, 2009)), the extraction of classes of entities over query logs is a pretty new task, recently introduced in (Pasca, 2007b). Pasca's system extracts entities of pre-defined classes in a semi-supervised fashion, starting with an input class represented by a set of seeds, which are used to induce typical query-contexts for the class. Contexts are then used to extract and select new candidate instances for the class. A similar approach is also adopted in (Sekine and Suzuki, 2007). Pasca shows an improvement of about 20% accuracy, compared to existing Web-based systems. Our extraction algorithm differs from Pasca's work in that it is completely unsupervised. Also, Pasca's cannot be applied to OIE, i.e. it only works for pre-defined classes. Our clustering approach is related to Lin and Wu's work (Lin and Wu, 2009). Authors propose a semi-supervised algorithm for query classification. First, they extract a large set of 20M phrases from a query log, as those unique queries appearing more than 100 times in a Web corpus. Then, they cluster the phrases using the K-means algorithm, where features are the phrases' bag-of-words contexts computed over a web corpus. Finally, they classify queries using a logistic regression algorithm. Our work differs from Lin and Wu, as we focus on entities instead of phrases. Also, the features we use for clustering are from query logs and click data, not web contexts.

6 Conclusions

We presented an open entity extraction approach over query logs that goes beyond the traditional web corpus, with the goal of modeling a 'user-space' as opposed to an established 'web-space'. We showed that the clusters generated by query logs substantially differ from those by a Web corpus; and that our method is able to induce state-of-the-art quality classes on a user-oriented evaluation on the real world task of keyword generation for sponsored search. As future work we plan to: (i) experiment different clustering algorithms and feature models, e.g. soft-clustering for handling ambiguous entities; (ii) integrate the Web space and the query log spaces; (iii) embed our methods in in existing tools for intent modeling, query suggestion and similia, to check its impact in production systems.

[6] Note that very high values for CL-CTX may be misleading, as many of the suggestions proposed by this system are incorrect (see precision results) and hence non-obvious (e.g., 'derek lewis' for 'galapagos islands').

Reranking Models in Fine-grained Opinion Analysis

Richard Johansson and **Alessandro Moschitti**
University of Trento
{johansson, moschitti}@disi.unitn.it

Abstract

We describe the implementation of reranking models for fine-grained opinion analysis – marking up opinion expressions and extracting opinion holders. The reranking approach makes it possible to model complex relations between multiple opinions in a sentence, allowing us to represent how opinions *interact* through the syntactic and semantic structure. We carried out evaluations on the MPQA corpus, and the experiments showed significant improvements over a conventional system that only uses local information: for both tasks, our system saw recall boosts of over 10 points.

1 Introduction

Recent years have seen a surge of interest in the automatic processing of *subjective language*. The technologies emerging from this research have obvious practical uses, either as stand-alone applications or supporting other NLP tools such as information retrieval or question answering systems. While early efforts in subjectivity analysis focused on coarse-grained tasks such as retrieving the subjective documents from a collection, most recent work on this topic has focused on fine-grained tasks such as determining the attitude of a particular person on a particular topic. The development and evaluation of such systems has been made possible by the release of manually annotated resources using fairly fine-grained representations to describe the structure of subjectivity in language, for instance the MPQA corpus (Wiebe et al., 2005).

A central task in the automatic analysis of subjective language is the indentification of *subjective expressions*: the text pieces that allow us to draw the conclusion that someone has a particular feeling about something. This is necessary for further analysis, such as the determination of opinion holder and the polarity of the opinion. The MPQA corpus defines two types of subjective expressions: *direct subjective expressions* (DSEs), which are explicit mentions of attitude, and *expressive subjective elements* (ESEs), which signal the attitude of the speaker by the choice of words. The prototypical example of a DSE would be a verb of statement or categorization such as *praise* or *disgust*, and the opinion holder would typically be a direct semantic argument of this verb. ESEs, on the other hand, are less easy to categorize syntactically; prototypical examples would include value-expressing adjectives such as *beautiful* and strongly charged words like *appeasement*, while the relation between the expression and the opinion holder is typically less clear-cut than for DSEs. In addition to DSEs and ESEs, the MPQA corpus also contains annotation for non-subjective statements, which are referred to as *objective speech events* (OSEs).

Examples (1) and (2) show two sentences from the MPQA corpus where DSEs and ESEs have been manually annotated.

(1) He [made such charges]$_{DSE}$ [despite the fact]$_{ESE}$ that women's political, social and cultural participation is [not less than that]$_{ESE}$ of men.

(2) [However]$_{ESE}$, it is becoming [rather fashionable]$_{ESE}$ to [exchange harsh words]$_{DSE}$ with each other [like kids]$_{ESE}$.

The task of marking up these expressions has usually been approached using straightforward sequence labeling techniques using using simple features in a small contextual window (Choi et al., 2006; Breck et al., 2007). However, due to

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 519–527,
Beijing, August 2010

the simplicity of the feature sets, this approach fails to take into account the fact that the semantic and pragmatic interpretation of sentences is not only determined by words but also by syntactic and shallow-semantic *relations*. Crucially, taking grammatical relations into account allows us to model how expressions *interact* in various ways that influence their interpretation as subjective or not. Consider, for instance, the word *said* in examples (3) and (4) below, where the interpretation as a DSE or an OSE is influenced by the subjective content of the enclosed statement.

(3) "We will identify the [culprits]$_{ESE}$ of these clashes and [punish]$_{ESE}$ them," he [said]$_{DSE}$.

(4) On Monday, 80 Libyan soldiers disembarked from an Antonov transport plane carrying military equipment, an African diplomat [said]$_{OSE}$.

In addition, the various opinions expressed in a sentence are very interdependent when it comes to the resolution of their *holders*, i.e. determining the entity that harbors the sentiment manifested textually in the opinion expression. Clearly, the structure of the sentence is influential also for this task: an ESE will be quite likely to be linked to the same opinion holder as a DSE directly above it in the syntactic tree.

In this paper, we demonstrate how syntactic and semantic structural information can be used to improve the detection of opinion expressions and the extraction of opinion holders. While this feature model makes it impossible to use the standard sequence labeling method, we show that with a simple strategy based on *reranking*, incorporating structural features results in a significant improvement. In an evaluation on the MPQA corpus, the best system we evaluated, a reranker using the Passive–Aggressive learning algorithm, achieved a 10-point absolute improvement in soft recall, and a 5-point improvement in F-measure, over the baseline sequence labeler. Similarly, the recall is boosted by almost 11 points for the holder extraction (3 points in F-measure) by modeling the interaction of opinion expressions with respect to holders.

2 Related Work

Since the most significant body of work in subjectivity analysis has been dedicated to coarse-grained tasks such as document polarity classification, most approaches to analysing the sentiment of natural-language text have relied fundamentally on purely lexical information (see (Pang et al., 2002; Yu and Hatzivassiloglou, 2003), *inter alia*) or low-level grammatical information such as part-of-speech tags and functional words (Wiebe et al., 1999). This is not unexpected since these problems have typically been formulated as text categorization problems, and it has long been agreed in the information retrieval community that very little can be gained by complex linguistic processing for tasks such as text categorization and search (Moschitti and Basili, 2004).

As the field moves towards increasingly sophisticated tasks requiring a detailed analysis of the text, the benefit of syntactic and semantic analysis becomes more clear. For the task of subjective expression detection, Choi et al. (2006) and Breck et al. (2007) used syntactic features in a sequence model. In addition, syntactic and shallow-semantic relations have repeatedly proven useful for subtasks of subjectivity analysis that are inherently *relational*, above all for determining the holder or topic of a given opinion. Choi et al. (2006) is notable for the use of a global model based on hand-crafted constraints and an integer linear programming optimization step to ensure a globally consistent set of opinions and holders.

Works using syntactic features to extract topics and holders of opinions are numerous (Bethard et al., 2005; Kobayashi et al., 2007; Joshi and Penstein-Rosé, 2009; Wu et al., 2009). Semantic role analysis has also proven useful: Kim and Hovy (2006) used a FrameNet-based semantic role labeler to determine holder and topic of opinions. Similarly, Choi et al. (2006) successfully used a PropBank-based semantic role labeler for opinion holder extraction. Ruppenhofer et al. (2008) argued that semantic role techniques are useful but not completely sufficient for holder and topic identification, and that other linguistic phenomena must be studied as well. One such linguistic pheonomenon is the *discourse* structure, which has recently attracted some attention in the subjectivity analysis community (Somasundaran et al., 2009).

3 Modeling Interaction over Syntactic and Semantic Structure

Previous systems for opinion expression markup have typically used simple feature sets which have allowed the use of efficient off-the-shelf sequence labeling methods based on Viterbi search (Choi et al., 2006; Breck et al., 2007). This is not possible in our case since we would like to extract structural, relational features that involve *pairs* of opinion expressions and may apply over an arbitrarily long distance in the sentence.

While it is possible that search algorithms for exact or approximate inference can be constructured for the $\arg\max$ problem in this model, we sidestepped this issue by using a *reranking* decomposition of the problem:

- Apply a standard Viterbi-based sequence labeler based on local context features but no structural interaction features. Generate a small candidate set of size k.
- Generate opinion holders for every proposed opinion expression.
- Apply a complex model using interaction features to pick the top candidate from the candidate set.

The advantages of a reranking approach compared to more complex approaches requiring advanced search techniques are mainly simplicity and efficiency: this approach is conceptually simple and fairly easy to implement provided that k-best output can be generated efficiently, and features can be arbitrarily complex – we don't have to think about how the features affect the algorithmic complexity of the inference step. A common objection to reranking is that the candidate set may not be diverse enough to allow for much improvement unless it is very large; the candidates may be trivial variations that are all very similar to the top-scoring candidate.

3.1 Syntactic and Semantic Structures

We used the syntactic–semantic parser by Johansson and Nugues (2008) to annnotate the sentences with dependency syntax (Mel'čuk, 1988) and shallow semantic structures in the PropBank (Palmer et al., 2005) and NomBank (Meyers et al., 2004) frameworks. Figure 1 shows an example of the annotation: The sentence *they called him a liar*, where *called* is a DSE and *liar* is an ESE, has been annotated with dependency syntax (above the text) and PropBank-based semantic role structure (below the text). The predicate *called*, which is an instance of the PropBank frame call.01, has three semantic arguments: the Agent (A0), the Theme (A1), and the Predicate (A2), which are realized on the surface-syntactic level as a subject, a direct object, and an object predicative complement, respectively.

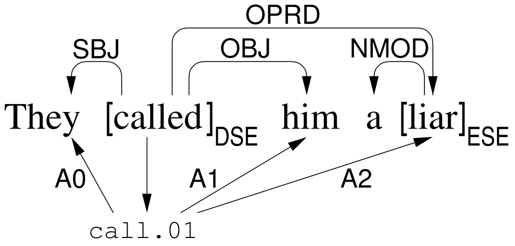

Figure 1: Syntactic and shallow semantic structure.

3.2 Base Sequence Labeling Model

To solve the first subtask, we implemented a standard sequence labeler for subjective expression markup, similar to the approach by Breck et al. (2007). We encoded the opinionated expression brackets using the IOB2 encoding scheme (Tjong Kim Sang and Veenstra, 1999) and trained the model using the metod by Collins (2002).

The sequence labeler used word, POS tag, and lemma features in a window of size 3. In addition, we used prior polarity and intensity features derived from the lexicon created by Wilson et al. (2005). It is important to note that prior subjectivity does not always imply subjectivity in a particular context; this is why contextual features are essential for this task.

This sequence labeler was used to generate the candidate set for the reranker. To generate reranking training data, we carried out a 5-fold hold-out procedure: We split the training set into 5 pieces, trained a sequence labeler on pieces 1 to 4, applied it to piece 5 and so on.

3.3 Base Opinion Holder Extractor

For every opinion expression, we extracted *opinion holders*, i.e. mentions of the entity holding the opinion denoted by the opinion expression. Since the problem of holder extraction is in many ways similar to semantic argument detection – when the opinion expression is a verb, finding the holder typically entails finding a SPEAKER argument – we approached this problem using methods inspired by semantic role labeling. We thus trained support vector machines using the LIBLINEAR software (Fan et al., 2008), and applied them to the noun phrases in the same sentence as the holder. Separate classifiers were trained to extract holders for DSEs, ESEs, and OSEs. The classifiers used the following feature set:

- **SYNTACTIC PATH**. Similarly to the path feature widely used in SRL, we extract a feature representing the path in the dependency tree between the expression and the holder (Johansson and Nugues, 2008). For instance, the path from the DSE *called* to the holder *They* is `SBJ↓`.
- **SHALLOW-SEMANTIC RELATION**. If there is a direct shallow-semantic relation between the expression and the holder, use a feature representing its semantic role, such as `A0` for *They* with respect to *called*.
- **EXPRESSION HEAD WORD AND POS**.
- **HOLDER HEAD WORD AND POS**.
- **DOMINATING EXPRESSION TYPE**.
- **CONTEXT WORDS AND POS FOR HOLDER**.
- **EXPRESSION VERB VOICE**.

However, there are also differences compared to typical argument extraction in SRL. First, it is important to note that the MPQA corpus does not annotate direct links from opinions to a holders, but from opinions to *holder coreference chains*. To handle this issue, we created positive training instances for *all* members of the coreference chain in the same sentence as the opinion, and negative instances for the other noun phrases.

Secondly, an opinion may be linked not to an overt noun phrase in a sentence, but to an *implicit* holder; a special case of implicit holder is the *writer* of the text. We trained separate classifiers to detect these situations. These classifiers did not use the features requiring a holder phrase.

Finally, there is a restriction that every expression may have at most one holder, so at test time we select only the highest-scoring opinion holder candidate.

3.4 Opinion Expression Reranker Features

The rerankers use two types of structural features: syntactic features extracted from the dependency tree, and semantic features extracted from the predicate–argument (semantic role) graph.

The syntactic features are based on paths through the dependency tree. This creates a small complication for multiword opinion expressions; we select the shortest possible path in such cases. For instance, in example (1) above, the path will be computed between *made* and *despite*, and in (2) between *fashionable* and *exchange*.

We used the following syntactic interaction features:

- **SYNTACTIC PATH**. Given a pair opinion expressions, we use a feature representing the labels of the two expressions and the path between them through the syntactic tree. For instance, for the DSE *called* and the ESE *liar* in Figure 1, we represent the syntactic configuration using the feature `DSE:OPRD↓:ESE`, meaning that the path from the DSE to the ESE follows an OPRD link downward.
- **LEXICALIZED PATH**. Same as above, but with lexical information attached: `DSE/called:OPRD↓:ESE/liar`.
- **DOMINANCE**. In addition to the features based on syntactic paths, we created a more generic feature template describing dominance relations between expressions. For instance, from the graph in Figure 1, we extract the feature `DSE/called→ESE/liar`, meaning that a DSE with the word *called* dominates an ESE with the word *liar*.

The semantic features were the following:

Predicate Sense Label. For every predicate found inside an opinion expression, we add a feature consisting of the expression label and the predicate sense identifier. For instance, the verb *call* which is also a DSE is represented with the feature `DSE/call.01`.

Predicate and Argument Label. For every argument of a predicate inside an opinion expression, we also create a feature representing the predicate–argument pair: `DSE/call.01:A0`.

Connecting Argument Label. When a predicate inside some opinion expression is connected to some argument inside another opinion expression, we use a feature consisting of the two expression labels and the argument label. For instance, the ESE *liar* is connected to the DSE *call* via an A2 label, and we represent this using a feature `DSE:A2:ESE`.

Apart from the syntactic and semantic features, we also used the score output from the base sequence labeler as a feature. We normalized the scores over the k candidates so that their exponentials summed to 1.

3.5 Opinion Holder Reranker Features

In addition, we modeled the interaction between different opinions with respect to their holders. We used the following two features to represent this interaction:

Shared Holders. A feature representing whether or not two opinion expressions have the same holder. For instance, if a DSE dominates an ESE and they have the same holder as in Figure 1 where the holder is *They*, we represent this by the feature `DSE:ESE:true`.

Holder types + Path. A feature representing the types of the holders, combined with the syntactic path between the expressions. The types take the following possible values: explicit, implicit, writer. In Figure 1, we would thus extract the feature `DSE/Expl:OPRD↓:ESE/Expl`.

Similar to base model feature for the expression detection, we also used a feature for the output score from the holder extraction classifier.

3.6 Training the Reranker

We trained the reranker using the method employed by many rerankers following Collins (2002), which learns a scoring function that is trained to maximize performance on the reranking task. While there are batch learning algorithms that work in this setting (Tsochantaridis et al., 2005), online learning methods have been more popular for performance reasons. We investigated two online learning algorithms: the popular *structured perceptron* (Collins, 2002) and the Passive–Aggressive (PA) algorithm (Crammer et al., 2006). To increase robustness, we used an averaged implementation (Freund and Schapire, 1999) of both algorithms.

The difference between the two algorithms is the way the weight vector is incremented in each step. In the perceptron, for a given input x, we update based on the difference between the correct output y and the predicted output $\hat{y}$, where Φ is the feature representation function:

$$\begin{aligned}&\hat{y} \leftarrow \arg\max_h w \cdot \Phi(x,h)\\ &w \leftarrow w + \Phi(x,y) - \Phi(x,\hat{y})\end{aligned}$$

In the PA algorithm, which is based on the theory of large-margin learning, we instead find the $\hat{y}$ that violates the margin constraints maximally. The update step length τ is computed based on the margin; this update is bounded by a regularization constant C:

$$\begin{aligned}&\hat{y} \leftarrow \arg\max_h w \cdot \Phi(x,h) + \sqrt{\rho(y,h)}\\ &\tau \leftarrow \min\left(C, \frac{w(\Phi(x,\hat{y})-\Phi(x,y))+\sqrt{\rho(y,\hat{y})}}{\|\Phi(x,\hat{y})-\Phi(x,y)\|^2}\right)\\ &w \leftarrow w + \tau(\Phi(x,y) - \Phi(x,\hat{y}))\end{aligned}$$

The algorithm uses a cost function ρ. We used the function $\rho(y,\hat{y}) = 1 - F(y,\hat{y})$, where F is the soft F-measure described in Section 4.1. With this approach, the learning algorithm thus directly optimizes the measure we are interested in, i.e. the F-measure.

4 Experiments

We carried out the experiments on version 2 of the MPQA corpus (Wiebe et al., 2005), which we split into a test set (150 documents, 3,743 sentences) and a training set (541 documents, 12,010 sentences).

4.1 Evaluation Metrics

Since expression boundaries are hard to define exactly in annotation guidelines (Wiebe et al., 2005), we used soft precision and recall measures to score the quality of the system output. To derive the soft precision and recall, we first define the *span coverage* c of a span s with respect to another span s', which measures h ow well s' is covered by s:

$$c(s, s') = \frac{|s \cap s'|}{|s'|}$$

In this formula, the operator $|\cdot|$ counts tokens, and the intersection $\cap$ gives the set of tokens tha t two spans have in common. Since our evaluation takes span labels (DSE, ESE, OSE) into account, we set $c(s, s')$ to zero if the labels associated with s and s' are different.

Using the span coverage, we define the *span set coverage* C of a set of spans $\boldsymbol{S}$ with respect to a set $\boldsymbol{S'}$:

$$C(\boldsymbol{S}, \boldsymbol{S'}) = \sum_{s_j \in \boldsymbol{S}} \sum_{s'_k \in \boldsymbol{S'}} c(s_j, s'_k)$$

We now define the soft precision P and recall R of a proposed set of spans $\hat{\boldsymbol{S}}$ with respect to a gold standard set $\boldsymbol{S}$ as follows:

$$P(\boldsymbol{S}, \hat{\boldsymbol{S}}) = \frac{C(\boldsymbol{S}, \hat{\boldsymbol{S}})}{|\hat{\boldsymbol{S}}|} \quad R(\boldsymbol{S}, \hat{\boldsymbol{S}}) = \frac{C(\hat{\boldsymbol{S}}, \boldsymbol{S})}{|\boldsymbol{S}|}$$

Note that the operator $|\cdot|$ counts spans in this formula.

Conventionally, when measuring the quality of a system for an information extraction task, a predicted entity is counted as correct if it exactly matches the boundaries of a corresponding entity in the gold standard; there is thus no reward for close matches. However, since the boundaries of the spans annotated in the MPQA corpus are not strictly defined in the annotation guidelines (Wiebe et al., 2005), measuring precision and recall using exact boundary scoring will result in figures that are too low to be indicative of the usefulness of the system. Therefore, most work using this corpus instead use overlap-based precision and recall measures, where a span is counted as correctly detected if it *overlaps* with a span in the gold standard (Choi et al., 2006; Breck et al., 2007). As pointed out by Breck et al. (2007), this is problematic since it will tend to reward long spans – for instance, a span covering the whole sentence will always be counted as correct if the gold standard contains any span for that sentence.

The precision and recall measures proposed here correct the problem with overlap-based measures: If the system proposes a span covering the whole sentence, the span coverage will be low and result in a low soft precision. Note that our measures are bounded below by the exact measures and above by the overlap-based measures: replacing $c(s, s')$ with $\lfloor c(s, s') \rfloor$ gives the exact measures and replacing $c(s, s')$ with $\lceil c(s, s') \rceil$ the overlap-based measures.

To score the extraction of opinion holders, we started from the same basic approach. However, the evaluation of this task is more complex because a) we only want to give credit for holders for correctly extracted opinion expressions; b) the gold standard links opinion expressions to coreference chains rather than individual mentions of holders; c) the holder may be the writer or implicit (see 3.3). We therefore used the following method: Given a holder h linked to an expression e, we first located the expression e' in the gold standard that most closely corresponds to e, that is $e' = \arg\max_x c(x, e)$, regardless of the labels of e and e'. We then located the gold standard holder h' by finding the closest corresponding holder in the coreference chain H linked to e': $h' = \arg\max_{x \in H} c(x, h)$. If h is proposed as the writer, we score it as perfectly detected (coverage 1) if the coreference chain H contains the writer, and a full error (coverage 0) otherwise, and similar if h is implicit.

4.2 Machine Learning Methods

We compared the machine learning methods described in Section 3. In these experiments, we used a candidate set size k of 8. Table 1 shows the results of the evaluations using the precision and recall measures described above. The baseline is the result of taking the top-scoring labeling from the base model.

System	P	R	F
Baseline	63.36	46.77	53.82
Perceptron	62.84	48.13	54.51
PA	63.50	51.79	57.04

Table 1: Evaluation of reranking learning methods.

We note that the best performance was obtained using the PA algorithm. While these results are satisfactory, it is possible that they could be improved further if we would use a batch learning method such as SVM$^{\text{struct}}$ (Tsochantaridis et al., 2005) instead of the online learning methods used here.

4.3 Candidate Set Size

In any method based on reranking, it is important to study the influence of the candidate set size on the quality of the reranked output. In addition, an interesting question is what the upper bound on reranker performance is – the *oracle* performance. Table 2 shows the result of an experiment that investigates these questions. We used the reranker based on the Passive–Aggressive method in this experiment since this reranker gave the best results in the previous experiment.

	Reranked			Oracle		
k	P	R	F	P	R	F
1	63.36	46.77	53.82	63.36	46.77	53.82
2	63.70	48.17	54.86	72.66	55.18	62.72
4	63.57	49.78	55.84	79.12	62.24	69.68
8	63.50	51.79	57.04	83.72	68.14	75.13
16	63.00	52.94	57.54	86.92	72.79	79.23
32	62.15	54.50	58.07	89.18	76.76	82.51
64	61.02	55.67	58.22	91.08	80.19	85.28
128	60.22	56.45	58.27	92.63	83.00	87.55
256	59.87	57.22	58.51	94.01	85.27	89.43

Table 2: Oracle and reranker performance as a function of candidate set size.

As is common in reranking tasks, the reranker can exploit only a fraction of the potential improvement – the reduction of the F-measure error is between 10 and 15 percent of the oracle error reduction for all candidate set sizes.

The most visible effect of the reranker is that the recall is greatly improved. However, this does not seem to have an adverse effect on the precision until the candidate set size goes above 16 – in fact, the precision actually improves over the baseline for small candidate set sizes. After the size goes above 16, the recall (and the F-measure) still rises, but at the cost of decreased precision.

4.4 Syntactic and Semantic Features

We studied the impact of syntactic and semantic structural features on the performance of the reranker. Table 3 shows the result of the investigation for syntactic features. Using all the syntactic features (and no semantic features) gives an F-measure roughly 4 points above the baseline, using the PA reranker with a k of 64. We then measured the F-measure obtained when each one of the three syntactic features has been removed. It is clear that the unlexicalized syntactic path is the most important syntactic feature; the effect of the two lexicalized features seems to be negligible.

System	P	R	F
Baseline	63.36	46.77	53.82
All syntactic	62.45	53.19	57.45
No SYN PATH	64.40	48.69	55.46
No LEX PATH	62.62	53.19	57.52
No DOMINANCE	62.32	52.92	57.24

Table 3: Effect of syntactic features.

A similar result was obtained when studying the semantic features (Table 4). Removing the connecting labels feature, which is unlexicalized, has a greater effect than removing the other two semantic features, which are lexicalized.

System	P	R	F
Baseline	63.36	46.77	53.82
All semantic	61.26	53.85	57.31
No PREDICATE SL	61.28	53.81	57.30
No PRED+ARGLBL	60.96	53.61	57.05
No CONN ARGLBL	60.73	50.47	55.12

Table 4: Effect of semantic features.

4.5 Opinion Holder Extraction

Table 5 shows the performance of the opinion holder extractor. The baseline applies the holder classifier (3.3) to the opinions extracted by the base sequence labeler (3.2), without modeling any interactions between opinions. A large performance boost is then achieved simply by applying the opinion expression reranker ($k = 64$); this is simply the consequence of improved expression detection, since a correct expression is required to get credit for a holder).

However, we can improve on this by adding the holder interaction features: both the SHARED HOLDERS and HOLDER TYPES + PATH features contribute to improving the recall even further.

System	P	R	F
Baseline	57.66	45.14	50.64
Reranked expressions	52.35	52.54	52.45
SHARED HOLDERS	52.43	55.21	53.78
HTYPES + PATH	52.22	54.41	53.30
Both	52.28	55.99	54.07

Table 5: Opinion holder extraction experiments.

5 Conclusion

We have shown that features derived from grammatical and semantic role structure can be used to improve two fundamental tasks in fine-grained opinion analysis: the detection of opinionated expressions in subjectivity analysis, and the extraction of opinion holders. Our feature sets are based on interaction between opinions, which makes exact inference intractable. To overcome this issue, we used an implementation based on reranking: we first generated opinion expression sequence candidates using a simple sequence labeler similar to the approach by Breck et al. (2007). We then applied SRL-inspired opinion holder extraction classifiers, and finally a global model applying to all opinions and holders.

Our experiments show that the interaction-based models result in drastic improvements. Significantly, we see significant boosts in recall (10 points for both tasks) while the precision decreases only slightly, resulting in clear F-measure improvements. This result compares favorably with previously published results, which have been precision-oriented and scored quite low on recall.

We analyzed the impact of the syntactic and semantic features and saw that the best model is the one that makes use of both types of features. The most effective features we have found are purely structural, i.e. based on tree fragments in a syntactic or semantic tree. Features involving words did not seem to have the same impact.

There are multiple opportunities for future work in this area. An important issue that we have left open is the coreference problem for holder extraction, which has been studied by Stoyanov and Cardie (2006). Similarly, recent work has tried to incorporate complex, high-level linguistic structure such as discourse representations (Somasundaran et al., 2009); it is clear that these structures are very relevant for explaining the way humans organize their expressions of opinions rhetorically. However, theoretical depth does not necessarily guarantee practical applicability, and the challenge is as usual to find a middle ground that balances our goals: explanatory power in theory, significant performance gains in practice, computational tractability, and robustness in difficult circumstances.

Unsupervised phonemic Chinese word segmentation using Adaptor Grammars

Abstract

Adaptor grammars are a framework for expressing and performing inference over a variety of non-parametric linguistic models. These models currently provide state-of-the-art performance on unsupervised word segmentation from phonemic representations of child-directed unsegmented English utterances. This paper investigates the applicability of these models to unsupervised word segmentation of Mandarin. We investigate a wide variety of different segmentation models, and show that the best segmentation accuracy is obtained from models that capture inter-word "collocational" dependencies. Surprisingly, enhancing the models to exploit syllable structure regularities and to capture tone information does improve overall word segmentation accuracy, perhaps because the information these elements convey is redundant when compared to the inter-word dependencies.

1 Introduction and previous work

The word-segmentation task is an abstraction of part of the problem facing a child learning its native language. Fluent speech, even the speech directed at children, doesn't come with silence or pauses delineating acoustic words the way that spaces separate orthographic words in writing systems like that of English. Instead, as most people listening to a language they don't understand can attest, words in fluent speech "run together", and a language user needs to learn how to segment utterances of the language they are learning into words. This kind of word segmentation is presumably an important first step in acquiring a language. It is scientifically interesting to know what information might be useful for word segmentation, and just how this information might be used. These scientific questions have motivated a body of research on computational models of word segmentation. Since as far as we can tell any child can learn any human language, our goal is to develop a single model that can learn to perform accurate word segmentation given input from any human language, rather than a model that specialised to perform well on a single language. This paper extends the previous work on word segmentation by investigating whether one class of models that work very well with English input also work with Chinese input. These models will permit us to study the role that syllable structure constraints and tone in Chinese might play in word segmentation.

While learners and fluent speakers undoubtedly use a wide variety of cues to perform word segmentation, computational models since Elman (1990) have tended to focus on the use of phonotactic constraints (e.g., syllable-structure constrains) and distributional information. Brent and Cartwright (1996) introduced the standard form of the word segmentation task still studied today. They extracted the orthographic representations of child-directed speech from the Bernstein-Ratner corpus (Bernstein-Ratner, 1987) and "phonologised" them by looking up each word in a pronouncing dictionary. For example, the orthographic utterance *you want to see the book* is mapped to the sequence of pronunciations *yu want tu si D6 bUk*, (the pronunciations are in an

ASCII encoding of the International Phonetic Alphabet representation of English phonemes). The input to the learner is obtained by concatenating together the phonemic representations of each utterance's words. The learner's task is to identify the locations of the word boundaries in this sequence, and hence identify the words (up to homophony). Brent and Cartwright (1996) pointed out the importance of both distributional information and phonotactic (e.g., syllable-structure) constraints for word segmentation (see also Swingley (2005) and Fleck (2008)).

Recently there has been considerable interest in applying Bayesian inference techniques for non-parametric models to this problem. Here the term "non-parametric" does not mean that the models have no parameters, rather, it is used to distinguish these models from the usual "parametric models" that have a fixed finite vector of parameters.

Goldwater et al. (2006) introduced two non-parametric Bayesian models of word segmentation, which are discussed in more detail in (Goldwater et al., 2009). The *unigram model*, which assumes that each word is generated independently to form a sentence, turned out to be equivalent to a model originally proposed by Brent (1999). The *bigram model* improves word segmentation accuracy by modelling bigram inter-word contextual dependencies, "explaining away" inter-word dependencies that would otherwise cause the unigram model to under-segment. Mochihashi et al. (2009) showed that segmentation accuracy could be improved by using a more sophisticated "base distribution" and a dynamic programming sampling algorithm very similar to the one used with the adaptor grammars below. They also applied their algorithm to Japanese and Chinese word segmentation, albeit from orthographic rather than phonemic forms, so unfortunately their results are not comparable with ours.

Johnson et al. (2007) introduced *adaptor grammars* as a grammar-based framework for expressing a variety of non-parametric models, and provided a dynamic programming Markov Chain Monte Carlo (MCMC) sampling algorithm for performing Bayesian inference on these models. For example, the unigram model can be expressed as a simple adaptor grammar as shown below, and the generic adaptor grammar inference procedure provides a dynamic programming sampling algorithm for this model. Johnson (2008b) showed how a variety of different word segmentation models can be expressed as adaptor grammars, and Johnson and Goldwater (2009) described a number of extensions and specialisations to the adaptor grammar framework that improve inference speed and accuracy (we use these techniques in our work below).

Previous work on unsupervised word segmentation from phonemic input has tended to concentrate on English. However, presumably children the world over segment their first language input in the same (innately-specified) way, so a correct procedure should work for all possible human languages. However, as far as we are aware there has been relatively little work on word segmentation from phonemic input except on English. Johnson (2008a) investigated whether the adaptor grammars models that do very well on English also apply to Sesotho (a Bantu language spoken in southern Africa with rich agglutinating morphology). He found that the models in general do very poorly (presumably because the adaptor grammars used cannot model the complex morphology found in Sesotho) and that the best segmentation accuracy was considerably worse than that obtained for English, even when that model incorporated some Bantu-specific information about morphology. Of course it may also be that the Sesotho and English corpora are not really comparable: the Bernstein-Ratner corpus that Brent and other researchers have used for English was spoken to pre-linguistic 1-year olds, while most non-English corpora are of child-directed speech to older children who are capable of talking back, and hence these corpora are presumably more complex. We discuss this issue in more detail in section 4 below.

2 A Chinese word segmentation corpus

Our goal here is to prepare a Chinese corpus of child-directed speech that parallels the English one used by Brent and other researchers. That corpus was in broad phonemic form, obtained by looking each word up in a pronouncing dictionary. Here instead we make use of a corpus in Pinyin format, which we translate into a broad phonemic IPA format using the freely-available Pinyin-to-IPA translation program “Pinyin to IPA Conversion Tools” version 2.1 available on http://sourceforge.net/projects/py2ipa.

We used the “Beijing” corpus (Tardif, 1993) available from the publicly-distributed Childes collection of corpora (MacWhinney and Snow, 1985). We are interested in child-directed speech (rather than children’s speech), so we removed all utterances from participants with an Id containing “Child”. (Tardif (1993) points out that Chinese-speaking children typically have a much richer social environment involving multiple adult caregivers than middle-class English-speaking children do, so we cannot simply collect only the mother’s utterances, as was done for the English corpus). We also ignored all utterances with codes $INTERJ, $UNINT, $VOC and $PRMPT, as these are not always linguistic utterances. In addition, we deleted all words that could not be analysed as a sequence of syllables, such as “xxx” and “hmm”, and also deleted “cluck”. The first few utterances of the corpus in Pinyin format are:

zen3me gei3 ta1 bei1 shang4 lai2 (1.) ?
ta1: (.) a1yi2 gei3 de (.) ta1 gei3 de .
hen3 jian3dan1 .

We then fed these into the Pinyin-to-IPA translation program, producing output of the following format:

tsən^{214}mɤ kei^{214} t^{h}a^{55} pei^{55} ʂɑŋ^{51} lai^{35}
t^{h}a^{55} a^{55}i^{35} kei^{214} tɤ t^{h}a^{55} kei^{214} tɤ
xən^{214} tɕiɛn^{214}tan^{55}

In the IPA format, the superscript indices indicate the tone patterns associated with syllables; these appear at the end of each syllable, as is standard. While we believe there are good linguistic reasons to analyse tones as associated with syllables, we moved all the tones so they immediately followed the final vowel in each syllable. We did this because we thought that locating tones after the syllable-final consonant might give our models a strong cue as to the location of syllable boundaries, and since words often end at syllable boundaries, this would make the word segmentation problem artificially easier. (Our models take a sequence of symbols as input, so the tones must be located somewhere in the sequence. However, the linguistically “correct” solution would probably be to extend the models so they could process input in an auto-segmental format (Goldsmith, 1990) where tones would be on a separate tier and unordered with respect to the segments within a syllable.)

In order to evaluate the importance of tone for our word-segmentation models we also constructed a version of our corpus in which all tones were removed. We present results for all of our models on two versions of the corpus, one that contains tones following the vowels, and another that contains no tones at all. These two corpora constitute the “gold standard” against which our word segmentation models will be evaluated. These corpora contain 50,118 utterances, consisting of 187,533 word tokens.

The training data provided to the word segmentation models is obtained by segmenting the gold data at all possible boundary locations. Consonant clusters, diphthongs and tones (if present) are treated as single units, so the training data appears as follows:

ts ə ^{214} n m ɤ k e i ^{214} t^{h} a ^{55} p e i ^{55} ʂ ɑ ^{51} ŋ l ai ^{35}
t^{h} a ^{55} a ^{55} i ^{35} k e i ^{214} t ɤ t^{h} a ^{55} k e i ^{214} t ɤ
x ə ^{214} n tɕ iɛ ^{214} n t a ^{55} n

The task of a word-segmentation model is to identify which of these possible boundary locations correspond to actual word boundaries. The training corpus without tones contains 531,384 segments, while the training corpus with tones contains 712,318 segments.

3 Adaptor grammars for word segmentation

Adaptor grammars were first introduced by Johnson et al. (2007) as a grammar-based framework for specifying hierarchical non-parametric Bayesian models, and Johnson and Goldwater (2009) describes a number of implementation details that significantly improve performance; the interested reader should consult those papers for a full technical introduction. Johnson (2008b) proposed a number of adaptor grammars for English word segmentation, which we review and minimally modify here so they can perform Chinese word segmentation as well. In section 4 we evaluate these adaptor grammars on the Chinese corpus just described.

The grammars vary along two orthogonal dimensions, which correspond to the kinds of generalisations that the model can learn. The simplest grammar is the unigram adaptor grammar, which generates an utterance as an i.i.d. sequences of words, where each word is a sequence of phonemes. The collocation adaptor grammars capture dependencies above the word level by generating collocations, or groups of words, as memoized units. The syllable adaptor grammars capture dependencies below the word level by generating words as sequences of syllables rather than phonemes.

3.1 Unigram adaptor grammars

In order to motivate adaptor grammars as an extension to Probabilistic Context-Free Grammars (PCFGs), consider an attempt to perform unsupervised word segmentation with a PCFG containing the following rules (ignore the underlining of the Word non-terminal for now).

$$\begin{array}{l} \text{Words} \rightarrow \text{Words } \underline{\text{Word}} \\ \text{Words} \rightarrow \underline{\text{Word}} \\ \underline{\text{Word}} \rightarrow \text{Phons} \\ \text{Phons} \rightarrow \text{Phon} \\ \text{Phons} \rightarrow \text{Phons Phon} \\ \text{Phons} \rightarrow \text{Phons Tone} \\ \text{Phon} \rightarrow \text{ai} \mid \text{o} \mid \ldots \mid \text{ʂ} \mid \text{tʂ}^{h} \mid \ldots \\ \text{Tone} \rightarrow 35 \mid 55 \mid 214 \mid \ldots \end{array} \qquad (1)$$

In this grammar, Phon expands to all the phonemes appearing in the phonemic training data, and Tone expands to all of the tone patterns. (In this and all of the other grammars in this paper, the start symbol is the non-terminal symbol of the first rule in the grammar. This grammar, like all others in this paper, is crafted so that a Word subtree can never begin with a Tone, so the presence of tones does not make the segmentation problem harder).

The trees generated by this grammar are sufficiently expressive to *represent* any possible segmentation of any sequence of phonemes into words (including the true segmentation); a typical segmentation is shown in Figure 1. However, it should also be clear that no matter how we vary the probabilities on the rules of this grammar, *the grammar itself cannot encode the subset of trees that correspond to words of the language*. In order to do this, a model would need to memorise the probabilities of entire Word subtrees, since these are the units that correspond to individual words, but this PCFG simply is not expressive enough to do this.

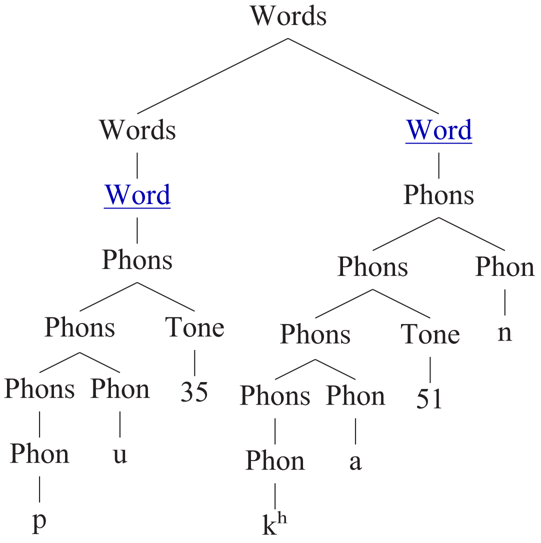

Figure 1: A parse tree generated by the unigram grammar, where adapted and non-adapted non-terminals are shown. It depicts a possible segmentation of p u ^{35} k^{h} a ^{51} n.

Adaptor grammars learn the probabilities of subtrees in just this way. An adaptor grammar is specified via a set of rules or productions, just like a CFG, and the set of trees that an adaptor grammar generates is exactly the same as the CFG with those rules.

However, an adaptor grammar defines probability distributions over trees in a completely different fashion to a PCFG: for simplicity we focus here on the sampling or predictive distribution, which defines the probability of generating an entire corpus of trees. In a PCFG, the probability of each non-terminal expanding using a given rule is determined by the probability of that rule, and is independent of the expansions of the other non-terminals in the tree. In an adaptor grammar a subset of the non-terminals are designated as *adapted*. We indicate adapted non-terminals by underlining them, so $\underline{\text{Word}}$ is the only adapted non-terminal in (1). Unadapted non-terminals expand just as in a PCFG: a production is chosen according to the production probabilities. An adapted non-terminal can expand in two different ways. With probability proportional to $n(t) - a_A$ an adapted non-terminal A expands to a tree t rooted in A that has been previously generated, while with probability proportional to $m(A)a_A + b_A$ the adapted non-terminal A expands using some grammar rule, just as in a PCFG. Here $n(t)$ is the number of times tree t has been previously generated, $m(A)$ is the number of trees rooted in A that have been previously generated using grammar rules, and $0 \leqslant a_A \leqslant 1$ and $b_A > 0$ are adjustable parameters associated with the adapted non-terminal A.

Technically, this is known as a *Pitman-Yor Process* (PYP) with *concentration parameters* a_A and b_A, where the PCFG rules define the *base distribution* of the process. (The PYP is a generalisation of the Chinese Restaurant Process (CRP); a CRP is a PYP with parameter $a = 0$). Rather than setting the concentration parameters by hand (there are two for each adapted non-terminal in the grammar) we follow Johnson and Goldwater (2009) and put uniform Beta and vague Gamma priors on each of these parameters, and use sampling to explore their posterior values.

Because the probability of selecting a tree t is proportional to $n(t)$, an adaptor grammar is a kind of "rich-get-richer" process that generates power-law distributions. Depending on the values of a_A and b_A, most of the probability mass can wind up concentrated on just a few trees. An adaptor grammar is a kind of "cache" model, in which previously generated subtrees are stored and more likely to be reused in later sentences. That is, while an adapted non-terminal A can expand to any tree rooted in A that can be constructed with the grammar rules, in practice it is increasingly likely to reuse the same trees over and over again. It can be viewed as a kind of tree substitution grammar (Joshi, 2003), but where the tree fragments (as well as their probabilities) are learnt from the data.

The unigram grammar is the simplest of the word segmentation models we investigate in this paper (it is equivalent to the unigram model investigated in Goldwater et al. (2009)). Because the grammars we present below rapidly become long and complicated to read if each grammar rule is explicitly stated, we adopt the following conventions. We use regular expressions to abbreviate our grammars, with the understanding that the regular expressions are always expanded produce a left-recursive structure. For example, the unigram grammar in (1) is abbreviated as:

$$\begin{aligned}
&\text{Words} \rightarrow \underline{\text{Word}}^{+} \\
&\underline{\text{Word}} \rightarrow \text{Phon (Phon} \mid \text{Tone)}^{\star} \\
&\text{Phon} \rightarrow \text{ai} \mid \text{o} \mid \ldots \mid \text{ʂ} \mid \text{tʂ}^{\text{h}} \mid \ldots \\
&\text{Tone} \rightarrow 35 \mid 55 \mid 214 \mid \ldots
\end{aligned} \qquad (2)$$

3.2 Collocation adaptor grammars

Goldwater et al. (2006) and Goldwater et al. (2009) demonstrated the importance of contextual dependencies for word segmentation, and proposed a bigram model in order to capture some of these. It turns out that while the bigram model cannot be expressed as an adaptor grammar, a *collocation model*, which captures similar kinds of contextual dependencies, can be expressed as an adaptor grammar (Johnson et al., 2007). In a collocation grammar there are two different adapted non-terminals; $\underline{\text{Word}}$ and $\underline{\text{Colloc}}$; $\underline{\text{Word}}$ expands exactly as in the unigram grammar (2), so it is not repeated here.

$$\begin{aligned}
&\text{Collocs} \rightarrow \underline{\text{Colloc}}^{+} \\
&\underline{\text{Colloc}} \rightarrow \text{Words} \\
&\text{Words} \rightarrow \underline{\text{Word}}^{+}
\end{aligned} \qquad (3)$$

A collocation adaptor grammar caches both words and collocations (which are sequences of words). An utterance is generated by generating one or more collocations. The PYP associated with collocations either regenerates a previously generated collocation or else generates a "fresh" collocation by generating a sequence of words according to the PYP model explained above.

The idea of aggregating words into collocations can be reapplied at a more abstract level by aggregating collocations into "super-collocations", which are sequences of collocations. This involves adding the following additional rules to the grammar in (3):

$$\begin{array}{l}\text{Colloc2s} \rightarrow \text{Colloc2}^{+}\\ \text{Colloc2} \rightarrow \text{Collocs}^{+}\end{array} \tag{4}$$

There are three PYPs in a grammar with 2 levels of collocations, arranged in a strict Bayesian hierarchy. It should be clear that this process can be repeated indefinitely; we investigate grammars with up to three levels of collocations below. (It should be possible to use Bayesian techniques to learn the appropriate number of levels in the hierarchy, but we leave this for future work).

3.3 Syllable structure adaptor grammars

Brent and Cartwright (1996) and others emphasise the role that syllable-structure and other phonotactic constraints might play in word segmentation. Johnson (2008b) pointed out that adaptor grammars can learn at least some of these kinds of generalisations. It's not unreasonable to assume that language learners can learn to group phonemes into syllables, and that they can exploit this syllabic structure to perform word segmentation. The syllable-structure grammars we describe below assume that word boundaries are always aligned with syllable boundaries; this is not universally true, but it is reliable enough to dramatically improve unsupervised word segmentation in English.

There is considerable cross-linguistic variation in the syllable-structure and phonotactic constraints operative in the languages of the world, so we'd like to avoid "building in" language-specific constraints into our model. We therefore make the relatively conservative assumption that the child can distinguish vowels from consonants, and that the child knows that syllables consist of Onsets, Nuclei and Codas, that Onsets and Codas consist of arbitrary sequences of consonants while Nuclei are arbitrary sequences of vowels and tones, and that Onsets and Codas are optional. Notice that syllable structure in both English and Chinese is considerably more constrained than this; we use this simple model here because it has proved successful for English word segmentation.

The syllable-structure adaptor grammars replace the rules expanding Words with the following rules:

$$\begin{array}{l}\text{Word} \rightarrow \text{Syll}\\ \text{Word} \rightarrow \text{Syll Syll}\\ \text{Word} \rightarrow \text{Syll Syll Syll}\\ \text{Word} \rightarrow \text{Syll Syll Syll Syll}\\ \text{Syll} \rightarrow (\text{Onset})^{?}\ \text{Rhy}\\ \text{Onset} \rightarrow \text{C}^{+}\\ \text{Rhy} \rightarrow \text{Nucleus}\ (\text{Coda})^{?}\\ \text{Nucleus} \rightarrow \text{V}\ (\text{V} \mid \text{Tone})^{\star}\\ \text{Coda} \rightarrow \text{C}^{+}\\ \text{C} \rightarrow \text{ʂ} \mid \text{tʂ}^{\text{h}} \mid \ldots\\ \text{V} \rightarrow \text{ai} \mid \text{o} \mid \ldots\end{array} \tag{5}$$

In these rules the superscript "?" indicates optionality. We used the relatively cumbersome mechanism of enumerating each possible number of syllables per word (we permit words to consist of from 1 to 4 syllables, although ideally this number would not be hard-wired into the grammar) because a relatively trivial modification of this grammar can distinguish word-initial and word-final consonant clusters from word-internal clusters. Johnson (2008b) demonstrated that this significantly improves English word segmentation accuracy. We do not expect this to improve Chinese word segmentation because Chinese clusters do not vary depending on their location within the word, but it will be interesting to see if the additional cluster flexibility that is useful for English segmentation hurts Chinese segmentation.

In this version of the syllable-structure grammar, we replace the Word rules in the syllable adaptor grammar with the following:

$$\begin{array}{l}\text{Word} \rightarrow \text{SyllIF}\\ \text{Word} \rightarrow \text{SyllI SyllF}\\ \text{Word} \rightarrow \text{SyllI Syll SyllF}\\ \text{Word} \rightarrow \text{SyllI Syll Syll SyllF}\end{array} \tag{6}$$

and add the following rules expanding the new kinds of syllables to the rules in (5).

$$\begin{array}{l}\text{SyllIF} \rightarrow (\text{OnsetI})^{?}\ \text{RhyF}\\ \text{SyllI} \rightarrow (\text{OnsetI})^{?}\ \text{Rhy}\\ \text{SyllF} \rightarrow (\text{OnsetI})^{?}\ \text{RhyF}\\ \text{Syll} \rightarrow (\text{Onset})^{?}\ \text{Rhy}\\ \text{OnsetI} \rightarrow \text{C}^{+}\\ \text{RhyF} \rightarrow \text{Nucleus}\ (\text{CodaF})^{?}\\ \text{CodaF} \rightarrow \text{C}^{+}\end{array} \tag{7}$$

	Syllables		
	None	General	Specialised
Unigram	0.57	0.50	0.50
Colloc	0.69	0.67	0.67
Colloc^2	0.72	0.75	0.75
Colloc^3	*0.64*	**0.77**	**0.77**

Table 1: F-score accuracies of word segmentations produced by the adaptor grammar models on the Chinese corpus *with tones*.

	Syllables		
	None	General	Specialised
Unigram	0.56	0.46	0.46
Colloc	0.70	0.65	0.65
Colloc^2	0.74	0.74	0.73
Colloc^3	0.75	0.76	**0.77**

Table 2: F-score accuracies of word segmentations produced by the adaptor grammar models on the Chinese corpus *without tones*.

These rules distinguish syllable onsets in word-initial position and syllable codas in word-final position; the standard adaptor grammar machinery will then learn distributions over onsets and codas in these positions that possibly differ from those in word-internal positions.

4 Results on Chinese word segmentation

The previous section described two dimensions along which adaptor grammars for word segmentation can independently vary. Above the Word level, there can be from zero to three levels of collocations, yielding four different values for this dimension. Below the Word level, phonemes can either be treated as independent entities, or else they can be grouped into onset, nuclei and coda clusters, and these can vary depending on where they appear within a word. Thus there are three different values for the syllable dimension, so there are twelve different adaptor grammars overall. In addition, we ran all of these grammars on two versions of the corpus, one with tones and one without tones, so we report results for 24 different runs here.

The adaptor grammar inference procedure we used is the one described in Johnson and Goldwater (2009). We ran 1,000 iterations of 8 MCMC chains for each run, and we discarded all but last 200 iterations in order to "burn-in" the sampler. The segmentation we predict is the one that occurs the most frequently in the samples that were not discarded. As is standard, we evaluate the models in terms of token f-score; the results are presented in Tables 1 and 2.

In these tables, "None" indicates that the grammar does not model syllable structure, "General" indicates that the grammar does not distinguish word-peripheral from word-internal clusters, while "Specialised" indicates that it does. "Unigram" indicates that the grammar does not model collocational structure, otherwise the superscript indicates the number of collocational levels that the grammar captures.

Broadly speaking, the results are consistent with the English word segmentation results using adaptor grammars presented by Johnson (2008b). The unigram grammar segmentation accuracy is similar to that obtained for English, but the results for the other models are lower than the results for the corresponding adaptor grammars on English.

We see a general improvement in segmentation accuracy as the number of collocation levels increases, just as for English. However, we do not see any general improvements associated with modelling syllables; indeed, it seems modelling syllables causes accuracy to decrease unless collocational structure is also modelled. This is somewhat surprising, as Chinese has a very regular syllabic structure. It is not surprising that distinguishing word-peripheral and word-medial clusters does not improve segmentation accuracy, as Chinese does not distinguish these kinds of clusters. There is also no sign of the "synergies" when modelling collocations and syllables together that Johnson (2008b) reported.

It is also surprising that tones seem to make little difference to the segmentation accuracy, since they are crucial for disambiguating lexical items. The segmentation accuracy of the models that capture little or no inter-word dependencies (e.g., Unigram, Colloc) improved slightly when the input contains tones, but the best-performing models that capture a more complex set of inter-word dependencies do equally well on the corpus without tones as they do on the corpus with tones. Because these models capture rich inter-word context (they model three levels of collocational structure), it is possible that this context provides sufficient information to segment words even in the absence of tone information, i.e., the tonal information is redundant given the richer inter-word dependencies that these models capture. It is also possible that word segmentation may simply require less information than lexical disambiguation.

One surprising result is the relatively poor performance of the Colloc^3 model without syllables but with tones; we have no explanation for this. However, all 8 of the MCMC chains in this run produced lower f-scores, so it unlikely to be simply a random fluctuation produced by a single outlier.

Note that one should be cautious when comparing the absolute f-scores from these experiments with those of the English study, as the English and Chinese corpora differ in many ways. As Tardif (1993) (the creator of the Chinese corpus) emphasises, this corpus was collected in a much more diverse linguistic environment with child-directed speech from multiple caregivers. The children involved in the Chinese corpus were also older than the children in the English corpus, which may also have affected the nature of the corpus.

5 Conclusion

This paper applied adaptor grammar models of phonemic word segmentation originally developed for English to Chinese data. While the Chinese data was prepared in a very different way to the English data, the adaptor grammars used to perform Chinese word segmentation were very similar to those used for the English word segmentation. They also achieved quite respectable f-score accuracies, which suggests that the same models can do well on both languages.

One puzzling result is that incorporating syllable structure phonotactic constraints, which enhances English word segmentation accuracy considerably, doesn't seem to improve Chinese word segmentation to a similar extent. This may reflect the fact that the word segmentation adaptor grammars were originally designed and tuned for English, and perhaps differently formulated syllable-structure constraints would work well for Chinese. But even if one can "tune" the adaptor grammars to improve performance on Chinese, the challenge is doing this in a way that improves performance on all languages, rather than just one.

Acknowledgments

The authors would like to thank the US NSF for support for this research, which was begun while they were on the faculty at Brown University in the USA. The NSF supported this work through NSF awards 0544127 and 0631667 to Mark Johnson and Katherine Demuth.

The adaptor grammar software is freely available for download from http://web.science.mq.edu.au/˜mjohnson, and the Chinese data was obtained from the Childes archive.

Data-Driven Parsing with Probabilistic Linear Context-Free Rewriting Systems

Laura Kallmeyer and **Wolfgang Maier**
SFB 833, University of Tübingen
{lk,wmaier}@sfs.uni-tuebingen.de

Abstract

This paper presents a first efficient implementation of a weighted deductive CYK parser for Probabilistic Linear Context-Free Rewriting Systems (PLCFRS), together with context-summary estimates for parse items used to speed up parsing. LCFRS, an extension of CFG, can describe discontinuities both in constituency and dependency structures in a straightforward way and is therefore a natural candidate to be used for data-driven parsing. We evaluate our parser with a grammar extracted from the German NeGra treebank. Our experiments show that data-driven LCFRS parsing is feasible with a reasonable speed and yields output of competitive quality.

1 Introduction

Data-driven parsing has largely been dominated by Probabilistic Context-Free Grammar (PCFG). The use of PCFG is tied to the annotation principles of popular treebanks, such as the Penn Treebank (PTB) (Marcus et al., 1994), which are used as a data source for grammar extraction. Their annotation generally relies on the use of trees without crossing branches, augmented with a mechanism that accounts for non-local dependencies. In the PTB, e.g., labeling conventions and trace nodes are used which establish additional implicit edges in the tree beyond the overt phrase structure. In contrast, some other treebanks, such as the German NeGra and TIGER treebanks allow annotation with crossing branches (Skut et al., 1997). Non-local dependencies can then be expressed directly by grouping all dependent elements under a single node.

However, given the expressivity restrictions of PCFG, work on data-driven parsing has mostly excluded non-local dependencies. When using treebanks with PTB-like annotation, labeling conventions and trace nodes are often discarded, while in NeGra, resp. TIGER, tree transformations are applied which resolve the crossing branches (Kübler, 2005; Boyd, 2007, e.g.). Especially for these treebanks, such a transformation is questionable, since it is non-reversible and implies information loss.

Some research has gone into incorporating non-local information into data-driven parsing. Levy and Manning (2004) distinguish three approaches: 1. Non-local information can be incorporated directly into the PCFG model (Collins, 1999), or can be reconstructed in a post-processing step after PCFG parsing (Johnson, 2002; Levy and Manning, 2004). 2. Non-local information can be incorporated into complex labels (Hockenmaier, 2003). 3. A formalism can be used which accommodates the direct encoding of non-local information (Plaehn, 2004). This paper pursues the third approach.

Our work is motivated by the following recent developments: Linear Context-Free Rewriting Systems (LCFRS) (Vijay-Shanker et al., 1987) have been established as a candidate for modeling both discontinuous constituents and non-projective dependency trees as they occur in treebanks (Kuhlmann and Satta, 2009; Maier and Lichte, 2009). LCFRS extend CFG such that non-terminals can span tuples of possibly non-

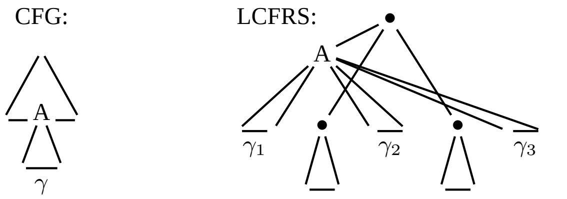

Figure 1: Different domains of locality

adjacent strings (see Fig. 1). PCFG techniques, such as Best-First Parsing (Charniak and Caraballo, 1998), Weighted Deductive Parsing (Nederhof, 2003) and A* parsing (Klein and Manning, 2003a), can be transferred to LCFRS. Finally, German has attracted the interest of the parsing community due to the challenges arising from its frequent discontinuous constituents (Kübler and Penn, 2008).

We bring together these developments by presenting a parser for probabilistic LCFRS. While parsers for subclasses of PLCFRS have been presented before (Kato et al., 2006), to our knowledge, our parser is the first for the entire class of PLCFRS. We have already presented an application of the parser on constituency and dependency treebanks together with an extensive evaluation (Maier, 2010; Maier and Kallmeyer, 2010). This article is mainly dedicated to the presentation of several methods for context summary estimation of parse items, and to an experimental evaluation of their usefulness. The estimates either act as figures-of-merit in a best-first parsing context or as estimates for A* parsing. Our evaluation shows that while our parser achieves a reasonable speed already without estimates, the estimates lead to a great reduction of the number of produced items, all while preserving the output quality.

Sect. 2 and 3 of the paper introduce probabilistic LCFRS and the parsing algorithm. Sect. 4 presents different context summary estimates. In Sect. 5, the implementation and evaluation of the work is discussed.

2 Probabilistic LCFRS

LCFRS are an extension of CFG where the nonterminals can span not only single strings but, instead, tuples of strings. We will notate LCFRS with the syntax of *simple Range Concatenation Grammars* (SRCG) (Boullier, 1998), a formalism that is equivalent to LCFRS.

A LCFRS (Vijay-Shanker et al., 1987) is a tuple $\langle N, T, V, P, S \rangle$ where a) N is a finite set of non-terminals with a function dim: $N \to \mathbb{N}$ that determines the *fan-out* of each $A \in N$; b) T and V are disjoint finite sets of terminals and variables; c) $S \in N$ is the start symbol with $dim(S) = 1$; d) P is a finite set of rules

$$A(\alpha_1, \ldots, \alpha_{dim(A)}) \to A_1(X_1^{(1)}, \ldots, X_{dim(A_1)}^{(1)}) \cdots A_m(X_1^{(m)}, \ldots, X_{dim(A_m)}^{(m)})$$

for $m \geq 0$ where $A, A_1, \ldots, A_m \in N$, $X_j^{(i)} \in V$ for $1 \leq i \leq m, 1 \leq j \leq dim(A_i)$ and $\alpha_i \in (T \cup V)^*$ for $1 \leq i \leq dim(A)$. For all $r \in P$, it holds that every variable X occurring in r occurs exactly once in the left-hand side (LHS) and exactly once in the right-hand side (RHS).

A rewriting rule describes how the yield of the LHS non-terminal can be computed from the yields of the RHS non-terminals. The rules $A(ab, cd) \to \varepsilon$ and $A(aXb, cYd) \to A(X, Y)$ for instance specify that 1. $\langle ab, cd \rangle$ is in the yield of A and 2. one can compute a new tuple in the yield of A from an already existing one by wrapping a and b around the first component and c and d around the second.

For every $A \in N$ in a LCFRS G, we define the yield of A, $yield(A)$ as follows:

a) For every $A(\vec{\alpha}) \to \varepsilon$, $\vec{\alpha} \in yield(A)$;

b) For every rule

$$A(\alpha_1, \ldots, \alpha_{dim(A)}) \to A_1(X_1^{(1)}, \ldots, X_{dim(A_1)}^{(1)}) \cdots A_m(X_1^{(m)}, \ldots, X_{dim(A_m)}^{(m)})$$

and all $\vec{\tau_i} \in yield(A_i)$ for $1 \leq i \leq m$, $\langle f(\alpha_1), \ldots, f(\alpha_{dim(A)}) \rangle \in yield(A)$ where f is defined as follows: (i) $f(t) = t$ for all $t \in T$, (ii) $f(X_j^{(i)}) = \vec{\tau_i}(j)$ for all $1 \leq i \leq m, 1 \leq j \leq dim(A_i)$ and (iii) $f(xy) = f(x)f(y)$ for all $x, y \in (T \cup V)^+$. f is the *composition function* of the rule.

c) Nothing else is in $yield(A)$.

The language is then $\{w \mid \langle w \rangle \in yield(S)\}$.

The *fan-out* of an LCFRS G is the maximal fan-out of all non-terminals in G. Furthermore, the RHS length of a rewriting rules $r \in P$ is called the *rank* of r and the maximal rank of all rules in P is called the *rank* of G. We call a LCFRS *ordered* if for every $r \in P$ and every RHS non-terminal A in r and each pair X_1, X_2 of arguments of A in the RHS of r, X_1 precedes X_2 in the RHS iff X_1 precedes X_2 in the LHS.

A *probabilistic LCFRS* (PLCFRS) (Kato et al., 2006) is a tuple $\langle N, T, V, P, S, p\rangle$ such that $\langle N, T, V, P, S\rangle$ is a LCFRS and $p : P \rightarrow [0..1]$ a function such that for all $A \in N$: $\Sigma_{A(\vec{x})\rightarrow\vec{\Phi}\in P} p(A(\vec{x}) \rightarrow \vec{\Phi}) = 1$.

3 The CYK Parser

We use a probabilistic version of the CYK parser from (Seki et al., 1991), applying techniques of weighted deductive parsing (Nederhof, 2003).

LCFRS can be binarized (Gómez-Rodríguez et al., 2009) and ε-components in the LHS of rules can be removed (Boullier, 1998). We can therefore assume that all rules are of rank 2 and do not contain ε components in their LHS. Furthermore, we assume POS tagging to be done before parsing. POS tags are non-terminals of fan-out 1. The rules are then either of the form $A(a) \rightarrow \varepsilon$ with A a POS tag and $a \in T$ or of the form $A(\vec{\alpha}) \rightarrow B(\vec{x})$ or $A(\vec{\alpha}) \rightarrow B(\vec{x})C(\vec{y})$ where $\vec{\alpha} \in (V^+)^{dim(A)}$, i.e., only the rules for POS tags contain terminals in their LHSs.

For every $w \in T^*$, where $w = w_1 \dots w_n$ with $w_i \in T$ for $1 \leq i \leq n$, we define: $Pos(w) := \{0, \dots, n\}$. A pair $\langle l, r\rangle \in Pos(w) \times Pos(w)$ with $l \leq r$ is a *range* in w. Its *yield* $\langle l, r\rangle(w)$ is the string $w_{l+1} \dots w_r$. The yield $\vec{\rho}(w)$ of a vector of ranges $\vec{\rho}$ is the vector of the yields of the single ranges. For two ranges $\rho_1 = \langle l_1, r_1\rangle, \rho_2 = \langle l_2, r_2\rangle$: if $r_1 = l_2$, then $\rho_1 \cdot \rho_2 = \langle l_1, r_2\rangle$; otherwise $\rho_1 \cdot \rho_2$ is undefined.

For a given rule $p : A(\alpha_1, \dots, \alpha_{dim(A)}) \rightarrow B(X_1, \dots, X_{dim(B)})C(Y_1, \dots, X_{dim(C)})$ we now extend the composition function f to ranges, given an input w: for all range vectors $\vec{\rho_B}$ and $\vec{\rho_C}$ of dimensions $dim(B)$ and $dim(C)$ respectively, $f_r(\vec{\rho_B}, \vec{\rho_C}) = \langle g(\alpha_1), \dots, g(\alpha_{dim(A)})\rangle$ is defined as follows: $g(X_i) = \vec{\rho_B}(i)$ for all $1 \leq i \leq dim(B)$, $g(Y_i) = \vec{\rho_C}(i)$ for all $1 \leq i \leq dim(C)$ and $g(xy) = g(x) \cdot g(y)$ for all $x, y \in V^+$. $p : A(f_r(\vec{\rho_B}, \vec{\rho_C})) \rightarrow B(\vec{\rho_B})C(\vec{\rho_C})$ is then called an *instantiated rule*.

For a given input w, our items have the form $[A, \vec{\rho}]$ where $A \in N$, $\vec{\rho} \in (Pos(w) \times Pos(w))^{dim(A)}$. The vector $\vec{\rho}$ characterizes the span of A. We specify the set of weighted parse items via the deduction rules in Fig. 2. Our parser performs a weighted deductive parsing (Nederhof, 2003), based on this deduction system. We use a chart $\mathcal{C}$ and an agenda $\mathcal{A}$, both initially empty, and we proceed as in Fig. 3.

Scan: $\dfrac{}{0 : [A, \langle\langle i, i+1\rangle\rangle]}$ A POS tag of w_{i+1}

Unary: $\dfrac{in : [B, \vec{\rho}]}{in + |log(p)| : [A, \vec{\rho}]}$ $p : A(\vec{\alpha}) \rightarrow B(\vec{\alpha}) \in P$

Binary: $\dfrac{in_B : [B, \vec{\rho_B}], in_C : [C, \vec{\rho_C}]}{in_B + in_C + log(p) : [A, \vec{\rho_A}]}$

where $p : A(\vec{\rho_A}) \rightarrow B(\vec{\rho_B})C(\vec{\rho_C})$ is an instantiated rule.

Goal: $[S, \langle\langle 0, n\rangle\rangle]$

    for all $y : I'$ deduced from $x : I$ and items in $\mathcal{C}$:
      if there is no $z$ with $z : I' \in \mathcal{C} \cup \mathcal{A}$
      then add $y : I'$ to $\mathcal{A}$
      else if $z : I' \in \mathcal{A}$ for some $z$
        then update weight of $I'$ in $\mathcal{A}$ to $max(y, z)$
```

Figure 3: Weighted deductive parsing

4 Outside Estimates

In order to speed up parsing, we add an estimate of the log of the outside probabilities of the items to their weights in the agenda. All our outside estimates are *admissible* (Klein and Manning, 2003a) which means that they never underestimate the actual outside probability of an item. However, most of them are not monotonic. In other words, it can happen that we deduce an item I_2 from an item I_1 where the weight of I_2 is greater than the weight of I_1. The parser can therefore end up in a local maximum that is not the global maximum we are searching for. In other words, our outside weights are only *figures of merit* (FOM). Only for the full SX estimate, the monotonicity is guaranteed and we can do true A* parsing as described in (Klein and Manning, 2003a) that always finds the best parse.

All outside estimates are computed for a certain maximal sentence length len_{max}.

POS tags: $\dfrac{}{0 : [A, \langle 1 \rangle]}$ A a POS tag

Unary: $\dfrac{in : [B, \vec{l}]}{in + log(p) : [A, \vec{l}]}$ $p : A(\vec{\alpha}) \rightarrow B(\vec{\alpha}) \in P$

Binary: $\dfrac{in_B : [B, \vec{l_B}], in_C : [C, \vec{l_C}]}{in_B + in_C + log(p) : [A, \vec{l_A}]}$

where $p : A(\vec{\alpha_A}) \rightarrow B(\vec{\alpha_B})C(\vec{\alpha_C}) \in P$ and the following holds: we define $\mathcal{B}(i)$ as $\{1 \leq j \leq dim(B) \,|\, \vec{\alpha_B}(j)$ occurs in $\vec{\alpha_A}(i)\}$ and $\mathcal{C}(i)$ as $\{1 \leq j \leq dim(C) \,|\, \vec{\alpha_C}(j)$ occurs in $\vec{\alpha_A}(i)\}$. Then for all i, $1 \leq i \leq dim(A)$: $\vec{l}_A(i) = \Sigma_{j \in \mathcal{B}(i)} \vec{l}_B(j) + \Sigma_{j \in \mathcal{C}(i)} \vec{l}_C(j)$.

$$\frac{w : [X, \vec{l}_X]}{w + in(A, \vec{l'}_A) + log(p) : [B, \vec{l}_B]}$$

Binary-left:

$$\frac{w : [X, \vec{l}_X]}{w + in(B, \vec{l'}_B) + log(p) : [A, \vec{l}_A]}$$

where, for both rules, there is an instantiated rule $p : X(\vec{\rho}) \rightarrow A(\vec{\rho_A})B(\vec{\rho_B})$ such that $\vec{l}_X = l_{out}(\rho)$, $\vec{l}_A = l_{out}(\rho_A), \vec{l'}_A = l_{in}(\rho_A), \vec{l}_B = l_{out}(\rho_B, \vec{l}_B = l_{in}(\rho_B$.

Figure 5: Full SX estimate top-down

4.1 Full SX estimate

The full SX estimate, for a given sentence length n, is supposed to give the minimal costs (maximal probability) of completing a category X with a span ρ into an S with span $\langle\langle 0, n \rangle\rangle$.

For the computation, we need an estimate of the inside probability of a category C with a span ρ, regardless of the actual terminals in our input. This inside estimate is computed as shown in Fig. 4. Here, we do not need to consider the number of terminals outside the span of C (to the left or right or in the gaps), they are not relevant for the inside probability. Therefore the items have the form $[A, \langle l_1, \dots, l_{dim(A)} \rangle]$, where A is a non-terminal and l_i gives the length of its ith component. It holds that $\Sigma_{1 \leq i \leq dim(A)} l_i \leq len_{max} - dim(A) + 1$.

A straight-forward extension of the CFG algorithm from (Klein and Manning, 2003a) for computing the SX estimate is given in Fig. 5. For a given range vector $\rho = \langle\langle l_1, r_1 \rangle, \dots, \langle l_k, r_k \rangle\rangle$ and a sentence length n, we define its *inside length vector* $l_{in}(\rho)$ as $\langle r_1 - l_1, \dots, r_k - l_k \rangle$ and its *outside length vector* $l_{out}(\rho)$ as $\langle l_1, r_1 - l_1, l_2 - r_1, \dots, l_k - r_{k-1}, r_k - l_k, n - r_k \rangle$.

This algorithm has two major problems: Since it proceeds top-down, in the *Binary* rules, we must compute all splits of the antecedent X span into the spans of A and B which is very expensive. Furthermore, for a category A with a certain number of terminals in the components and the gaps, we compute the lower part of the outside estimate several times, namely for every combination of number of terminals to the left and to the right (first and last element in the outside length vector). In order to avoid these problems, we now abstract away from the lengths of the part to the left and the right, modifying our items such as to allow a bottom-up strategy.

The idea is to compute the weights of items representing the derivations from a certain lower C up to some A (C is a kind of "gap" in the yield of A) while summing up the inside costs of off-spine nodes and the log of the probabilities of the corresponding rules. We use items $[A, C, \rho_A, \rho_C, \mathit{shift}]$ where $A, C \in N$ and ρ_A, ρ_C are range vectors, both with a first component starting at position 0. The integer $\mathit{shift} \leq len_{max}$ tells us how many positions to the right the C span is shifted, compared to the starting position of the A. ρ_A and ρ_C represent the spans of C and A while disregarding the number of terminals to the left the right. I.e., only the lengths of the components and of the gaps are encoded. This means in particular that the length n of the sentence does not play a role here. The right boundary of the last range in the vectors is limited to len_{max}. For any $i, 0 \leq i \leq len_{max}$, and any range vector ρ, we define $\mathit{shift}(\rho, i)$ as the range vector one obtains from adding i to all range boundaries in ρ and $\mathit{shift}(\rho, -i)$ as the range vector one obtains from subtracting i from all boundaries in ρ.

The weight of $[A, C, \rho_A, \rho_C, i]$ estimates the costs for completing a C tree with yield ρ_C into an A tree with yield ρ_A such that, if the span of A starts at position j, the span of C starts at position $i + j$. Fig. 6 gives the computation. The value of $in(A, \vec{l})$ is the inside estimate of $[A, \vec{l}]$.

The SX-estimate for some predicate C with

POS tags: $\frac{}{0 : [C, C, \langle 0,1\rangle, \langle 0,1\rangle, 0]}$ C a POS tag

Unary: $\frac{0 : [B, B, \rho_B, \rho_B, 0]}{\mathit{log}(p) : [A, B, \rho_B, \rho_B, 0]}$ $p : A(\vec{\alpha}) \to B(\vec{\alpha}) \in P$

Binary-right:

$$\frac{0 : [A, A, \rho_A, \rho_A, 0], 0 : [B, B, \rho_B, \rho_B, 0]}{\mathit{in}(A, l(\rho_A)) + \mathit{log}(p) : [X, B, \rho_X, \rho_B, i]}$$

Binary-left:

$$\frac{0 : [A, A, \rho_A, \rho_A, 0], 0 : [B, B, \rho_B, \rho_B, 0]}{\mathit{in}(B, l(\rho_B)) + \mathit{log}(p) : [X, A, \rho_X, \rho_A, 0]}$$

where i is such that for $\mathit{shift}(\rho_B, i) = \rho'_B$ $p : X(\rho_X) \to A(\rho_A)B(\rho'_B)$ is an instantiated rule.

Starting sub-trees with larger gaps:

$$\frac{w : [B, C, \rho_B, \rho_C, i]}{0 : [B, B, \rho_B, \rho_B, 0]}$$

Transitive closure of sub-tree combination:

$$\frac{w_1 : [A, B, \rho_A, \rho_B, i], w_2 : [B, C, \rho_B, \rho_C, j]}{w_1 + w_2 : [A, C, \rho_A, \rho_C, i + j]}$$

Figure 6: Full SX estimate bottom-up

span ρ where i is the left boundary of the first component of ρ and with sentence length n is then given by the maximal weight of $[S, C, \langle 0, n\rangle, \mathit{shift}(-i, \rho), i]$. Among our estimates, the full SX estimate is the only one that is monotonic and that allows for true A* parsing.

4.2 SX with Left, Gaps, Right, Length

A problem of the previous estimate is that with a large number of non-terminals the computation of the estimate requires too much space. Our experiments have shown that for treebank parsing where we have, after binarization and markovization, appr. 12,000 non-terminals, its computation is not feasible. We therefore turn to simpler estimates with only a single non-terminal per item. We now estimate the outside probability of a non-terminal A with a span of a length length (the sum of the lengths of all the components of the span), with left terminals to the left of the first component, right terminals to the right of the last component and gaps terminals in between the components of the A span, i.e., filling the gaps. Our items have the form $[X, \mathit{len}, \mathit{left}, \mathit{right}, \mathit{gaps}]$ with $X \in N$, $\mathit{len} + \mathit{left} + \mathit{right} + \mathit{gaps} \leq \mathit{len}_{max}$, $\mathit{len} \geq \mathit{dim}(X)$, $\mathit{gaps} \geq \mathit{dim}(X) - 1$.

Let us assume that, in the rule $X(\vec{\alpha}) \to A(\vec{\alpha_A})B(\vec{\alpha_B})$, when looking at the vector $\vec{\alpha}$, we have $left_A$ variables for A-components preceding the first variable of a B component, $right_A$ variables for A-components following the last variable of a B component and $right_B$ variables for B-components following the last variable of a A component. (In our grammars, the first LHS argument always starts with the first variable from A.) Furthermore, $gaps_A = \mathit{dim}(A) - left_A - right_A$, $gaps_B = \mathit{dim}(B) - right_B$.

Axiom : $\frac{}{0 : [S, \mathit{len}, 0, 0, 0]}$ $1 \leq \mathit{len} \leq \mathit{len}_{max}$

Unary: $\frac{w : [X, \mathit{len}, l, r, g]}{w + \mathit{log}(p) : [A, \mathit{len}, l, r, g]}$

where $p : X(\vec{\alpha}) \to A(\vec{\alpha}) \in P$.

Binary-right:

$$\frac{w : [X, \mathit{len}, l, r, g]}{w + \mathit{in}(A, \mathit{len} - \mathit{len}_B) + \mathit{log}(p) : [B, \mathit{len}_B, l_B, r_B, g_B]}$$

Binary-left:

$$\frac{w : [X, \mathit{len}, l, r, g]}{w + \mathit{in}(B, \mathit{len} - \mathit{len}_A) + \mathit{log}(p) : [A, \mathit{len}_A, l_A, r_A, g_A]}$$

where, for both rules, $p : X(\vec{\alpha}) \to A(\vec{\alpha_A})B(\vec{\alpha_B}) \in P$.

Figure 7: SX with length, left, right, gaps

POS tags: $\frac{}{0 : [A, 1]}$ A a POS tag

Unary: $\frac{\mathit{in} : [B, l]}{\mathit{in} + \mathit{log}(p) : [A, l]}$ $p : A(\vec{\alpha}) \to B(\vec{\alpha}) \in P$

Binary: $\frac{\mathit{in}_B : [B, l_B], \mathit{in}_C : [C, l_C]}{\mathit{in}_B + \mathit{in}_C + \mathit{log}(p) : [A, l_B + l_C]}$

where either $p : A(\vec{\alpha_A}) \to B(\vec{\alpha_B})C(\vec{\alpha_C}) \in P$ or $p : A(\vec{\alpha_A}) \to C(\vec{\alpha_C})B(\vec{\alpha_B}) \in P$.

Figure 8: Inside estimate with total span length

Fig. 7 gives the computation of the estimate. The following side conditions must hold: For *Binary-right* to apply, the following constraints must be satisfied: a) $\mathit{len} + l + r + g = \mathit{len}_B + l_B + r_B + g_B$, b) $l_B \geq l + left_A$, c) if $right_A > 0$, then $r_B \geq r + right_A$, else ($right_A = 0$), $r_B = r$, d) $g_B \geq gaps_A$. Similarly, for *Binary-left* to apply, the following constraints must be satisfied: a) $\mathit{len} + l + r + g = \mathit{len}_A + l_A + r_A + g_A$, b) $l_A = l$, c) if $right_B > 0$, then $r_A \geq r + right_B$, else ($right_B = 0$), $r_A = r$ d) $g_A \geq gaps_B$.

The value $\mathit{in}(X, l)$ for a non-terminal X and a length l, $0 \leq l \leq \mathit{len}_{max}$ is an estimate of the probability of an X category with a span of length l. Its computation is specified in Fig. 8.

The SX-estimate for a sentence length n and for some predicate C with a range characterized by $\vec{\rho} = \langle\langle l_1, r_1\rangle, \ldots, \langle l_{\mathit{dim}(C)}, r_{\mathit{dim}(C)}\rangle\rangle$ where $\mathit{len} = \Sigma_{i=1}^{\mathit{dim}(C)}(r_i - l_i)$ and $r = n - r_{\mathit{dim}(C)}$ is then given by the maximal weight of the item $[C, \mathit{len}, l_1, r, n - \mathit{len} - l_1 - r]$.

Axiom : $\dfrac{}{0 : [S, len, 0, 0]}\ 1 \le len \le len_{max}$

Unary: $\dfrac{w : [X, len, lr, g]}{w + log(p) : [A, len, lr, g]}$

where $p : X(\vec{\alpha}) \to A(\vec{\alpha}) \in P$.

Binary-right:

$$\frac{w : [X, len, lr, g]}{w + in(A, len - len_B) + log(p) : [B, len_B, lr_B, g_B]}$$

Binary-left:

$$\frac{w : [X, len, lr, g]}{w + in(B, len - len_A) + log(p) : [A, len_A, lr_A, g_A]}$$

where, for both rules, $p : X(\vec{\alpha}) \to A(\vec{\alpha_A})B(\vec{\alpha_B}) \in P$.

Figure 9: SX estimate with length, LR, gaps

4.3 SX with LR, Gaps, Length

In order to further decrease the space complexity, we can simplify the previous estimate by subsuming the two lengths $left$ and $right$ in a single length lr. I.e., the items now have the form $[X, len, lr, gaps]$ with $X \in N$, $len + lr + gaps \le len_{max}$, $len \ge dim(X)$, $gaps \ge dim(X) - 1$.

The computation is given in Fig. 9. Again, we define $left_A$, $gaps_A$, $right_A$ and $gaps_B$, $right_B$ for a rule $X(\vec{\alpha}) \to A(\vec{\alpha_A})B(\vec{\alpha_B})$ as above. The side conditions are as follows: For *Binary-right* to apply, the following constraints must be satisfied: a) $len + lr + g = len_B + lr_B + g_B$, b) $lr < lr_B$, and c) $g_B \ge gaps_A$. For *Binary-left* to apply, the following must hold: a) $len + lr + g = len_A + lr_A + g_A$, b) if $right_B = 0$ then $lr = lr_A$, else $lr < lr_A$ and c) $g_A \ge gaps_B$.

The SX-estimate for a sentence length n and for some predicate C with a span $\vec{\rho} = \langle\langle l_1, r_1\rangle, \ldots, \langle l_{dim(C)}, r_{dim(C)}\rangle\rangle$ where $len = \Sigma_{i=1}^{dim(C)}(r_i - l_i)$ and $r = n - r_{dim(C)}$ is then the maximal weight of $[C, len, l_1 + r, n - len - l_1 - r]$.

5 Evaluation

The goal of our evaluation of our parser is to show that, firstly, reasonable parser speed can be achieved and, secondly, the parser output is of promising quality.

5.1 Data

Our data source is the German NeGra treebank (Skut et al., 1997). In a preprocessing step, following common practice (Kübler and Penn, 2008), we attach punctuation (not included in the NeGra annotation) as follows: In a first pass, using heuristics, we attach punctuation as high as possible while avoiding to introduce new crossing branches. In a second pass, parentheses and quotation marks preferably attach to the same node. Grammatical function labels on the edges are discarded.

We create data sets of different sizes in order to see how the size of the training set relates to the gain using context summary estimates and to the output quality of the parser. The first set uses the first 4000 sentences and the second one all sentences of NeGra. Due to memory limitations, in both sets, we limit ourselves to sentences of a maximal length of 25 words. We use the first 90% of both sets as training set and the remaining 10% as test set. Tab. 1 shows the resulting sizes.

	NeGra-small		NeGra	
	training	test	training	test
size	2839	316	14858	1651

Table 1: Test and training sets

5.2 Treebank Grammar Extraction

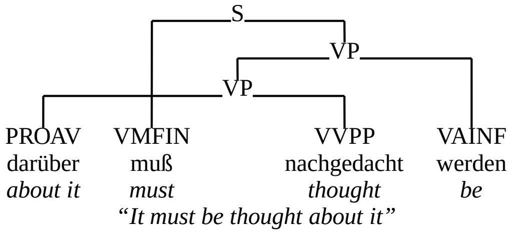

Figure 10: A sample tree from NeGra

As already mentioned, in NeGra, discontinuous phrases are annotated with crossing branches (see Fig. 10 for an example with two discontinuous VPs). Such discontinuities can be straightforwardly modelled with LCFRS. We use the algorithm from Maier and Søgaard (2008) to extract LCFRS rules from NeGra and TIGER. It first creates rules of the form $P(a) \to \varepsilon$ for each preterminal P dominating some terminal a. Then for all other nonterminals A_0 with the children $A_1 \cdots A_m$, a clause $A_0 \to A_1 \cdots A_m$ is created. The arguments of the $A_1 \cdots A_m$ are single variables where the number of arguments is the number of discontinuous parts in the yield of a predicate. The arguments of A_0 are concatenations of these variables that describe how the discontinuous parts of the yield of A_0 are obtained from the yields of its daughters. Different occurrences of the same non-terminal, only with different fan-outs, are distinguished by corresponding subscripts. Note that this extraction algorithm yields only *monotone* LCFRS (equivalent to ordered simple RCG). See Maier and Søgaard (2008) for further details. For Fig. 10, we obtain for instance the rules in Fig. 11.

PROAV(Darüber) $\rightarrow \varepsilon$ VMFIN(muß) $\rightarrow \varepsilon$
VVPP(nachgedacht) $\rightarrow \varepsilon$ VAINF(werden) $\rightarrow \varepsilon$
S$_1(X_1X_2X_3) \rightarrow$ VP$_2(X_1, X_3)$ VMFIN(X_2)
VP$_2(X_1, X_2X_3) \rightarrow$ VP$_2(X_1, X_2)$ VAINF(X_3)
VP$_2(X_1, X_2) \rightarrow$ PROAV(X_1) VVPP(X_2)

Figure 11: LCFRS rules for the tree in Fig. 10

5.3 Binarization and Markovization

Before parsing, we binarize the extracted LCFRS. For this we first apply Collins-style head rules, based on the rules the Stanford parser (Klein and Manning, 2003b) uses for NeGra, to mark the resp. head daughters of all non-terminal nodes. Then, we reorder the RHSs such that the sequence γ of elements to the right of the head daughter is reversed and moved to the beginning of the RHS. We then perform a binarization that proceeds from left to right. The binarization works like the transformation into Chomsky Normal Form for CFGs in the sense that for RHSs longer than 2, we introduce a new non-terminal that covers the RHS without the first element. The rightmost new rule, which covers the head daughter, is binarized to unary. We do not use a unique new non-terminal for every new rule. Instead, to the new symbols introduced during the binarization (VP$_{bin}$ in the example), a variable number of symbols from the vertical and horizontal context of the original rule is added in order to achieve *markovization*. Following the literature, we call the respective quantities v and h. For reasons of space we restrict ourselves here to the example in Fig. 12. Refer to Maier and Kallmeyer (2010) for a detailed presentation of the binarization and markovization.

The probabilities are then computed based on the rule frequencies in the transformed treebank, using a Maximum Likelihood estimator.

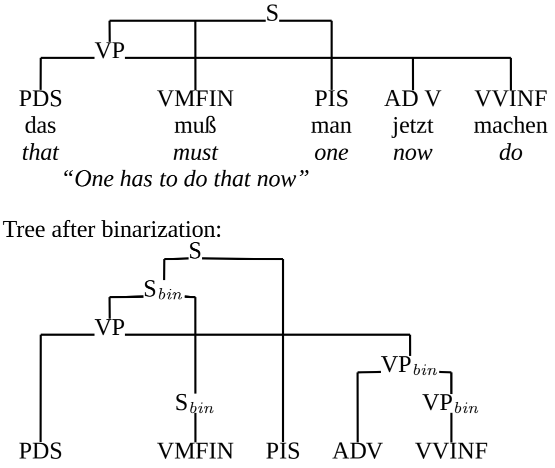

Figure 12: Sample binarization

5.4 Evaluation of Parsing Results

In order to assess the quality of the output of our parser, we choose an EVALB-style metric, i.e., we compare phrase boundaries. In the context of LCFRS, we compare sets of items $[A, \vec{\rho}]$ that characterize the span of a non-terminal A in a derivation tree. One set is obtained from the parser output, and one from the corresponding treebank trees. Using these item sets, we compute labeled and unlabeled recall (LR/UR), precision (LP/UP), and the F_1 measure (LF_1/UF_1). Note that if $k = 1$, our metric is identical to its PCFG equivalent.We are aware of the recent discussion about the shortcomings of EVALB. A discussion of this issue is presented in Maier (2010).

5.5 Experiments

In all experiments, we provide the parser with gold part-of-speech tags. For the experiments with *NeGra-small*, the parser is given the markovization settings $v = 1$ and $h = 1$. We compare the parser performance without estimates (OFF) with its performance with the estimates described in 4.2 (SIMPLE) and 4.3 (LR). Tab. 2 shows the results. Fig. 13 shows the number of items produced by the parser, indicating that the estimates have the desired effect of preventing unnecessary items from being produced. Note that it is even the case that the parser produces less items for the big set with LR than for the small set without estimate.

We can see that the estimates lead to a slightly

	OFF	SIMPLE	LR
UP/UR	72.29/72.40	70.49/71.81	72.10/72.60
UF_1	72.35	71.14	72.35
LP/LR	68.31/68.41	64.93/66.14	67.35/66.14
LF_1	68.36	65.53	65.53
Parsed	313 (99.05%)	313 (99.05%)	313 (99.05%)

Table 2: Experiments with *NeGra-small*

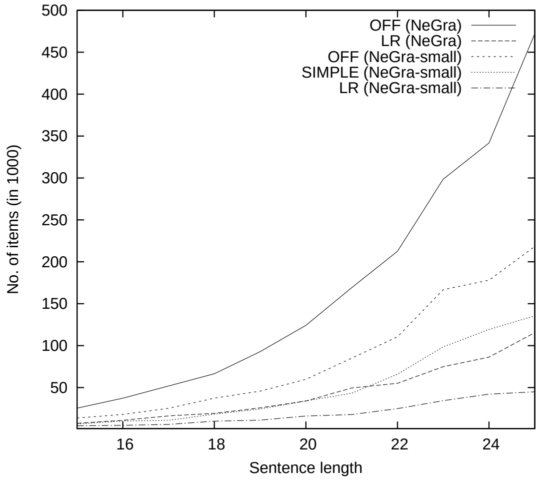

Figure 13: Items produced by the parser

lower F-score. However, while the losses in terms of F_1 are small, the gains in parsing time are substantial, as Fig. 13 shows.

Tab. 3 shows the results of experiments with *NeGra*, with the markovization settings $v = 2$ and $h = 1$ which have proven to be successful for PCFG parsing of NeGra (Rafferty and Manning, 2008). Unfortunately, due to memory restrictions, we were not able to compute SIMPLE for the large data set.[1] Resp. LR, the findings are comparable to the ones for *NeGra-short*. The speedup is paid with a lower F_1.

	OFF	LR
UP/UR	76.89/77.35	75.22/75.99
UF_1	77.12	75.60
LP/LR	73.03/73.46	70.98/71.70
LF_1	73.25	71.33
Parsed	1642 (99.45%)	1642 (99.45%)

Table 3: Experiments with *NeGra*

Our results are not directly comparable with PCFG parsing results, since LCFRS parsing is a harder task. However, since the EVALB metric coincides for constituents without crossing branches, in order to place our results in the context of previous work on parsing NeGra, we cite some of the results from the literature which were obtained using PCFG parsers[2]: Kübler (2005) (Tab. 1, plain PCFG) obtains 69.4, Dubey and Keller (2003) (Tab. 5, sister-head PCFG model) 71.12, Rafferty and Manning (2008) (Tab. 2, Stanford parser with markovization $v = 2$ and $h = 1$) 77.2, and Petrov and Klein (2007) (Tab. 1, Berkeley parser) 80.1. Plaehn (2004) obtains 73.16 Labeled F_1 using Probabilistic Discontinuous Phrase Structure Grammar (DPSG), albeit only on sentences with a length of up to 15 words. On those sentences, we obtain 81.27.

The comparison shows that our system delivers competitive results. Additionally, when comparing this to PCFG parsing results, one has to keep in mind that LCFRS parse trees contain non-context-free information about discontinuities. Therefore, a correct parse with our grammar is actually better than a correct CFG parse, evaluated with respect to a transformation of NeGra into a context-free treebank where precisely this information gets lost.

6 Conclusion

We have presented the first parser for unrestricted Probabilistic Linear Context-Free Rewriting Systems (PLCFRS), implemented as a CYK parser with weighted deductive parsing. To speed up parsing, we use context summary estimates for parse items. An evaluation on the NeGra treebank, both in terms of output quality and speed, shows that data-driven parsing using PLCFRS is feasible. Already in this first attempt with a straightforward binarization, we obtain results that are comparable to state-of-the-art PCFG results in terms of F_1, while yielding parse trees that are richer than context-free trees since they describe discontinuities. Therefore, our approach demonstrates convincingly that PLCFRS is a natural and tractable alternative for data-driven parsing which takes non-local dependencies into consideration.

[1] SIMPLE also proved to be infeasible to compute for the small set for the markovization settings $v = 2$ and $h = 1$ due to the greatly increased label set with this settings.

[2] Note that these results were obtained on sentences with a length of ≤ 40 words and that those parser possibly would deliver better results if tested on our test set.

Abstract

In this paper we consider the problem of building a system to predict readability of natural-language documents. Our system is trained using diverse features based on syntax and language models which are generally indicative of readability. The experimental results on a dataset of documents from a mix of genres show that the predictions of the learned system are more accurate than the predictions of naive human judges when compared against the predictions of linguistically-trained expert human judges. The experiments also compare the performances of different learning algorithms and different types of feature sets when used for predicting readability.

1 Introduction

An important aspect of a document is whether it is easily processed and understood by a human reader as intended by its writer, this is termed as the document's *readability*. Readability involves many aspects including grammaticality, conciseness, clarity, and lack of ambiguity. Teachers, journalists, editors, and other professionals routinely make judgements on the readability of documents. We explore the task of learning to automatically judge the readability of natural-language documents.

In a variety of applications it would be useful to be able to automate readability judgements. For example, the results of a web-search can be ordered taking into account the readability of the retrieved documents thus improving user satisfaction. Readability judgements can also be used for automatically grading essays, selecting instructional reading materials, etc. If documents are generated by machines, such as summarization or machine translation systems, then they are prone to be less readable. In such cases, a readability measure can be used to automatically filter out documents which have poor readability. Even when the intended consumers of text are machines, for example, information extraction or knowledge extraction systems, a readability measure can be used to filter out documents of poor readability so that the machine readers will not extract incorrect information because of ambiguity or lack of clarity in the documents.

As part of the DARPA Machine Reading Program (MRP), an evaluation was designed and conducted for the task of rating documents for readability. In this evaluation, 540 documents were rated for readability by both experts and novice human subjects. Systems were evaluated based on whether they were able to match expert readability ratings better than novice raters. Our system learns to match expert readability ratings by employing regression over a set of diverse linguistic features that were deemed potentially relevant to readability. Our results demonstrate that a rich combination of features from syntactic parsers, language models, as well as lexical statistics all contribute to accurately predicting expert human readability judgements. We have also considered the effect of different genres in predicting readability and how the genre-specific language models can be exploited to improve the readability predictions.

2 Related Work

There is a significant amount of published work on a related problem: predicting the reading difficulty of documents, typically, as the school grade-level of the reader from grade 1 to 12. Some early methods measure simple characteristics of documents like average sentence length, average number of syllables per word, etc. and combine them using a linear formula to predict the grade level of a document, for example FOG (Gunning, 1952), SMOG (McLaughlin, 1969) and Flesh-Kincaid (Kincaid et al., 1975) metrics. These methods do not take into account the content of the documents. Some later methods use pre-determined lists of words to determine the grade level of a document, for example the Lexile measure (Stenner et al., 1988), the Fry Short Passage measure (Fry, 1990) and the Revised Dale-Chall formula (Chall and Dale, 1995). The word lists these methods use may be thought of as very simple language models. More recently, language models have been used for predicting the grade level of documents. Si and Callan (2001) and Collins-Thompson and Callan (2004) train unigram language models to predict grade levels of documents. In addition to language models, Heilman et al. (2007) and Schwarm and Ostendorf (2005) also use some syntactic features to estimate the grade level of texts.

Pitler and Nenkova (2008) consider a different task of predicting text quality for an educated adult audience. Their system predicts readability of texts from Wall Street Journal using lexical, syntactic and discourse features. Kanungo and Orr (2009) consider the task of predicting readability of web summary snippets produced by search engines. Using simple surface level features like the number of characters and syllables per word, capitalization, punctuation, ellipses etc. they train a regression model to predict readability values.

Our work differs from this previous research in several ways. Firstly, the task we have considered is different, we predict the readability of general documents, not their grade level. The documents in our data are also not from any single domain, genre or reader group, which makes our task more general. The data includes human written as well as machine generated documents. The task and the data has been set this way because it is aimed at filtering out documents of poor quality for later processing, like for extracting machine-processable knowledge from them. Extracting knowledge from openly found text, such as from the internet, is becoming popular but the quality of text found “in the wild”, like found through searching the internet, vary considerably in quality and genre. If the text is of poor readability then it is likely to lead to extraction errors and more problems downstream. If the readers are going to be humans instead of machines, then also it is best to filter out poorly written documents. Hence identifying readability of general text documents coming from various sources and genres is an important task. We are not aware of any other work which has considered such a task.

Secondly, we note that all of the above approaches that use language models train a language model for each difficulty level using the training data for that level. However, since the amount of training data annotated with levels is limited, they can not train higher-order language models, and most just use unigram models. In contrast, we employ more powerful language models trained on large quantities of generic text (which is not from the training data for readability) and use various features obtained from these language models to predict readability. Thirdly, we use a more sophisticated combination of linguistic features derived from various syntactic parsers and language models than any previous work. We also present ablation results for different sets of features. Fourthly, given that the documents in our data are not from a particular genre but from a mix of genres, we also train genre-specific language models and show that including these as features improves readability predictions. Finally, we also show comparison between various machine learning algorithms for predicting readability, none of the previous work compared learning algorithms.

3 Readability Data

The readability data was collected and released by LDC. The documents were collected from the following diverse sources or genres: newswire/newspaper text, weblogs, newsgroup posts, manual transcripts, machine translation output, closed-caption transcripts and Wikipedia articles. Documents for newswire, machine translation and closed captioned genres were collected automatically by first forming a candidate pool from a single collection stream and then randomly selecting documents. Documents for weblogs, newsgroups and manual transcripts were also collected in the same way but were then reviewed by humans to make sure they were not simply spam articles or something objectionable. The Wikipedia articles were collected manually, by searching through a data archive or the live web, using keyword and other search techniques. Note that the information about genres of the documents is not available during testing and hence was not used when training our readability model.

A total of 540 documents were collected in this way which were uniformly distributed across the seven genres. Each document was then judged for its readability by eight expert human judges. These expert judges are native English speakers who are language professionals and who have specialized training in linguistic analysis and annotation, including the machine translation post-editing task. Each document was also judged for its readability by six to ten naive human judges. These non-expert (naive) judges are native English speakers who are not language professionals (e.g. editors, writers, English teachers, linguistic annotators, etc.) and have no specialized language analysis or linguistic annotation training. Both expert and naive judges provided readability judgments using a customized web interface and gave a rating on a 5-point scale to indicate how readable the passage is (where 1 is lowest and 5 is highest readability) where readability is defined as a subjective judgment of how easily a reader can extract the information the writer or speaker intended to convey.

4 Readability Model

We want to answer the question whether a machine can accurately estimate readability as judged by a human. Therefore, we built a machine-learning system that predicts the readability of documents by training on expert human judgements of readability. The evaluation was then designed to compare how well machine and naive human judges predict expert human judgements. In order to make the machine's predicted score comparable to a human judge's score (details about our evaluation metrics are in Section 6.1), we also restricted the machine scores to integers. Hence, the task is to predict an integer score from 1 to 5 that measures the readability of the document.

This task could be modeled as a multi-class classification problem treating each integer score as a separate class, as done in some of the previous work (Si and Callan, 2001; Collins-Thompson and Callan, 2004). However, since the classes are numerical and not unrelated (for example, the score 2 is in between scores 1 and 3), we decided to model the task as a regression problem and then round the predicted score to obtain the closest integer value. Preliminary results verified that regression performed better than classification. Heilman et al. (2008) also found that it is better to treat the readability scores as ordinal than as nominal. We take the average of the expert judge scores for each document as its gold-standard score. Regression was also used by Kanungo and Orr (2009), although their evaluation did not constrain machine scores to be integers.

We tested several regression algorithms available in the Weka[1] machine learning package, and in Section 6.2 we report results for several which performed best. The next section describes the numerically-valued features that we used as input for regression.

5 Features for Predicting Readability

Good input features are critical to the success of any regression algorithm. We used three main categories of features to predict readability: syntactic features, language-model features, and lexical features, as described below.

5.1 Features Based on Syntax

Many times, a document is found to be unreadable due to unusual linguistic constructs or ungram-

[1] http://www.cs.waikato.ac.nz/ml/weka/

matical language that tend to manifest themselves in the syntactic properties of the text. Therefore, syntactic features have been previously used (Bernth, 1997) to gauge the "clarity" of written text, with the goal of helping writers improve their writing skills. Here too, we use several features based on syntactic analyses. Syntactic analyses are obtained from the Sundance shallow parser (Riloff and Phillips, 2004) and from the English Slot Grammar (ESG) (McCord, 1989).

Sundance features: The Sundance system is a rule-based system that performs a shallow syntactic analysis of text. We expect that this analysis over readable text would be "well-formed", adhering to grammatical rules of the English language. Deviations from these rules can be indications of unreadable text. We attempt to capture such deviations from grammatical rules through the following Sundance features computed for each text document: proportion of sentences with no verb phrases, average number of clauses per sentence, average sentence length in tokens, average number of noun phrases per sentence, average number of verb phrases per sentence, average number of prepositional phrases per sentence, average number of phrases (all types) per sentence and average number of phrases (all types) per clause.

ESG features: ESG uses slot grammar rules to perform a deeper linguistic analysis of sentences than the Sundance system. ESG may consider several different interpretations of a sentence, before deciding to choose one over the other interpretations. Sometimes ESG's grammar rules fail to produce a single complete interpretation of a sentence, in which case it generates partial parses. This typically happens in cases when sentences are ungrammatical, and possibly, less readable. Thus, we use the proportion of such incomplete parses within a document as a readability feature. In case of extremely short documents, this proportion of incomplete parses can be misleading. To account for such short documents, we introduce a variation of the above incomplete parse feature, by weighting it with a log factor as was done in (Riloff, 1996; Thelen and Riloff, 2002).

We also experimented with some other syntactic features such as average sentence parse scores from Stanford parser and an in-house maximum entropy statistical parer, average constituent scores etc., however, they slightly degraded the performance in combination with the rest of the features and hence we did not include them in the final set. One possible explanation could be that averaging diminishes the effect of low scores caused by ungrammaticality.

5.2 Features Based on Language Models

A probabilistic language model provides a prediction of how likely a given sentence was generated by the same underlying process that generated a corpus of training documents. In addition to a general n-gram language model trained on a large body of text, we also exploit language models trained to recognize specific "genres" of text. If a document is translated by a machine, or casually produced by humans for a weblog or newsgroup, it exhibits a character that is distinct from documents that go through a dedicated editing process (e.g., newswire and Wikipedia articles). Below we describe features based on generic as well as genre-specific language models.

Normalized document probability: One obvious proxy for readability is the score assigned to a document by a generic language model (LM). Since the language model is trained on well-written English text, it penalizes documents deviating from the statistics collected from the LM training documents. Due to variable document lengths, we normalize the document-level LM score by the number of words and compute the normalized document probability $NP(\mathcal{D})$ for a document $\mathcal{D}$ as follows:

$$NP(\mathcal{D}) = \big(P(\mathcal{D}|\mathcal{M})\big)^{\frac{1}{|\mathcal{D}|}}, \qquad (1)$$

where $\mathcal{M}$ is a general-purpose language model trained on clean English text, and $|\mathcal{D}|$ is the number of words in the document $\mathcal{D}$.

Perplexities from genre-specific language models: The usefulness of LM-based features in categorizing text (McCallum and Nigam, 1998; Yang and Liu, 1999) and evaluating readability (Collins-Thompson and Callan, 2004; Heilman et al., 2007) has been investigated in previous work. In our experiments, however, since documents were acquired through several different channels, such as machine translation or web logs, we also build models that try to predict the genre of a document. Since the genre information for many English documents is readily available, we trained a series of genre-specific 5-gram LMs using the modified Kneser-Ney smoothing (Kneser and Ney, 1995; Stanley and Goodman, 1996). Table 1 contains a list of a base LM and genre-specific LMs.

Given a document $\mathcal{D}$ consisting of tokenized word sequence $\{w_i : i = 1, 2, \cdots, |\mathcal{D}|\}$, its perplexity $L(\mathcal{D}|\mathcal{M}_j)$ with respect to a LM $\mathcal{M}_j$ is computed as:

$$L(\mathcal{D}|\mathcal{M}_j) = \ e^{\left(-\frac{1}{|\mathcal{D}|}\sum_{i=1}^{|\mathcal{D}|}\log P(w_i|h_i;\mathcal{M}_j)\right)}, \quad (2)$$

where $|\mathcal{D}|$ is the number of words in $\mathcal{D}$ and h_i are the history words for w_i, and $P(w_i|h_i;\mathcal{M}_j)$ is the probability $\mathcal{M}_j$ assigns to w_i, when it follows the history words h_i.

Posterior perplexities from genre-specific language models: While perplexities computed from genre-specific LMs reflect the absolute probability that a document was generated by a specific model, a model's *relative* probability compared to other models may be a more useful feature. To this end, we also compute the posterior perplexity defined as follows. Let $\mathcal{D}$ be a document, $\{\mathcal{M}_i\}_{i=1}^{G}$ be G genre-specific LMs, and $L(\mathcal{D}|\mathcal{M}_i)$ be the perplexity of the document $\mathcal{D}$ with respect to $\mathcal{M}_i$, then the posterior perplexity, $R(\mathcal{M}_i|\mathcal{D})$, is defined as:

$$R(\mathcal{M}_i|\mathcal{D}) = \frac{L(\mathcal{D}|\mathcal{M}_i)}{\sum_{j=1}^{G} L(\mathcal{D}|\mathcal{M}_j)}. \quad (3)$$

We use the term "posterior" because if a uniform prior is adopted for $\{\mathcal{M}_i\}_{i=1}^{G}$, $R(\mathcal{M}_i|\mathcal{D})$ can be interpreted as the posterior probability of the genre LM $\mathcal{M}_i$ given the document $\mathcal{D}$.

5.3 Lexical Features

The final set of features involve various lexical statistics as described below.

Out-of-vocabulary (OOV) rates: We conjecture that documents containing typographical errors (e.g., for closed-caption and web log documents) may receive low readability ratings. Therefore, we compute the OOV rates of a document with respect to the various LMs shown in Table 1. Since modern LMs often have a very large vocabulary, to get meaningful OOV rates, we truncate the vocabularies to the top (i.e., most frequent) 3000 words. For the purpose of OOV computation, a document $\mathcal{D}$ is treated as a sequence of tokenized words $\{w_i : i = 1, 2, \cdots, |\mathcal{D}|\}$. Its OOV rate with respect to a (truncated) vocabulary $\mathcal{V}$ is then:

$$OOV(\mathcal{D}|\mathcal{V}) = \frac{\sum_{i=1}^{\mathcal{D}} I(w_i \notin \mathcal{V})}{|\mathcal{D}|}, \quad (4)$$

where $I(w_i \notin \mathcal{V})$ is an indicator function taking value 1 if w_i is not in $\mathcal{V}$, and 0 otherwise.

Ratio of function words: A characteristic of documents generated by foreign speakers and machine translation is a failure to produce certain function words, such as "the," or "of." So we predefine a small set of function words (mainly English articles and frequent prepositions) and compute the ratio of function words over the total number words in a document:

$$RF(\mathcal{D}) = \frac{\sum_{i=1}^{\mathcal{D}} I(w_i \in \mathcal{F})}{|\mathcal{D}|}, \quad (5)$$

where $I(w_i \in \mathcal{F})$ is 1 if w_i is in the set of function words $\mathcal{F}$, and 0 otherwise.

Ratio of pronouns: Many foreign languages that are source languages of machine-translated documents are pronoun-drop languages, such as Arabic, Chinese, and romance languages. We conjecture that the pronoun ratio may be a good indicator whether a document is translated by machine or produced by humans, and for each document, we first run a POS tagger, and then compute the ratio of pronouns over the number of words in the document:

$$RP(\mathcal{D}) = \frac{\sum_{i=1}^{\mathcal{D}} I(POS(w_i) \in \mathcal{P})}{|\mathcal{D}|}, \quad (6)$$

where $I(POS(w_i) \in \mathcal{F})$ is 1 if the POS tag of w_i is in the set of pronouns, $\mathcal{P}$, and 0 otherwise.

Fraction of known words: This feature measures the fraction of words in a document that occur either in an English dictionary or a gazetteer of names of people and locations.

6 Experiments

This section describes the evaluation methodology and metrics and presents and discusses our

Genre	Training Size(M tokens)	Data Sources
base	5136.8	mostly LDC's GigaWord set
NW	143.2	newswire subset of base

wikipedia	2264.6	Wikipedia text
CC	0.1	closed caption
ZhEn	79.6	output of Chinese to English Machine Translation
ArEn	126.8	output of Arabic to English Machine Translation

Table 1: Genre-specific LMs: the second column contains the number of tokens in LM training data (in million tokens).

experimental results. The results of the official evaluation task are also reported.

6.1 Evaluation Metric

The evaluation process for the DARPA MRP readability test was designed by the evaluation team led by SAIC. In order to compare a machine's predicted readability score to those assigned by the expert judges, the Pearson correlation coefficient was computed. The mean of the expert-judge scores was taken as the gold-standard score for a document.

To determine whether the machine predicts scores closer to the expert judges' scores than what an average naive judge would predict, a sampling distribution representing the underlying novice performance was computed. This was obtained by choosing a random naive judge for every document, calculating the Pearson correlation coefficient with the expert gold-standard scores and then repeating this procedure a sufficient number of times (5000). The upper critical value was set at 97.5% confidence, meaning that if the machine performs better than the upper critical value then we reject the null hypothesis that machine scores and naive scores come from the same distribution and conclude that the machine performs significantly better than naive judges in matching the expert judges.

6.2 Results and Discussion

We evaluated our readability system on the dataset of 390 documents which was released earlier during the training phase of the evaluation task. We used stratified 13-fold cross-validation in which the documents from various genres in each fold was distributed in roughly the same proportion as in the overall dataset. We first conducted experiments to test different regression algorithms using all the available features. Next, we ablated various feature sets to determine how much each feature set was contributing to making accurate readability judgements. These experiments are described in the following subsections.

Algorithm	Correlation
Bagged Decision Trees	0.8173
Decision Trees	0.7260
Linear Regression	0.7984
SVM Regression	0.7915
Gaussian Process Regression	0.7562
Naive Judges	
Upper Critical Value	0.7015
Distribution Mean	0.6517
Baselines	
Uniform Random	0.0157
Proportional Random	-0.0834

Table 2: Comparing different algorithms on the readability task using 13-fold cross-validation on the 390 documents using all the features. Exceeding the upper critical value of the naive judges' distribution indicates statistically significantly better predictions than the naive judges.

6.2.1 Regression Algorithms

We used several regression algorithms available in the Weka machine learning package and Table 2 shows the results obtained. The default values

Feature Set	Correlation
Lexical	0.5760
Syntactic	0.7010
Lexical + Syntactic	0.7274
Language Model based	0.7864
All	0.8173

Table 3: Comparison of different linguistic feature sets.

in Weka were used for all parameters, changing these values did not show any improvement. We used decision tree (reduced error pruning (Quinlan, 1987)) regression, decision tree regression with bagging (Breiman, 1996), support vector regression (Smola and Scholkopf, 1998) using polynomial kernel of degree two,[2] linear regression and Gaussian process regression (Rasmussen and Williams, 2006). The distribution mean and the upper critical values of the correlation coefficient distribution for the naive judges are also shown in the table.

Since they are above the upper critical value, all algorithms predicted expert readability scores significantly more accurately than the naive judges. Bagged decision trees performed slightly better than other methods. As shown in the following section, ablating features affects predictive accuracy much more than changing the regression algorithm. Therefore, on this task, the choice of regression algorithm was not very critical once good readability features are used. We also tested two simple baseline strategies: predicting a score uniformly at random, and predicting a score proportional to its frequency in the training data. As shown in the last two rows of Table 2, these baselines perform very poorly, verifying that predicting readability on this dataset as evaluated by our evaluation metric is not trivial.

6.2.2 Ablations with Feature Sets

We evaluated the contributions of different feature sets through ablation experiments. Bagged decision-tree was used as the regression algorithm in all of these experiments. First we compared syntactic, lexical and language-model based features as described in Section 5, and Table 3 shows the results. The language-model feature set performs the best, but performance improves when it is combined with the remaining features. The lexical feature set by itself performs the worst, even below the naive distribution mean (shown in Table 2); however, when combined with syntactic features it performs well.

In our second ablation experiment, we compared the performance of genre-independent and genre-based features. Since the genre-based features exploit knowledge of the genres of text used in the MRP readability corpus, their utility is somewhat tailored to this specific corpus. Therefore, it is useful to evaluate the performance of the system when genre information is not exploited. Of the lexical features described in subsection 5.3, the ratio of function words, ratio of pronoun words and all of the out-of-vocabulary rates except for the base language model are genre-based features. Out of the language model features described in the Subsection 5.2, all of the perplexities except for the base language model and all of the posterior perplexities[3] are genre-based features. All of the remaining features are genre-independent. Table 4 shows the results comparing these two feature sets. The genre-based features do well by themselves but the rest of the features help further improve the performance. While the genre-independent features by themselves do not exceed the upper critical value of the naive judges' distribution, they are very close to it and still outperform its mean value. These results show that for a dataset like ours, which is composed of a mix of genres that themselves are indicative of readability, features that help identify the genre of a text improve performance significantly.[4] For applications mentioned in the introduction and related work sections, such as filtering less readable documents from web-search, many of the input documents could come from some of the common genres considered in our dataset.

In our final ablation experiment, we evaluated

[2] Polynomial kernels with other degrees and RBF kernel performed worse.

[3] Base model for posterior perplexities is computed using other genre-based LMs (equation 3) hence it can not be considered genre-independent.

[4] We note that none of the genre-based features were trained on supervised readability data, but were trained on readily-available large unannotated corpora as shown in Table 1.

Feature Set	Correlation
Genre-independent	0.6978
Genre-based	0.7749
All	0.8173

Table 4: Comparison of genre-independent and genre-based feature sets.

Feature Set	By itself	Ablated from All
Sundance features	0.5417	0.7993
ESG features	0.5841	0.8118
Perplexities	0.7092	0.8081
Posterior perplexities	0.7832	0.7439
Out-of-vocabulary rates	0.3574	0.8125
All	0.8173	-

Table 5: Ablations with some individual feature sets.

the contribution of various individual feature sets. Table 5 shows that posterior perplexities perform the strongest on their own, but without them, the remaining features also do well. When used by themselves, some feature sets perform below the naive judges' distribution mean, however, removing them from the rest of the feature sets degrades the performance. This shows that no individual feature set is critical for good performance but each further improves the performance when added to the rest of the feature sets.

6.3 Official Evaluation Results

An official evaluation was conducted by the evaluation team SAIC on behalf of DARPA in which three teams participated including ours. The evaluation task required predicting the readability of 150 test documents using the 390 training documents. Besides the correlation metric, two additional metrics were used. One of them computed for a document the difference between the average absolute difference of the naive judge scores from the mean expert score and the absolute difference of the machine's score from the mean expert score. This was then averaged over all the documents. The other one was "target hits" which measured if the predicted score for a document fell within the width of the lowest and the highest expert scores for that document, and if so, computed a score inversely proportional to that width. The final target hits score was then computed by averaging it across all the documents. The upper critical values for these metrics were computed in a way analogous to that for the correlation metric which was described before. Higher score is better for all the three metrics. Table 6 shows the results of the evaluation. Our system performed favorably and always scored better than the upper critical value on each of the metrics. Its performance was in between the performance of the other two systems. The performances of the systems show that the correlation metric was the most difficult of the three metrics.

System	Correl.	Avg. Diff.	Target Hits
Our (A)	0.8127	0.4844	0.4619
System B	0.6904	0.3916	0.4530
System C	0.8501	0.5177	0.4641
Upper CV	0.7423	0.0960	0.3713

Table 6: Results of the systems that participated in the DARPA's readability evaluation task. The three metrics used were correlation, average absolute difference and target hits measured against the expert readability scores. The upper critical values are for the score distributions of naive judges.

7 Conclusions

Using regression over a diverse combination of syntactic, lexical and language-model based features, we built a system for predicting the readability of natural-language documents. The system accurately predicts readability as judged by linguistically-trained expert human judges and exceeds the accuracy of naive human judges. Language-model based features were found to be most useful for this task, but syntactic and lexical features were also helpful. We also found that for a corpus consisting of documents from a diverse mix of genres, using features that are indicative of the genre significantly improve the accuracy of readability predictions. Such a system could be used to filter out less readable documents for machine or human processing.

Value for Money: Balancing Annotation Effort, Lexicon Building and Accuracy for Multilingual WSD

Mitesh M. Khapra **Saurabh Sohoney** **Anup Kulkarni** **Pushpak Bhattacharyya**

Indian Institute of Technology Bombay
{miteshk,saurabhsohoney,anup,pb}@cse.iitb.ac.in

Abstract

Sense annotation and lexicon building are costly affairs demanding prudent investment of resources. Recent work on multilingual WSD has shown that it is possible to leverage the annotation work done for WSD of one language (S_L) for another (T_L), by projecting Wordnet and sense marked corpus parameters of S_L to T_L. However, this work does not take into account the cost of manually cross-linking the words within aligned synsets. Further, it does not answer the question of *"Can better accuracy be achieved if a user is willing to pay additional money?"* We propose a measure for ***cost-benefit analysis*** which measures the *"value for money"* earned in terms of accuracy by investing in annotation effort and lexicon building. Two key ideas explored in this paper are (i) the use of ***probabilistic cross-linking model*** to reduce manual cross-linking effort and (ii) the use of ***selective sampling*** to inject a few training examples for hard-to-disambiguate words from the target language to boost the accuracy.

1 Introduction

Word Sense Disambiguation (WSD) is one of the most widely investigated problems of Natural Language Processing (NLP). Previous works have shown that supervised approaches to Word Sense Disambiguation which rely on sense annotated corpora (Ng and Lee, 1996; Lee et al., 2004) outperform unsupervised (Veronis, 2004) and knowledge based approaches (Mihalcea, 2005). However, creation of sense marked corpora has always remained a costly proposition, especially for some of the resource deprived languages.

To circumvent this problem, Khapra et al. (2009) proposed a WSD method that can be applied to a language even when no sense tagged corpus for that language is available. This is achieved by ***projecting Wordnet and corpus parameters*** from another language to the language in question. The approach is centered on a novel synset based multilingual dictionary (Mohanty et al., 2008) where the synsets of different languages are aligned and thereafter the words within the synsets are manually cross-linked. For example, the word W_{L_1} belonging to synset S of language L_1 will be manually cross-linked to the word W_{L_2} of the corresponding synset in language L_2 to indicate that W_{L_2} is the best substitute for W_{L_1} according to an experienced bilingual speaker's intuition.

We extend their work by addressing the following question on the economics of annotation, lexicon building and performance:

- *Is there an optimal point of balance between the annotation effort and the lexicon building (i.e. manual cross-linking) effort at which one can be assured of best value for money in terms of accuracy?*

To address the above question we first propose a probabilistic cross linking model to eliminate the effort of manually cross linking words within the source and target language synsets and calibrate the resultant trade-off in accuracy. Next, we show that by injecting examples for most frequent hard-to-disambiguate words from the target domain one can achieve higher accuracies at optimal

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 555–563,
Beijing, August 2010

cost of annotation. Finally, we propose a measure for ***cost-benefit analysis*** which identifies the optimal point of balance between these three related entities, viz., cross-linking, sense annotation and accuracy of disambiguation.

The remainder of this paper is organized as follows. In section 2 we present related work. In section 3 we describe the Synset based multilingual dictionary which enables parameter projection. In section 4 we discuss the work of Khapra et al. (2009) on parameter projection for multilingual WSD. Section 5 is on the economics of multilingual WSD. In section 6 we propose a probabilistic model for representing the cross-linkage of words within synsets. In section 7 we present a strategy for injecting hard-to-disambiguate cases from the target language using selective sampling. In section 8 we introduce a measure for **cost-benefit analysis** for calculating the value for money in terms of accuracy, annotation effort and lexicon building effort. In section 9 we describe the experimental setup. In section 10 we present the results followed by discussion in section 11. Section 12 concludes the paper.

2 Related Work

Knowledge based approaches to WSD such as Lesk's algorithm (Lesk, 1986), Walker's algorithm (Walker and Amsler, 1986), Conceptual Density (Agirre and Rigau, 1996) and PageRank (Mihalcea, 2005) are less demanding in terms of resources but fail to deliver good results. Supervised approaches like SVM (Lee et al., 2004) and k-NN (Ng and Lee, 1996), on the other hand, give better accuracies, but the requirement of large annotated corpora renders them unsuitable for resource scarce languages.

Recent work by Khapra et al. (2009) has shown that it is possible to project the parameters learnt from the annotation work of one language to another language provided aligned Wordnets for two languages are available. However, their work does not address the question of further improving the accuracy of WSD by using a small amount of training data from the target language. Some similar work has been done in the area of domain adaptation where Chan et al. (2007) showed that adding just 30% of the target data to the source data achieved the same performance as that obtained by taking the entire source and target data. Similarly, Agirre and de Lacalle (2009) reported a 22% error reduction when source and target data were combined for training a classifier, compared to the case when only the target data was used for training the classifier. However, such combining of training statistics has not been tried in cases where the source data is in one language and the target data is in another language.

To the best of our knowledge, no previous work has attempted to perform resource conscious **all-words multilingual Word Sense Disambiguation** by finding a trade-off between the cost (in terms of annotation effort and lexicon creation effort) and the quality in terms of F-score.

3 Synset based multilingual dictionary

A novel and effective method of storage and use of dictionary in a multilingual setting was proposed by Mohanty et al. (2008). For the purpose of current discussion, we will refer to this multilingual dictionary framework as *MultiDict*. One important departure in this framework from the traditional dictionary is that **synsets are linked, and after that the words inside the synsets are linked**. The basic mapping is thus between synsets and thereafter between the words.

Concepts	L1 (English)	L2 (Hindi)	L3 (Marathi)
04321: a youthful male person	{malechild, boy}	{लड़का *(ladkaa)*, बालक *(baalak)*, बच्चा *(bachchaa)*}	{मुलगा *(mulgaa)*, पोरगा *(porgaa)*, पोर *(por)*}

Table 1: Multilingual Dictionary Framework

Table 1 shows the structure of MultiDict, with one example row standing for the concept of *boy*. The first column is the pivot describing a concept with a unique ID. The subsequent columns show the words expressing the concept in respective languages (in the example table, *English, Hindi and Marathi*). After the synsets are linked, cross linkages are set up manually from the words of a synset to the words of a linked synset of the pivot language. For example, for the Marathi word मुलगा *(mulgaa)*, "a youthful male person", the correct lexical substitute from the corresponding Hindi synset is *लड़का(ladkaa)*. The average number of such links per synset per language pair is approximately 3.

4 Parameter Projection

Khapra et al. (2009) proposed that the various parameters essential for domain-specific Word Sense Disambiguation can be broadly classified into two categories:

Wordnet-dependent parameters:

- belongingness-to-dominant-concept
- conceptual distance
- semantic distance

Corpus-dependent parameters:

- sense distributions
- corpus co-occurrence

They proposed a scoring function (Equation (1)) which combines these parameters to identify the correct sense of a word in a context:

$$S^* = \arg\max_i(\theta_i V_i + \sum_{j \in J} W_{ij} * V_i * V_j) \qquad (1)$$

where,

$$\begin{aligned} i &\in \textit{Candidate Synsets} \\ J &= \textit{Set of disambiguated words} \\ \theta_i &= BelongingnessToDominantConcept(S_i) \\ V_i &= P(S_i|word) \\ W_{ij} &= CorpusCooccurrence(S_i, S_j) \\ &\quad * 1/WNConceptualDistance(S_i, S_j) \\ &\quad * 1/WNSemanticGraphDistance(S_i, S_j) \end{aligned}$$

The first component $\theta_i V_i$ of Equation (1) captures influence of the corpus specific sense of a word in a domain. The other component $W_{ij} * V_i * V_j$ captures the influence of interaction of the candidate sense with the senses of context words weighted by factors of co-occurrence, conceptual distance and semantic distance.

Wordnet-dependent parameters depend on the structure of the Wordnet whereas the ***Corpus-dependent parameters*** depend on various statistics learnt from a sense marked corpora. Both the tasks of (a) constructing a Wordnet from scratch and (b) collecting sense marked corpora for multiple languages are tedious and expensive. Khapra et al. (2009) observed that by ***projecting relations*** from the Wordnet of a language and by ***projecting corpus statistics*** from the sense marked corpora of the language to those of the target language, *the effort required in constructing semantic graphs for multiple Wordnets and collecting sense marked corpora for multiple languages can be avoided or reduced.* At the heart of their work lies the *MultiDict* described in previous section which facilitates parameter projection in the following manner:

1. By linking with the synsets of a pivot resource rich language (Hindi, in our case), the cost of building Wordnets of other languages is partly reduced (semantic relations are inherited). The Wordnet parameters of Hindi Wordnet now become projectable to other languages.

2. For calculating corpus specific sense distributions, $P(Sense\ S_i|Word\ W)$, we need the counts, $\#(S_i, W)$. By using cross linked words in the synsets, these counts become projectable to the target language (Marathi, in our case) as they can be approximated by the counts of the cross linked Hindi words calculated from the Hindi sense marked corpus as follows:

$$P(S_i|W) = \frac{\#(S_i, marathi\_word)}{\sum_j \#(S_j, marathi\_word)}$$

$$P(S_i|W) \approx \frac{\#(S_i, cross\_linked\_hindi\_word)}{\sum_j \#(S_j, cross\_linked\_hindi\_word)}$$

The rationale behind the above approximation is the observation that within a domain sense distributions remain the same across languages.

5 The Economics of Multilingual WSD

The problem of multilingual WSD using parameter projection can be viewed as an economic system consisting of three factors. The first factor is the cost of manually cross-linking the words in a synsets of the target language to the words in the corresponding synset in the pivot language. The second factor is the cost of sense annotated data from the target language. The third factor is the accuracy of WSD The first two factors in some sense relate to the cost of purchasing a commodity and the third factor relates to the commodity itself.

The work of Khapra et al. (2009) as described above does not attempt to reach an optimal cost-benefit point in this economic system. They place their bets on manual cross-linking only and settle for the accuracy achieved thereof. Specifically, they do not explore the inclusion of small amount of annotated data from the target language to boost the accuracy (as mentioned earlier, supervised systems which use annotated data from the target language are known to perform better). Further, it is conceivable that with respect to accuracy-cost trade-off, there obtains a case for *balancing* one cost against the other, *viz.*, the cost of cross-linking and the cost of annotation. In some cases bilingual lexicographers (needed for manual cross-linking) may be more expensive compared to monolingual annotators. There it makes sense to place fewer bets on manual cross-linking and more on collecting annotated corpora. On the other hand if manual cross-linking is cheap then a very small amount of annotated corpora can be used in conjunction with full manual cross-linking to boost the accuracy. Based on the above discussion, if k_a is the cost of sense annotating one word, k_c is the cost of manually cross-linking a word and A is the accuracy desired then the problem of multilingual WSD can be cast as an optimization problem:

$$\begin{aligned} &minimize \quad w_a * k_a + w_c * k_c \\ &\qquad s.t. \\ &\qquad\quad Accuracy \geq A \end{aligned}$$

where, w_c and w_a are the number of words to be manually cross linked and annotated respectively. Ours is thus a 3-factor economic model (cross-linking, annotation and accuracy) as opposed to the 2-factor model (cross-linking, accuracy) proposed by Khapra et al. (2009).

6 Optimal cross-linking

As mentioned earlier, in some cases where bilingual lexicographers are expensive we might be interested in reducing the effort of manual cross-linking. For such situations, we propose that only a small number of words, comprising of the most frequently appearing ones should be manually cross linked and the rest of the words should be cross-linked using a probabilistic model. The rationale here is simple: invest money in words which are bound to occur frequently in the test data and achieve maximum impact on the accuracy. In the following paragraphs, we explain our probabilistic cross linking model.

The model proposed by Khapra et al. (2009) is a deterministic model where the expected count for (Sense S, Marathi_Word W), *i.e.*, the number of times the word W appears in sense S is approximated by the count for the corresponding cross linked Hindi word. Such a model assumes that each Marathi word links to appropriate Hindi word(s) as identified manually by a lexicographer. Instead, **we propose a probabilistic model where a Marathi word can link to every word in the corresponding Hindi synset with some probability**. The expected count for (S, W) can then be estimated as:

$$E[\#(S,W)] = \sum_{h_i \in cross\_links} P(h_i|W,S) * \#(S,h_i) \quad (2)$$

where, $P(h_i|W,S)$ is the probability that the word h_i from the corresponding Hindi synset is the correct cross-linked word for the given Marathi word. For example, one of the senses of the Marathi word *maan* is {neck} *i.e.* *"the body part which connects the head to the rest of the body"*. The corresponding Hindi synset has 10 words {*gardan, gala, greeva, halak, kandhar and so on*}. Thus, using Equation (2), the expected count, $E[C(\{neck\}, maan)]$, is calculated as:

$$\begin{aligned} &E[\#(\{neck\}, maan)] = \\ &\quad P(gardan|maan, \{neck\}) * \#(\{neck\}, gardan) \\ &+ P(gala|maan, \{neck\}) * \#(\{neck\}, gala) \\ &+ P(greeva|maan, \{neck\}) * \#(\{neck\}, greeva) \\ &+ \ \ldots \ so\ on\ for\ all\ words\ in\ the\ Hindi\ synset \end{aligned}$$

Instead of using a uniform probability distribution over the Hindi words we go by the empirical observation that some words in a synset are more representative of that sense than other words, *i.e. some words are more preferred while expressing that sense*. For example, out of the 10 words in the Hindi synset only 2 words $\{$*gardan, gala*$\}$ appeared in the corpus. We thus estimate the value of $P(h_i|W, S)$ empirically from the Hindi sense marked corpus by making the following independence assumption:

$$P(h_i|W, S) = P(h_i|S)$$

The rationale behind the above independence assumption becomes clear if we represent words and synsets using the Bayesian network of Figure 1. Here, the Hindi word h_i and the Marathi word W are considered to be derived from the same parent concept S. In other words, they represent two different manifestations- one in Hindi and one in Marathi- of the same synset S. Given the above representation, it is easy to see that given the parent synset S, the Hindi word h_i is independent of the Marathi word W.

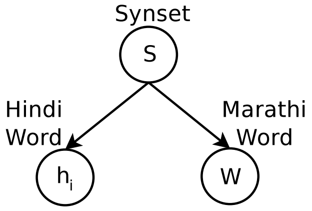

Figure 1: Bayesian network formed by a synset S and the constituent Hindi and Marathi words

7 Optimal annotation using Selective Sampling

In the previous section we dealt with the question of optimal cross-linking. Now we take up the other dimension of this economic system, *viz.*, optimal use of annotated corpora for better accuracy. In other words, if an application demands higher accuracy for WSD and is willing to pay for some annotation then there should be a way of ensuring best possible accuracy at lowest possible cost. This can be done by including small amount of sense annotated data from the target language. The simplest strategy is to randomly annotate text from the target language and use it as training data. However, this strategy of random sampling may not be the most optimum in terms of cost. Instead, we propose a selective sampling strategy where the aim is to identify ***hard-to-disambiguate*** words from the target language and use them for training.

The algorithm proceeds as follows:

1. First, using the probabilistic cross linking model and aligned Wordnets we learn the parameters described in Section 4.

2. We then apply this scoring function on untagged examples (development set) from the target language and identify ***hard-to-disambiguate*** words *i.e.*, the words which were disambiguated with a very low confidence.

3. Training instances of these words are then injected into the training data and the parameters learnt from them are used instead of the projected parameters learnt from the source language corpus.

Thus, the selective sampling strategy ensures that we get maximum value for money by spending it on annotating only those words which would otherwise not have been disambiguated correctly. A random selection strategy, in contrast, might bring in words which were disambiguated correctly using only the projected parameters.

8 A measure for cost-benefit analysis

We need a measure for cost-benefit analysis based on the three dimensions of our economic system, *viz.*, annotation effort, lexicon creation effort and performance in terms of F-score. The first two dimensions can be fused into a single dimension by expressing the annotation effort and lexicon creation effort in terms of cost incurred. For example, we assume that the cost of annotating one word is k_a and the cost of cross-linking one word is k_c rupees. Further, we define a baseline and an upper bound for the F-score. In this case, the baseline would be the accuracy that can be obtained without spending any money on cross-linking and annotation in the target language. An upper bound could be the best F-score obtained using a large amount of annotated corpus in the target domain. Based on the above description, an ideal measure for cost-benefit analysis would assign a

1. reward depending on the improvement over the baseline performance.

2. penalty depending on the difference from the upper bound on performance.

3. reward inversely proportional to the cost incurred in terms of annotation effort and/or manual cross-linking.

Based on the above wish-list we propose a measure for cost-benefit analysis. Let,

$$\begin{aligned} MGB &= Marginal\ Gain\ over\ Baseline\ (MGB) \\ &= \frac{Performance(P) - Baseline(B)}{Cost(C)} \\ MDU &= Marginal\ Drop\ from\ Upperbound\ (MDU) \\ &= \frac{UpperBound(U) - Performance(P)}{Cost(C)} \end{aligned}$$

then

$$CostBenefit(CB) = MGB - MDU$$

9 Experimental Setup

We used Hindi as the source language (S_L) and trained a WSD engine using Hindi sense tagged corpus. The parameters thus learnt were then projected using the *MultiDict* (refer section 3 and 4) to build a resource conscious Marathi (T_L) WSD engine. We used the same dataset as described in Khapra et al. (2009) for all our experiments. The data was collected from two domains, *viz.*, Tourism and Health. The data for Tourism domain was collected by manually translating English documents downloaded from Indian Tourism websites into Hindi and Marathi. Similarly, English documents for Health domain were obtained from two doctors and were manually translated into Hindi and Marathi. The Hindi and Marathi documents thus created were manually sense annotated by two lexicographers adept in Hindi and Marathi using the respective Wordnets as sense repositories. Table 2 summarizes some statistics about the corpora.

As for cross-linking, Hindi is used as the pivot language and words in Marathi synset are linked to the words in the corresponding Hindi synset. The total number of cross-links that were manually setup were 3600 for Tourism and 1800 for Health. The cost of cross-linking as well as sense annotating one word was taken to be 10 rupees. These costs were estimated based on quotations from lexicographers. However, these costs need to be taken as representative values only and may vary greatly depending on the availability of skilled bilingual lexicographers and skilled monolingual annotators.

Language	#of polysemous words		average degree of polysemy	
	Tourism	Health	Tourism	Health
Hindi	56845	30594	3.69	3.59
Marathi	34156	10337	3.41	3.60

Table 2: Number of polysemous words and average degree of polysemy.

10 Results

Tables 3 and 4 report the average 4-fold performance on Marathi Tourism and Health data using different proportions of available resources, *i.e.*, annotated corpora and manual cross-links. In each of these tables, along the rows, we increase the amount of Marathi sense annotated corpora from 0K to 6K. Similarly, along the columns we show the increase in the number of manual cross links (MCL) used. For example, the second column of Tables 3 and 4 reports the F-scores when probabilistic cross-linking (PCL) was used for all words (*i.e.*, no manual cross-links) and varying amounts of sense annotated corpora from Marathi were used. Similarly, the first row represents the case in which no sense annotated corpus from Marathi was used and varying amounts of manual cross-links were used.

We report three values in the tables, *viz.*, F-score (F), cost in terms of money (C) and the cost-benefit (CB) obtained by using x amount of annotated corpus and y amount of manual cross-links. The cost was estimated using the values given in section 9 (*i.e.*, 10 rupees for cross-linking or sense annotating one word). For calculating, the cost-benefit baseline was taken as the F-score obtained by using no cross-links and no annotated corpora *i.e.* 68.21% for Tourism and 67.28% for Health (see first F-score cell of Tables 3 and 4). Similarly the upper bound (F-scores obtained by training on entire Marathi sense marked corpus) for Tourism and Health were 83.16% and 80.67% respectively (see last row of Table 5).

Due to unavailability of large amount of tagged Health corpus, the injection size was varied from 0-to-4K only. In the other dimension, we varied the cross-links from 0 to 1/3rd to 2/3rd to full only

Only Annotation	57.86	62.32	64.84	66.86	68.89	69.64	71.82

Table 7: Comparing F-scores obtained using Only Annotation and Annotation + PCL(Tourism)

(refer to Tables 3 and 4). However, to give an idea about the soundness of probabilistic cross-linking we performed a separate set of experiments by varying the number of cross-links and using no sense annotated corpora. Table 5 summarizes these results and compares them with the baseline (Wordnet first sense) and skyline.

In Table 6 we compare our selective sampling strategy with random sampling when fully probabilistic cross-linking (PCL) is used and when fully manual cross-linking (MCL) is used. Here again, due to lack of space we report results only on Tourism domain. However, we would like to mention that similar experiments on Health domain showed that the results were indeed consistent.

Finally, in Table 7 we compare the accuracies obtained when certain amount of annotated corpus from Marathi is used alone, with the case when the same amount of annotated corpus is used in conjunction with probabilistic cross-linking. While calculating the results for the second row in Table 7, we found that the recall was very low due to the small size of injections. Hence, to ensure a fair comparison with our strategy (first row) we used the Wordnet first sense (WFS) for these recall errors (a typical practice in WSD literature).

11 Discussions

We make the following observations:

1. PCL v/s MCL: Table 5 shows that the probabilistic cross-linking model performs much better than the WFS (a typically reported baseline) and it comes very close to the performance of manual cross-linking. This establishes the soundness of the probabilistic model and suggests that with a little compromise in the accuracy, the model can be used as an approximation to save the cost of manual cross-linking. Further, in Table 7 we see that when PCL is used in conjunction with certain amount of annotated corpus we get up to 9% improvement in F-score as compared to the case when the same amount of annotated corpus is used alone. Thus, in the absence of skilled bilingual lexicographers, PCL can still be used to boost the accuracy obtained using annotated corpora.

2. Selective Sampling v/s Random Annotation: Table 6 shows the benefit of selective sampling over random annotation. This benefit is felt more when the amount of training data injected from Marathi is small. For example, when an annotated corpus of size 2K is used, selective sampling gives an advantage of 3% to 4% over random selection. Thus the marginal gain (*i.e.*, value for money) obtained by using selective sampling is more than that obtained by using random annotation.

3. Optimal cost-benefit: Finally, we address the main message of our work, *i.e.*, finding the best cost benefit. By referring to Tables 3 and 4, we see that the best value for money in Tourism domain is obtained by manually cross-linking 2/3rd of all corpus words and sense annotating 2K target words and in the Health domain it is obtained by manually cross-linking 2/3rd of all corpus words but sense annotating only 1K words. This suggests that striking a balance between cross-linking and annotation gives the best value for money. Further, we would like to highlight that our 3-factor economic model is able to capture these relations better than the 2-factor model of Khapra et al. (2010). As per their model the best F-score achieved using manual cross-linking for ALL words was 73.34% for both Tourism and Health domain at a cost of 36K and 18K respectively. On the other hand, using our model we obtain higher accuracies of 76.96% in the Tourism domain (using 1/3rd manual cross-links and 2K injection) at a lower total cost (32K rupees) and 75.57% in the Health domain (using only 1/3rd cross-linking and 1K injection) at a lower cost (16K rupees).

12 Conclusion

We reported experiments on multilingual WSD using different amounts of annotated corpora and manual cross-links. We showed that there exists some trade-off between the accuracy and *balancing* the cost of annotation and lexicon creation. In the absence of skilled bilingual lexicographers one can use a probabilistic cross-linking model and still obtain good accuracies. Also, while sense annotating a corpus, careful selection of words using selective sampling can give better marginal gain as compared to random sampling.

Abstract

While extensive studies on relation extraction have been conducted in the last decade, statistical systems based on supervised learning are still limited because they require large amounts of training data to achieve high performance. In this paper, we develop a cross-lingual annotation projection method that leverages parallel corpora to bootstrap a relation detector without significant annotation efforts for a resource-poor language. In order to make our method more reliable, we introduce three simple projection noise reduction methods. The merit of our method is demonstrated through a novel Korean relation detection task.

1 Introduction

Relation extraction aims to identify semantic relations of entities in a document. Many relation extraction studies have followed the Relation Detection and Characterization (RDC) task organized by the Automatic Content Extraction project (Doddington et al., 2004) to make multilingual corpora of English, Chinese and Arabic. Although these datasets encourage the development and evaluation of statistical relation extractors for such languages, there would be a scarcity of labeled training samples when learning a new system for another language such as Korean. Since manual annotation of entities and their relations for such *resource-poor languages* is very expensive, we would like to consider instead a weakly-supervised learning technique in order to learn the relation extractor without significant annotation efforts. To do this, we propose to leverage parallel corpora to project the relation annotation on the source language (e.g. English) to the target (e.g. Korean).

While many supervised machine learning approaches have been successfully applied to the RDC task (Kambhatla, 2004; Zhou et al., 2005; Zelenko et al., 2003; Culotta and Sorensen, 2004; Bunescu and Mooney, 2005; Zhang et al., 2006), few have focused on weakly-supervised relation extraction. For example, (Zhang, 2004) and (Chen et al., 2006) utilized weakly-supervised learning techniques for relation extraction, but they did not consider weak supervision in the context of cross-lingual relation extraction. Our key hypothesis on the use of parallel corpora for learning the relation extraction system is referred to as *cross-lingual annotation projection*. Early studies of cross-lingual annotation projection were accomplished for lexically-based tasks; for example part-of-speech tagging (Yarowsky and Ngai, 2001), named-entity tagging (Yarowsky et al., 2001), and verb classification (Merlo et al., 2002). Recently, there has been increasing interest in applications of annotation projection such as dependency parsing (Hwa et al., 2005), mention detection (Zitouni and Florian, 2008), and semantic role labeling (Pado and Lapata, 2009). However, to the best of our knowledge, no work has reported on the RDC task.

In this paper, we apply a cross-lingual annotation projection approach to binary *relation detection*, a task of identifying the relation between two entities. A simple projection method propagates the relations in source language sentences to

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 564–571,
Beijing, August 2010

word-aligned target sentences, and a target relation detector can bootstrap from projected annotation. However, this automatic annotation is unreliable because of mis-classification of source text and word alignment errors, so it causes a critical falling-off in annotation projection quality. To alleviate this problem, we present three noise reduction strategies: a heuristic filtering; an alignment correction with dictionary; and an instance selection based on assessment, and combine these to yield a better result.

We provide a quantitive evaluation of our method on a new Korean RDC dataset. In our experiment, we leverage an English-Korean parallel corpus collected from the Web, and demonstrate that the annotation projection approach and noise reduction method are beneficial to build an initial Korean relation detection system. For example, the combined model of three noise reduction methods achieves F1-scores of 36.9% (59.8% precision and 26.7% recall), favorably comparing with the 30.5% shown by the supervised baseline.[1]

The remainder of this paper is structured as follows. In Section 2, we describe our cross-lingual annotation projection approach to relation detection task. Then, we present the noise reduction methods in Section 3. Our experiment on the proposed Korean RDC evaluation set is shown in Section 4 and Section 5, and we conclude this paper in Section 6.

2 Cross-lingual Annotation Projection for Relation Detection

The annotation projection from a resource-rich language L_1 to a resource-poor language L_2 is performed by a series of three subtasks: annotation, projection and assessment.

The annotation projection for relation detection can be performed as follows:

1) For a given pair of bi-sentences in parallel corpora between a resource-rich language L_1 and a target language L_2, the relation detection task is carried out for the sentence in L_1.

2) The annotations obtained by analyzing the sentence in L_1 are projected onto the sentence in L_2 based on the word alignment information.

3) The projected annotations on the sentence in L_2 are utilized as resources to perform the relation detection task for the language L_2.

2.1 Annotation

The first step to projecting annotations from L_1 onto L_2 is obtaining annotations for the sentences in L_1. Since each instance for relation detection is composed of a pair of entity mentions, the information about entity mentions on the given sentences should be identified first. We detect the entities in the L_1 sentences of the parallel corpora. Entity identification generates a number of instances for relation detection by coupling two entities within each sentence. For each instance, the existence of semantic relation between entity mentions is explored, which is called relation detection. We assume that there exist available models or systems for all annotation processes, including not only an entity tagger and a relation detector themselves, but also required preprocessors such as a part-of-speech tagger, base-phrase chunker, and syntax parser for analyzing text in L_1.

Figure 1 shows an example of annotation projection for relation detection of a bitext in English and Korean. The annotation of the sentence in English shows that “Jan Mullins” and “Computer Recycler Incorporated” are entity mentions of a person and an organization, respectively. Furthermore, the result indicates that the pair of entities has a semantic relationship categorized as “ROLE.Owner” type.

2.2 Projection

In order to project the annotations from the sentences in L_1 onto the sentences in L_2, we utilize the information of word alignment which plays an important role in statistical machine translation techniques. The word alignment task aims to identify translational relationships among the words in a bitext and produces a bipartite graph with a set of edges between words with translational relationships as shown in Figure 1. In the same manner as the annotation in L_1, entities are

[1] The dataset and the parallel corpus are available on the author’s website,
http://isoft.postech.ac.kr/~megaup/research/resources/.

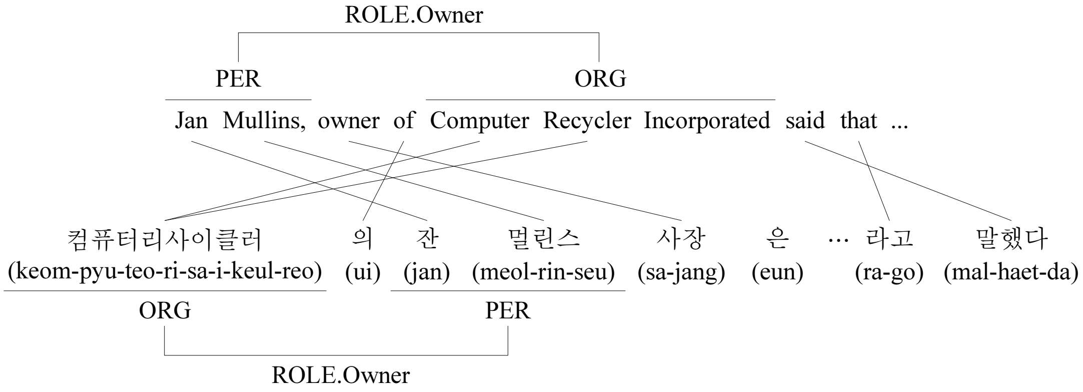

Figure 1: An example of annotation projection for relation detection of a bitext in English and Korean

considered as the first units to be projected. We assume that the words of the sentences in L_2 aligned with a given entity mention in L_1 inherit the information about the original entity in L_1.

After projecting the annotations of entity mentions, the projections for relational instances follow. A projection is performed on a projected instance in L_2 which is a pair of projected entities by duplicating annotations of the original instance in L_1.

Figure 1 presents an example of projection of a positive relational instance between “Jan Mullins” and “Computer Recycler Incorporated” in the English sentence onto its translational counterpart sentence in Korean. “Jan meol-rin-seu” and “keom-pyu-teo-ri-sa-i-keul-reo” are labeled as entity mentions with types of a person’s name and an organization’s name respectively. In addition, the instance composed of the two projected entities is annotated as a positive instance, because its original instance on the English sentence also has a semantic relationship.

As the description suggests, the annotation projection approach is highly dependant on the quality of word alignment. However, the results of automatic word alignment may include several noisy or incomplete alignments because of technical difficulties. We present details to tackle the problem by relieving the influence of alignment errors in Section 3.

2.3 Assessment

The most important challenge for annotation projection approaches is how to improve the robustness against the erroneous projections. The noise produced by not only word alignment but also mono-lingual annotations in L_1 accumulates and brings about a drastic decline in the quality of projected annotations.

The simplest policy of utilizing the projected annotations for relation detection in L_2 is to consider that all projected instances are equivalently reliable and to employ entire projections as training instances for the task without any filtering. In contrast with this policy, which is likely to be substandard, we propose an alternative policy where the projected instances are assessed and only the instances judged as reliable by the assessment are utilized for the task. Details about the assessment are provided in Section 3.

3 Noise Reduction Strategies

The efforts to reduce noisy projections are considered indispensable parts of the projection-based relation detection method in a resource-poor language. Our noise reduction approach includes the following three strategies: heuristic-based alignment filtering, dictionary-based alignment correction, and assessment-based instance selection.

3.1 Heuristic-based Alignment Filtering

In order to improve the performance of annotation projection approaches, we should break the bottleneck caused by the low quality of automatic word alignment results. As relation detection is carried out for each instance consisting of two entity mentions, the annotation projection for relation detection concerns projecting only entity mentions and their relational instances. Since this is different from other shallower tasks such as part-of-speech tagging, base phrase chunking, and dependency parsing which should consider projections for all word units, we define and apply some heuristics specialized to projections of entity mentions and relation instances to improve robustness of the method against erroneous alignments, as follows:

- A projection for an entity mention should be based on alignments between contiguous word sequences. If there are one or more gaps in the word sequence in L2 aligned with an entity mention in the sentence in L1, we assume that the corresponding alignments are likely to be erroneous. Thus, the alignments of non-contiguous words are excluded in projection.

- Both an entity mention in L_1 and its projection in L_2 should include at least one base noun phrase. If no base noun phrase occurs in the original entity mention in L_1, it may suggest some errors in annotation for the sentence in L_1. The same case for the projected instance raises doubts about alignment errors. The alignments between word sequences without any base noun phrase are filtered out.

- The projected instance in L2 should satisfy the clausal agreement with the original instance in L1. If entities of an instance are located in the same clause (or different clauses), its projected instance should be in the same manner. The instances without clausal agreement are ruled out.

3.2 Dictionary-based Alignment Correction

The errors in word alignment are composed of not only imprecise alignments but also incomplete alignments. If an alignment of an entity among two entities of a relation instance is not provided in the result of the word alignment task, the projection for the corresponding instance is unavailable. Unfortunately, the above-stated alignment filtering heuristics for improving the quality of projections make the annotation loss problems worse by filtering out several alignments likely to be noisy.

In order to solve this problem, a dictionary-based alignment correction strategy is incorporated in our method. The strategy requires a bilingual dictionary for entity mentions. Each entry of the dictionary is a pair of entity mention in L_1 and its translation or transliteration in L_2. For each entity to be projected from the sentence in L_1, its counterpart in L_2 is retrieved from the bilingual dictionary. Then, we seek the retrieved entity mention from the sentence in L_2 by finding the longest common subsequence. If a subsequence matched to the retrieved mention is found in the sentence in L_2, we make a new alignment between it and its original entity on the L_1 sentence.

3.3 Assessment-based Instance Selection

The reliabilities of instances projected via a series of independent modules are different from each other. Thus, we propose an assessment strategy for each projected instance. To evaluate the reliability of a projected instance in L_2, we use the confidence score of monolingual relation detection for the original counterpart instance in L_1. The acceptance of a projected instance is determined by whether the score of the instance is larger than a given threshold value θ. Only accepted instances are considered as the results of annotation projection and applied to solve the relation detection task in target language L_2.

4 Experimental Setup

To demonstrate the effectiveness of our cross-lingual annotation projection approach for relation detection, we performed an experiment on relation detection in Korean text with propagated annotations from English resources.

4.1 Annotation

The first step to evaluate our method was annotating the English sentences in a given parallel corpus. We use an English-Korean parallel corpus crawled from an English-Korean dictionary on the web. The parallel corpus consists of 454,315 bi-sentence pairs in English and Korean [2]. The English sentences in the parallel corpus were prepro-

[2] The parallel corpus collected and other resources are all available in our website
http://isoft.postech.ac.kr/∼megaup/research/resources/

cessed by the Stanford Parser [3] (Klein and Manning, 2003) which provides a set of analyzed results including part-of-speech tag sequences, a dependency tree, and a constituent parse tree for a sentence.

The annotation for English sentences is divided into two subtasks: entity mention recognition and relation detection. We utilized an off-the-shelf system, Stanford Named Entity Recognizer [4] (Finkel et al., 2005) for detecting entity mentions on the English sentences. The total number of English entities detected was 285,566. Each pair of recognized entities within a sentence was considered as an instance for relation detection.

A classification model learned with the training set of the ACE 2003 corpus which consists of 674 documents and 9,683 relation instances was built for relation detection in English. In our implementation, we built a tree kernel-based SVM model using SVM-Light [5] (Joachims, 1998) and Tree Kernel Tools [6] (Moschitti, 2006). The subtree kernel method (Moschitti, 2006) for shortest path enclosed subtrees (Zhang et al., 2006) was adopted in our model. Our relation detection model achieved 81.2/69.8/75.1 in Precision/Recall/F-measure on the test set of the ACE 2003 corpus, which consists of 97 documents and 1,386 relation instances.

The annotation of relations was performed by determining the existence of semantic relations for all 115,452 instances with the trained model for relation detection. The annotation detected 22,162 instances as positive which have semantic relations.

4.2 Projection

The labels about entities and relations in the English sentences of the parallel corpora were propagated into the corresponding sentences in Korean. The Korean sentences were preprocessed by our part-of-speech tagger [7] (Lee et al., 2002) and a dependency parser implemented by MSTParser with a model trained on the Sejong corpus (Kim, 2006).

Filter	Without assessing	With assessing
none	97,239	39,203
+ heuristics	31,652	12,775
+ dictionary	39,891	17,381

Table 1: Numbers of projected instances

The annotation projections were performed on the bi-sentences of the parallel corpus followed by descriptions mentioned in Section 2.2. The bi-sentences were processed by the GIZA++ software (Och and Ney, 2003) in the standard configuration in both English-Korean and Korean-English directions. The bi-direcional alignments were joined by the grow-diag-final algorithm, which is widely used in bilingual phrase extraction (Koehn et al., 2003) for statistical machine translation. This system achieved 65.1/41.6/50.8 in Precision/Recall/F-measure in our evaluation of 201 randomly sampled English-Korean bi-sentences with manually annotated alignments.

The number of projected instances varied with the applied strategies for reducing noise as shown in Table 1. Many projected instances were filtered out by heuristics, and only 32.6% of the instances were left. However, several instances were rescued by dictionary-based alignment correction and the number of projected instances increased from 31,652 to 39,891. For all cases of noise reduction strategies, we performed the assessment-based instance selection with a threshold value θ of 0.7, which was determined empirically through the grid search method. About 40% of the projected instances were accepted by instance selection.

4.3 Evaluation

In order to evaluate our proposed method, we prepared a dataset for the Korean RDC task. The dataset was built by annotating the information about entities and relations in 100 news documents in Korean. The annotations were performed by two annotators following the guidelines for the ACE corpus processed by LDC. Our Korean RDC corpus consists of 835 sentences, 3,331 entity mentions, and 8,354 relation instances. The sen-

Heuristic + Dictionary	55.3	19.4	28.7	59.8	26.7	36.9

Table 2: Experimental Results

tences of the corpus were preprocessed by equivalent systems used for analyzing Korean sentences for projection. We randomly divided the dataset into two subsets with the same number of instances for use as a training set to build the baseline system and for evaluation.

For evaluating our approach, training instance sets to learn models were prepared for relation detection in Korean. The instances of the training set (half of the manually built Korean RDC corpufs) were used to train the baseline model. All other sets of instances include these baseline instances and additional instances propagated by the annotation projection approach. The training sets with projected instances are categorized into three groups by the level of applied strategies for noise reduction. While the first set included all projections without any noise reduction strategies, the second included only the instances accepted by the heuristics. The last set consisted of the results of a series of heuristic-based filtering and dictionary-based correction. For each training set with projected instances, an additional set was derived by performing assessment-based instance selection.

We built the relation detection models for all seven training sets (a baseline set, three projected sets without assessing, and three projected sets with assessing). Our implementations are based on the SVM-Light and Tree Kernel Tools described in the former subsection. The shortest path dependency kernel (Bunescu and Mooney, 2005) implemented by the subtree kernel method (Moschitti, 2006) was adopted to learn all models.

The performance for each model was evaluated with the predictions of the model on the test set, which was the other half of Korean RDC corpus. We measured the performances of the models on true entity mentions with true chaining of coreference. Precision, Recall and F-measure were adopted for our evaluation.

5 Experimental Results

Table 2 compares the performances of the different models which are distinguished by the applied strategies for noise reduction. It shows that:

- The model with non-filtered projections achieves extremely poor performance due to a large number of erroneous instances. This indicates that the efforts for reducing noise are urgently needed.

- The heuristic-based alignment filtering helps to improve the performance. However, it is much worse than the baseline performance because of a falling-off in recall.

- The dictionary-based correction to our projections increased both precision and recall compared with the former models with projected instances. Nevertheless, it still fails to achieve performance improvement over the baseline model.

- For all models with projection, the assessment-based instance selection boosts the performances significantly. This means that this selection strategy is crucial in improving the performance of the models by excluding unreliable instances with low confidence.

- The model with heuristics and assessments finally achieves better performance than the baseline model. This suggests that the projected instances have a beneficial influence on the relation detection task when at least these two strategies are adopted for reducing noises.

- The final model incorporating all proposed noise reduction strategies outperforms the baseline model by 6 in F-measure. This is due to largely increased recall by absorbing more useful features from the well-refined set of projected instances.

The experimental results show that our proposed techniques effectively improve the performance of relation detection in the resource-poor Korean language with a set of annotations projected from the resource-rich English language.

6 Conclusion

This paper presented a novel cross-lingual annotation projection method for relation extraction in a resource-poor language. We proposed methods of propagating annotations from a resource-rich language to a target language via parallel corpora. In order to relieve the bad influence of noisy projections, we focused on the strategies for reducing the noise generated during the projection. We applied our methods to the relation detection task in Korean. Experimental results show that the projected instances from an English-Korean parallel corpus help to improve the performance of the task when our noise reduction strategies are adopted.

We would like to introduce our method to the other subtask of relation extraction, which is relation categorization. While relation detection is a binary classification problem, relation categorization can be solved by a classifier for multiple classes. Since the fundamental approaches of the two tasks are similar, we expect that our projection-based relation detection methods can be easily adapted to the relation categorization task.

For this further work, we are concerned about the problem of low performance for Korean, which was below 40 for relation detection. The relation categorization performance is mostly lower than detection because of the larger number of classes to be classified, so the performance of projection-based approaches has to be improved in order to apply them. An experimental result of this work shows that the most important factor in improving the performance is how to select the reliable instances from a large number of projections. We plan to develop more elaborate strategies for instance selection to improve the projection performance for relation extraction.

Abstract

This paper describes a feasibility study of n-gram-based evaluation metrics for automatic keyphrase extraction. To account for near-misses currently ignored by standard evaluation metrics, we adapt various evaluation metrics developed for machine translation and summarization, and also the R-precision evaluation metric from keyphrase evaluation. In evaluation, the R-precision metric is found to achieve the highest correlation with human annotations. We also provide evidence that the degree of semantic similarity varies with the location of the partially-matching component words.

1 Introduction

Keyphrases are noun phrases (NPs) that are representative of the main content of documents. Since they represent the key topics in documents, extracting good keyphrases benefits various natural language processing (NLP) applications such as summarization, information retrieval (IR) and question-answering (QA). Keyphrases can also be used in text summarization as semantic metadata (Barzilay and Elhadad, 1997; Lawrie et al., 2001; D'Avanzo and Magnini, 2005). In search engines, keyphrases supplement full-text indexing and assist users in creating good queries.

In the past, a large body of work on keyphrases has been carried out as an extraction task, utilizing three types of cohesion: (1) document cohesion, i.e. cohesion between documents and keyphrases (Frank et al., 1999; Witten et al., 1999; Matsuo and Ishizuka, 2004; Medelyan and Witten, 2006; Nguyen and Kan, 2007; Wan and Xiao, 2008); (2) keyphrase cohesion, i.e. cohesion among keyphrases (Turney, 2003); and (3) term cohesion, i.e. cohesion among terms in a keyphrase (Park et al., 2004).

Despite recent successes in keyphrase extraction (Frank et al., 1999; Turney, 2003; Park et al., 2004; Medelyan and Witten, 2006; Nguyen and Kan, 2007), current work is hampered by the inflexibility of standard metrics in evaluating different approaches. As seen in other fields, e.g. machine translation (MT) and multi-document summarization, the advent of standardized automatic evaluation metrics, combined with standardized datasets, has enabled easy comparison of systems and catalyzed the respective research areas. Traditionally, the evaluation of automatic keyphrase extraction has relied on the number of exact matches in author-assigned keyphrases and reader-assigned keyphrases. The main problem with this approach is that even small variants in the keyphrases are not given any credit. For example, given the gold-standard keyphrase *effective grid computing algorithm*, *grid computing algorithm* is a plausible keyphrase candidate and should be scored appropriately, rather than being naively evaluated as wrong. Additionally, author-assigned keyphrases and even reader-assigned keyphrases often have their own problems in this type of evaluation (Medelyan and Witten, 2006). For example, some keyphrases are often partly or wholly subsumed by other candidates or may not even occur in the document. Therefore, counting the exactly-matching candidates has been shown to be suboptimal (Jarmasz

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 572–580,
Beijing, August 2010

and Barriere, 2004).

Our goal in this paper is to evaluate the reliability of automatic evaluation metrics that better account for near-misses. Prior research based on semantic similarity (Jarmasz and Barriere, 2004; Mihalcea and Tarau, 2004; Medelyan and Witten, 2006) has taken the approach of using external resources such as large corpora, Wikipedia or manually-curated index words. While we acknowledge that these methods can help address the near-miss problem, they are impractical due to the effort required to compile the requisite resources for each individual evaluation exercise, and furthermore, the resources tend to be domain-specific. In order to design a cheap, practical and stable keyphrase evaluation metric, our aim is to properly account for these near-misses without reliance on costly external resources.

According to our analysis, the degree of semantic similarity of keyphrase candidates varies relative to the location of overlap. For example, the candidate *grid computing algorithm* has higher semantic similarity than *computing algorithm* with the gold-standard keyphrase *effective grid computing algorithm*. Also, *computing algorithm* is closer than *effective grid* to the same gold-standard keyphrase. From these observations, we infer that n-gram-based evaluation metrics can be applied to evaluating keyphrase extraction, but also that candidates with the same relative n-gram overlap are not necessarily equally good.

Our primary goal is to test the utility of n-gram based evaluation metrics to the task of keyphrase extraction evaluation. We test the following evaluation metrics: (1) evaluation metrics from MT and multi-document summarization (BLEU, NIST, METEOR and ROUGE); and (2) R-precision (Zesch and Gurevych, 2009), an n-gram-based evaluation metric developed specifically for keyphrase extraction evaluation which has yet to be evaluated against humans at the extraction task. Secondarily, we attempt to shed light on the bigger question of whether it is feasible to expect that n-gram-based metrics without access to external resources should be able to capture subtle semantic differences in keyphrase candidates. To this end, we experimentally verify the impact of lexical overlap of different types on keyphrase similarity, and use this as the basis for proposing a variant of R-precision.

In the next section, we present a brief primer on keyphrases. We then describe the MT and summarization evaluation metrics trialled in this research, along with R-precision, modified R-precision and a semantic similarity-based evaluation metric for keyphrase evaluation (Section 3). In Section 4, we discuss our gold-standard and candidate extraction method. We compare the evaluation metrics with human assigned scores for suitability in Section 5, before concluding the paper.

2 A Primer on Keyphrases

Keyphrases can be either simplex words (e.g. *query*, *discovery*, or *context-awareness*)[1] or larger N-bars/noun phrases (e.g. *intrusion detection*, *mobile ad-hoc network*, or *quality of service*). The majority of keyphrases are 1–4 words long (Paukkeri et al., 2008).

Keyphrases are normally composed of nouns and adjectives, but may occasionally contain adverbs (e.g. *dynamically allocated task*, or *partially observable Markov decision process*) or other parts of speech. They may also contain hyphens (e.g. *sensor-grouping* or *multi-agent system*) and apostrophes for possessives (e.g. *Bayes' theorem* or *agent's goal*).

Keyphrases can optionally incorporate PPs (e.g. *service quality* vs. *quality of service*). A variety of prepositions can be used (e.g. *incentive <u>for</u> cooperation, inequality <u>in</u> welfare, agent security <u>via</u> approximate policy*), although the genetive *of* is the most common.

Keyphrases can also be coordinated, either as simple nouns at the top level (e.g. *performance and scalability* or *group and partition*) or within more complex NPs or between N-bars (e.g. *history of past encounter and transitivity* or *task and resource allocation in agent system*).

When candidate phrases get too long, abbreviations also help to form valid keyphrases (e.g. *computer support collaborative work* vs. *CSCW*, or *partially observable Markov decision process* vs. *POMDP*).

[1] All examples in this section are taken from the data set outlined in Section 4.

3 Evaluation Metrics

There have been various evaluation metrics developed and validated for reliability in fields such as MT and summarization (Callison-Burch et al., 2009). While n-gram-based metrics don't capture systematic alternations in keyphrases, they do support partial match between keyphrase candidates and the reference keyphrases.

In this section, we first introduce a range of popular n-gram-based evaluation metrics from the MT and automatic summarization literature, which we naively apply to the task of keyphrase evaluation. We then present R-precision, an n-gram-based evaluation metric developed specifically for keyphrase evaluation, and propose a modified version of R-precision which weights n-grams according to their relative position in the keyphrase. Finally, we present a semantic similarity method.

3.1 Machine Translation and Summarization Evaluation Metrics

In this research, we experiment with four popular n-gram-based metrics from the MT and automatic summarization fields — BLEU, METEOR, NIST and ROUGE. The basic task performed by the respective evaluation metrics is empirical determination of *how good an approximation is string*$_1$ *of string*$_2$*?*, which is not far removed from the requirements of keyphrase evaluation. We briefly outline each of the methods below.

One subtle property of keyphrase evaluation is that there is no a priori preference for shorter keyphrases over longer keyphrases, unlike MT where shorter strings tend to be preferred. Hence, we use the longer NP as reference and the shorter NP as a translation, to avoid the length penalty in most MT metrics.[2]

BLEU (Papineni et al., 2002) is an evaluation metric for measuring the relative similarity between a candidate translation and a set of reference translations, based on n-gram composition. It calculates the number of overlapping n-grams between the candidate translation and the set of reference translations. In order to avoid having very short translations receive artificially high scores, BLEU adds a brevity penalty to the scoring equation.

METEOR (Agarwal and Lavie, 2008) is similar to BLEU, in that it measures string-level similarity between the reference and candidate translations. The difference is that it allows for more match flexibility, including stem variation and WordNet synonymy. The basic metric is based on the number of mapped unigrams found between the two strings, the total number of unigrams in the translation, and the total number of unigrams in the reference.

NIST (Martin and Przybocki, 1999) is once again similar to BLEU, but integrates a proportional difference in the co-occurrences for all n-grams while weighting more heavily n-grams that occur less frequently, according to their information value.

ROUGE (Lin and Hovy, 2003) — and its variants including ROUGE-N and ROUGE-L — is similarly based on n-gram overlap between the candidate and reference summaries. For example, ROUGE-N is based on co-occurrence statistics, using higher-order n-grams ($n > 1$) to estimate the fluency of summaries. ROUGE-L uses longest common subsequence (LCS)-based statistics, based on the assumption that the longer the substring overlap between the two strings, the greater the similar Saggion et al. (2002). ROUGE-W is a weighted LCS-based statistic that prioritizes consecutive LCSes. In this research, we experiment exclusively with the basic ROUGE metric, and unigrams (i.e. ROUGE-1).

3.2 R-precision

In order to analyze near-misses in keyphrase extraction evaluation, Zesch and Gurevych (2009) proposed R-precision, an n-gram-based evaluation metric for keyphrase evaluation.[3] R-precision contrasts with the majority of previous work on keyphrase extraction evaluation, which has used semantic similarity based on external resources

[2] While we don't present the numbers in this paper, the results were lower for the MT evaluation metrics without this reordering of the reference and candidate keyphrases.

[3] Zesch and Gurevych's R-precision has nothing to do with the information retrieval evaluation metric of the same name, where P@N is calculated for N equal to the number of relevant documents.

(Jarmasz and Barriere, 2004; Mihalcea and Tarau, 2004; Medelyan and Witten, 2006). As our interest is in fully automated evaluation metrics which don't require external resources and are domain independent (for maximal reproducibility of results), we experiment only with R-precision in this paper.

R-precision is based on the number of overlapping words between a keyphrase and a candidate, as well as the length of each. The metric differentiates three types of near-misses: *INCLUDE*, *PARTOF* and *MORPH*. The first two types are based on an n-gram approach, while the third relies on lexical variation. As we use stemming, in line with the majority of previous work on keyphrase extraction evaluation, we focus exclusively on the first two cases, namely *INCLUDE*, and *PARTOF*. The final score returned by R-precision is:

$$\frac{\text{number of overlapping word(s)}}{\text{length of keyphrase/candidate}}$$

where the denominator is the longer of the keyphrase and candidate.

Zesch and Gurevych (2009) evaluated R-precision over three corpora (Inspec, DUC and SP) based on 566 non-exact matching candidates. In order to evaluate the human agreement, they hired 4 human annotators to rate the near-miss candidates, and reported agreements of 80% and 44% for the INCLUDE and PARTOF types, respectively. They did not, however, perform holistic evaluation with human scores to verify its reliability in full system evaluation. This is one of our contributions in this paper.

3.3 Modified R-precision

In this section, we describe a modification to R-precision which assigns different weights for component words based on their position in the keyphrase (unlike R-precision which assigns the same score for each matching component word). The head noun generally encodes the core semantics of the keyphrase, and as a very rough heuristic, the further a word is from the head noun, the less semantic import on the keyphrase it has. As such, modified R-precision assigns a score to each component word relative to its position as $CW = \frac{1}{N-i+1}$ where N is the number of component words in the keyphrase and i is the position of the component word in the keyphrase (1 = leftmost word).

For example, *AB* and *BC* from *ABC* would be scored as $\frac{\frac{1}{3}+\frac{1}{2}}{\frac{1}{3}+\frac{1}{2}+\frac{1}{1}} = \frac{5}{11}$ and $\frac{\frac{1}{2}+\frac{1}{1}}{\frac{1}{3}+\frac{1}{2}+\frac{1}{1}} = \frac{9}{11}$, respectively. Thus, with the keyphrase *effective grid computing algorithm* and candidates *effective grid*, *grid computing* and *computing algorithm*, modified R-precision assigns different scores for each candidate (*computing algorithm* $>$ *grid computing* $>$ *effective grid*). In contrast, the original R-precision assigns the same score to all candidates.

3.4 Semantic Similarity

In Jarmasz and Barriere (2004) and Mihalcea and Tarau (2004), the authors used a large data set to compute the semantic similarity of two NPs to assign partial credits for semantically similar candidate keyphrases. To simulate these methods, we adopted the distributional semantic similarity using web documents. That is, we computed the similarity between a keyphrase and its substring by cosine measure over collected the snippets from Yahoo! BOSS.[4] We use the computed similarity as our score for near-misses.

4 Data

4.1 Data Collection

We constructed a keyphrase extraction dataset using papers across 4 different categories[5] of the ACM Digital Library.[6] In addition to author-assigned keyphrases provided as part of the ACM Digital Library, we generated reader-assigned keyphrases by assigning 250 students 5 papers each, a list of candidate keyphrases (see below for details), and standardized instructions on how to assign keyphrases. It took them an average of 15 minutes to annotate each paper. This is the same

Table 2: Regular expressions for candidate selection

document collection and set of keyphrase annotations as was used in the SemEval 2010 keyphrase extraction task (Kim et al., 2010).

Table 1 shows the details of the final dataset. The numbers after the slashes indicate the number of keyphrases after including alternate keyphrases based on *of*-PPs. Despite the reliability of author-assigned keyphrases discussed in Medelyan and Witten (2006), many author-assigned keyphrases and some reader-assigned keyphrases are not found verbatim in the source documents because: (1) many of them are substrings of the candidates or vice versa (about 75% of the total keyphrases are found in the documents); and (2) our candidate selection method does not extract keyphrases in forms such as coordinated NPs or adverbial phrases.

4.2 Candidate Selection

During preprocessing, we first converted the PDF versions of the papers into text using `pdftotext`. We then lemmatized and POS tagged all words using `morpha` and the `Lingua` POS tagger. Next, we applied the regular expressions in Table 2 to extract candidates, based on Nguyen and Kan (2007). Finally, we selected candidates in terms of their frequency: simplex words with frequency ≥ 2 and NPs with frequency ≥ 1. We observed that for reader-assigned keyphrases, NPs were often selected regardless of their frequency in the source document. In addition, we allowed variation in the possessive form, noun number and abbreviations.

Rule1 detects simplex nouns or N-bars as candidates. *Rule2* extracts N-bars with post-modifying PPs. In Nguyen and Kan (2007), *Rule2* was not used to additionally extract N-bars inside modifying PPs. For example, our rules extract not only *performance of grid computing* as a candidate, but also *grid computing*. However, we did not extend the candidate selection rules to cover NPs including adverbs (e.g. *partially-observable Markov decision process*) or conjunctions (e.g. *behavioral evolution and extrapolation*), as they are rare.

4.3 Human Assigned Score

We hired four graduate students working in NLP to assign human scores to substrings in the gold-standard data. The scores are between 0 and 4 (0 means no semantic overlap between a NP and its substring, while 4 means semantically indistinguishable).

We broke down the candidate–keyphrases pairs into subtypes, based on where the overlap occurs relative to the keyphrase (e.g. *ABCD*): (1) *Head*: the candidate contains the head noun of the keyphrase (e.g. *CD*); (2) *First*: the candidate contains the first word of the keyphrase (e.g. *AB*); and (3) *Middle*: the candidate overlaps with the keyphrase, but contains neither its first word nor its head word (e.g. *BC*). The average human scores are 1.94 and 2.11 for *First* and *Head*, respectively, when the candidate is shorter, while they are 2.00, 1.89 and 2.15 for *First*, *Middle*, and *Head*, respectively when the candidate is longer. Note that we did not have *Middle* instances with candidates as the shorter string. The scores are slightly higher for the keyphrases as substrings than for the candidates as substrings.

5 Correlation

To check the feasibility of metrics for keyphrase evaluation, we checked the Spearman rank correlation between the machine-generated score and the human-assigned score for each keyphrase–candidate pairing.

As the percentage of annotators who agree on the exact score is low (i.e. 2 subjects agree ex-

actly on 55%-70% of instances, 3 subjects agree exactly on 25%-35% of instances), we require a method for combining the annotations. We experiment with two combination methods: majority and average. The majority is simply the label with the majority of annotations associated with it; in the case of a tie, we break the tie by selecting that annotation which is closest to the median. The average is simply the average score across all annotators.

5.1 Overall Correlation with Human Scores

Table 3 presents the correlations between the human scores (acting as an upper bound for the task), as well as those between human scores with machine-generated scores. We first present the overall results, then results over the subset of keyphrases of length 4 words or less, and also 3 words or less. We present the results for the annotator average and majority in top and bottom half, respectively, of the table.

To compute the correlation between the human annotators, we used leave-one-out cross-validation, holding out one annotator, and comparing them to the combination of the remaining annotators (using either the majority or average method to combine the remaining annotations). This was repeated across all annotators, and the Spearman's ρ was averaged across the annotators.

Overall, we found that R-precision achieved the highest correlation with humans, above the inter-annotator correlation in all instances. That is, based on the evaluation methodology employed, it is performing slightly above the average level of a single annotator. The relatively low inter-annotator correlation is, no doubt, due to the difficulty of the task, as all of our near-misses have 2 or more terms, and the annotators have to make very fine-grained, and ultimately subjective, decisions about the true quality of the candidate.

Comparing the n-gram-based methods with the semantic similarity-based method, the n-gram-based metrics achieved higher correlations across the board, with BLEU, METEOR, NIST and ROUGE all performing remarkably consistently, but well

Table 5: Rank correlation between human majority and n-gram-based metrics

below the level of R-precision. Due to the markedly lower performance of the semantic similarity-based method, we do not consider it for the remainder of our experiments. A general finding was that as the length of the keyphrase (L) got longer, the correlation tended to be higher across all n-gram-based metrics.

One disappointment at this stage is that the results for modified R-precision are well below those of the original, especially over the average of the human annotators.

5.2 Correlation with Different NP Subtypes

To get a clearer sense of how the different evaluation metrics are performing, we broke down the keyphrases according to three syntactic subclassifications: (1) the location of overlap (see Section 4.3); (2) the complexity of the NP (does the keyphrase contain a preposition [PP], a conjunction [CC] or neither a preposition nor a conjunction [Simple]?); and (3) the word class sequence of the keyphrase (is the keyphrase an NN [NN] or an AdjN sequence [AdjN]?). We present the results in Tables 4 and Table 4 for the human average and majority, respectively, presenting results in **boldface** when the correlation for a given method is higher than for that same method in our holistic evaluation in Table 3 (i.e. .4506 and .4603, for the average and majority human scores, respectively).

All methods, including inter-annotator correlation, improve in raw numbers over the subsets of the data based on overlap location, indicating that the data was partitioned into more internally-consistent subsets. Encouragingly, modified R-precision equalled or bettered the performance of the original R-precision over each subset of the data based on overlap location. Where modified R-precision appears to fall down most noticeably is over keyphrases including prepositions, as our assumption about the semantic import based on linear ordering clearly breaks down in the face of post-modifying PPs. It is also telling that it does worse over noun–noun sequences than adjective–noun sequences. In being agnostic to the effects of syntax, the original R-precision appears to benefit overall. Another interesting effect is that the performance of BLEU, METEOR and ROUGE is notably better over candidates which match with non-initial and non-final words in the keyphrase.

We conclude from this analysis that keyphrase scoring should be sensitive to overlap location. Furthermore, our study also shows that n-gram-based MT and summarization metrics are surprisingly adept at capturing partial matches in keyphrases, despite them being much shorter than the strings they are standardly applied to. More compellingly, we found that R-precision is the best overall performer, and that it matches the performance of our human annotators across the board. This is the first research to establish this fact. Our findings for modified R-precision were more sobering, but its location sensitivity was shown to improve over R-precision for instances of overlap in the middle or with the head of the keyphrase.

6 Conclusion

In this work, we have shown that preexisting n-gram-based evaluation metrics from MT, summarization and keyphrase extraction evaluation are able to handle the effects of near-misses, and that R-precision performs at or above the average level of a human annotator. We have also shown that a semantic similarity-based method which uses web data to model distributional similarity performed below the level of all of the n-gram-based methods, despite them requiring no external resources (web or otherwise). We proposed a modification to R-precision based on the location of match, but found that while it could achieve better performance over certain classes of keyphrases, its net effect was to drag the performance of R-precision down. Other methods were found to be remarkably consistent across different subtypes of keyphrase.

Abstract

Text Understanding systems often commit to a *single best* interpretation of a sentence before analyzing subsequent text. This interpretation is chosen by resolving ambiguous alternatives to the one with the highest confidence, given the context available at the time of commitment. Subsequent text, however, may contain information that changes the confidence of alternatives. This may especially be the case with multiple redundant texts on the same topic. Ideally, systems would delay choosing among ambiguous alternatives until more text has been read.

One solution is to maintain multiple candidate interpretations of each sentence until the system acquires disambiguating evidence. Unfortunately, the number of alternatives explodes quickly. In this paper, we propose a *packed graphical (PG) representation* that can efficiently represent a large number of alternative interpretations along with dependencies among them. We also present an algorithm for combining multiple PG representations to help resolve ambiguity and prune alternatives when the time comes to commit to a single interpretation.

Our controlled experiments show that by delaying ambiguity resolution until multiple texts have been read, our prototype's accuracy is higher than when committing to interpretations sentence-by-sentence.

1 Introduction

A typical text understanding system confronts ambiguity while parsing, mapping words to concepts and formal relations, resolving co-references, and integrating knowledge derived from separate sentences or texts. The system discards many candidate interpretations to avoid combinatorial explosion. Commonly, after reading each sentence, a system will commit to its top ranked interpretation of the sentence before reading the next.

If a text understanding system could postpone committing to an interpretation without being swamped by a combinatorial explosion of alternatives, its accuracy would almost surely improve. This intuition follows from the observation that text is redundant in at least two ways. First, within a single coherent text (about the same entities and events), each sentence informs the interpretation of its neighbors. Second, within a corpus of texts on the same topic, the same information is expressed in different surface forms, ambiguous in different ways. Related fields, such as Information Extraction, exploit textual redundancy to good effect, and perhaps text understanding can as well.

One approach is for the text understanding system to maintain multiple complete candidate interpretations. After reading each sentence, for example, the system would retain a beam of the n-best interpretations of the sentence. While this approach avoids a combinatorial explosion (for reasonable values of n), several problems remain. First, because the beam width is limited, the system may still discard correct interpretations before benefiting from the extra context from related text. Second, enumeration of the candidate interpreta-

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 581–589,
Beijing, August 2010

tions does not represent the dependencies among them. For example, there may be multiple candidate word senses and semantic roles for a given sentence, but sense alternatives might be dependent on role selection (and vice-versa). The set of reasonable interpretations may be a subset of all combinations. Finally, maintaining distinct interpretations does not contribute to addressing the problem of combining evidence to narrow down alternatives and ultimately select a single best interpretation of a text.

This paper addresses these three problems. We propose an approach that postpones committing to an interpretation of a text by representing ambiguities and the dependencies among them. There may still be combinatorial growth in the set of alternative interpretations, but they are represented only intensionally, using a packed representation, which maintains alternatives while avoiding enumerating them. We also propose an algorithm for updating and pruning the packed representation as more sentences and texts are read.

We evaluate our approach by comparing two reading systems: a baseline system that commits to its best interpretation after each sentence, and our prototype system that uses a packed representation to maintain all interpretations until further reading enables it to prune. For this initial proof of concept, we use a small corpus of redundant texts. The results indicate that our approach improves the quality of text interpretation by preventing aggressive pruning while avoiding combinatorial explosion.

In the following sections, we first describe our target semantic representation of the interpretation of sentences. We then present the details of our *packed graphical representation (PG representation)* and our algorithm to resolve ambiguities in the PG representations as disambiguating evidence from subsequent text accrues. We describe the architecture of a prototype that produces PG representations for text and implements the disambiguating algorithm. Finally, we present the results from controlled experiments designed to compare the accuracy of the prototype to a baseline system that prunes more aggressively.

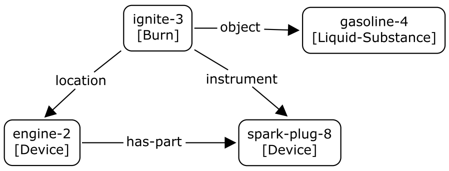

Figure 1: The target semantic graph representation for S1

2 Target semantic representation

Our target representation is a semantic graph in which nodes are words and the ontological types to which they map. Edges are semantic relations corresponding either to function words or syntactic relations in the sentence's parse.

Fig. 1 shows the target semantic representation for the following simple sentence:

S1: *An engine ignites gasoline with its spark plug.*

3 PG representation

Alternative semantic interpretations for a sentence can be captured with a single PG representation with ambiguities represented as local alternatives. Because candidate representations are often structurally similar, a PG representation can significantly compress the representation of alternatives.

Fig. 2 shows the PG representation of alternate interpretations of S1 (PG1). The different types of ambiguity captured by the PG representation are as follows.

3.1 Word-Type ambiguity

In PG1, the node engine-2a corresponds to the word "engine" in S1. Its annotation [LIVING-ENTITY .3 | DEVICE .7] captures the mapping to either LIVING-ENTITY (probability 0.3) or DEVICE (probability 0.7). The PG representation does not presume a particular uncer-

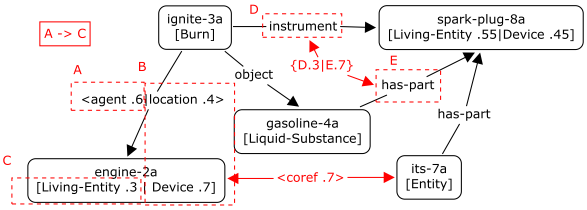

Figure 2: The PG representation for S1 (PG1)

tainty formalism. Any formalism, (Dempster-Shafer theory (Pearl, 1988), Markov Logic Networks (Richardson and Domingos, 2006), etc.) could be used.

3.2 Semantic Relation ambiguity

In PG1, the edge label <agent .6 | location .4> from ignite-3a to engine-2a says that the engine is either *agent* or *location* of the ignition.

3.3 Structural ambiguity

In PG1, edges D and E are alternatives corresponding to the different prepositional phrase attachments for "with its spark plug" (to ignite-3a or gasoline-4a). The annotation {D .3 | E .7} says that the choices are mutually exclusive with probabilities of 0.3 and 0.7.

3.4 Co-reference ambiguity

Co-reference of nodes in a PG representation is captured using a "co-reference" edge. In PG1, the edge labeled <coref .7> represents the probability that engine-2a and its-7a are co-referent.

In addition to storing ambiguities explicitly, the PG representation also captures dependencies among alternatives.

3.5 Simple dependency

The existence of one element in the graph depends on the existence of another element. If subsequent evidence suggests that an element is incorrect, its dependents should be pruned. For example, the dependency A → C, means that if LIVING-ENTITY is ultimately rejected as the type for engine-2a, the agent relation should be pruned.

3.6 Mutual dependency

Elements of a mutual dependency set are mutually confirming. Evidence confirming or rejecting an element also confirms or rejects other elements in the set. In the example, the box labeled B says that (engine-2a type DEVICE) and (ignite-3a location engine-2a) should both be confirmed or pruned when either of them is confirmed or pruned.

Formally, the PG representation is a structure consisting of (a) *semantic triples* – e.g., (ignite-3a type BURN), (b) *macros* – e.g., the symbol A refers to (ignite-3a agent engine-2a), and (c) *constraints* – e.g., A depends on C.

4 Combining PG representations

Maintaining ambiguity within a PG representation allows us to delay commitment to an interpretation until disambiguating evidence appears. For any text fragment that results in a PG representation (PGa) containing ambiguity, there may exist other text fragments that are partly redundant, but result in a less ambiguous (or differently ambiguous) representation (PGb). PGb can be used to adjust confidences in PGa. Enough such evidence allows us to prune unlikely interpretations, ultimately disambiguating the original representation.

For example, sentence S3 does not have sufficient context to disambiguate between the MOTOR sense of "engine" and the VEHICLE sense (as in *locomotive*).

S3: *General Electric announced plans this week for their much anticipated new engine.*

The PG3 representation for S3 (PG3) would maintain the ambiguous representation (with confidences for each sense based on prior probabilities, for example). On subsequently encountering sentence S4, a Lesk-based word sense disambiguation module (as in our prototype) would produce a PG4 with a strong preference for the locomotive sense of "engine", given the more specific context of S4.

S4: *The announcement comes to the relief of many in the railway industry looking to replace the engines in their aging locomotive fleets.*

To use PG4 to help disambiguate PG3, we need to align PG3 and PG4 semantically and merge their conflict sets. (In the simple example, the conflict sets for the word "engine" might be [MOTOR .5 | VEHICLE .5] in PG3 and [MOTOR .2 | VEHICLE .8] in PG4).

Algorithm 1 describes how two PG representations can be combined to help resolve their ambiguities. The algorithm identifies their isomorphic subgraphs (redundant portions of the interpretations) and uses the information to disambiguate their ambiguities. For illustration, we will step through Algorithm 1, merging PG1 (Fig. 2) with

Algorithm 1 Disambiguating PG representations

Input : PG1, PG2

Output: new PG representation

1. *Identify semantically aligned parts between PG1 and PG2.* Use graph matching to identify alignments (redundant portions) between PG1 and PG2: align nodes with the same base word or with taxonomically related types; from the node alignments, align identical types as type alignments; align relations if the relations are the same and their head and tail nodes have been aligned.

2. *Use alignments to disambiguate PG1 and PG2.* With the available information (the confidence scores and the constraints in PG1 and PG2 and the alignments between them), use joint inference to calculate the confidence score of each candidate interpretation. If the confidence score of one interpretation becomes much higher than competing ones, the interpretation is chosen while the others are discarded.

3. *Combine the disambiguated PG1 and PG2 into one PG representation using the alignments identified in the first step.*

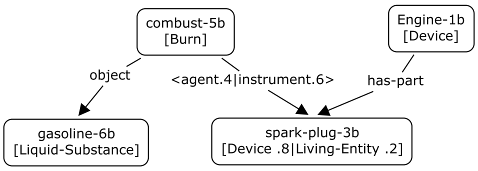

Figure 3: PG representation for S2, *"The engine's spark plug combusts gasoline."*

PG2 (Fig. 3).

1. The graph matcher identifies alignments between PG1 and PG2. Type alignments include (engine-2a[Device], Engine-1b[Device]), (spark-plug-8a[Living-Entity], spark-plug-3b[Living-Entity]). Relation alignments include ((combust-5b instrument spark-plug-3b), (ignite-3 instrument spark-plug-8)), ((ignite-3a instrument spark-plug-8a) (combust-5b instrument spark-plug-3b)).

2. In this example, when two interpretations are aligned, we simply add their confidence scores. (We are currently incorporating *Alchemy* (Richardson and Domingos, 2006) in the prototype system to do the joint inference). For example, aligning engine-2a with Engine-1b results in a score of 1.7 for Device (1 + .7). The confidence score of Living-Entity in engine-2a is unchanged at .3. Since the resulting score for Device is much higher than [1] the score for Living-Entity, Living-Entity is discarded. Deleting Living-Entity causes deletion of the *agent* edge between ignite-3a and engine-2a due to the dependency constraint A → C.

3. The disambiguated PG1 and PG2 are merged into a single PG representation (PG1+2) based on the alignments. Any remaining ambiguity persists in PG1+2, possibly to be resolved with another sentence.

5 Prototype system

5.1 Parser

Our prototype system uses the Stanford Parser (Klein and Manning, 2003). To capture structural ambiguity for our experiments, we manually edited the parser output by adding corrections as alternatives wherever the parse tree was incorrect. This gave a syntactic PG representation with both incorrect and correct alternatives. We gave the original, incorrect alternatives high confidence scores and the added, correct alternatives low scores, simulating a parser pruning correct interpretations in favor of incorrect ones with higher confidence scores. The syntactic PG for S1 is shown in Fig. 4. We have recently designed a modification to the Stanford Parser to make it produce syntactic PG representations natively, based on the complete chart built during parsing.

5.2 Semantic Interpreter

The semantic interpreter assigns types to nodes in the syntactic PG representation and semantic relations to the edges.

Type ambiguity. Types and confidence scores are assigned to words using SenseRelate (Patwardhan et al., 2005), WSD software based on the

[1] In our prototype, we set the pruning threshold at $\frac{1}{3}\times$the score of the top-scored interpretation.

Lesk Algorithm (Lesk, 1986). Assigned senses are then mapped to our *Component Library* ontology (Barker et al., 2001) using its built-in WordNet mappings.

Relational ambiguity. Semantic relations are assigned to the dependency relations in the syntactic PG representation according to semantic interpretation rules. Most rules consider the head and tail types as well as the dependency relation, but do not produce confidence scores. Our prototype scores candidates equally. We plan to incorporate a more sophisticated scoring method such as (Punyakanok et al., 2005).

Structural ambiguity. Parse ambiguities (such as PA vs. PB in Fig. 4) are converted directly to structural ambiguity representations (D vs. E in Fig. 2) in the semantic PG representation.

Simple Dependency. A dependency is installed between a type t for word w and a semantic relation r when (1) r is produced by a rule based on t and (2) r is dependent on no other candidate type for w. In Fig. 2, a dependency relation is installed from A to C, because (1) LIVING-ENTITY in engine-2a was used in the rule assigning *agent* between ignite-3a and engine-2a and (2) the assignment of *agent* is not dependent on DEVICE, the other candidate type of engine-2a.

Mutual dependency. If multiple interpretations depend on one another, a mutual dependency set is created to include them.

5.3 PG Merger

The PG Merger implements Algorithm 1 to combine PG representations. The PG representation for each sentence is merged with the cumulative PG from previous sentences. The global PG representation integrates sentence-level PG representations to the extent that they align semantically. In the worst case (completely unrelated sentences), the global PG representation would simply be the union of individual PG representations. The extent to which the global PG is more coherent reflects redundancy and semantic overlap in the sentences.

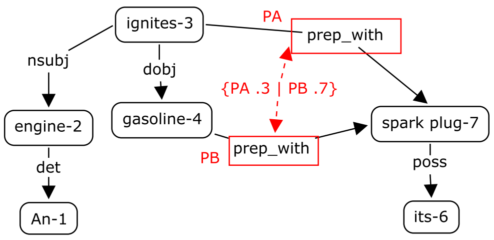

Figure 4: Syntactic PG representation for S1, capturing the PP-attachment ambiguity of “with its spark plug”.

Original Text Hearts pump blood through the body. Blood carries oxygen to organs throughout the body. Blood leaves the heart, then goes to the lungs where it is oxygenated. The oxygen given to the blood by the lungs is then burned by organs throughout the body. Eventually the blood returns to the heart, depleted of oxygen.
Paraphrase The heart begins to pump blood into the body. The blood first travels to the lungs, where it picks up oxygen. The blood will then be deposited into the organs, which burn the oxygen. The blood will then return to the heart, where it will be lacking oxygen, and start over again.

Figure 5: The original text and a paraphrase

6 Experiment 1

We first wanted to evaluate our hypothesis that Algorithm 1 can improve interpretation accuracy over multiple redundant texts. We manually generated ten redundant texts by having volunteers rewrite a short, tutorial text, using Amazon Turk (http://mturk.com) [2] The volunteers had no knowledge of the purpose of the task, and were asked to rewrite the text using “different” language. Fig. 5 shows the original text and one volunteer’s rewrite. The total number of sentences over the ten texts was 37. Average sentence length was 14.5 words.

6.1 Evaluation Procedure

We ran two systems over the ten texts. The baseline system commits to the highest scoring consistent interpretation after each sentence. The prototype system produces an ambiguity-preserving

[2] We ultimately envision a system whose task is to develop a model of a particular topic by interpreting multiple texts. Such a system might be given a cluster of documents or use its own information retrieval to find similar documents given a tutorial text.

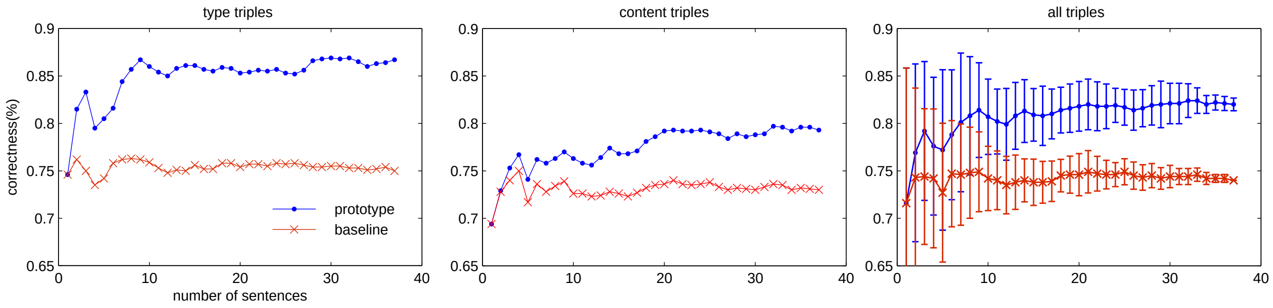

Figure 6: Correctness scores for the prototype vs. baseline system on (a) type triples (word sense assignment), (b) content triples (semantic relations) and (c) all triples (with standard deviation).

PG representation. For each sentence, the prototype's PG Merger merges the PG of the sentence with the merged PG of the previous sentences. After N sentences (varying N from 1..37), the system is forced to commit to the highest scoring consistent interpretation in the merged PG. For N=1 (commit after the first sentence), both the baseline and prototype produce the same result. For N=2, the baseline produces the union of the highest scoring interpretations for each of the first two sentences. The prototype produces a merged PG for the first two sentences and then prunes to the highest scoring alternatives.

At each value of N, we measured the correctness of the interpretations (the percentage of correct semantic triples) for each system by comparing the committed triples against human-generated gold standard triples.

We repeated the experiment ten times with different random orderings of the 37 sentences, averaging the results.

6.2 Evaluation result

Fig. 6 shows that both type assignment and semantic relation assignment by the prototype improve as the system reads more sentences. This result confirms our hypothesis that delaying commitment to an interpretation resolves ambiguities better by avoiding overly aggressive pruning.

To determine an upper bound of correctness for the prototype, we inspected the PG representations to see how many alternative sets contained the correct interpretation even if not the highest scoring alternative. This number is different from the correctness score in Fig. 6, which is the percentage of gold standard triples that are the highest scoring alternatives in the merged PG.

	baseline	prototype
nodes w/ the correct type	76	**91**
edges w/ the correct relation	74	**88**

Table 1: Percentage of nodes and edges containing the correct types and semantic relations in the baseline and the prototype for all 37 sentences.

Table. 1 shows that 91% of the nodes in the PG contain the correct type (though not necessarily the highest scoring). 88% of the edges contain the correct semantic relations among the alternatives. In contrast, the baseline has pruned away 24% of the correct types and 26% of the correct semantic relations.

7 Experiment 2

Our second experiment aims to evaluate the claim that the prototype can efficiently manage a large number of alternative interpretations. The top line in Fig. 7 shows the number of triples in the PG representations input to the prototype. This is the total number of triples (including ambiguous alternatives) in the PG for each sentence prior to invoking Algorithm 1. The middle line is the number of triples remaining after merging and pruning by Algorithm 1. The bottom line is the number of triples after pruning all but the highest scoring alternatives (the baseline system). The results show that Algorithm 1 achieves significant compression over unmerged PG representations. The resulting size of the merged PG representations more closely tracks the size of the aggressively pruned

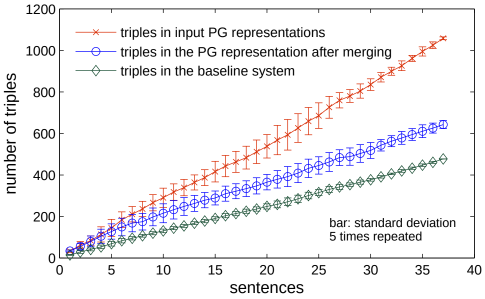

Figure 7: Total number of triples in individual sentence PG representations (top); total number of triples in the PG representation after merging in the prototype system (middle); total number of triples after pruning to the highest scoring alternative (bottom).

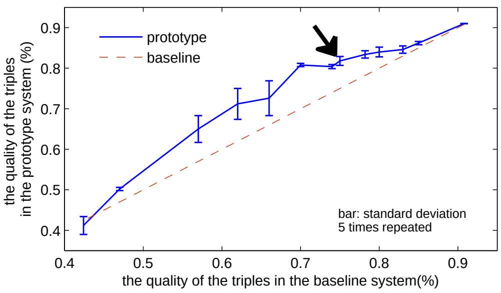

Figure 8: Sensitivity of the prototype and baseline systems to the quality of the NL system output. The quality of input triples is perturbed affecting performance accuracy of the two systems. For example, when the quality of input triples is such that the baseline system performs at 70% accuracy, the prototype system performs at 80%. The arrow indicates unperturbed language interpreter performance.

representations.

8 Experiment 3

Finally, we wanted to measure the sensitivity of our approach to the quality of the natural language interpretation. In this experiment, we artificially varied the confidence scores for the correct interpretations in the PG representations input to the prototype and baseline systems by a fixed percentage. For example, consider a node heart-1 with multiple candidate types, including the correct sense for its context: INTERNAL-ORGAN with confidence 0.8. We reran Experiment 1 varying the confidence in INTERNAL-ORGAN in increments of +/-10%, while scaling the confidences in the incorrect types equally. As the confidence in correct interpretations is increased, all correct interpretations become the highest scoring, so aggressive pruning is justified and the baseline performance approaches the prototype performance. As the confidences in correct interpretations are decreased, they are more likely to be pruned by both systems.

Fig. 8 shows that Algorithm 1 is able to recover at least some correct interpretations even when their original scores (relative to incorrect alternatives) is quite low.

9 Discussion and Future Work

Our controlled experiments suggest that it is both desirable and feasible to delay ambiguity resolution beyond sentence and text boundaries. Improvements in the correctness of semantic interpretation of sentences is possible without an explosion in size when maintaining multiple interpretations.

Nevertheless, these experiments are proofs of concept. The results confirm that it is worthwhile to subject our prototype to a more real-world, practical application. To do so, we need to address several issues.

First, we manually simulated structural (parse) ambiguities. We will complete modifications to the Stanford Parser to produce PG representations natively. This change will result in a significant increase in the number of alternatives stored in the PG representation over the current prototype. Our initial investigations suggest that there is still enough structural overlap among the candidate parse trees to allow the PG representation to control explosion, but this is an empirical question that will need to be confirmed.

We are modifying our semantic interpreter to admit induced semantic interpretation rules which will allow us to train the system in new domains.

The current prototype uses a naive heuristic for identifying co-reference candidates. We are investigating the use of off-the-shelf co-reference systems.

Finally, we are incorporating the Alchemy (Richardson and Domingos, 2006) probabilistic inference engine to calculate the probability that a candidate interpretation is correct given the PG constraints and alignments, in order to inform confirmation or pruning of interpretations.

Once these updates are complete, we will perform more wide-scale evaluations. We will investigate the automatic construction of a test corpus using text clustering to find redundant texts, and we will conduct experiments in multiple domains.

10 Related Work

Succinctly representing multiple interpretations has been explored by several researchers. The packed representation (Maxwell III and Kaplan, 1981; Crouch, 2005) uses logical formulae to denote alternative interpretations and treats the disambiguation task as the propositional satisfiability problem. Core Language Engine (Alshawi, 1992) introduces two types of packing mechanism. First, a quasi logical form allows the underspecification of several types of information, such as anaphoric references, ellipsis and semantic relations (Alshawi and Crouch, 1992). Second, a packed quasi logical form (Alshawi, 1992) compactly represents the derivations of alternative quasi logical forms. In contrast, the PG representation is (1) based on a graphical representation, (2) explicitly represents constraints and (3) includes confidence scores.

These representations and the PG representation have one feature in common: they represent a set of complete alternative interpretations of a text. Another class of compact representations, called "underspecification", has been studied as a formal representation of ambiguous sentences. These representations include Hole Semantics (Bos, 2004), Underspecified Discourse Representation Semantics (Reyle, 1995), Minimal Recursion Semantics (Copestake et al., 2005) and Dominance Constraints (Egg et al., 2001). These representations, rather than packing fully-represented candidate interpretations, specify fragments of interpretations which are unambiguously interpreted, along with constraints on their combination (corresponding to different interpretations). They generally focus on specific ambiguities such as scope ambiguity (Bos, 2004) (Egg et al., 2001) (Copestake et al., 2005) or discourse relations (Schilder, 1998) (Regneri et al., 2008).

Disambiguating compact representations has received relatively less attention. (Riezler et al., 2002; Geman and Johnson, 2002) use a packed representation to train parsers on a corpus and uses the learned statistics to disambiguate packed representations. (Clark and Harrison, 2010) uses paraphrase databases and a hand-built knowledge base to resolve underspecified representations.

Different architectures have been proposed to improve the pipeline architecture. (Sutton and McCallum, 2005; Wellner et al., 2004) maintain a beam of n best interpretations in the pipeline architecture. Their pipeline, however, consists of only two components. (Finkel et al., 2006) uses sampling over the distribution of alternative interpretations at each stage of the pipeline and then passes the sampled data to the next component. The packed representation (Crouch, 2005) and CLE (Alshawi, 1992) use packed representation in the pipeline, though both, at some stages, unpack them and re-pack the processed result. (Crouch and King, 2006) later proposes a new method that does not require unpacking and then repacking.

11 Conclusion

We have begun to address the challenge of efficiently managing multiple alternative interpretations of text. We have presented (1) a *packed graphical representation* that succinctly represents multiple alternative interpretations as well as the constraints among them, and (2) an algorithm for combining multiple PG representations to reinforce correct interpretations and discount implausible interpretations. Controlled experiments show that it is possible to improve the correctness of semantic interpretations of text by delaying disambiguation, without incurring the cost of an exponentially expanding representation.

Automatic generation of inter-passage links based on semantic similarity

Petr Knoth, Jakub Novotny, Zdenek Zdrahal

Abstract

This paper investigates the use and the prediction potential of semantic similarity measures for automatic generation of links across different documents and passages. First, the correlation between the way people link content and the results produced by standard semantic similarity measures is investigated. The relation between semantic similarity and the length of the documents is then also analysed. Based on these findings a new method for link generation is formulated and tested.

1 Introduction

Text retrieval methods are typically designed to find documents relevant to a query based on some criterion, such as BM25 or cosine similarity (Manning et al., 2008). Similar criteria have also been used to identify documents relevant to the given reference document, thus in principle linking the reference document to the related documents (Wilkinson and Smeaton, 1999). This paper studies the correspondence between the results of this approach and the way linking is performed by people. The study confirms that the length of documents is an important factor usually causing the quality of current link generation approaches to deteriorate. As a result, methods working at a finer granularity than documents should be investigated. This will also improve the speed of access to information. For example, when users read through a long document, they should be able to quickly access a passage in another possibly long document related to the discussed topic. The automatic detection of document pairs containing highly related passages is the task addressed in this paper.

A number of approaches for automatic link generation have used measures of semantic similarity. While these measures were widely used for the discovery of related documents in practise, their correspondence to the way people link content has not been sufficiently investigated (see Section 2). As our contribution to this topic, we present in this paper an approach which tries to first investigate this correspondence on a large text corpus. The resulting method is then motivated by the outcomes of this analysis.

It has been recognised in information retrieval that when a collection contains long documents, better performance is often achieved by breaking each document into subparts or passages and comparing these rather than the whole documents to a query (Manning et al., 2008). A suitable granularity of the breakdown is dependent on a number of circumstances, such as the type of the document collection or the information need. In this work, we have decided to work at the level of documents and paragraphs. Our task can be formalized as a two-step process:

1. Given a collection of documents, our goal is to identify candidate pairs of documents between which a link may be induced.
2. Given each candidate pair of documents, our task is to identify pairs of passages, such that the topics in the passages are related in both documents.

The method presented in this paper has many

This work has been partially supported by Eurogene - Contract no. ECP-2006-EDU-410018)

potential applications. First, it may be used for the interlinking of resources that were not originally created as hypertext documents and for the maintenance or the discovery of new links as the collection grows. Second, the method can be applied to improve navigation in collections with long texts, such as books or newspaper articles. A link may be identified by the system automatically and the user can be pointed immediately to the part of the text which is relevant to the block of text currently being read. Similar application has been developed by (Kolak and Schilit, 2008) who provided a method for mining repeated word sequences (quotations) from very large text collections and integrated it with the Google Books archive. Other application areas may involve text summarization and information retrieval.

The paper makes the following contributions:

- It provides a new interpretation and insight in the use of semantic similarity measures for the automatic generation of links.
- It develops a novel two-step approach for the discovery of passage-passage links across potentially long documents and it identifies and discusses the selection of the parameters.

The rest of the paper is organized as follows. Section 2 presents the related work in the field. Section 3 discusses the data selected for our experiment and Section 4 describes how the data were processed in order to perform our investigation. In Section 5, the analysis in which we compared the results produced by semantic similarity measures with respect to the way people link content is presented. Section 6 then draws on this analysis and introduces the method for automatic generation of links which is finally evaluated in Section 7.

2 Related Work

In the 1990s, the main application area for link generation methods were hypertext construction systems. A survey of these methods is provided by (Wilkinson and Smeaton, 1999). In the last decade, methods for finding related documents became the de-facto standard in large digital repositories, such as PubMed or the ACM Digital Library. Search engines including Google also generate links to related pages or research articles.

Generating links pointing to units of a smaller granularity than a document, which can be considered as a task of *passage* or *focused* retrieval, has also been addressed recently. In this task, the system locates the relevant information inside the document instead of only providing a link to the document. The Initiative for the Evaluation of XML retrieval (INEX) started to play an essential role in link generation by providing tracks for the evaluation of link generation systems (Huang et al., 2008; Huang et al., 2009) using the Wikipedia collection at both the document and the passage level.

Current approaches can be divided into three groups: (1) *link-based* approaches discover new links by exploiting an existing link graph (Itakura and Clarke, 2008; Jenkinson et al., 2008; Lu et al., 2008). (2) *semi-structured* approaches try to discover new links using semi-structured information, such as the anchor texts or document titles (Geva, 2007; Dopichaj et al., 2008; Granitzer et al., 2008). (3) *purely content-based* approaches use as an input plain text only. They typically discover related resources by calculating semantic similarity based on document vectors (Allan, 1997; Green, 1998; Zeng and Bloniarz, 2004; Zhang and Kamps, 2008; He, 2008). Some of the mentioned approaches, such as (Lu et al., 2008), combine multiple approaches.

Although link generation methods are widely used in practise, more work is needed to understand which features contribute to the quality of the generated links. Work in this area includes the study of (Green, 1999) who investigated how lexical chaining based on ontologies can contribute to the quality of the generated links, or the experiments of (Zeng and Bloniarz, 2004) who compared the impact of the manually and automatically extracted keywords. There has also been effort in developing methods that can in addition to link generation assign a certain semantic type to the extracted links and thus describe the relationship between documents (Allan, 1997).

The method presented in this paper is purely content-based and therefore is applicable in any text collection. Its use in combination with link-based or semi-structured approaches is also possible. The rationale for the method comes from the analysis of the prediction potential of semantic similarity for automatic link generation presented in Section 5. Related analysis is presented in (He, 2008) which claims that linked articles are more likely to be semantically similar[1], however, the study does not provide sufficient evidence to confirm and describe this relationship. In link generation, we are more interested in asking the opposite question, i.e. whether articles with higher semantic similarity are more likely to be linked. Our study provides a new insight into this relationship and indicates that the relationship is in fact more complex than originally foreseen by He.

3 Data selection

This section introduces the document collection used for the analysis and the experiments. The following properties were required for the document collection to be selected for the experiments. First, in order to be able to measure the correlation between the way people link content and the results produced by semantic similarity measures, it was necessary to select a document collection which can be considered as relatively well interlinked. Second, it was important for us to work with a collection containing a diverse set of topics. Third, we required the collection to contain articles of varied length. We were mostly interested in long documents, which create conditions for the testing of passage retrieval methods. We decided to use the Wikipedia collection, because it satisfies all our requirements and has also been used in the INEX Link-The-Wiki-Track.

Wikipedia consists of more than four million pages spread across five hundred thousands categories. As it would be for our calculation unnecessarily expensive to work with the whole encyclopedia, a smaller, but still a sufficiently large subset of Wikipedia, which satisfies our requirements of topic diversity and document length, was selected. Our document collection was generated from articles in categories containing the words United Kingdom. This includes categories, such as United Kingdom, Geography of United Kingdom or History of the United Kingdom. There are about 3,000 such categories and 57,000 distinct articles associated to them. As longer articles provide better test conditions for passage retrieval methods, we selected the 5,000 longest articles out of these 57,000. This corresponds to a set where each article has the length of at least 1,280 words.

4 Data preprocessing

Before discussing the analysis performed on the document collection, let us briefly describe how the documents were processed and the semantic similarity calculated.

First, the N articles/documents $D = \{d_1, d_2, \ldots, d_N\}$ in our collection were preprocessed to extract plain text by removing the Wiki markup. The documents were then tokenized and a dictionary of terms $T = \{t_1, t_2, \ldots, t_M\}$ was created. Assuming that the order of words can be neglected (the bag-of-words assumption) the document collection can be represented using a $N \times M$ term-document matrix. In this way, each document is modelled as a vector corresponding to a particular row of the matrix. As it is inefficient to represent such a sparse vector in memory (most of the values are zeros), only the non-zero values were stored. *Term frequency - inverse document frequency (tfidf)* weighting was used to calculate the values of the matrix. Term frequency tf_{t_i,d_j} is a normalized frequency of term t_i in document d_j:

$$tf_{t_i,d_j} = \frac{f(t_i, d_j)}{\sum_k f(t_k, d_j)}$$

Inverse document frequency idf_{t_i} measures the general importance of term t_i in the collection of documents D by counting the number of documents which contain term t_i:

$$idf_{t_i} = \log \frac{|D|}{|d_j : t_i \in d_j|}$$

$$tfidf_{t_i,d_j} = tf_{t_i,d_j} . idf_{t_i}$$

Similarity is then defined as the function $sim(\overrightarrow{x}, \overrightarrow{y})$ of the document vectors $\overrightarrow{x}$ and $\overrightarrow{y}$. There exists a number of similarity measures used for the calculation of similarity between two vectors (Manning and Schuetze, 1999), such as *cosine*, *overlap*, *dice* or *Jaccard* measures. Some studies employ algorithms for the reduction of dimensions of the vectors prior to the calculation

[1] With respect to the cosine similarity measure.

of similarity to improve the results. These approaches may involve techniques, such as lexical chaining (Green, 1999), Latent Semantic Indexing (Deerwester et al., 1990), random indexing (Widdows and Ferraro, 2008) and Latent Dirichlet Allocation (Blei et al., 2003). In this work we intentionally adopted perhaps the most standard similarity measure - cosine similarity calculated on the *tfidf* vectors and no dimensionality reduction technique was used. The formula is provided for completeness:

$$sim_{cosine}(\overrightarrow{x}, \overrightarrow{y}) = \frac{\overrightarrow{x}.\overrightarrow{y}}{|x|.|y|}$$

Cosine similarity with *tfidf* vectors has been previously used in automatic link generation systems producing state-of-the-art results when compared to other similarity measures (Chen et al., 2004). This allows us to report on the effectiveness of the most widely used measure with respect to the way the task is completed by people. While more advanced techniques might be in some cases better predictors for link generation, we did not experiment with them as we preferred to focus on the investigation of the correlation between the most widely used measure and manually created links. Such study has to our knowledge never been done before, but it is necessary for the justification of automatic link generation methods.

5 Semantic similarity as a predictor for link generation

The document collection described in Section 3 has been analysed as follows. First, pair-wise similarities using the formulas described in Section 4 were calculated. Cosine similarity is a symmetric function and, therefore, the calculation of all inter-document similarities in the dataset of $5,000$ documents requires the evaluation of $\frac{5,000^2}{2} - 5,000 = 12,495,000$ combinations. Figure 1 shows the distribution of the document pairs (on a log_{10} scale) with respect to their similarity value. The frequency follows a power law distribution. In our case, 99% of the pairs have similarity lower than 0.1.

To compare the semantic similarity measures with the links created by Wikipedia authors, all inter-document intra-collection links, i.e. links created by users of Wikipedia commencing from and pointing to a document within our collection, were extracted. These links represent the connections as seen by the users regardless of their direction. Each of these links can be associated with a similarity value calculated in the previous step. Documents with similarity lower than 0.1 were ignored. Out of the $120,602$ document pairs with inter-document similarity higher than 0.1, $17,657$ pairs were also connected by a user-created link.

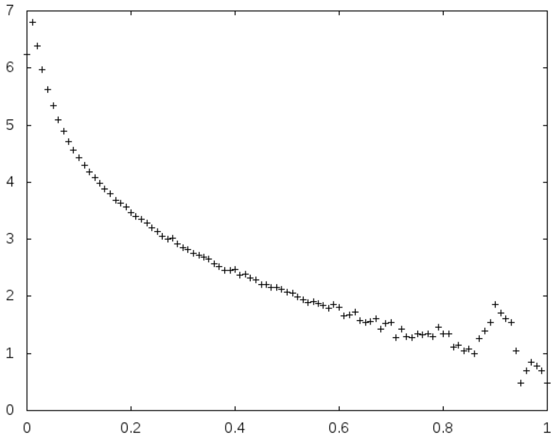

Figure 1: The histogram shows the number of document pairs on a $\log_{10}$ scale (y-axis) with respect to their cosine similarity (x-axis).

For the evaluation, interval with cosine similarity $[0.1, 1]$ was divided evenly into 100 buckets and all 120,602 document pairs were assigned to the buckets according their similarity values. From the distribution shown in Figure 1, buckets corresponding to higher similarity values contain fewer document pairs than buckets corresponding to smaller similarity values. Therefore, for each bucket, the number of user created links within the bucket was normalized by the number of document pairs in the bucket. This number is the likelihood of the document pair being linked and will be called *linked-pair likelihood.* The relation between semantic similarity and linked-pair likelihood is shown in Figure 2.

As reported in Section 2, semantic similarity has been previously used as a predictor for the automatic generation of links. The typical scenario was that the similarity between pairs of documents was calculated and the links between the

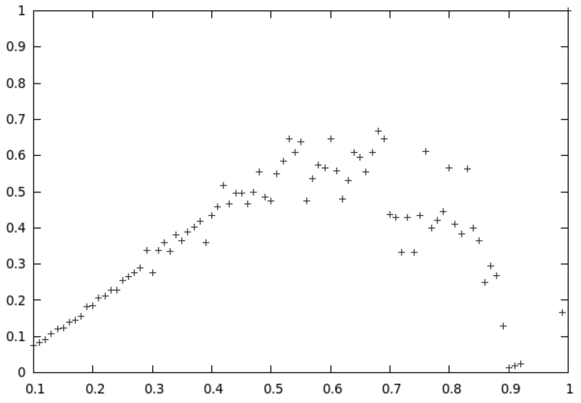

Figure 2: The linked-pair likelihood (y-axis) with respect to the cosine similarity (x-axis).

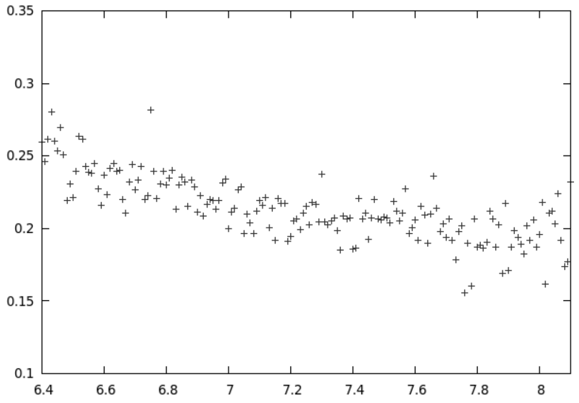

Figure 3: The average cosine similarity (y-axis) of document pairs of various length (x-axis) between which there exists a link. The x-axis is calculated as a $\log_{10}(l_1.l_2)$

most similar documents were generated (Wilkinson and Smeaton, 1999). If this approach was correct, we would expect the curve shown in Figure 2 to be monotonically increasing. However, the relation shown in Figure 2 is in accordance with our expectations only up to the point 0.55. For higher values of inter-document similarity the linked-pair likelihood does not rise or it even decreases.

Spearman's rank correlation and Pearson correlation were applied to estimate the correlation coefficients and to test the statistical significance of our observation. This was performed in two intervals: $[0, 0.55]$ and $[0.55, 1]$. A very strong positive correlation 0.986 and 0.987 have been received in the first interval for the Spearman's and Pearson coefficients respectively. A negative correlation -0.640 and -0.509 have been acquired for the second interval again for the Spearman's and Pearson coefficients respectively. All the measured correlations are significant for p-value well beyond $p < 0.001$. Very similar results have been achieved using different collections of documents.

The results indicate that high similarity value is not necessarily a good predictor for automatic link generation. A possible explanation for this phenomenon is that people create links between related documents that provide new information and therefore do not link nearly identical content. However, as content can be in general linked for various purposes, more research is needed to investigate if document pairs at different similarity levels also exhibit different qualitative properties. More specifically, can the value of semantic similarity be used as a predictor for relationship typing?

An important property of semantic similarity as a measure for automatic generation of links is the robustness with respect to the length of documents. As mentioned in Section 4, cosine similarity is by definition normalized by the product of the documents length. Ideally the cosine similarity should be independent of the documents length. To verify this in our dataset, we have taken pairs of documents between which Wikipedia users assigned links and divided them into buckets with respect to the function $\log_{10}(l_1.l_2)$, where l_1 and l_2 are the lengths of the two documents in the document pair and the logarithm is used for scaling. The value of each bucket was calculated as an average similarity of the bucket members. The results are shown in Figure 3. The graph shows that the average similarity value is slightly decreasing with respect to the length of the articles. Values -0.484 and -0.231 were obtained for Spearman's and Pearson correlation coefficients respectively. Both correlations are statistically significant for $p < 0.001$. A much stronger correlation was measured for Spearman's than for Pearson which can be explained by the fact that Spearman's correlation is calculated based on ranks rather than real values and is thus less sensitive to outliers.

Our experience from repeating the same experiment on another Wikipedia subset generated from categories containing the word Geography tells us that the decrease is even more noticeable when short and long articles are combined. The decrease in average similarity suggests that if cosine similarity is used for the automatic generation of links then document pairs with higher value of $l_1.l_2$ have a higher linked-pair likelihood than pairs with a smaller value of this quantity. In other words, links created between documents with small $l_1.l_2$ typically exhibit a larger value of semantic similarity than links created between documents with high value of $l_1.l_2$. Although the decrease may seem relatively small, we believe that this knowledge may be used for improving automatic link generation methods by adaptively modifying the thresholds with respect to the $l_1.l_2$ length.

6 Link generation method

In this section we introduce the method for the automatic generation of links. The method can be divided into two parts (1) Identification of candidate link pairs (i.e. the generation of document-to-document links) (2) Recognition of passages sharing a topic between the two documents (i.e. the generation of passage-to-passage links).

6.1 Document-to-document links

The algorithm for link generation at the granularity of a document is motivated by the findings reported in Section 5.

```
Algorithm 1: Generate document links
Input: A set of document vectors $D$,
min. sim. $\alpha$, max. sim. $\beta \in [0,1], C = \emptyset$
Output: A set $C$ of candidate links
of form $\langle d_i, d_j, sim \rangle \in C$ where $d_i$ and $d_j$ are
documents and $sim \in [0,1]$ is their similarity
for each $\{\langle d_i, d_j \rangle | i, j \in \aleph_0 \wedge i < j < |D|\}$ do
    $sim_{d_i,d_j} := similarity(d_i, d_j)$
    if $sim_{d_i,d_j} > \alpha \wedge sim_{d_i,d_j} < \beta$ then
        $C := C \cup \langle d_i, d_j, sim_{d_i,d_j} \rangle$
```

The algorithm takes as the input a set of document vectors and two constants - the minimum and maximum similarity thresholds - and iterates over all pairs of document vectors. It outputs all document vector pairs, such that their similarity is higher than α and smaller than β. For well chosen β, the algorithm does not generate links between nearly duplicate pairs. If we liked to rank the discovered links according to the confidence of the system, we would suggest to assign each pair a value using the following function.

$$rank_{d_i,d_j} = |sim_{d_i,d_j} - (\alpha + \frac{\beta - \alpha}{2})|$$

The ranking function makes use of the fact that the system is most confident in the middle of the similarity region defined by constants α and β, under the assumption that suitable values for these constants are used. The higher the rank of a document pair, the better the system's confidence.

6.2 Passage-to-passage links

Due to a high number of combinations, it is typically infeasible even for relatively small collections to generate passage-to-passage links across documents directly. However, the complexity of this task is substantially reduced when passage-to-passage links are discovered in a two-step process.

```
Algorithm 2: Generate passage links
Input: Sets $P_i, P_j$ of paragraph document
vectors for each pair in $C$
min. sim. $\gamma$, max. sim. $\delta \in [0,1]$ such that
$\alpha < \gamma \wedge \beta < \delta, , L = \emptyset$
Output: A set $L$ of passage links
of form $\langle p_{k_i}, p_{l_j}, sim \rangle \in L$ where $p_{k_i}$ and
$p_{l_j}$ are paragraphs in documents $d_i, d_j$
and $sim \in [0,1]$ is their similarity
for each $\{\langle p_{k_i}, p_{l_j} \rangle | p_{k_i} \in P_i, p_{l_j} \in P_j\}$ do
    $sim_{p_{k_i},p_{l_j}} := similarity(p_{k_i}, p_{l_j})$
    if $sim_{p_{k_i},p_{l_j}} > \gamma \wedge sim_{p_{k_i},p_{l_j}} < \delta$ then
        $L := L \cup \langle p_{k_i}, p_{l_j}, sim_{p_{k_i},p_{l_j}} \rangle$
```

As Section 5 suggests, the results of Algorithm 1 may be improved by adaptive changing of the thresholds α and β based on the length of the document vectors. More precisely, in the case of cosine similarity, this is the quantity $lr = l_1.l_2$. The value α should be higher (β lower) for pairs with low lr than for pairs with high lr and vice versa. Although the relative quantification of this ratio is left for future work, we believe that we can exploit these findings for the generation of passage-to-passage links.

More specifically, we know that the length of passages (paragraphs in our case) is lower than the length of the whole documents. Hence, the similarity of a linked passage-to-passage pair should be on average higher than the similarity of a linked document-to-document pair, as revealed by the results of our analysis. This knowledge is used within Algorithm 2 to set the parameters γ and δ. The algorithm shows, how passage-to-passage links are calculated for a single document pair previously identified by Algorithm 1. Applying the two-step process allows the discovery of document pairs, which are likely to contain strongly linked passages, at lower similarity levels and to recognize the related passages at higher similarity levels while still avoiding duplicate content.

7 Results

The experimental evaluation of the methods presented in Section 6 is divided into two parts: (1) the evaluation of document-to-document links (Algorithm 1) and (2) the evaluation of passage-to-passage links (Algorithm 2).

7.1 Evaluation of document-to-document links

As identified in Section 5 (and shown in Figure 2), the highest linked-pair likelihood does not occur at high similarity values, but rather somewhere between similarity 0.5 and 0.7. According to Figure 2, the linked-pair likelihood in this similarity region ranges from 60% to 70%. This value is in our view relatively high and we think that it can be explained by the fact that Wikipedia articles are under constant scrutiny by users who eventually discover most of the useful connections. However, how many document pairs that could be linked in this similarity region have been missed by the users? That is, how much can our system help in the discovery of possible connections?

Suppose that our task would be to find document pairs about linking of which the system is most certain. In that case we would set the thresholds α and β somewhere around these values depending on how many links we would like to obtain. In our evaluation, we have extracted pairs of documents from the region between $\alpha = 0.65$ and $\beta = 0.70$ regardless of whether there originally was a link assigned by Wikipedia users. An evaluation tool which allowed a subject to display the pair of Wiki documents next to each other and to decide whether there should or should not be a link between the documents was then developed. We did not inform the subject about the existence or non-existence of links between the pages. More specifically, the subject was asked to decide yes (link generated correctly) if and only if they found it beneficial for a reader of the first or the second article to link them together regardless of the link direction. The subject was asked to decide no (link generated incorrectly) if and only if they felt that navigating the user from or to the other document does not provide additional value. For example, in cases where the relatedness of the documents is based on their lexical rather than their semantic similarity.

The study revealed that 91% of the generated links were judged by the subject as correct and 9% as incorrect. Table 1 shows the results of the experiment with respect to the links originally assigned by the users of Wikipedia. It is interesting to notice that in 3% of the cases the subject decided not to link the articles even though they were in fact linked on Wikipedia. Overall, the algorithm discovered in 30% of the cases a useful connection which was missing in Wikipedia. This is in line with the findings of (Huang et al., 2008) who claims that the validity of existing links in Wikipedia is sometimes questionable and useful links may be missing.

An interesting situation in the evaluation occurred when the subject discovered a pair of articles with titles *Battle of Jutland* and *Night Action at the Battle of Jutland*. The Wikipedia page indicated that it is an orphan and asked users of Wikipedia to link it to other Wikipedia articles. Our method would suggest the first article as a good choice.

		Wikipedia link	
		yes	no
Subject's decision	yes	0.61	0.30
	no	0.03	0.06

Table 1: Document-to-document links from the $[0.65, 0.7]$ similarity region. The subject's decision in comparison to the Wikipedia links.

		Wikipedia link	
		yes	no
Subject's decision at page level	yes	0.16	0.10
	no	0.18	0.56

Table 2: Document-to-document candidate links generation from the $[0.2, 0.21]$ similarity region and document pairs with high lr ($lr \in [7.8 - 8]$).

7.2 Evaluation of passage-to-passage linking

The previous section provided evidence that the document-to-document linking algorithm is capable of achieving high performance when parameters α, β are well selected. However, Section 5 indicated that it is more difficult to discover links across long document pairs. Thereby, we have evaluated the passage-to-passage linking on document pairs with quite low value of similarity $[0.2, 0.21]$. According to Figure 2, this region has only 15% linked-pair likelihood.

Clearly, our goal was not to evaluate the approach in the best possible environment, but rather to check whether the method is able to discover valuable passage-to-passage links from very long articles with low similarity. Articles with this value of similarity would be typically ranked very poorly by link generation methods working at the document level.

Table 2 shows the results after the first step of the approach, described in Section 6, with respect to the links assigned by Wikipedia users. As in the previous experiment, the subject was given pairs of documents and decided whether they should or should not be linked. Parameters α and β were set to 0.2, 0.21 respectively. Table 2 indicates that that the accuracy $(16\% + 10\% = 26\%)$ is at this similarity region much lower than the one reported in Table 1, which is exactly in line with our expectations. It should be noticed that 34% of the document pairs were linked by Wikipedia users, even though only 15% would be predicted by linked-pair likelihood shown in Figure 2. This confirms that long document pairs exhibit a higher probability of being linked in the same similarity region than shorter document pairs.

		System's decision	
		yes	no
Subject's decision	yes (correct)	0.14	0.46
	no (incorrect)	0.24	0.16

Table 3: Passage-to-passage links generation for very long documents. Passages extracted from the $[0.4, 0.8]$ similarity region.

If our approach for passage-to-passage link generation (Algorithm 2) is correct, we should be able to process the documents paragraphs and detect possible passage-to-passage links. The selection of the parameters γ and δ influences the willingness of the system to generate links. For this experiment, we set the parameters γ, δ to 0.4, 0.8 respectively. The subject was asked to decide: (1) if the connection discovered by the link generation method at the granularity of passages was useful (when the system generated a link) (2) whether the decision not to generate link is correct (when the system did not generate a link). The results of this evaluation are reported in Table 3. It can be seen that the system made in 60% $(14\% + 46\%)$ of the cases the correct decision. Most mistakes were made by generating links that were not sufficiently related (24%). This might be improved by using a higher value of γ (lower value of δ).

8 Conclusions

This paper provided a new insight into the use of semantic similarity as a predictor for automatic link generation by performing an investigation in the way people link content. This motivated us in the development of a novel purely content-based approach for automatic generation of links at the granularity of both documents and paragraphs which does not expect semantic similarity and linked-pair likelihood to be directly proportional.

Abstract

This paper proposes a dependency-driven scheme to dynamically determine the syntactic parse tree structure for tree kernel-based anaphoricity determination in coreference resolution. Given a full syntactic parse tree, it keeps the nodes and the paths related with current mention based on constituent dependencies from both syntactic and semantic perspectives, while removing the noisy information, eventually leading to a dependency-driven dynamic syntactic parse tree (D-DSPT). Evaluation on the ACE 2003 corpus shows that the D-DSPT outperforms all previous parse tree structures on anaphoricity determination, and that applying our anaphoricity determination module in coreference resolution achieves the so far best performance.

1 Introduction

Coreference resolution aims to identify which noun phrases (NPs, or mentions) refer to the same real-world entity in a text. According to Webber (1979), coreference resolution can be decomposed into two complementary sub-tasks: (1) anaphoricity determination, determining whether a given NP is anaphoric or not; and (2) anaphor resolution, linking together multiple mentions of a given entity in the world. Although machine learning approaches have performed reasonably well in coreference resolution without explicit anaphoricity determination (e.g. Soon et al. 2001; Ng and Cardie 2002b; Yang et al. 2003, 2008; Kong et al. 2009), knowledge of NP anaphoricity is expected to much improve the performance of a coreference resolution system, since a non-anaphoric NP does not have an antecedent and therefore does not need to be resolved.

Recently, anaphoricity determination has been drawing more and more attention. One common approach involves the design of some heuristic rules to identify specific types of non-anaphoric NPs, such as pleonastic *it* (e.g. Paice and Husk 1987; Lappin and Leass 1994, Kennedy and Boguraev 1996; Denber 1998) and definite descriptions (e.g. Vieira and Poesio 2000). Alternatively, some studies focus on using statistics to tackle this problem (e.g., Bean and Riloff 1999; Bergsma et al. 2008) and others apply machine learning approaches (e.g. Evans 2001;Ng and Cardie 2002a, 2004,2009; Yang et al. 2005; Denis and Balbridge 2007; Luo 2007; Finkel and Manning 2008; Zhou and Kong 2009).

As a representative, Zhou and Kong (2009) directly employ a tree kernel-based method to automatically mine the non-anaphoric information embedded in the syntactic parse tree. One main advantage of the kernel-based methods is that they are very effective at reducing the burden of feature engineering for structured objects. Indeed, the kernel-based methods have been successfully applied to mine structured information in various NLP applications like syntactic parsing (Collins and Duffy, 2001; Moschitti, 2004), semantic relation extraction (Zelenko et al., 2003; Zhao and Grishman, 2005; Zhou et al. 2007; Qian et al., 2008), semantic role labeling (Moschitti, 2004); coreference resolution (Yang et al., 2006; Zhou et al., 2008). One of the key problems for the kernel-based methods is how to effectively capture the structured information according to the nature of the structured object in the specific task.

This paper advances the state-of-the-art performance in anaphoricity determination by ef-

[*] Corresponding author

fectively capturing the structured syntactic information via a tree kernel-based method. In particular, a dependency-driven scheme is proposed to dynamically determine the syntactic parse tree structure for tree kernel-based anaphoricity determination by exploiting constituent dependencies from both the syntactic and semantic perspectives to keep the necessary information in the parse tree as well as remove the noisy information. Our motivation is to employ critical dependency information in constructing a concise and effective syntactic parse tree structure, specifically targeted for tree kernel-based anaphoricity determination.

The rest of this paper is organized as follows. Section 2 briefly describes the related work on both anaphoricity determination and exploring syntactic parse tree structures in related tasks. Section 3 presents our dependency-driven scheme to determine the syntactic parse tree structure. Section 4 reports the experimental results. Finally, we conclude our work in Section 5.

2 Related Work

This section briefly overviews the related work on both anaphoricity determination and exploring syntactic parse tree structures.

2.1 Anaphoricity Determination

Previous work on anaphoricity determination can be broadly divided into three categories: heuristic rule-based (e.g. Paice and Husk 1987;Lappin and Leass 1994; Kennedy and Boguraev 1996; Denber 1998; Vieira and Poesio 2000; Cherry and Bergsma 2005), statistics-based (e.g. Bean and Riloff 1999; Cherry and Bergsma 2005; Bergsma et al. 2008) and learning-based methods (e.g. Evans 2001; Ng and Cardie 2002a; Ng 2004; Yang et al. 2005; Denis and Balbridge 2007; Luo 2007; Finkel and Manning 2008; Zhou and Kong 2009; Ng 2009).

The heuristic rule-based methods focus on designing some heuristic rules to identify specific types of non-anaphoric NPs. Representative work includes: Paice and Husk (1987), Lappin and Leass (1994) and Kennedy and Boguraev (1996). For example, Kennedy and Boguraev (1996) looked for modal adjectives (e.g. “necessary”) or cognitive verbs (e.g. “It is thought that…” in a set of patterned constructions) in identifying pleonastic *it*.

Among the statistics-based methods, Bean and Riloff (1999) automatically identified existential definite NPs which are non-anaphoric. The intuition behind is that many definite NPs are not anaphoric since their meanings can be understood from general world knowledge, e.g. “the FBI”. They found that existential NPs account for 63% of all definite NPs and 76% of them could be identified by syntactic or lexical means. Cherry and Bergsma (2005) extended the work of Lappin and Leass (1994) for large-scale anaphoricity determination by additionally detecting pleonastic *it*. Bergsma et al. (2008) proposed a distributional method in detecting non-anaphoric pronouns. They first extracted the surrounding context of the pronoun and gathered the distribution of words that occurred within the context from a large corpus, and then identified the pronoun either anaphoric or non-anaphoric based on the word distribution.

Among the learning-based methods, Evans (2001) automatically identified the non-anaphoricity of pronoun *it* using various kinds of lexical and syntactic features. Ng and Cardie (2002a) employed various domain-independent features in identifying anaphoric NPs. They trained an anaphoricity classifier to determine whether a NP was anaphoric or not, and employed an independently-trained coreference resolution system to only resolve those mentions which were classified as anaphoric. Experiments showed that their method improved the performance of coreference resolution by 2.0 and 2.6 to 65.8 and 64.2 in F1-measure on the MUC-6 and MUC-7 corpora, respectively. Ng (2004) examined the representation and optimization issues in computing and using anaphoricity information to improve learning-based coreference resolution. On the basis, he presented a corpus-based approach (Ng, 2009) for achieving global optimization by representing anaphoricity as a feature in coreference resolution. Experiments on the ACE 2003 corpus showed that their method improved the overall performance by 2.8, 2.2 and 4.5 to 54.5, 64.0 and 60.8 in F1-measure on the NWIRE, NPAPER and BNEWS domains, respectively. However, he did not look into the contribution of anaphoricity determination on coreference resolution of different NP types. Yang et al. (2005) made use of non-anaphors to create a special class of training instances in the twin-candidate model (Yang et al. 2003) and improved the performance by 2.9 and 1.6 to 67.3 and 67.2 in F1-measure on the MUC-6 and MUC-7 corpora, respectively. However, their experiments show that eliminating non-anaphors using an anaphoricity determination module in advance harms the performance. Denis and Balbridge (2007) employed an integer linear programming (ILP) formulation for coreference resolution which modeled anaphoricity and coreference as a joint task, such that each local model informed the other for the final assignments. Experiments on the ACE 2003 corpus showed that this joint anaphoricity-coreference ILP formulation improved the F1-measure by 3.7-5.3 on various domains. However, their experiments assume true ACE mentions (i.e. all the ACE mentions are already known from the annotated corpus). Therefore, the actual effect of this joint anaphoricity-coreference ILP formulation on fully automatic coreference resolution is still unclear. Luo (2007) proposed a twin-model for coreference resolution: a link component, which models the coreferential relationship between an anaphor and a candidate antecedent, and a creation component, which models the possibility that a NP was not coreferential with any candidate antecedent. This method combined the probabilities returned by the creation component (an anaphoricity model) with the link component (a coreference model) to score a coreference partition, such that a partition was penalized whenever an anaphoric mention was resolved. Finkel and Manning (2008) showed that transitivity constraints could be incorporated into an ILP-based coreference resolution system and much improved the performance. Zhou and Kong (2009) employed a global learning method in determining the anaphoricity of NPs via a label propagation algorithm to improve learning-based coreference resolution. Experiments on the ACE 2003 corpus demonstrated that this method was very effective. It could improve the F1-measure by 2.4, 3.1 and 4.1 on the NWIRE, NPAPER and BNEWS domains, respectively. Ng (2009) presented a novel approach to the task of anaphoricity determination based on graph minimum cuts and demonstrated the effectiveness in improving a learning-based coreference resolution system.

In summary, although anaphoricity determination plays an important role in coreference resolution and achieves certain success in improving the overall performance of coreference resolution, its contribution is still far from expectation.

2.2 Syntactic Parse Tree Structures

For a tree kernel-based method, one key problem is how to represent and capture the structured syntactic information. During recent years, various tree kernels, such as the convolution tree kernel (Collins and Duffy, 2001), the shallow parse tree kernel (Zelenko et al 2003) and the dependency tree kernel (Culota and Sorensen, 2004), have been proposed in the literature. Among these tree kernels, the convolution tree kernel represents the state-of-the art and has been successfully applied by Collins and Duffy (2002) on syntactic parsing, Zhang et al. (2006) on semantic relation extraction and Yang et al. (2006) on pronoun resolution.

Given a tree kernel, the key issue is how to generate a syntactic parse tree structure for effectively capturing the structured syntactic information. In the literature, various parse tree structures have been proposed and successfully applied in some NLP applications. As a representative, Zhang et al. (2006) investigated five parse tree structures for semantic relation extraction and found that the Shortest Path-enclosed Tree (SPT) achieves the best performance on the 7 relation types of the ACE RDC 2004 corpus. Yang et al. (2006) constructed a document-level syntactic parse tree for an entire text by attaching the parse trees of all its sentences to a new-added upper node and examined three possible parse tree structures (Min-Expansion, Simple-Expansion and Full-Expansion) that contain different substructures of the parse tree for pronoun resolution. Experiments showed that their method achieved certain success on the ACE 2003 corpus and the simple-expansion scheme performs best. However, among the three explored schemes, there exists no obvious overwhelming one, which can well cover structured syntactic information. One problem of Zhang et al. (2006)

and Yang et al. (2006) is that their parse tree structures are context-free and do not consider the information outside the sub-trees. Hence, their ability of exploring structured syntactic information is much limited. Motivated by Zhang et al. (2006) and Yang et al. (2006), Zhou et al. (2007) extended the SPT to become context-sensitive (CS-SPT) by dynamically including necessary predicate-linked path information. Zhou et al. (2008) further proposed a dynamic-expansion scheme to automatically determine a proper parse tree structure for pronoun resolution by taking predicate- and antecedent competitor-related information in consideration. Evaluation on the ACE 2003 corpus showed that the dynamic-expansion scheme can well cover necessary structured information in the parse tree for pronoun resolution. One problem with the above parse tree structures is that they may still contain unnecessary information and also miss some useful context-sensitive information. Qian et al. (2008) dynamically determined the parse tree structure for semantic relation extraction by exploiting constituent dependencies to keep the necessary information in the parse tree as well as remove the noisy information. Evaluation on the ACE RDC 2004 corpus showed that their dynamic syntactic parse tree structure outperforms all previous parse tree structures. However, their solution has the limitation in that the dependencies were found according to some manually-written ad-hoc rules and thus may not be easily applicable to new domains and applications.

This paper proposes a new scheme to dynamically determine the syntactic parse tree structure for anaphoricity determination and systematically studies the application of an explicit anaphoricity determination module in improving coreference resolution.

3 Dependency-driven Dynamic Syntactic Parse Tree

Given a full syntactic parse tree and a NP in consideration, one key issue is how to choose a proper syntactic parse tree structure to well cover structured syntactic information in the tree kernel computation. Generally, the more a syntactic parse tree structure includes, the more structured syntactic information would be available, at the expense of more noisy (or unnecessary) information.

It is well known that dependency information plays a key role in many NLP problems, such as syntactic parsing, semantic role labeling as well as semantic relation extraction. Motivated by Qian et al. (2008) and Zhou et al. (2008), we propose a new scheme to dynamically determine the syntactic parse tree structure for anaphoricity determination by exploiting constituent dependencies from both the syntactic and semantic perspectives to distinguish the necessary evidence from the unnecessary information in the syntactic parse tree. That is, constituent dependencies are explored from two aspects: syntactic dependencies and semantic dependencies.

1) **Syntactic Dependencies:** The Stanford dependency parser[1] is employed as our syntactic dependency parser to automatically extract various syntactic (i.e. grammatical) dependencies between individual words. In this paper, only immediate syntactic dependencies with current mention are considered. The intuition behind is that the immediate syntactic dependencies carry the major contextual information of current mention.
2) **Semantic Dependencies:** A state-of-the-art semantic role labeling (SRL) toolkit (Li et al. 2009) is employed for extracting various semantic dependencies related with current mention. In this paper, semantic dependencies include all the predicates heading any node in the root path from current mention to the root node and their compatible arguments (except those overlapping with current mention).

We name our parse tree structure as a dependency-driven dynamic syntactic parse tree (D-DSPT). The intuition behind is that the dependency information related with current mention in the same sentence plays a critical role in anaphoricity determination. Given the sentence enclosing the mention under consideration, we can get the D-DSPT as follows: (Figure 1 illustrates an example of the D-DSPT generation given the sentence “Mary said the woman in the room bit her” with “woman” as current mention.)

xcomp(said-2, her-9)

(c) the syntactic dependencies returned from the Stanford dependency parser with immediate ones in *italic*

(d) the parse tree after attaching all the immediate syntactic dependencies

(e) the parse tree after attaching semantic dependencies

Figure 1: An example of generating the dependency-driven dynamic syntactic parse tree

1) Generating the full syntactic parse tree of the given sentence using a full syntactic parser. In this paper, the Charniak parser (Charniak 2001) is employed and Figure 1 (a) shows the resulting full parse tree.

2) Keeping only the root path from current mention to the root node of the full parse tree. Figure 1(b) shows the root path corresponding to the current mention "woman". In the following steps, we attach the above two types of dependency information to the root path.

3) Extracting all the syntactic dependencies in the sentence using a syntactic dependency parser, and attaching all the nodes, which have immediate dependency relationship with current mention, and their corresponding paths to the root path. Figure 1(c) illustrates the syntactic dependences extracted from the sentence, where the ones in italic mean immediate dependencies with current mention. Figure 1(d) shows the parse tree structure after considering syntactic dependencies.

4) Attaching all the predicates heading any node in the root path from current mention to the root node and their corresponding paths to the root path. For the example sentence, there are two predicates "said" and "bit", which head the "VP" and "S" nodes in the root path respectively. Therefore, these two predicates and their corresponding paths should be attached to the root path as shown in Figure 1(e). Note that the predicate "bit" and its corresponding path has already been attached in Stop (3). As a result, the predicate-related information can be attached. According to Zhou and Kong (2009), such information is important to definite NP resolution.

5) Extracting the semantic dependencies related with those attached predicates using a (shallow) semantic parser, and attaching all the compatible arguments (except those overlapping with current mention) and their corresponding paths to the root path. For example, as shown in Figure 1(e), since the arguments "Mary" and "her" are compatible with current mention "woman", these two nodes and their corresponding paths are attached while the argument "room" is not since its gender does not agree with current mention.

In this paper, the similarity between two parse trees is measured using a convolution tree kernel, which counts the number of common sub-tree as the syntactic structure similarity between two parse trees. For details, please refer to Collins and Duffy (2001).

4 Experimentation and Discussion

This section evaluates the performance of dependency-driven anaphoricity determination and its application in coreference resolution on the ACE 2003 corpus.

4.1 Experimental Setting

The ACE 2003 corpus contains three domains: newswire (NWIRE), newspaper (NPAPER), and broadcast news (BNEWS). For each domain, there exist two data sets, training and devtest, which are used for training and testing.

For preparation, all the documents in the corpus are preprocessed automatically using a pipeline of NLP components, including tokenization and sentence segmentation, named entity recognition, part-of-speech tagging and noun phrase chunking. Among them, named entity recognition, part-of-speech tagging and noun phrase chunking apply the same state-of-the-art HMM-based engine with error-driven learning capability (Zhou and Su, 2000 & 2002). Our statistics finds that 62.0%, 58.5% and 61.4% of entity mentions are preserved after preprocessing on the NWIRE, NPAPER and BNEWS domains of the ACE 2003 training data respectively while only 89.5%, 89.2% and 94% of entity mentions are preserved after preprocessing on the NWIRE, NPAPER and BNEWS domains of the ACE 2003 devtest data. This indicates the difficulty of coreference resolution. In addition, the corpus is parsed using the Charniak parser for syntactic parsing and the Stanford dependency parser for syntactic dependencies while corresponding semantic dependencies are extracted using a state-of-the-art semantic role labeling toolkit (Li et al. 2009). Finally, we use the SVM-light[2] toolkit with the tree kernel function as the classifier. For comparison purpose, the training parameters C (SVM) and λ (tree kernel) are set to 2.4 and 0.4 respectively, as done in Zhou and Kong (2009).

For anaphoricity determination, we report the performance in Acc^+ and Acc^-, which measure the accuracies of identifying anaphoric NPs and non-anaphoric NPs, respectively. Obviously, higher Acc^+ means that more anaphoric NPs would be identified correctly, while higher Acc^- means that more non-anaphoric NPs would be filtered out. For coreference resolution, we report the performance in terms of recall, precision, and F1-measure using the commonly-used model theoretic MUC scoring program (Vilain et al. 1995). To see whether an improvement is significant, we also conduct significance testing using paired t-test. In this paper, '***', '**' and '*' denote p-values of an improvement smaller than 0.01, in-between (0.01, 0,05] and bigger than 0.05, which mean significantly better, moderately better and slightly better, respectively.

4.2 Experimental Results

Performance of anaphoricity determination

Table 1 presents the performance of anaphoricity determination using the convolution tree kernel on D-DSPT. It shows that our method achieves the accuracies of 83.27/77.13, 86.77/80.25 and 90.02/64.24 on identifying anaphoric/non-anaphoric NPs in the NWIRE, NPAPER and BNEWS domains, respectively. This suggests that our approach can effectively filter out about 75% of non-anaphoric NPs and keep about 85% of anaphoric NPs. In comparison, in the three domains Zhou and Kong (2009) achieve the accuracies of 76.5/82.3, 78.9/81.6 and 74.3/83.2, respectively, using the tree kernel on a dynamically-extended tree (DET). This suggests that their method can filter out about 82% of non-anaphoric NPs and only keep about 76% of anaphoric NPs. In comparison, their method outperforms our method on filtering out more non-anaphoric NPs while our method outperforms their method on keeping more anaphoric NPs in coreference resolution. While a coreference resolution system can detect some non-anaphoric NPs (when failing to find the antecedent candidate), filtering out anaphoric NPs in anaphoricity determination would definitely cause errors and it is almost impossible to recover. Therefore, it is normally more important to keeping more anaphoric NPs than filtering out more non-anaphoric NPs. Table 1 further presents the performance of anaphoricity determination on different NP types. It shows that our method performs best at keeping pronominal NPs and filtering out proper NPs.

Table 4: Performance comparison with other systems

Table 2 further presents the contribution of including syntactic and semantic dependencies in the D-DSPT on anaphoricity determination by excluding one or both of them. It shows that both syntactic dependencies and semantic dependencies contribute significantly (***).

Performance of coreference resolution

We have evaluated the effect of our D-DSPT-based anaphoricity determination module on coreference resolution by including it as a preprocessing step to a baseline coreference resolution system without explicit anaphoricity determination, by filtering our those non-anaphoric NPs according to the anaphoricity determination module. Here, the baseline system employs the same set of features, as adopted in the single-candidate model of Yang et al. (2003) and uses a SVM-based classifier with the feature-based RBF kernel. Table 3 presents the detailed performance of the coreference resolution system without anaphoricity determination, with D-DSPT-based anaphoricity determination and. with golden anaphoricity determination. Table 3 shows that:

1) There is a performance gap of 6.4, 6.1 and 7.0 in F1-measure on the NWIRE, NPAPER and BNEWS domain, respectively, between the coreference resolution system with golden anaphoricity determination and the baseline system without anaphoricity determination. This suggests the usefulness of proper anaphoricity determination in coreference resolution. This also agrees with Stoyanov et al. (2009) which measured the impact of golden anaphoricity determination on coreference resolution using only the annotated anaphors in both training and testing.

2) Compared to the baseline system without anaphoricity determination, the D-DSPT-based anaphoricity determination module improves the performance by 4.1(***), 3.9(***) and 5.0(***) to 63.2, 67.4 and 61.6 in F1-measure on the NWIRE, NPAPER and BNEWS domains, respectively, due to a large gain in precision and a much smaller drop in recall. In addition, D-DSPT-based anaphoricity determination can not only much improve the performance of coreference resolution on pronominal NPs (***) but also on definite NPs(***) and indefinite NPs(***) while the improvement on proper NPs can be ignored due to the fact that proper NPs can be well addressed by the simple abbreviation feature in the baseline system.

3) D-DSPT-based anaphoricity determination still lags (2.3, 2.2 and 2.0 on the NWIRE, NPAPER and BNEWS domains, respectively) behind golden anaphoricity determination in improving the overall performance of coreference resolution. This suggests that there exists some room in the performance improvement for anaphoricity determination.

Performance comparison with other systems

Table 4 compares the performance of our system with other systems. Here, Zhou and Kong (2009) use the same set of features with ours in the baseline system and a dynamically-extended tree structure in anaphoricity determination. Ng (2009) uses 33 features as described in Ng (2007) and a graph minimum cut algorithm in anaphoricity determination. It shows that the overall performance of our baseline system is almost as good as that of Zhou and Kong (2009) and a bit better than Ng's (2009).

For overall performance, our coreference resolution system with D-DSPT-based anaphoricity determination much outperforms Zhou and Kong (2009) in F1-measure by 1.4, 2.2 and 2.0 on the NWIRE, NPAPER and BNEWS domains, respectively, due to the better inclusion of dependency information. Detailed evaluation shows that such improvement comes from coreference resolution on both pronominal and definite NPs (Please refer to Table 6 in Zhou and Kong, 2009). Compared with Zhou and Kong (2009) and Ng (2009), our approach achieves the best F1-measure so far for each dataset.

5 Conclusion and Further Work

This paper systematically studies a dependency-driven dynamic syntactic parse tree (DDST) for anaphoricity determination and the application of an explicit anaphoricity determination module in improving learning-based coreference resolution. Evaluation on the ACE 2003 corpus indicates that D-DSPT-based anaphoricity determination much improves the performance of coreference resolution.

To our best knowledge, this paper is the first research which directly explores constituent dependencies in tree kernel-based anaphoricty determination from both syntactic and semantic perspectives.

For further work, we will explore more structured syntactic information in coreference resolution. In addition, we will study the interaction between anaphoricity determination and coreference resolution and better integrate anaphoricity determination with coreference resolution.

Abstract

This paper describes how to cluster together the phrases of a phrase-based statistical machine translation (SMT) system, using information in the phrase table itself. The clustering is symmetric and recursive: it is applied both to source-language and target-language phrases, and the clustering in one language helps determine the clustering in the other. The phrase clusters have many possible uses. This paper looks at one of these uses: smoothing the conditional translation model (TM) probabilities employed by the SMT system. We incorporated phrase-cluster-derived probability estimates into a baseline loglinear feature combination that included relative frequency and lexically-weighted conditional probability estimates. In Chinese-English (C-E) and French-English (F-E) learning curve experiments, we obtained a gain over the baseline in 29 of 30 tests, with a maximum gain of 0.55 BLEU points (though most gains were fairly small). The largest gains came with medium (200-400K sentence pairs) rather than with small (less than 100K sentence pairs) amounts of training data, contrary to what one would expect from the paraphrasing literature. We have only begun to explore the original smoothing approach described here.

1 Introduction and Related Work

The source-language and target-language "phrases" employed by many statistical machine translation (SMT) systems are anomalous: they are arbitrary sequences of contiguous words extracted by complex heuristics from a bilingual corpus, satisfying no formal linguistic criteria. Nevertheless, phrase-based systems perform better than word-based systems (Koehn 2010, pp. 127-129). In this paper, we look at what happens when we cluster together these anomalous but useful entities.

Here, we apply phrase clustering to obtain better estimates for "backward" probability P(**s**|**t**) and "forward" probability P(**t**|**s**), where **s** is a source-language phrase, **t** is a target-language phrase, and phrase pair (**s**,**t**) was seen at least once in training data. The current work is thus related to work on smoothing P(**s**|**t**) and P(**t**|**s**) – see (Foster *et al.*, 2006). The relative frequency estimates for P(**s**|**t**) and P(**t**|**s**) are $P_{RF}(s \mid t) = \#(s,t)/\#t$ and $P_{RF}(t \mid s) = \#(s,t)/\#s$, where *#(s,t)* denotes the number of times phrase pair (**s**,**t**) was observed, *etc*. These estimates are typically smoothed with "lexical" estimates found by breaking phrases **s** and **t** into words. We adopt a different idea, that of smoothing P_{RF}(**s**|**t**) and P_{RF}(**t**|**s**) with estimates obtained from phrases that have similar meanings to **s** and **t**. In our experiments, the two methods were combined, yielding an improvement over lexical smoothing alone – this indicates they provide complementary information. *E.g.*, lexical estimates don't work well for non-compositional phrases like "kick the bucket" - our method might cluster this phrase with "die" and "expire" and thus provide better smoothing. The research that comes closest to ours is the work of Schwenk *et al.* (2007) on continuous space N-gram models, where a neural network is employed to smooth translation probabilities. However, both Schwenk *et al.*'s smoothing technique

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 608–616,
Beijing, August 2010

and the system to which it is applied are quite different from ours.

Phrase clustering is also somewhat related to work on paraphrases for SMT. Key papers in this area include (Bannard and Callison-Burch, 2005), which pioneered the extraction of paraphrases from bilingual parallel corpora, (Callison-Burch *et al.*, 2006) which showed that paraphrase generation could improve SMT performance, (Callison-Burch, 2008) and (Zhao *et al.*, 2008) which showed how to improve the quality of paraphrases, and (Marton *et al.*, 2009) which derived paraphrases from monolingual data using distributional information. Paraphrases typically help SMT systems trained on under 100K sentence pairs the most.

The phrase clustering algorithm in this paper outputs groups of source-language and target-language phrases with similar meanings: paraphrases. However, previous work on paraphrases for SMT has aimed at finding translations for source-language phrases in the system's input that weren't seen during system training. Our approach is completely useless in this situation: it only generates new information for target or source phrases that are already in the system's phrase table. Thus, we find paraphrases for many of the source and target phrases that **are** in the phrase table, while the work cited above looks for paraphrases of source phrases that are **not** in the phrase table.

Our work also differs from most work on paraphrases in that information is extracted not from sources outside the SMT system (*e.g.*, pivot languages or thesauri) but from the system's phrase table. In this respect if no other, it is similar to Chiang's classic work on hierarchical phrase-based systems (Chiang, 2005), though Chiang was mining a very different type of information from phrase tables.

Because of all these differences between work on paraphrasing and the phrase clustering approach, both in terms of the input information and where they are best applied, we did not experimentally compare the two approaches.

2 Deriving Conditional Probabilities from Phrase Clusters

Given phrase clusters in the source and target languages, how would one derive estimates for conditional probabilities P(**s**|**t**) and P(**t**|**s**)? We assume that the clustering is "hard": each source phrase **s** belongs to exactly one cluster C(**s**), and each target phrase **t** belongs to exactly one cluster C(**t**). Some of these clusters will contain singleton phrases, and others will contain more than one phrase. Let "#" denote the total number of observations in the training data associated with a phrase or phrase cluster. *E.g.*, suppose the English cluster C_S contains the three phrases "red", "dark red", and "burgundy", with 50, 25, and 10 observations in the training data respectively – then $\#(C_S) = 85$. Also, let $\#(C_S,C_T)$ be the number of co-occurrences in the training data of source-language cluster C_S and target-language cluster C_T.

The phrase-cluster-based probabilities P_{PC} are:

$$P_{PC}(s \mid t) = P(s \mid C(s)) \times P(C(s) \mid C(t)) = \frac{\#(s)}{\#C(s)} \times \frac{\#(C(s),C(t))}{\#C(t)} \quad (1)$$

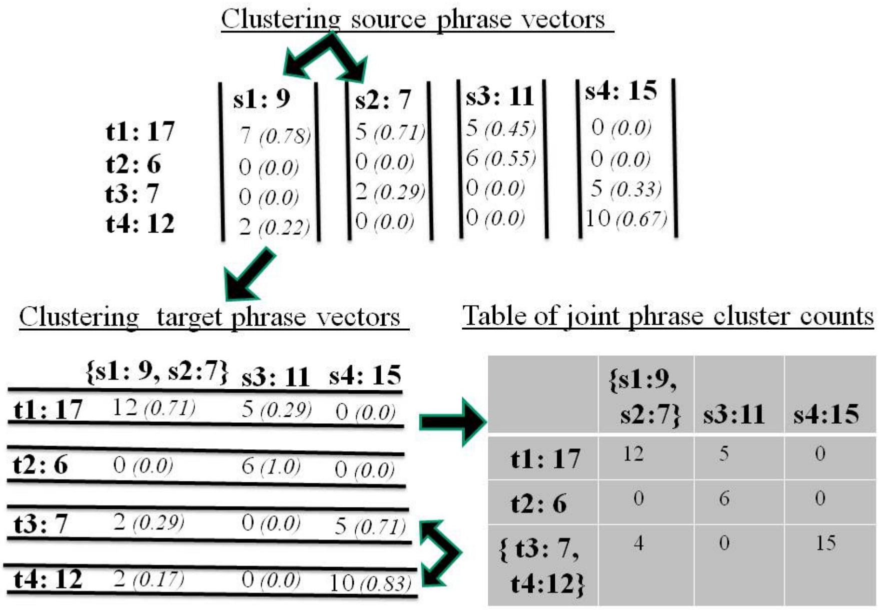
and

$$P_{PC}(t \mid s) = P(t \mid C(t)) \times P(C(t) \mid C(s)) = \frac{\#(t)}{\#C(t)} \times \frac{\#(C(s),C(t))}{\#C(s)} \quad (2)$$

Note that the P_{PC} will often be non-zero where the corresponding relative frequency estimates P_{RF} were zero (the opposite can't happen). Also, the P_{PC} will be most useful where the phrase being conditioned on was seldom seen in the training data. If **t** was seen 1,000 times during training, the P_{RF}(**s**|**t**) are reliable and don't need smoothing; but if **t** was seen 6 times, P_{PC}(**s**|**t**) may yield valuable extra information. The same kind of argument applies to estimation of P(**t**|**s**).

3 Clustering Phrases

We used only information "native" to phrase tables to cluster phrases. Two types of similarity metric between phrases or phrase clusters were employed: count-based metrics and edit-based metrics. The former are based on phrase co-occurrence counts; the latter are based on the word sequences that make up the phrases. Each has its advantages. Count-based metrics can deduce from the similar translations of two phrases that they have similar meanings, despite dissimilarity between the two word sequences – *e.g.*, they can deduce that "red" and "burgundy" belong in the same cluster. However, these metrics are unreliable when total counts are low, since phrase co-occurrences are determined by a noisy alignment process. Edit-based metrics are independent of how often phrases were observed. However, sometimes they can be fooled by phrases that have similar word sequences but different meanings (*e.g.*, "the dog bit the man"



Clustering source phrase vectors

Figure 1: Example of phrase clustering

and "the man bit the dog", or "walk on the beach" and "don't walk on the beach"). In our experiments, we used a combination of count-based and edit-based metrics to cluster phrases (by simply multiplying the metrics together). However, we invested most of our effort in perfecting the count-based component: our edit-based metric was fairly naïve.

If we rely mainly on count-based similarity between phrases to cluster them, and this kind of similarity is most reliable when phrases have high counts, yet we need phrase-cluster-based estimates most for phrases with low counts, aren't we carrying out clustering on the phrases that need it least? Our hope was that there is a class of phrases with intermediate counts (*e.g.*, with 3-15 observations in the training data) that can be clustered reliably, but still benefit from phrase-cluster-based probability estimates.

3.1 Count-based clustering: overview

Figure 1 shows count-based phrase clustering. One first arbitrarily picks a language (either source or target) and then clusters together some of the phrases in that language. One then switches to the other language and clusters phrases in that language, then switches back to the first one, and so on until enough clustering has taken place.

Each phrase or phrase cluster is represented by the vector of its co-occurrence counts. To calculate the similarity between two phrase clusters, one first normalizes their count vectors. At the top of **Figure 1**, source phrase **s1** occurred 9 times: 7 times aligned with target phrase **t1**, 2 times aligned with **t4**. For source similarity computation, the entry for (**s1**,**t1**) is normalized to 7/9 = 0.78 and the entry for (**s1**,**t4**) is normalized to 2/9 = 0.22 (these normalized values are shown in brackets and italics after the counts).

The two most similar normalized vectors at the top of **Figure 1** are those associated with phrases **s1** and **s2**. These phrases are merged by adding corresponding counts, yielding a new vector associated with the new phrase cluster {**s1**, **s2**}. In real life, one would now do more source-language clustering on the source language side; in this example, we immediately proceed to target-language clustering (carried out in target language space). Note that the target similarity calculations are affected by the previous source clustering (because **s1** and **s2** are now represented by the same coordinate, **t3** and **t4** are now closer than they were in the initial table). In this manner, we can iterate back and forth between the two languages. The final output is a table of joint phrase cluster counts, which is used to estimate the P_{PC} (see previous section).

3.2 Count-based clustering: details

Count-based similarity is computed as follows:

1. Phrase alignment is a noisy process, so we first apply a transformation analogous to *tf-idf* in information retrieval (Salton and McGill, 1986) to phrase cluster

counts. For source similarity computation, each co-occurrence count #(C$_{\mathbf{S}}$,C$_{\mathbf{T}}$) between source cluster C$_{\mathbf{S}}$ and target cluster C$_{\mathbf{T}}$ is multiplied by a factor that reflects the information content of C$_{\mathbf{T}}$. Let #diff(C$_{\mathbf{S}}$) be number of clusters on the source side, and let #[C$_{\mathbf{T}}$>0] for a particular target cluster C$_{\mathbf{T}}$ be the number of source clusters C$_{\mathbf{S}}$ that co-occur with C$_{\mathbf{T}}$. Then let $\#'(C_S,C_T)=\#(C_S,C_T)\times\log(\#\mathit{diff}(C_S)/\#[C_T>0])$. Similarly, for target similarity computation, let $\#'(C_S,C_T)=\#(C_S,C_T)\times\log(\#\mathit{diff}(C_T)/\#[C_S>0])$. *E.g.*, in source similarity computation, if C$_{\mathbf{T}}$ co-occurs with all source clusters, its contribution will be set to zero (because it carries little information).

2. We normalize by dividing each vector of *tf-idf* counts $\#'(C_S,C_T)$ by the total number of observations in the vector.
3. We compute the similarity between each pair of *tf-idf* vectors using either the cosine measure (Salton and McGill, 1986) or one of a family of probabilistic metrics described below.
4. We cluster together the most similar vectors; this involves summing the unmodified counts #(C$_{\mathbf{S}}$,C$_{\mathbf{T}}$) of the vectors (*i.e.*, the *tf-idf* transformation is only applied for the purposes of similarity calculation and is not retained).

Now, we'll describe the probabilistic metrics we considered. For a count vector of dimension D, **u** = (u_1, u_2, …, u_D), define a function $I(\underline{\mathbf{u}})=u_1\times\log(u_1/\sum_i u_i)+\ldots+u_D\times\log(u_D/\sum_i u_i)$. *I*(**u**) is a measure of how well the data in **u** are modeled by the normalized vector ($u_1/\Sigma_i u_i$, …, $u_D/\Sigma_i u_i$). Thus, when two count vectors **u** and **v** are merged (by adding them) we have the following measure of the loss in modeling accuracy:

Probability Loss (PL):

$$PL(\underline{\mathbf{u}},\underline{\mathbf{v}})=I(\underline{\mathbf{u}})+I(\underline{\mathbf{v}})-I(\underline{\mathbf{u}}+\underline{\mathbf{v}})\ . \qquad (3)$$

However, if we choose merges with the lowest PL, we will usually merge only vectors with small counts. We are more interested in the average impact of a merge, so we define

Average Probability Loss (APL):

$$APL(\underline{\mathbf{u}},\underline{\mathbf{v}})=(I(\underline{\mathbf{u}})+I(\underline{\mathbf{v}})-I(\underline{\mathbf{u}}+\underline{\mathbf{v}}))/(\sum_i u_i+\sum_i v_i)\ . \quad (4)$$

In our initial experiments, APL worked better than PL. However, APL had a strange side-effect. Most of the phrase clusters it induced made intuitive sense, but there were typically three or four clusters with large numbers of observations on both language sides that grouped together phrases with wildly disparate meanings. Why does APL induce these "monster clusters"?

Consider two count vectors **u** and **v**. If $\Sigma_i u_i$ is very big and $\Sigma_i v_i$ is small, then *I*(**u**) and *I*(**u** + **v**) will be very similar, and APL will be approximately *I*(**v**) /[$\Sigma_i u_i + \Sigma_i v_i$] which will be close to zero. Thus, the decision will probably be made to merge **u** and **v**, even if they have quite different semantics. The resulting cluster, whose counts are represented by **u** + **v**, is now even bigger and even more likely to swallow up other small count vectors in the next rounds of merging: it becomes a kind of black hole.

To deal with this problem, we devised another metric. Let $I(\underline{\mathbf{u}}\,|\,\underline{\mathbf{v}})=u_1\times\log(v_1/\sum_i v_i)+\ldots+u_D\times\log(v_D/\sum_i v_i)$. This is a measure of how well the counts in **v** predict the distribution of counts in **u**. Then let

Maximum Average Probability Loss (MAPL):

$$MAPL(\underline{\mathbf{u}},\underline{\mathbf{v}})=\max(\frac{I(\underline{\mathbf{u}})-I(\underline{\mathbf{u}}\,|\,\underline{\mathbf{u}}+\underline{\mathbf{v}})}{\sum_i u_i},\frac{I(\underline{\mathbf{v}})-I(\underline{\mathbf{v}}\,|\,\underline{\mathbf{u}}+\underline{\mathbf{v}})}{\sum_i v_i})\ .(5)$$

The first term inside the maximum indicates the average probability loss for an observation in **u** when it is modeled by **u**+**v** instead of **u**; similarly, the second term indicates the average probability loss for an observation in **v**. If we merge vector pairs with the lowest values of MAPL, we will never merge vectors in a way that will cause a large loss to either of the two parents.

In practice, we found that all these metrics worked better when multiplied by the Dice coefficient based distance. For **u** and **v**, this is $Dice(\underline{\mathbf{u}},\underline{\mathbf{v}})=1-\frac{2\times|\underline{\mathbf{u}}\cap\underline{\mathbf{v}}|}{|\underline{\mathbf{u}}|+|\underline{\mathbf{v}}|}$, where "|**u**|" means the number of non-zero count entries in **u**, and "$|\underline{\mathbf{u}}\cap\underline{\mathbf{v}}|$" is the number of count entries that are non-zero in **u** and **v.**

3.3 Edit-based similarity

In most of our experiments, count-based metrics were combined with edit-based metrics; we put little effort into optimizing the edit metrics. Let MCWS stand for "maximum common word sequence". For phrases p_1 and p_2, we define

$$Edit(p_1, p_2) = 1 - \frac{2 \times len(MCWS(p_1, p_2))}{len(p_1) + len(p_2)}. \quad (6)$$

where *len*() returns the number of words. This metric doesn't take word identities into account; in future work, we may weight differences involving content words more heavily.

We also defined an edit-based metric for distance between phrase clusters. Let cluster 1 have phrases "red" (10); "burgundy" (5); "resembling scarlet" (2) and cluster 2 have "dark burgundy" (7); "scarlet" (3) (number of observations in brackets). What is the edit distance between clusters 1 and 2? We defined the distance as that between the two phrases with the most observations in each cluster. Thus, distance between clusters 1 and 2 would be Edit("red", "dark burgundy")=1.0. Other definitions are possible.

3.4 Examples of phrase clusters

Figure 2 shows an English phrase cluster learned during C-E experiments by a metric combining count-based and edit-based information. Each phrase is followed by its count in brackets; we don't show phrases with low counts. Since our edit distance sees words as atoms (it doesn't know about morphology), the phrases containing "emancipating" were clustered with phrases containing "emancipation" based on count information, rather than because of the common stem.

Figure 3 shows part of a French phrase cluster learned during F-E experiments by the same mixed metric. The surface forms are quite varied, but most of the phrases mean "to assure or to guarantee that something will happen". An interesting exception is "pas faire" – it means not to do something ("pas" is negative). This illustrates why we need a better edit distance that heavily weights negative words.

emancipating (247), emancipate (167), emancipate our (73), emancipating thinking (67), emancipate our minds (46), further emancipate (45), emancipate the (38), emancipate the mind (38), emancipating minds (33), emancipate their (32), emancipate their minds (27), emancipating our minds (24), emancipating our (21), emancipate our mind (21), further emancipate our (19), emancipate our thinking (14), further emancipate their (11), emancipating the minds (9), emancipate thinking (8), unfettering (8) ...

garantir que (64), assurer que (46), veiller à ce que (27), afin de garantir (24), faire en sorte (19), de garantir que (16), afin de garantir que (14), faire des (14), de veiller à ce (14), s' assurer que (13), de veiller à ce que (13), pour garantir que (13), de faire en sorte (8), de faire en sorte que (7), à garantir que (6), pas faire (5), de veiller (5)…

Figure 3: partial French phrase cluster

4 Experiments

We carried out experiments on a standard one-pass phrase-based SMT system with a phrase table derived from merged counts of symmetrized IBM2 and HMM alignments; the system has both lexicalized and distance-based distortion components (there is a 7-word distortion limit) and employs cube pruning (Huang and Chiang, 2007). The baseline is a loglinear feature combination that includes language models, the distortion components, relative frequency estimators $P_{RF}(\mathbf{s}|\mathbf{t})$ and $P_{RF}(\mathbf{t}|\mathbf{s})$ and lexical weight estimators $P_{LW}(\mathbf{s}|\mathbf{t})$ and $P_{LW}(\mathbf{t}|\mathbf{s})$. The $P_{LW}()$ components are based on (Zens and Ney, 2004); Foster *et al.* (2006) found this to be the most effective lexical smoothing technique. The phrase-cluster-based components $P_{PC}(\mathbf{s}|\mathbf{t})$ and $P_{PC}(\mathbf{t}|\mathbf{s})$ are incorporated as additional loglinear feature functions. Weights on feature functions are found by lattice MERT (Macherey *et al.*, 2008).

4.1 Data

We evaluated our method on C-E and F-E tasks. For each pair, we carried out experiments on training corpora of different sizes. C-E data were from the NIST[1] 2009 evaluation; all the allowed bilingual corpora except the *UN corpus*, *Hong Kong Hansard and Hong Kong Law corpus* were used to estimate the translation model. For C-E, we trained two 5-gram language models: the first on the English side of the parallel data, and the second on the English *Gigaword corpus*.

Our C-E development set is made up mainly of data from the NIST 2005 test set; it also includes some balanced-genre web-text from the NIST training material. Evaluation was performed on the NIST 2006 and 2008 test sets. **Table 1** gives figures for training, development and test corpora for C-E tasks; |S| is the number of sentences, and |W| is the number of words. There are four references for dev and test sets.

	After clustering	11.9M	5.6M	25.6M	18.5M
	#clustered	0	0.4M	0	1.9M

Table 3: # phrase classes before & after clustering.

For F-E tasks, we used WMT 2010[2] F-E track data sets. Parallel *Europarl* data are used for training; WMT Newstest 2008 set is the dev set, and WMT Newstest 2009 and 2010 are the test sets. One reference is provided for each source input sentence. Two language models are used in this task: one is the English side of the parallel data, and the second is the English side of the *GigaFrEn* corpus. **Table 2** summarizes the training, development and test corpora for F-E tasks.

4.2 Amount of clustering and metric

For both C-E and E-F, we assumed that phrases seen only once in training data couldn't be clustered reliably, so we prevented these "count 1" phrases from participating in clustering. The key clustering parameter is the number of merge operations per iteration, given as a percentage of the number of potential same-language phrase pairs satisfying a simple criterion (some overlap in translations to the other language). Preliminary tests involving the FBIS corpus (about 8% of the C-E data) caused us to set this parameter at 5%. For C-E, we first clustered Chinese with this 5% value, then English with the same amount. For F-E, we first clustered French, then English, using 5% in both cases.

Table 3 shows the results. Only 2-4% of the total phrases in each language end up in a cluster (that's 6.5-9% of eligible phrases, *i.e.*, of phrases that aren't "count 1"). However, about 20-25% of translation probabilities are smoothed for both language pairs. Based on these preliminary tests, we decided to use $Edit \times Dice \times MAPL$ ($Edit \times DMAPL$) as our metric (though $Edit \times Cosine$ was a close runner-up).

4.3 Results and discussion

Our evaluation metric is IBM BLEU (Papineni *et al.*, 2002), which performs case-insensitive matching of n-grams up to $n = 4$. Our first experiment evaluated the effects of the phrase clustering features given various amounts of training data. **Figure 4** gives the BLEU score improvements for the two language pairs, with results for each pair averaged over two test sets (training data size shown as #sentences). The improvement is largest for medium amounts of training data. Since the F-E training data has more words per sentence than C-E, the two peaks would have been closer together if we'd put #words on the x axis: improvements for both tasks peak around 6-8 M English words. For more details, refer to **Table 4** and **Table 5**. The biggest improvement is 0.55 BLEU for the NIST06 test. More importantly, cluster features yield gains in 29 of 30 experiments. Surprisingly, a reviewer asked if we'd done significance tests on the individual results shown in **Tables 4** and **5.** Most likely, many of these individual results are insignificant, but so what? Based on the tables, the probability of the null hypothesis that our method has no effect is equivalent to that of tossing a fair coin 30 times and getting 29 heads (if we adopt an independence approximation).

In the research on paraphrases cited earlier, paraphrases tend to be most helpful for <u>small</u> amounts of training data. By contrast, our approach seems to be most helpful for <u>medium</u> amounts of training data (200-400K sentence

pairs). We attribute this to the properties of count-based clustering. When there is little training data, clustering is unreliable; when there is much data, clustering is reliable but unneeded, because most relative frequencies are well-estimated. In between, phrase cluster probability estimates are both reliable and useful.

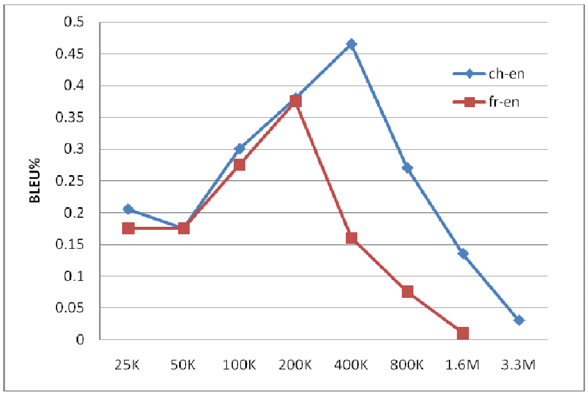

Figure 4: Average BLEU improvement for C-E and F-E tasks (each averaged over two tests) *vs*. #training sent.

Finally, we carried out experiments to see if some of our earlier decisions were correct. Were we right to use DMAPL instead of cosine as the count-based component of our metric? Experiments with $Edit \times DMAPL$ *vs.* $Edit \times Cosine$ on 400K C-E (tested on NIST06 and NIST08) and on 200K F-E (tested on Newstest2009 and 2010) showed a tiny advantage for $Edit \times DMAPL$ of about 0.06 BLEU. So we probably didn't make the wrong decision here (though it doesn't matter much). Were we right to include the *Edit* component? Carrying out analogous experiments with $Edit \times DMAPL$ *vs.* *DMAPL*, we found that dropping *Edit* caused a loss of 0.1-0.2 BLEU for all four test sets. Here again, we made the right decision.

In a final experiment, we allowed "count 1" phrases to participate in clustering (using $Edit \times DMAPL$). The resulting C-E system had somewhat more clustered phrases than the previous one (for both Chinese and English, about 3.5% of phrases were in clusters compared to 2.5% in the previous system). To our surprise, this led to a slight improvement in BLEU: the 400K C-E system now yielded 30.25 on NIST06 (up 0.09) and 23.88 on NIST08 (up 0.13). The F-E system where "count 1" clustering is allowed also had more phrases in clusters than the system where it's prohibited (the former has just under 10% of French and English phrases in clusters *vs.*

4% for the latter). For F-E, the 200K system allowing “count 1” clustering again yielded a slightly higher BLEU: 24.07 on Newstest2009 and 24.76 on Newstest2010 (up 0.05 in both cases). Thus, our decision not to allow “count 1” phrases to participate in clustering in the Table 4 and 5 experiments appears to have been a mistake. We suspect we can greatly improve handling of “count 1” phrases – *e.g.*, by weighting the Edit component of the similarity metric more heavily when assigning these phrases to clusters.

5 Conclusion and Future Work

We have shown that source-language and target-language phrases in the phrase table can be clustered, and that these clusters can be used to smooth “forward” and “backward” estimates P(**t**|**s**) and P(**s**|**t**), yielding modest but consistent BLEU gains over a baseline that included lexical smoothing. Though our experiments were done on a phrase-based system, this method could also be applied to hierarchical phrase-based SMT and syntactic SMT systems. There are several possibilities for future work based on new applications for phrase clusters:

- In the experiments above, we used phrase clusters to smooth P(t|s) and P(s|t) when the pair (s,t) was observed in training data. However, the phrase clusters often give non-zero probabilities for P(t|s) and P(s|t) when s and t were both in the training data, but didn’t co-occur. We could allow the decoder to consider such “invented” phrase pairs (s,t).
- Phrase clusters could be used to construct target language models (LMs) in which the basic unit is a phrase cluster rather than a word. For instance, a tri-cluster model would estimate the probability of phrase p at time i as a function of its phrase cluster, Ci(p), and the two preceding phrase clusters Ci-1 and Ci-2: $P(\mathbf{p}) = f(\mathbf{p} \mid C_i(\mathbf{p})) \times f(C_i \mid C_{i-1}C_{i-2})$.
- Lexicalized distortion models could be modified so as to condition distortion events on phrase clusters.
- We could build SMT grammars in which the terminals are phrases and the parents of terminals are phrase clusters.

The phrase clustering algorithm described above could be improved in several ways:

- In the above, the edit distance between phrases and between phrase clusters was crudely defined. If we improve edit distance, it will have an especially large impact on “count 1” phrases, for which count-based metrics are unreliable and which are a large proportion of all phrases. The edit distance between two phrases weighted all words equally: preferably, weights for word substitution, insertion, or deletion would be learned from purely count-derived phrase clusters (content words and negative words might have heavier weights than other words). The edit distance between two phrase clusters was defined as the edit distance between the phrases with the most observations in each cluster. E.g., distance to the phrase cluster in Figure 2 is defined as the phrase edit distance to “emancipating”. Instead, one could allow a cluster to be characterized by (e.g.) up to three phrases, and let distance between two clusters be the minimum or average pairwise edit distance between these characteristic phrases.
- To cluster phrases, we only used information derived from phrase tables. In future, we could also use the kind of information used in work on paraphrases, such as the context surrounding phrases in monolingual corpora, entries in thesauri, and information from pivot languages.
- The phrase clustering above was “hard”: each phrase in either language belongs to exactly one cluster. We could modify our algorithms to carry out “soft” clustering. For instance, we could interpolate the probabilities associated with a phrase with probabilities from its neighbours.
- Clustering is a primitive way of finding latent structure in the table of joint phrase counts. One could apply principal component analysis or a related algorithm to this table.

Revisiting Context-based Projection Methods for Term-Translation Spotting in Comparable Corpora

Abstract

Context-based projection methods for identifying the translation of terms in comparable corpora has attracted a lot of attention in the community, *e.g.* (Fung, 1998; Rapp, 1999). Surprisingly, none of those works have systematically investigated the impact of the many parameters controlling their approach. The present study aims at doing just this. As a test-case, we address the task of translating terms of the medical domain by exploiting pages mined from Wikipedia. One interesting outcome of this study is that significant gains can be obtained by using an association measure that is rarely used in practice.

1 Introduction

Identifying translations of terms in comparable corpora is a challenge that has attracted many researchers. A popular idea that emerged for solving this problem is based on the assumption that the context of a term and its translation share similarities that can be used to rank translation candidates (Fung, 1998; Rapp, 1999). Many variants of this idea have been implemented.

While a few studies have investigated pattern matching approaches to compare source and target contexts (Fung, 1995; Diab and Finch, 2000; Yu and Tsujii, 2009), most variants make use of a bilingual lexicon in order to translate the words of the context of a term (often called *seed words*). Déjean et al. (2005) instead use a bilingual thesaurus for translating these.

Another distinction between approaches lies in the way the context is defined. The most common practice, the so-called window-based approach, defines the context words as those cooccuring significantly with the source term within windows centered around the term.[1] Some studies have reported gains by considering syntactically motivated co-occurrences. Yu and Tsujii (2009) propose a resource-intensive strategy which requires both source and target dependency parsers, while Otero (2007) investigates a lighter approach where a few hand coded regular expressions based on POS tags simulate source parsing. The latter approach only requires a POS tagger of the source and the target languages as well as a small parallel corpus in order to project the source regular expressions.

Naturally, studies differ in the way each co-occurrence (either window or syntax-based) is weighted, and a plethora of association scores have been investigated and compared, the likelihood score (Dunning, 1993) being among the most popular. Also, different similarity measures have been proposed for ranking target context vectors, among which the popular cosine measure.

The goal of the different authors who investigate context-projection approaches also varies. Some studies are tackling the problem of identifying the translation of general words (Rapp, 1999; Otero, 2007; Yu and Tsujii, 2009) while others are addressing the translation of domain specific terms. Among the latter, many are translating single-word terms (Chiao and Zweigenbaum, 2002; Déjean et al., 2005; Prochasson et

[1] A stoplist is typically used in order to prevent function words from populating the context vectors.

al., 2009), while others are tackling the translation of multi-word terms (Daille and Morin, 2005). The type of discourse might as well be of concern in some of the studies dedicated to bilingual terminology mining. For instance, Morin et al. (2007) distinguish popular science versus scientific terms, while Saralegi et al. (2008) target popular science terms only.

The present discussion only focuses on a few number of representative studies. Still, it is already striking that a direct comparison of them is difficult, if not impossible. Differences in resources being used (in quantities, in domains, etc.), in technical choices made (similarity measures, context vector computation, etc.) and in objectives (general versus terminological dictionary extraction) prevent one from establishing a clear landscape of the various approaches.

Indeed, many studies provide some figures that help to appreciate the influence of some parameters in a given experimental setting. Notably, Otero (2008) studies no less than 7 similarity measures for ranking context vectors while comparing window and syntax-based methods. Morin et al. (2007) consider both the log-likelihood and the mutual information association scores as well as the Jaccard and the cosine similarity measures.

Ideally, a benchmark on which researchers could run their translation finder would ease the comparison of the different approaches. However, designing such a benchmark that would satisfy the evaluation purposes of all the researchers is far too ambitious a goal for this contribution. Instead, we investigate the impact of some major factors influencing projection-based approaches on a task of translating 5,000 terms of the medical domain (the most studied domain), making use of French and English Wikipedia pages extracted monolingually thanks to an information retrieval engine. While the present work does not investigate all the parameters that could potentially impact results, we believe it constitutes the most complete and systematic comparison made so far with variants of the context-based projection approach.

In the remainder of this paper, we describe the projection-based approach to translation spotting in Section 2 and detail the parameters that directly influence its performance. The experimental protocol we followed is described in Section 3 and we analyze our results in Section 4. We discuss the main results in the light of previous work and propose some future avenues in Section 5.

2 Projection-based variants

The approach we investigate for identifying term translations in comparable corpora is similar to (Rapp, 1999) and many others. We describe in the following the different steps it encompasses and the parameters we are considering in the light of typical choices made in the literature.

2.1 Approach

Step 1 A comparable corpus is constructed for each term to translate. In this study, the source and target corpora are sets of Wikipedia pages related to the source term (S) and its reference translation (T) respectively (see Section 3.1). The degree of corpus preprocessing varies greatly from one study to another. Complex linguistic tools such as terminological extractors (Daille and Morin, 2005), parsers (Yu and Tsujii, 2009) or lemmatizers (Rapp, 1999) are sometimes used.

In our case, the only preprocessing that takes place is the deletion of the Wikipedia symbols pertaining to its particular syntax (*e.g.* `[[ ]]`).[2] It is to be noted that, for the sake of simplicity and generality, our implementation does not exploit interlanguage links nor structural elements specific to Wikipedia documents, as opposed to (Yu and Tsujii, 2009).

Step 2 A context vector v_s for the source term S is built (see Figure 1 for a made-up example). This vector contains the words that are in the context of the occurrences of S and are strongly correlated to S. The definition of "context" is one of the parameters whose best value we want to find. Context length can be based on a number of units, for instance 3 sentences (Daille and Morin, 2005), windows of 3 (Rapp, 1999) or 25 words (Prochasson et al., 2009), etc. It is an important parameter of the projection-based approach. Should the context length be too small, we would miss words that would be relevant in finding the translation. On the other hand, if the context is too large, it

[2] We used a set of about 40 regular expressions to do this.

might contain too much noise. At this step, a stoplist made of function words is applied in order to filter out context words and reduce noise in the context vector.

Additionally, an association measure is used to score the strength of correlation between S and the words in its contexts; it serves to normalize corpus frequencies. Words that have a high association score with S are more prominent in the context vector. The association measure is the second important parameter we want to study. As already noted, most authors use the log-likelihood ratio to measure the association between collocates; some, like (Rapp, 1999), informally compare the performance of a small number of association measures, or combine the results obtained with different association measures (Daille and Morin, 2005).

Figure 1: Step 2

Step 3 Words in v_s are projected into the target language with the help of the bilingual seed lexicon (Figure 2). Each word in v_s which is present in the bilingual lexicon is translated, and those translations define the projected context vector v_p. Words that are not found in the bilingual lexicon are simply ignored. The size of the seed lexicon and its content are therefore two important parameters of the approach. In previous studies, seed lexicons vary between 16,000 (Rapp, 1999) and 65,000 (Déjean et al., 2005) entries, a typical size being around 20,000 (Fung, 1998; Chiao and Zweigenbaum, 2002; Daille and Morin, 2005).

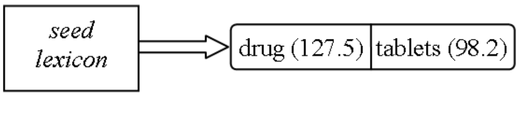

Figure 2: Step 3

Step 4 Context vectors v_t are computed for each candidate term in the target language corpus (Figure 3). The dimension of the target-vector space is defined to be the one induced by the projection mechanism described in Step 3. The context vector v_t of each candidate term is computed as in Step 2. Therefore, in Step 4, the parameters of context definition and association measure are important and take the same values as those in Step 2. Note that in this study, on top of all single terms, we also consider target bigrams as potential candidates (99.5 % of our reference target terms are composed of at most two words). As such, our method can handle complex terms (of up to two words), as opposed to most previous studies, without having to resort to a separate terminological extraction as in (Daille and Morin, 2005).

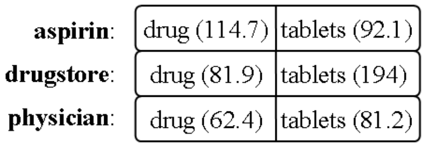

Figure 3: Step 4

Step 5 Context vectors v_t are ranked in decreasing order of their similarity with v_p (Figure 4). The similarity measure between context vectors varies among studies: city-block measure (Rapp, 1999), cosine (Fung, 1998; Chiao and Zweigenbaum, 2002; Daille and Morin, 2005; Prochasson et al., 2009), Dice or Jaccard indexes (Chiao and Zweigenbaum, 2002; Daille and Morin, 2005), etc. It is among the parameters whose effect we experimentally evaluate.

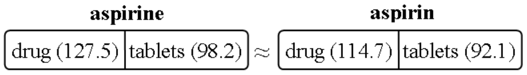

Figure 4: Step 5

2.2 Parameters studied

The five steps we described involve many parameters, the values of which can influence at varying degrees the performance of a translation spotter. In the current study, we considered the following parameter values.

Context We considered contexts defined as the current sentence or the current paragraph involving S. We also considered windows of 5 and 25 words on both sides of S.

Association measure Following the aforementioned studies, we implemented these popular measures: pointwise mutual information (PMI), log-likelihood ratio (LL) and chi-square (χ^2). We also implemented the discounted log-odds (LO) described by (Evert, 2005, p. 86) in his work on collocation mining. To our knowledge, this association measure has not been used yet in translation spotting. It is computed as:

$$\text{odds-ratio}_{disc} = \log \frac{(O_{11} + \frac{1}{2})(O_{22} + \frac{1}{2})}{(O_{12} + \frac{1}{2})(O_{21} + \frac{1}{2})}$$

where O_{ij} are the cells of the 2×2 contingency matrix of a word token s cooccurring with the term S within a given window size.[3]

Similarity measure We implemented four measures: city-block, cosine, as well as Dice and Jaccard indexes (Jurafsky and Martin, 2008, p. 666). Our implementations of Dice and Jaccard are identical to the *DiceMin* and *JaccardMin* similarity measures reported in (Otero, 2008) and which outperformed the other five metrics he tested.

Seed lexicon We investigated the impact of both the size of the lexicon and its content. We started our study with a mixed lexicon of around 5,000 word entries: roughly 2,000 of them belong to the medical domain, while the other entries belong to the general language. We also considered mixed lexicons of 7,000, 9,000 and 11,000 entries (where 2,000 entries are related to the medical domain), as well as a 5,000-entry general language only lexicon.

2.3 Cognate heuristic

Many authors are embedding heuristics in order to improve their approach. For instance, Chiao and Zweigenbaum (2002) propose to integrate a reverse translation spotting strategy in order to improve precision. Prochasson et al. (2009) boost the strength of context words that happen to be transliterated in the other language. A somehow generalized version of this heuristic has been described in (Shao and Ng, 2004).

In this work, we examine the performance of the best configuration of parameters we found, combined with a simple heuristic based on graphic similarity between source and target terms, similar to the orthographic features in (Haghighi et al., 2008)'s generative model. This is very specific to our task where medical terms often (but not always) share Latin or Greek roots, such as *microvillosités* in French and *microvilli* in English.

In this heuristic, translation candidates which are cognates of the source term are ranked first among the list of translation candidates. In our implementation, two words are cognates if their first four characters are identical (Simard et al., 1992). One interesting note concerns the word-order mismatch typically observed in French and English complex terms, such as in *ADN mitochondrial* (French) and *mitochondrial DNA* (English). We do treat this case adequately.

3 Experimental protocol

In order to pinpoint the best configuration of values for the parameters identified in Section 2.2, four series of experiments were carried out. In all of them, the task consists of spotting translation candidates for each source language term using the resources[4] described below. The quality of the results is evaluated with the help of the metrics described in Section 3.2.

3.1 Resources

Corpora The comparable corpora are made of the (at most) 50 French and English Wikipedia documents that are the most relevant to the source term and to its reference translation respectively. These documents are retrieved with the NLGbAse Information Retrieval tool.[5] The average token count of all the 50-document corpora as well as the average frequency of the source and target terms in these corpora for our four series of experiments are listed in Table 1.

[3] For instance, O_{21} stands for the number of windows containing S but not s.

[4] Our resources are available at `http://olst.ling.umontreal.ca/~audrey/coling2010/`. They were acquired as described in (Rubino, 2009).

[5] `http://nlgbase.org/`

	Experiment			
	1	2	3	4
Tokens$_s$	89,431	73,809	42,762	90,328
Tokens$_t$	52,002	27,517	12,891	38,929
$\|S\|$	296	184	66	306
$\|T\|$	542	255	104	404

Table 1: 50-document corpora averages

The corpora are somewhat small (most corpora in previous studies are made of at least a million words). We believe this is more representative of a task where we try to translate domain specific terms. Some of the Wikipedia documents may contain a handful of parallel sentences (Smith et al., 2010), but this information is not used in our approach. The construction of the corpus involves a bias in that the reference translations are used to obtain the most relevant target language documents. However, since our objective is to compare the relative performance of different sets of parameters, this does not affect our results. In fact, as per (Déjean et al., 2005) (whose comparable corpora are English and German abstracts), the use of such an "ideal" corpus is common (as in (Chiao and Zweigenbaum, 2002), where the corpus is built from a specific query).

Seed lexicon The mixed seed lexicon we use is taken from the Heymans Institute of Pharmacology's *Multilingual glossary of technical and popular medical terms*.[6] Random general language entries from the `FreeLang`[7] project are also incorporated into the lexicon for some of our experiments.

Reference translations The test set is composed of 5,000 nominal single and multi-word pairs of French and English terms from the MeSH (*Medical Subject Heading*) thesaurus.[8]

3.2 Evaluation metrics

The performance of each set of parameters in the experiments is evaluated with Top N precision (P_N), recall (R_N) and F-measure (F_N), as well as Mean Average Precision (MAP). Precision is the number of correct translations (at most 1 per source term) divided by the number of terms for which our system gave at least one answer; recall is equal to the ratio of correct translations to the total number of terms. F-measure is the harmonic mean of precision and recall:

$$\text{F-measure} = \frac{2 \times (precision \times recall)}{(precision + recall)}$$

The MAP represents in a single figure the quality of a system according to various recall levels (Manning et al., 2008, p. 147–148):

$$\text{MAP(Q)} = \frac{1}{|Q|} \sum_{|Q|}^{j=1} \frac{1}{m_j} \sum_{m_j}^{k=1} Precision(R_{jk})$$

where $|Q|$ is the number of terms to be translated, m_j is the number of reference translations for the j^{th} term (always 1 in our case), and $Precision(R_{jk})$ is 0 if the reference translation is not found for the j^{th} term or $1/r$ if it is (r is the rank of the reference translation in the translation candidates).

4 Experiments

In Experiment 1, 500 single and multi-word terms must be translated from French to English using each of the 64 possible configurations of these parameters: context definition, association measure and similarity measure. In Experiment 2, we submit to the 8 best variants 1,500 new terms to determine with greater confidence the best 2, which are again tested on the last 3,000 of the test terms (Experiment 3). In Experiment 4, using 1,350 frequent terms, we examine the effects of seed lexicon size and specificity and we apply a heuristic based on cognates.

4.1 Experiment 1

The results of the first series of experiments on 500 terms can be analysed from the point of view of each of the parameters whose values varied among 64 configurations (Section 2.2). The maximal MAP reached for each parametric value is given in Table 2.

The most notable result is that, of the four association measures studied, the log-odds ratio is

[6] `http://users.ugent.be/~rvdstich/eugloss/welcome.html`

[7] `http://www.freelang.net/`

[8] `http://www.nlm.nih.gov/mesh/`

	Param.	Value	Best MAP	In config.
association	LO	**0.536**	sentence_cosine
	LL	0.413	sentence_Dice
	PMI	0.299	sentence_city-block
	χ^2	0.179	sentence_Dice
similarity	cosine	**0.536**	sentence_LO
	Dice	0.520	sentence_LO
	Jaccard	0.520	sentence_LO
	city-block	0.415	sentence_LO
context	sentence	**0.536**	cosine_LO
	paragraph	0.460	cosine_LO
	25 words	0.454	cosine_LO
	5 words	0.361	Dice_LO

Table 2: Best MAP in Experiment 1

significantly superior to the others in every variant. There is as much as 34 % difference between LO and other measures for Top 1 recall. This is interesting since most previous works use the log-likelihood, and none use LO. Our best results for LO (with cosine_sentence) and LL (with Dice_sentence) are in Table 3. Note that the oracle recall is 93 % (7 % of the source and target terms were not in the corpus).

Assoc.	R1	R20	P1	P20	F1	F20	MAP
LO	**39.4**	**84.8**	**42.3**	**91.0**	**40.8**	**87.8**	**0.536**
LL	29.0	75.2	31.3	81.0	30.1	78.0	0.413

Table 3: Best LO and LL configurations scores

Another relevant observation is that the parameters interact with each other. When the similarity measure is cosine, PMI results in higher Top 1 F-scores than LL, but the Top 20 F-scores are better with LL. PMI is better than LL when using city-block as a similarity measure, but LL is better than PMI when using Dice and Jaccard indexes. χ^2 gives off the worst MAP in all but 4 of the 64 parametric configurations.

As for similarity measures, the Dice and Jaccard indexes have identical performances, in accordance with the fact that they are equivalent (Otero, 2008).[9] Influences among parameters are also observable in the performance of similarity measures. When the association measure is LO, the cosine measure gives slightly better Top 1 F-scores, while the Dice index performs slightly better with regards to Top 20 F-scores. Dice is better when the association measure is LL, with a Top 1 F-score gain of about 15 % compared to the cosine.

Again, in the case of context definitions, relative performances depend on the other parameters and on the number of top translation candidates considered. With LO, sentence contexts have the highest Top 1 F-measures, while Top 20 F-measures are highest with paragraphs, and 5-word contexts are the worst.

4.2 Experiment 2

The best parametric values found in Experiment 1 were put to the test on 1,500 different test terms for scale-up verification. Along with LO, which was the best association measure in the previous experiment, we used LL to double-check its relative inefficiency. For all of the 8 configurations evaluated, LL's recall, precision and MAP remain worse than LO's. In particular, LO's MAP scores with the cosine measure are more than twice as high as LL's (respectively 0.33 and 0.124 for sentence contexts). As in Experiment 1, the Dice index is significantly better for LL compared to the cosine, but not for LO. In the case of LO, sentence contexts have better Top 1 performances than paragraphs, and vice versa for Top 20 performances (see Table 4; oracle recall is 93.5 %). Hence, paragraph contexts would be more useful in tasks consisting of proposing candidate translations to lexicographers, while sentences would be more appropriate for automatic bilingual lexicon construction.

Ctx	R1	R20	P1	P20	F1	F20	MAP
Sent.	**23.1**	63.9	**27.8**	76.6	**25.23**	69.68	**0.336**
Parag.	20.1	**70.0**	22.9	**79.7**	21.41	**74.54**	0.325

Table 4: LO_Dice configuration scores

The cosine and Dice similarity measures have similar performances when LO is used. Moreover, we observe the effect of source and target term frequencies in corpus. As seen in Table 1, these frequencies are on average about half smaller in Experiment 2 as they are in Experiment 1, which results in significantly lower performances for all

[9] For this reason, whenever "Dice" is mentioned from this point on, it also applies to the Jaccard index.

8 variants. As Figure 5 shows for the variant LO_cosine_sentence, terms that are more frequent have a greater chance of being correctly translated at better ranks.

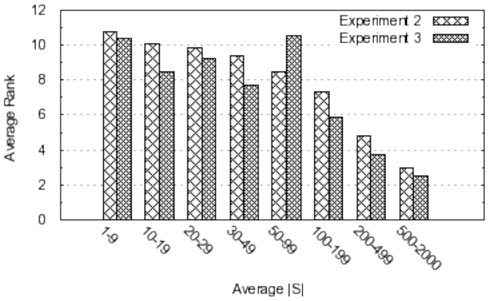

Figure 5: Average rank of correct translation according to average source term frequency

However, the relative performance of the different parametric configurations still holds.

4.3 Experiment 3

In Experiment 3, we evaluate the two best configurations from Experiment 2 with 3,000 new terms in order to verify the relative performance of the cosine and Dice similarity measures. As Table 5 shows, cosine has slightly better Top 1 figures, while Dice is a little better when considering the Top 20 translation candidates. Therefore, as previously mentioned, the choice of similarity measure (cosine or Dice) should depend on the goal of translation spotting. Note that the scores in Experiment 3 are much lower than those of Experiments 1 and 2 because of low term frequencies in the corpus (see Table 1 and Figure 5). Also, oracle recall is only 71.1 %.

Sim.	R1	R20	P1	P20	F1	F20	MAP
Cosine	**9.8**	28.1	**20.7**	59.4	**13.3**	38.15	0.232
Dice	9.4	**28.9**	19.8	**61.2**	12.75	**39.26**	**0.286**

Table 5: LO_sentence configuration scores

4.4 Experiment 4

In the last series of experiments, we examine the influence of the bilingual seed lexicon specificity and size, using the 1,350 terms which have source and target frequencies $\geq$ 30 from the 1,500 and 3,000 sets used in Experiments 2 and 3 (oracle recall: 100 %). We tested the different lexicons (see Section 2.2) on the 4 parametric configurations made of sentence contexts, LO or LL association measures, and cosine or Dice similarity measures.

Yet again, LO is better than LL. MAP scores for LO in all variants are comprised in [0.466–0.489]; LL MAPs vary between 0.135 and 0.146 when the cosine is used and between 0.348 and 0.380 when the Dice index is used.

According to our results, translation spotting is more accurate when the seed lexicon contains (5,000) entries from both the medical domain and general language instead of general language words only, but only by a very small margin. Table 6 shows the results for the configuration LO_cosine_sentence. The fact that the difference is so small could be explained by our resources' properties. The reference translations from MeSH contain terms that are also used in other domains or in the general language, *e.g.* terms from the category "people" (Névéol and Ozdowska, 2006). Wikipedia documents retrieved by using those references may in turn not belong to the medical domain, in which case medical terms from the seed lexicon are not appropriate. Still, the relatively good performance of the general language-only lexicon supports (Déjean et al., 2005, p. 119)'s claim that general language words are useful when spotting translations of domain specific terms, since the latter can appear in generic contexts.

Lex.	R1	R20	P1	P20	F1	F20	MAP
Gen. + med.	**39.3**	87.0	**39.6**	87.6	**39.4**	87.3	**0.473**
Gen. only	38.8	**88.1**	39.0	**88.5**	38.9	**88.3**	0.471

Table 6: LO_cosine_sentence configuration scores

Lexicon sizes tested are 5,000 (the mixed lexicon used in previous experiments), 7,000, 9,000 and 11,000 entries. The performance (based on MAP) is better when 7,000- and 9,000-entry lexicons are used, because more source language context words can be taken into account. However, when the lexicon reaches 11,000, Top 1 MAP scores and F-measures are slightly lower than those obtained with the 7,000-entry one. This may happen because the lexicon is increased with general language words; 9,000 of the 11,000 entries are not from the medical domain, making it harder for the context words to be specific. It would be interesting to study the specificity of context vectors built from the source corpus. Still, the differences in scores are small, as Table 7 shows (see Table 6 for the results obtained with 5,000 entries). This is because, in our implementation, context vector size is limited to 20, as in (Daille and Morin, 2005), in order to reduce processing time. The influence of context vector sizes should be studied.

Lex. size	R1	R20	P1	P20	F1	F20	MAP
7,000	**41.5**	88.8	**41.6**	89.1	**41.5**	88.9	0.488
9,000	40.9	89.3	41.1	89.7	41.0	89.5	**0.489**
11,000	40.1	**89.8**	40.2	**90.1**	40.1	**89.9**	0.484

Table 7: LO_cosine_sentence configuration scores

The parameters related to the seed lexicon do not have as great an impact on the performance as the choice of association measure does: the biggest difference in F-measures for Experiment 4 is 2.9 %. At this point, linguistic-based heuristics such as graphic similarity should be used to significantly increase performance. We applied the cognate heuristic (Section 2.3) on the Top 20 translation candidates given by the variant LO_sentence_9,000-entry lexicon using cosine and Dice similarity measures. Without the heuristic, Top 1 performances are better with cosine, while Dice is better for Top 20. Applying the cognate heuristic makes the Top 1 precision go from 41.1 % to 55.2 % in the case of cosine, and from 39.6 % to 53.9 % in the case of Dice.

5 Discussion

Our results show that using the log-odds ratio as the association measure allows for significantly better translation spotting than the log-likelihood. A closer look at the translation candidates obtained when using LL, the most popular association measure in projection-based approaches, shows that they are often collocates of the reference translation. Therefore, LL may fare better in an indirect approach, like the one in (Daille and Morin, 2005).

Moreover, we have seen that the cosine similarity measure and sentence contexts give more correct top translation candidates, at least when LO is used. Indeed, the values of the different parameters influence one another in most cases. Parameters related to the seed lexicon (size, domain specificity) are not of great influence on the performance, but this may in part be due to our resources and the way they were built.

The highest Top 1 precision, 55.2 %, was reached with the following parameters: sentence contexts, LO, cosine and a 9,000-entry mixed lexicon, with the use of a cognate heuristic.

In future works, other parameters which influence the performance will be studied, among which the use of a terminological extractor to treat complex terms (Daille and Morin, 2005), more contextual window configurations, and the use of syntactic information in combination with lexical information (Yu and Tsujii, 2009). It would also be interesting to compare the projection-based approaches to (Haghighi et al., 2008)'s generative model for bilingual lexicon acquisition from monolingual corpora.

One latent outcome of this work is that Wikipedia is surprisingly suitable for mining medical terms. We plan to check its adequacy for other domains and verify that LO remains a better association measure for different corpora and domains.

Acknowledgments

We are deeply grateful to Raphaël Rubino who provided us with the data material we have been using in this study. We thank the anonymous reviewers for their suggestions.

Abstract

We present a constituent parsing-based reordering technique that improves the performance of the state-of-the-art English-to-Japanese phrase translation system that includes distortion models by 4.76 BLEU points. The phrase translation model with reordering applied at the pre-processing stage outperforms a syntax-based translation system that incorporates a phrase translation model, a hierarchical phrase-based translation model and a tree-to-string grammar. We also show that combining constituent reordering and the syntax model improves the translation quality by additional 0.84 BLEU points.

1 Introduction

Since the seminal work by (Wu, 1997) and (Yamada and Knight, 2001), there have been great advances in syntax-based statistical machine translation to accurately model the word order distortion between the source and the target languages.

Compared with the IBM source-channel models (Brown et al., 1994) and the phrase translation models (Koehn et al., 2003), (Och and Ney, 2004) which are good at capturing local reordering within empirical phrases, syntax-based models have been effective in capturing the long-range reordering between language pairs with very different word orders like Japanese-English (Yamada and Knight, 2001), Chinese-English (Chiang, 2005) and Urdu-English (Zollmann et al. 2008), (Callison-Burch et al. 2010).

However, (Xu et al., 2009) show that applying dependency parsing-based reordering as pre-processing (pre-ordering hereafter) to phrase translation models produces translation qualities significantly better than a hierarchical phrase-based translation model (Hiero hereafter) implemented in (Zollman and Venugopal, 2006) for English-to-Japanese translation. They also report that the two models result in comparable translation qualities for English-to-Korean/Hindi/Turkish/Urdu, underpinning the limitations of syntax-based models for handling long-range reordering exhibited by the strictly head-final Subject-Object-Verb (SOV) order languages like Japanese and the largely head-initial Subject-Verb-Object (SVO) order languages like English.

In this paper, we present a novel constituent parsing-based reordering technique that uses manually written context free (CFG hereafter) and context sensitive grammar (CSG hereafter) rules. The technique improves the performance of the state-of-the-art English-to-Japanese phrase translation system that includes distortion models by 4.76 BLEU points. The phrase translation model with constituent pre-ordering consistently outperforms a syntax-based translation system that integrates features from a phrase translation model, Hiero and a tree-to-string grammar. We also achieve an additional 0.84 BLEU point improvement by applying an extended set of reordering rules that incorporate new rules learned from the syntax model for decoding.

The rest of the paper is organized as follows. In Section 2, we summarize previous work related to this paper. In Section 3, we give an overview of the syntax model with which we compare the performance of a phrase translation model with pre-ordering. We also discuss a chart-based decoder used in all of our experiments. In Section 4, we describe the constituent parsing-based reordering rules. We show the impact of pre-ordering on a phrase translation model and compare its performance with the syntax model. In Section 5, we discuss experimental results from the combination of syntax model and pre-ordering. Finally in Section 6, we discuss future work.

2 Related Work

Along the traditions of unsupervised learning by (Wu, 1997), (Chiang, 2005) presents a model that uses hierarchical phrases, Hiero. The model is a synchronous context free grammar learned from a parallel corpus without any linguistic annotations and is applied to Chinese-to-English translation. (Galley and Manning, 2008) propose a hierarchical phrase reordering model that uses shift-reduce parsing.

In line with the syntax-based model of (Yamada and Knight, 2001) that transforms a source language parse tree into a target language string for Japanese-English translation, linguistically motivated syntactic features have been directly incorporated into both modeling and decoding. (Liu, et. al. 2006), (Zhao and Al-Onaizan, 2008) propose a source tree to target string grammar (tree-to-string grammar hereafter) in order to utilize the source language parsing information for translation. (Liu, et. al. 2007) propose packed forest to allow ambiguities in the source structure for the tree-to-string grammar. (Ding and Palmer, 2005) and (Zhang et. al., 2006) propose a tree-to-tree grammar, which generates the target tree structure from the high-precision source syntax. (Shen, et. al., 2008) propose a string to dependency tree grammar to use the target syntax when the target is English for which parsing is more accurate than other languages. (Marcu et al., 2006) introduce a syntax model that uses syntactified target language phrases. (Chang and Toutanova, 2007) propose a global discriminative statistical word order model that combines syntactic and surface movement information, which improves the translation quality by 2.4 BLEU points in English-to-Japanese translation. (Zollmann, et. al., 2008) compare various translation models and report that the syntax augmented model works better for Chinese-to-English and Urdu-to-English, but not for Arabic-to-English translation. (Carreras and Collins, 2009) propose a highly flexible reordering operations during tree adjoining grammar parsing for German-English translation. (Callison-Burch et al., 2010) report a dramatic impact of syntactic translation models on Urdu-to-English translation.

Besides the approaches which integrate the syntactic features into translation models, there are approaches showing improvements via pre-ordering for model training and decoding. (Xia and McCord, 2004), (Collins et al., 2005) and (Wang, et. al. 2007) apply pre-ordering to the training data according to language-pair specific reordering rules to improve the translation qualities of French-English, German-English and Chinese-English, respectively. (Habash, 2007) uses syntactic preprocessing for Arabic-to-English translation. (Xu et al., 2009) use a dependency parsing-based pre-ordering to improve translation qualities of English to five SOV languages including Japanese.

The current work is related to (Xu et al., 2009) in terms of the language pair and translation models explored. However, we use constituent parsing with hierarchical rules, while (Xu et al., 2009) use dependency parsing with precedence rules. The two approaches have different rule coverage and result in different word orders especially for phrases headed by verbs and prepositions. We also present techniques for combining the syntax model with tree-to-string grammar and pre-ordering for additional performance improvement. The total improvement by the current techniques over the state-of-the-art phrase translation model is 5.6 BLEU points, which is an improvement gap not attested elsewhere with reordering approaches.

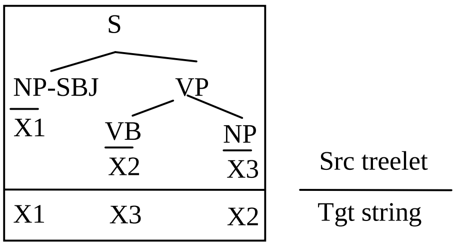
3 Syntax Model and Chart-Based Decoder

In this section, we give an overview of the syntax model incorporating a tree-to-string grammar. We will compare the syntax model performance with a phrase translation model that uses the pre-ordering technique we propose in Section 4. We also describe the chart-based decoder that we use in all of the experiments reported in this paper.

3.1 Tree-to-String Grammar

Tree-to-string grammar utilizes the source language parse to model reordering probabilities from a source tree to the target string (Liu et. al., 2006), (Liu et. al., 2007), (Zhao and Al-Onaizan, 2008) so that long distance word reordering becomes local in the parse tree.

Reordering patterns of the source language syntax and their probabilities are automatically learned from the word-aligned source-parsed parallel data and incorporated as a tree-to-string grammar for decoding. Source side parsing and the resulting reordering patterns bound the search space. Parsing also assigns linguistic labels to the chunk, e.g. NP-SBJ, and allows statistics to be clustered reasonably. Each synchronous context free grammar (SCFG) rewriting rule rewrites a source treelet into a target string, with both sides containing hiero-style variables. For instance, the rule [X, VP] [X, VB] [X,NP] → [X, NP] [X, VB] rewrites a VP with two constituents VB and NP into an NP VB order in the target, shown below.



The tree-to-string grammar introduces possible search space to generate an accurate word order, which is refined on the basis of supports from other models. However, if the correct word order cannot be generated by the tree-to-string grammar, the system can resort to rules from Hiero or a phrase translation model for extended rule coverage.

3.2 Chart-based Decoder

We use a chart-based decoder − a template decoder that generalizes over various decoding schemes in terms of the dot-product in Earley-style parsing (Earley, 1970) − to support various decoding schemes such as phrase, Hiero (Chiang, 2005), Tree-to-String, and the mixture of all of the above.

This framework allows one to strictly compare different decoding schemes using the same feature and parameter setups. For the experimental results in Sections 4 & 5, we applied (1) phrase decoding for the baseline phrase translation system that includes distortion models, (2) Hiero decoding for the Hiero system that incorporates a phrase translation model, and (3) Tree-to-string decoding for the syntax-based systems that incorporate features from phrase translation, Hiero and tree-to-string grammar models.

The decoder seeks the best hypothesis e^* according to the Bayesian decision rule (1):

$$e^* = \underset{\{e,d \in D\}}{\arg\min}\, \phi(e) \cdot \phi(d) \qquad (1)$$

d is one derivation path, rewriting the source tree into the target string via the probabilistic synchronous context free tree-to-string grammar (PSCFG). $\phi(e)$ is the cost functions computed from general n-gram language models. In this work, we use two sets of interpolated 5-gram language models. $\phi(d)$ is a vector of cost functions defined on the derivation sequence. We have integrated 18 cost functions ranging from the basic relative frequencies and IBM model-1 scores to counters for different types of rules including blocks, glue, Hiero, and tree-to-string grammar rules. Additional cost functions are also integrated into the decoder, including measuring the function/content-word mismatch between source and target, similar to (Chiang et. al., 2009) and length distribution for non-terminals in (Shen et. al., 2009).

4 Parsing and Reordering Rules

We apply a set of manually acquired reordering rules to the parsing output from a constituent parser to pre-order the data for model training and decoding.

4.1 Parsing with Functional Tags

We use a maximum entropy English parser (Ratnaparkhi, 1999) trained on OntoNotes (Hovy, 2006) data. OntoNotes data include most of the Wall Street Journal data in Penn Treebank (Marcus et al., 1993) and additional data from broadcast conversation, broadcast news and web log.

Figure 2. Parse Tree and Word Alignment after Reordering

The parser is trained with all of the functional and part-of-speech (POS) tags in the original distribution: total 59 POS tags and 364 phrase labels.

We use functional tags since reordering decisions for machine translation are highly influenced by the function of a phrase, as will be shown later in this section. An example parse tree with functional tags is given at the top half of Figure 1. NP-SBJ indicates a subject noun phrase, SBAR-ADV, an adverbial clause.

4.2 Structural Divergence between English and Japanese

Japanese is a strictly head-final language, i.e. the head is located at the end of a phrase. This leads to a high degree of distortions with English, which is largely head initial.

The word order contrast between the two languages is illustrated by the human word alignment at the bottom half of Figure 1. All instances of word alignments are non-monotonic except for the sequence *that installation*, which is monotonically aligned to the Japanese morpheme sequence その インストール. Note that there are no word boundaries in Japanese written text, and we apply Japanese morpheme segmentation to obtain morpheme sequences in the figure. All of the Japanese examples in this paper are presented with morpheme segmentation.

The manual reordering rules are written by a person who is proficient with English and Japanese/Korean grammars, mostly on the basis of perusing parsed English texts.

4.3 CFG Reordering Rules

Our reordering rules are mostly CFG rules and divided into head and modifier rules.

Head reordering rules in Table 1 move verbs and prepositions from the phrase initial to the phrase final positions (Rules 1-11). Reordering of the head phrase in an adverbial clause also belongs to this group (Rules 12-14). The label sequences in **Before RO** and **After RO** are the immediate children of the **Parent Node** before and after reordering. VBX stands for VB, VBZ, VBP, VBD, VBN and VBG. XP^+ stands for one or more POS and/or phrase labels such as MD, VBX, NP, PP, VP, etc. In 2 & 4, RB is the tag for negation *not*. In 5, RP is the tag for a verb particle.

Modifier reordering rules in Table 2 move modified phrases from the phrase initial to the phrase final positions within an NP (Rules 1-3). They also include placement of NP, PP, ADVP within a VP (Rules 4 & 5). The subscripts in a rule, e.g. PP_1 and PP_2 in Rule 3, indicate the distinctness of each phrase sharing the same label.

4.4 CSG Reordering Rules

Some reordering rules cannot be captured by CFG rules, and we resort to CSG rules.[1]

	Parent Node	**Before RO**	**After RO**
1	VP	MD VP	VP MD
2	VP	MD RB VP	VP MD RB
3	VP	VBX XP^+	XP^+ VBX
4	VP	VBX RB XP^+	XP^+ VBX RB
5	VP	VBX RP XP^+	XP^+ VBX RP
6	ADJP-PRD	JJ XP^+	XP^+ JJ

10	SBAR-ADV	IN S	S IN
11	SBAR-PRP	IN S	S IN
12	SBAR-TMP	WHADVP S	S WHADVP
13	SBAR-ADV	WHADVP S	S WHADVP
14	SBAR-PRP	WHADVP S	S WHADVP

Table 1. Head Reordering Rules

	Parent Node	**Before RO**	**After RO**
1	NP	NP SBAR	SBAR NP
2	NP	NP PP	PP NP
3	NP	NP PP_1 PP_2	PP_1 PP_2 NP
4	VP	VBX NP PP	PP NP VBX
5	VP	VBX NP ADVP-TMP PP	PP NP ADVP-TMP VBX

Table 2. Modifier Reordering Rules

For instance, in the parse tree and word alignment in Figure 1, the last two English words *if needed* under SBAR-ADV is aligned to the first two Japanese words 必要な 場合は. In order to change the English order to the corresponding Japanese order, SBAR-ADV dominated by the VP should move across the VP to sentence initial position, as shown in the top half of Figure 2, requiring a CSG rule.

The adverbial clause reordering in Figure 2 is denoted as Rule 1 in Table 3, which lists two other CSG rules, Rule 2 & 3.[2] The subscripts in Table 3 are interpreted in the same way as those in Table 2.

[1] These CSG rules apply to trees of depth two or more, and the applications are dependent on surrounding contexts. Therefore, they are different from CFG rules which apply only to trees of depth one, and TSG (tree substitution grammar) rules for which variables are independently substituted by substitution. The readers are referred to (Joshi and Schabes, 1997) for formal definitions of various grammar formalisms.

[2] Rule 3 is applied after all CFG rules, see Section 4.6. Therefore, VBX's are located at the end of each corresponding VP.

	Before RO → After RO
1	(S XP_1^+ (VP XP_2^+ SBAR-ADV)) → (S SBAR-ADV XP_1^+ (VP XP_2^+))
2	(S XP_1^+ (VP (XP_2^+ SBAR-ADV))) → (S XP_1^+ SBAR-ADV (VP (XP_2^+)))
3	(VP_1 ADVP-MNR (VP_2 XP^+ VBX_2) VBX_1) →(VP_1 (VP_2 XP^+ ADVP-MNR VBX_2) VBX_1)

Table 3. CSG Reordering Rules

ADVP-MNR stands for a manner adverbial phrase such as *explicitly* in the following: *The software version has been explicitly verified as working*. Rule 3 in Table 3 indicates that a ADVP-MNR has to immediately precede a verb in Japanese, resulting in the substring '*...as working explicitly verified...*' after reordering.

Note that functional tags allow us to write reordering rules specific to semantic phrases. For instance, in Rule 1, SBAR-ADV under VP moves to the sentence initial position under S, but an SBAR without any functional tags do not. It typically stays within a VP as the complement of the verb.

4.5 Subject Marker Insertion

Japanese extensively uses case particles that denote the role of the preceding noun phrase, for example, as subject, object, etc. We insert *sbj*, denoting the subject marker, at the end of a subject noun phrase NP-SBJ. The inserted subject marker *sbj* mostly gets translated into the subject particle が or は in Japanese.[3]

4.6 Reordering Rule Application

The rules are applied categorically, sequentially and recursively. CSG Rules 1 and 2 in Table 3 are applied before all of the CFG rules. Among CFG rules, the modifier rules in Table 2 are applied before the head rules in Table 1. CSG Rule 3 in Table 3 is applied last, followed by the subject marker insertion operation.

CFG head and modifier rules are applied recursively. The top half of Figure 2 is the parse tree obtained by applying reordering rules to the parse tree in Figure 1. After reordering, the word alignment becomes mostly monotonic, as shown at the bottom half of Figure 2.

4.7 Experimental Results

All systems are trained on a parallel corpus, primarily from the Information Technology (IT) domain and evaluated on the data from the same domain. The training data statistics is in Table 4 and the evaluation data statistics is in Table 5. Japanese tokens are morphemes and English tokens are punctuation tokenized words.

Corpus Stats	English	Japanese
sentence count	3,358,635	3,358,635
token count	57,231,649	68,725,865
vocabulary size	242,712	348,221

Table 4. Training Corpus Statistics

Data Sets	Sentence Count	Token Count
Tuning	600	11,761
DevTest	437	8,158
Eval	600	11,463

Table 5. Evaluation Data Statistics

We measure the translation quality with IBM BLEU (Papineni et al., 2002) up to 4 grams, using 2 reference translations, BLEUr2n4. For BLEU score computation, we character-segment Kanji and Kana sequences in the reference and the machine translation output. Various system performances are shown in Table 6.

Models	Tuning	DevTest	Eval
Phrase (BL)	0.5102	0.5330	0.5486
Hiero	0.5385	0.5574	0.5724
Syntax	0.5561	0.5777	0.5863
Phrase+RO1	0.5681	0.5793	0.5962

Table 6. Model Performances (BLEUr2n4)

Phrase (BL) is the baseline phrase translation system that incorporates lexical distortion models (Al-Onaizan and Papineni, 2006). Hiero is the hierarchical phrase-based system (Chiang, 2006) that incorporates the phrase translation model. Syntax is the syntax model described in Section 3, which incorporates the phrase translation, Hiero and tree-to-string grammar models. Phrase+RO1 is the phrase translation model with pre-ordering for system training and decoding, using the rules described in this section. Phrase+RO1 improves the translation quality of the baseline model by 4.76 BLEU points and outperforms the syntax model by over 0.9 BLEU points.

[3] The subject marker insertion is analogous to the insertion operation in (Yamada and Knight, 2001), which covers a wide range of insertion of case particles and verb inflections in general.

5 Constituent Reordering and Syntax Model Combined

Translation qualities of systems that combine the syntax model and pre-ordering are shown in Table 7. Syntax+RO1 indicates the syntax model with pre-ordering discussed in Section 4. Syntax+RO2 indicates the syntax model with a more extensive pre-ordering for decoding discussed below .

Models	Tuning	DevTest	Eval
Phrase+RO1	0.5681	0.5793	0.5962
Syntax+RO1	0.5742	0.5802	0.6003
Syntax+RO2	0.5769	0.5880	0.6046

Table 7. Syntax Model with Pre-ordering

Analyses of the syntax model in Table 6 revealed that automatically learned rules by the tree-to-string grammar include new rules not covered by the manually written rules, some of which are shown in Table 8.

Parent Node	**Before RO**	**After RO**
ADJP-PRD	RB JJ PP	PP RB JJ
ADVP-TMP	RB PP	PP RB
ADVP	ADVP PP	PP ADVP
NP	NP VP	VP NP

Table 8. New CFG rules automatically learned by Tree-to-String grammar

We augment the manual rules with the new automatically learned rules. We call this extended set of reordering rules RO2. We use the manual reordering rules RO1 for model training, but use the extended rules RO2 for decoding. And we obtain the translation output Syntax+RO2 in Table 7. Syntax+RO2 outperforms Phrase+RO1 by 0.84 BLEU points, and Syntax+RO1 by 0.43 BLEU points.

In Table 9, we show the ratio of each rule type preserved in the derivation of one-best translation output of the following two models: Syntax and Syntax+RO2. In the table, 'Blocks' indicate phrases from the phrase translation model and 'Glue Rules' denote the default grammar rule for monotone decoding.

The syntax model without pre-ordering (Syntax) heavily utilizes the Hiero and tree-to-string grammar rules, whereas the syntax model with pre-ordering (Syntax+RO2) mostly depends on monotone decoding with blocks and glue rules.

Rule Type	Syntax	Syntax+RO2
Blocks	46.3%	51.2%
Glue Rules	6.0%	37.3%
Hiero Rules	18.3%	1.3%
Tree-to-String	29.4%	10.2%

Table 9. Ratio of each rule type preserved in the translation derivation of Syntax and Syntax+RO2

6 Summary and Future Research

We have proposed a constituent pre-ordering technique for English-to-Japanese translation. The technique improves the performance of the state-of-the-art phrase translation models by 4.76 BLEU points and outperforms a syntax-based translation system that incorporates a phrase translation model, Hiero and a tree-to-string grammar. We have also shown that combining constituent pre-ordering and the syntax model improves the translation quality by additional 0.84 BLEU points.

While achieving solid performance improvement over the existing translation models for English-to-Japanese translation, our work has revealed some limitations of syntax models both in terms of grammar representations and modeling. Whereas many syntax models are based on CFG rules for probability acquisition, the current research shows that there are various types of reordering that require the generative capacity beyond CFG. While most of the reordering rules for changing the English order to the Japanese order (and vice versa) should apply categorically,[4] often the probabilities of tree-to-string grammar rules are not high enough to survive in the translation derivations.

As for the reordering rules that require the generative capacity beyond CFG, we may model mildly context sensitive grammars such as tree adjoining grammars (Joshi and Schabes, 1997), as in (Carreras and Collins, 2009). The

[4] Assuming that the parses are correct, the head reordering rules in Table 1 have to apply categorically to change the English order into the Japanese order because English is head initial and Japanese is head final without any exceptions. Similarly, most of the modifier reordering rules in Table 2 have to apply categorically because most modifiers follow the modified head phrase in English, e.g. a relative clause modifier follows the head noun phrase, a prepositional phrase modifier follows the head noun phrase, etc., whereas modifier phrases precede the modified head phrases in Japanese.

extended domain of locality of tree adjoining grammars should suffice to capture non-CFG reordering rules for many language pairs. Alternatively, we can adopt enriched feature representations so that a tree of depth one can actually convey information on a tree of several depths, such as parent annotation of (Klein and Manning, 2003).

Regarding the issue of modeling, we can introduce a rich set of features, as in (Ittycheriah and Roukos, 2007), the weights of which are trained to ensure that the tree-to-string grammar rules generating the accurate target orders are assigned probabilities high enough not to get pruned out in the translation derivation.

Abstract

Polarity shifting marked by various linguistic structures has been a challenge to automatic sentiment classification. In this paper, we propose a machine learning approach to incorporate polarity shifting information into a document-level sentiment classification system. First, a feature selection method is adopted to automatically generate the training data for a binary classifier on polarity shifting detection of sentences. Then, by using the obtained binary classifier, each document in the original polarity classification training data is split into two partitions, polarity-shifted and polarity-unshifted, which are used to train two base classifiers respectively for further classifier combination. The experimental results across four different domains demonstrate the effectiveness of our approach.

1 Introduction

Sentiment classification is a special task of text classification whose objective is to classify a text according to the sentimental polarities of opinions it contains (Pang et al., 2002), e.g., *favorable* or *unfavorable*, *positive* or *negative*. This task has received considerable interests in the computational linguistic community due to its potential applications.

In the literature, machine learning approaches have dominated the research in sentiment classification and achieved the state-of-the-art performance (e.g., Kennedy and Inkpen, 2006; Pang et al., 2002). In a typical machine learning approach, a document (text) is modeled as a bag-of-words, i.e. a set of content words without any word order or syntactic relation information. In other words, the underlying assumption is that the sentimental orientation of the whole text depends on the sum of the sentimental polarities of content words. Although this assumption is reasonable and has led to initial success, it is linguistically unsound since many function words and constructions can shift the sentimental polarities of a text. For example, in the sentence '*The chair is not comfortable*', the polarity of the word '*comfortable*' is positive while the polarity of the whole sentence is reversed because of the negation word '*not*'. Therefore, the overall sentiment of a document is not necessarily the sum of the content parts (Turney, 2002). This phenomenon is one main reason why machine learning approaches fail under some circumstances.

As a typical case of polarity shifting, negation has been paid close attention and widely studied in the literature (Na et al., 2004; Wilson et al., 2009; Kennedy and Inkpen, 2006). Generally, there are two steps to incorporate negation information into a system: negation detection and negation classification. For negation detection, some negation trigger words, such as '*no*', '*not*', and '*never*', are usually applied to recognize negation phrases or sentences. As for negation classification, one way to import negation information is to directly reverse the polarity of the words which contain negation trigger words as far as term-counting approaches are considered (Kennedy and Inkpen, 2006). An alternative way is to add some negation features (e.g., negation bigrams or negation phrases) into

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 635–643,
Beijing, August 2010

machine learning approaches (Na et al., 2004). Such approaches have achieved certain success.

There are, however, some shortcomings with current approaches in incorporating negation information. In terms of negation detection, firstly, the negation trigger word dictionary is either manually constructed or relies on existing resources. This leads to certain limitations concerning the quality and coverage of the dictionary. Secondly, it is difficult to adapt negation detection to other languages due to its language dependence nature of negation constructions and words. Thirdly, apart from negation, many other phenomena, e.g., contrast transition with trigger words like '*but*', '*however*', and '*nevertheless*', can shift the sentimental polarity of a phrase or sentence. Therefore, considering negation alone is inadequate to deal with the polarity shifting problem, especially for document-level sentiment classification.

In terms of negation classification, although it is easy for term-counting approaches to integrate negation information, they rarely outperform a machine learning baseline (Kennedy and Inkpen, 2006). Even for machine learning approaches, although negation information is sometimes effective for local cases (e.g., *not good*), it fails on long-distance cases (e.g., *I don't think it is good*).

In this paper, we first propose a feature selection method to automatically generate a large scale polarity shifting training data for polarity shifting detection of sentences. Then, a classifier combination method is presented for incorporating polarity shifting information. Compared with previous ones, our approach highlights the following advantages：First of all, we apply a binary classifier to detect polarity shifting rather than merely relying on trigger words or phrases. This enables our approach to handle different kinds of polarity shifting phenomena. More importantly, a feature selection method is presented to automatically generate the labeled training data for polarity shifting detection of sentences.

The remainder of this paper is organized as follows. Section 2 introduces the related work of sentiment classification. Section 3 presents our approach in details. Experimental results are presented and analyzed in Section 4. Finally, Section 5 draws the conclusion and outlines the future work.

2 Related Work

Generally, sentiment classification can be performed at four different levels: word level (Wiebe, 2000), phrase level (Wilson et al., 2009), sentence level (Kim and Hovy, 2004; Liu et al., 2005), and document level (Turney, 2002; Pang et al., 2002; Pang and Lee, 2004; Riloff et al., 2006). This paper focuses on document-level sentiment classification.

In the literature, there are mainly two kinds of approaches on document-level sentiment classification: term-counting approaches (lexicon-based) and machine learning approaches (corpus-based). Term-counting approaches usually involve deriving a sentiment measure by calculating the total number of negative and positive terms (Turney, 2002; Kim and Hovy, 2004; Kennedy and Inkpen, 2006). Machine learning approaches recast the sentiment classification problem as a statistical classification task (Pang and Lee, 2004). Compared to term-counting approaches, machine learning approaches usually achieve much better performance (Pang et al., 2002; Kennedy and Inkpen, 2006), and have been adopted to more complicated scenarios, such as domain adaptation (Blitzer et al., 2007), multi-domain learning (Li and Zong, 2008) and semi-supervised learning (Wan, 2009; Dasgupta and Ng, 2009) for sentiment classification.

Polarity shifting plays a crucial role in phrase-level, sentence-level, and document-level sentiment classification. However, most of previous studies merely focus on negation shifting (polarity shifting caused by the negation structure). As one pioneer research on sentiment classification, Pang et al. (2002) propose a machine learning approach to tackle negation shifting by adding the tag 'not' to every word between a negation trigger word/phrase (e.g., *not*, *isn't*, *didn't*, etc.) and the first punctuation mark following the negation trigger word/phrase. To their disappointment, considering negation shifting has a negligible effect and even slightly harms the overall performance. Kennedy and Inkpen (2006) explore negation shifting by incorporating negation bigrams as additional features into machine learning approaches. The experimental results show that considering sentiment shifting greatly improves the performance of term-counting approaches but only slightly improves the performance of machine learning approaches. Other studies such as Na et al. (2004), Ding et al. (2008), and Wilson et al. (2009) also explore negation shifting and achieve some improvements[1]. Nonetheless, as far as machine learning approaches are concerned, the improvement is rather insignificant (normally less than 1%). More recently, Ikeda et al. (2008) first propose a machine learning approach to detect polarity shifting for sentence-level sentiment classification, based on a manually-constructed dictionary containing thousands of positive and negative sentimental words, and then adopt a term-counting approach to incorporate polarity shifting information.

Polarity Classifier

Figure 1: General framework of our approach

The motivation of our approach is to improve the performance of sentiment classification by robust treatment of sentiment polarity shifting between sentences. With the help of a binary classifier, the sentences in a document are divided into two parts: sentences which contain polarity shifting structures and sentences without any polarity shifting structure. Figure 1 illustrates the general framework of our approach. Note that this framework is a general one, that is, different polarity shifting detection methods can be applied to differentiate polarity-shifted sentences from those polarity-unshifted sentences and different polarity classification methods can be adopted to incorporate sentiment shifting information. For clarification, the training data used for polarity shifting detection and polarity classification are referred to as the polarity shifting training data and the polarity classification training data, respectively.

3.1 Polarity Shifting Detection

In this paper, polarity shifting means that the polarity of a sentence is different from the polarity expressed by the sum of the content words in the sentence. For example, in the sentence "*I am not disappointed*", the negation structure makes the polarity of the word '*disappointed*' different from that of the whole sentence (*negative* vs. *positive*). Apart from the negation structure, many other linguistic structures allow polarity shifting, such as contrast transition, modals, and pre-suppositional items (Polanyi and Zaenen, 2006). We refer these structures as polarity shifting structures.

One of the great challenges in building a polarity shifting detector lies on the lack of relevant training data since manually creating a large scale corpus of polarity shifting sentences is time-consuming and labor-intensive. Ikeda et al. (2008) propose an automatic way for collecting the polarity shifting training data based on a manually-constructed large-scale dictionary. Instead, we adopt a feature selection method to build a large scale training corpus of polarity shifting sentences, given only the already available document-level polarity classification training data. With the help of the feature selection method, the top-ranked word features with strong sentimental polarity orientation, e.g., '*great*', '*love*', '*worst*' are first chosen as the polarity trigger words. Then, those sentences with the top-ranked polarity trigger words in both categories of positive and negative documents are selected. Finally, those candidate sentences taking opposite-polarity compared to the containing trigger word are deemed as polarity-shifted.

The basic idea of automatically generating the polarity shifting training data is based on the assumption that the real polarity of a word or phrase is decided by the major polarity category where the word or phrase appears more often. As a result, the sentences in the

[1] Note that Ding et al. (2006) also consider *but*-clause, another important structure for sentiment shifting. Wilson et al. (2009) use conjunctive and dependency relations among polarity words.

frequently-occurring category would be seen as polarity-unshifted while the sentences in the infrequently-occurring category would be seen as polarity-shifted.

In the literature, various feature selection methods, such as Mutual Information (MI), Information Gain (IG) and Bi-Normal Separation (BNS) (Yang and Pedersen, 1997; Forman 2003), have been employed to cope with the problem of the high-dimensional feature space which is normal in sentiment classification.

In this paper, we employ the theoretical framework, proposed by Li et al. (2009), including two basic measurements, i.e. *frequency measurement* and *ratio measurement*, where the first measures, the document frequency of a term in one category, and the second measures, the ratio between the document frequency in one category and other categories. In particular, a novel method called Weighed Frequency and Odds (WFO) is proposed to incorporate both basic measurements:

$$WFO(t,c_i)=P(t\,|\,c_i)^{\lambda}\{\max(0,\log\frac{P(t\,|\,c_i)}{P(t\,|\,\overline{c_i})})\}^{1-\lambda}$$

where $P(t\,|\,c_i)$ denotes the probability that a document *x* contains the term *t* with the condition that *x* belongs to category c_i ; $P(t\,|\,\overline{c_i})$ denotes the probability that a document *x* contains the term *t* with the condition that *x* does not belong to category c_i. The left part of the formula $P(t\,|\,c_i)$ implies the first basic measurement and the right part $\log(P(t\,|\,c_i)/P(t\,|\,\overline{c_i}))$ implies the second one. The parameter λ $(0\le\lambda\le1)$ is thus to tune the weight between the two basic measurements. Especially, when λ equals 0, the WFO method fades to the MI method which fully prefers the second basic measurement.

Figure 2 illustrates our algorithm for automatically generating the polarity shifting training data where c_1 and c_2 denote the two sentimental orientation categories, i.e. negative and positive. *Step A* segments a document into sentences with punctuations. Besides, two special words, ‘*but*’ and ‘*and’*, are used to further segment some contrast transition structures and compound sentences. *Step B* employs the WFO method to rank all features including the words. *Step D* extracts those polarity-shifted and polarity-unshifted sentences containing t_{top-i} where $N_{\max}$ denotes the upper-limit number of sentences in each category of the polarity shifting training data and *#(x)* denotes the total number of the elements in *x*. Apart from that, the first word in the following sentence is also included to capture a common kind of long-distance polarity shifting structure: contrast transition. Thus, important trigger words like ‘*however*’ and ‘*but*’ may be considered. Finally, *Step E* guarantees the balance between the two categories of the polarity shifting training data.

Given the polarity shifting training data, we apply SVM classification algorithm to train a polarity-shifting detector with word unigram features.

```
Input:
    The polarity classification training data: the negative sentimental document set $D_{c_1}$ and the positive sentimental document set $D_{c_2}$.
Output:
    The polarity shifting training data: the polarity-unshifted sentence set $S_{unshift}$ and the polarity-shifted sentence set $S_{shift}$.
Procedure:
A.  Segment documents $D_{c_1}$ and $D_{c_2}$ to single sentences $S_{c_1}$ and $S_{c_2}$.
B.  Apply feature selection on the polarity classification training data and get the ranked features, $(t_{top-1},...,t_{top-i},...,t_{top-N})$
C.  $S_{shift}$ = {}, $S_{unshift}$ = {}
D.  For $t_{top-i}$ in $(t_{top-1},...,t_{top-i},...,t_{top-N})$ :
    D1) if #($S_{shift}$)> $N_{\max}$ : break
    D2) Collect all sentences $S_{top-i,c_1}$ and $S_{top-i,c_2}$ which contain $t_{top-i}$ from $S_{c_1}$ and $S_{c_2}$ respectively
    D3) if #($S_{top-i,c_1}$)>#($S_{top-i,c_2}$):
                put $S_{top-i,c_2}$ into $S_{shift}$
                put $S_{top-i,c_1}$ into $S_{unshift}$
            else:
                put $S_{top-i,c_1}$ into $S_{shift}$
                put $S_{top-i,c_2}$ into $S_{unshift}$
E.  Randomly select $N_{\max}$ sentences from $S_{unshift}$ as the output of $S_{unshift}$
```

Figure 2: The algorithm for automatically generating the polarity shifting training data

3.2 Polarity Classification with Classifier Combination

After polarity shifting detection, each document in the polarity classification training data is divided into two parts, one containing polarity-shifted sentences and the other containing polarity-unshifted sentences, which are used to form the polarity-shifted training data and the polarity-unshifted training data. In this way, two different polarity classifiers, f_1 and f_2 , can be trained on the polarity-shifted training data and the polarity-unshifted training data respectively. Along with classifier f_3 , trained on all original polarity classification training data, we now have three base classifiers in hand for possible classifier combination via a multiple classifier system.

The key issue in constructing a multiple classifier system (MCS) is to find a suitable way to combine the outputs of the base classifiers. In MCS literature, various methods are available for combining the outputs, such as fixed rules including the voting rule, the product rule and the sum rule (Kittler et al., 1998) and trained rules including the weighted sum rule (Fumera and Roli, 2005) and the meta-learning approaches (Vilalta and Drissi, 2002). In this study, we employ the product rule, a popular fixed rule, and stacking (Džeroski and Ženko, 2004), a well-known trained rule, to combine the outputs.

Formally, each base classifier provides some kind of confidence measurements, e.g., posterior probabilities of the test sample belonging to each class. Formally, each base classifier f_l $(l = 1, 2, 3)$ assigns a test sample (denoted as x_l) a posterior probability vector $\vec{P}(x_l)$:

$$\vec{P}(x_l) = (p(c_1 \mid x_l), p(c_2 \mid x_l))^t$$

where $p(c_1 \mid x_l)$ denotes the probability that the l-th base classifier considers the sample belonging c_1 .

The product rule combines the base classifiers by multiplying the posterior possibilities and using the multiplied possibility for decision, i.e.

$$assign \quad y \to c_j \; when\; j = \arg\max_i \prod_{l=1}^{3} p(c_i \mid x_l)$$

Stacking belongs to well-known meta-learning (Vilalta and Drissi, 2002). The key idea behind meta-learning is to train a meta-classifier with input attributes that are the outputs of the base classifiers. Hence, meta-learning usually needs some development data for generating the meta-training data. Let x' denote a feature vector of a sample from the development data. The output of the l-th base classifier f_l on this sample is the probability distribution over the category set $\{c_1, c_2\}$, i.e.

$$\vec{P}(x'_l) = (p(c_1 \mid x'_l), p_l(c_2 \mid x'_l))$$

A meta-classifier can be trained using the development data with the meta-level feature vector $x^{meta} \in R^{2\times3}$

$$x^{meta} = (\vec{P}(x'_{l=1}), \vec{P}(x'_{l=2}), \vec{P}(x'_{l=3}))$$

Stacking is a specific meta-learning rule, in which a leave-one-out or a cross-validation procedure on the training data is applied to generate the meta-training data instead of using extra development data. In our experiments, we perform stacking with 10-fold cross-validation to generate the meta-training data.

4 Experimentation

4.1 Experimental Setting

The experiments are carried out on product reviews from four domains: books, DVDs, electronics, and kitchen appliances (Blitzer et al., 2007)[2]. Each domain contains 1000 positive and 1000 negative reviews.

For sentiment classification, all classifiers including the polarity shifting detector, three base classifiers and the meta-classifier in stacking are trained by SVM using the SVM-light tool [3] with Logistic Regression method for probability measuring (Platt, 1999).

In all the experiments, each dataset is randomly and evenly split into two subsets: 50% documents as the training data and the remaining 50% as the test data. The features include word unigrams and bigrams with Boolean weights.

4.2 Experimental Results on Polarity Shifting Data

To better understand the polarity shifting phenomena in document-level sentiment classification, we randomly investigate 200

[2] This data set is collected by Blitzer et al. (2007): http://www.seas.upenn.edu/~mdredze/datasets/sentiment/

[3] It is available at: http://svmlight.joachims.org/

polarity-shifted sentences, together with their contexts (i.e. the sentences before and after it), automatically generated by the WFO ($\lambda = 0$) feature selection method. We find that nearly half of the automatically generated polarity-shifted sentences are actually polarity-unshifted sentences or difficult to decide. That is to say, the polarity shifting training data is noisy to some extent. One main reason is that some automatically selected trigger words do not really contain sentiment information, e.g., ‘*hear*’, ‘*information*’ etc. Another reason is that some reversed opinion is given in a review without any explicit polarity shifting structures.

To gain more insights, we manually checked 100 sentences which are explicitly polarity-shifted and can also be judged by human according to their contexts. Table 1 presents some typical structures causing polarity shifting. It shows that the most common polarity shifting type is Explicit Negation (37%), usually expressed by trigger words such as ‘*not*’, ‘*no*’, or ‘*without*’, e.g., in the sentence ‘*I am not happy with this flashcard at all*’. Another common type of polarity shifting is Contrast Transition (20%), expressed by trigger words such as ‘*however*’, e.g., in the sentence ‘*It is large and stylish, however, I cannot recommend it because of the lid*’. Other less common yet productive polarity shifting types include Exception and Until. Exception structure is usually expressed by the trigger phrase ‘*the only*’ to indicate the one and only advantage of the product, e.g., in the sentence ‘*The only thing that I like about it is that bamboo is a renewable resource*’. Until structure is often expressed by the trigger word ‘*until*’ to show the reversed polarity, e.g. in the sentence ‘*This unit was a great addition until the probe went bad after only a few months*’.

Polarity Shifting Structures	Trigger Words/Phrases	Distribution (%)
Explicit Negation	*not, no, without*	37
Contrast Transition	*but, however, unfortunately*	20
Implicit Negation	*avoid, hardly,*	7
False Impression	*look, seem*	6
Likelihood	*probably, perhaps*	5
Counter-factual	*should, would*	5
Exception	*the only*	5
Until	*until*	3

Table 1: Statistics on various polarity shifting structures

4.3 Experimental Results on Polarity Classification

For comparison, several classifiers with different classification methods are developed.

1) Baseline classifier, which applies SVM with all unigrams and bigrams. Note that it also serves as a base classifier in the following combined classifiers.

2) Base classifier 1, a base classifier for the classifier combination method. It works on the polarity-unshifted data.

3) Base classifier 2, another base classifier for the classifier combination method. It works on the polarity-shifted data.

4) Negation classifier, which applies SVM with all unigrams and bigrams plus negation bigrams. It is a natural extension of the baseline classifier with the consideration of negation bigrams. In this study, the negation bigrams are collected using some negation trigger words, such as ‘*not*’ and ‘*never*’. If a negation trigger word is found in a sentence, each word in the sentence is attached with the word ‘*_not*’ to form a negation bigram.

5) Product classifier, which combines the baseline classifier, the base classifier 1 and the base classifier 2 using the product rule.

6) Stacking classifier, a combined classifier similar to the **Product classifier**. It uses the stacking classifier combination method instead of the product rule.

Please note that we do not compare our approach with the one as proposed in Ikeda et al. (2008) due to the absence of a manually-collected sentiment dictionary. Besides, it is well known that a combination strategy itself is capable of improving the classification performance. To justify whether the improvement is due to the combination strategy or our polarity shifting detection or both, we first randomly split the training data into two portions and train two base classifiers on each portion, then apply the stacking method to combine them along with the baseline classifier. The corresponding results are shown as ‘Random+Stacking’ in Table 2. Finally, in our experiments, *t*-test is performed to evaluate the significance of the performance improvement between two systems employing different methods (Yang and Liu, 1999).

Domain	Baseline	Base Classifier 1	Base Classifier 2	Negation Classifier	Random + Stacking	Shifting + Product	Shifting + Stacking
Book	0.755	0.756	0.670	0.759	0.764	0.772	**0.785**
DVD	0.750	0.743	0.667	0.748	0.759	0.768	**0.770**
Electronic	0.779	0.786	0.711	0.785	0.789	0.820	**0.830**
Kitchen	0.818	0.814	0.683	0.826	0.835	0.840	**0.849**

Table 2: Performance comparison of different classifiers with equally-splitting between training and test data

Performance comparison of different classifiers

Table 2 shows the accuracy results of different methods using 2000 polarity shifted sentences and 2000 polarity-unshifted sentences to train the polarity shifting detector (N_{max}=2000). Compared to the baseline classifier, it shows that: 1) The base classifier 1, which only uses the polarity-unshifted sentences as the training data, achieves similar performance. 2) The base classifier 2 achieves much lower performance due to much fewer sentences involved. 3) Including negation bigrams usually allows insignificant improvements (*p-value*>0.1), which is consistent with most of previous works (Pang et al., 2002; Kennedy and Inkpen, 2006). 4) Both the product and stacking classifiers with polarity shifting detection significantly improve the performance (*p-value*<0.05). Compared to the product rule, the stacking classifier is preferable, probably due to the performance unbalance among the individual classifiers, e.g., the performance of the base classifier 2 is much lower than the other two. Although stacking with two randomly generated base classifiers, i.e. "Random + Stacking", also consistently outperforms the baseline classifier, the improvements are much lower than what has been achieved by our approach. This suggests that both the classifier combination strategy and polarity shifting detection contribute to the overall performance improvement.

Effect of WFO feature selection method

Figure 3 presents the accuracy curve of the stacking classifier when using different Lambda (λ) values in the WFO feature selection method. It shows that those feature selection methods which prefer frequency information, e.g., MI and BNS, are better in automatically generating the polarity shifting training data. This is reasonable since high frequency terms, e.g., '*is*', '*it*', '*a*', etc., tend to obey our assumption that the real polarity of one top term should belong to the polarity category where the term appears frequently.

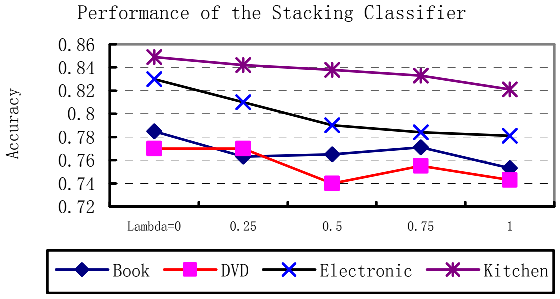

Figure 3: Performance of the stacking classifier using WFO with different Lambda (λ) values

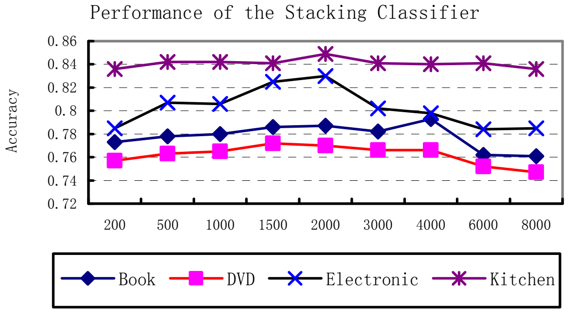

Figure 4: Performance of the stacking classifier over different sizes of the polarity shifting training data (with N_{max} sentences in each category)

Effect of a classifier over different sizes of the polarity shifting training data

Another factor which might influence the overall performance is the size of the polarity shifting training data. Figure 4 presents the overall performance on different numbers of the polarity shifting sentences when using the stacking classifier. It shows that 1000 to 4000 sentences are enough for the performance improvement. When the number is too large, the noisy training data may harm polarity shifting detection. When the number is too small, it is not enough for the automatically generated polarity shifting training data to capture various polarity shifting structures.

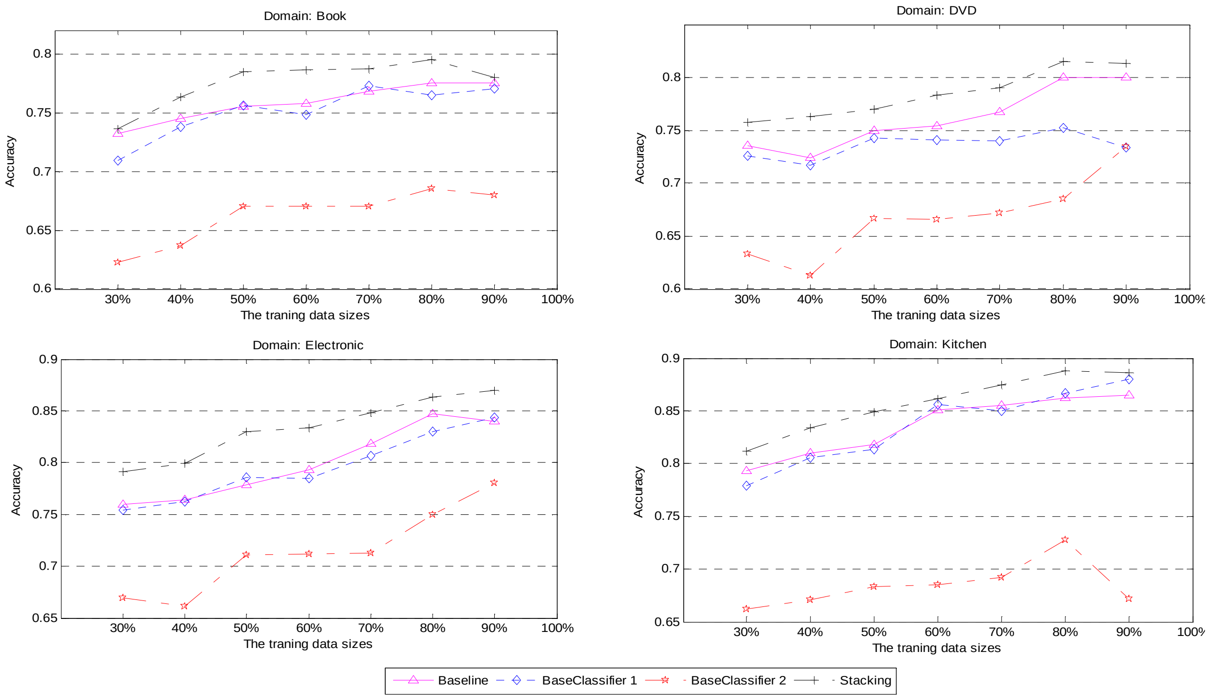

Figure 5: Performance of different classifiers over different sizes of the polarity classification training data

Effect of different classifiers over different sizes of the polarity classification training data

Figure 5 shows the classification results of different classifiers with varying sizes of the polarity classification training data. It shows that our approach is able to improve the overall performance robustly. We also notice the big difference between the performance of the baseline classifier and that of the base classifier 1 when using 30% training data in Book domain and 90% training data in DVD domain. Detailed exploration of the polarity shifting sentences in the training data shows that this difference is mainly attributed to the poor performance of the polarity shifting detector. Even so, the stacking classifier guarantees no worse performance than the baseline classifier.

5 Conclusion and Future Work

In this paper, we propose a novel approach to incorporate polarity shifting information into document-level sentiment classification. In our approach, we first propose a machine-learning-based classifier to detect polarity shifting and then apply two classifier combination methods to perform polarity classification. Particularly, the polarity shifting training data is automatically generated through a feature selection method. As shown in our experimental results, our approach is able to consistently improve the overall performance across different domains and training data sizes, although the automatically generated polarity shifting training data is prone to noise. Furthermore, we conclude that those feature selection methods, which prefer frequency information, e.g., MI and BNS, are good choices for generating the polarity shifting training data.

In our future work, we will explore better ways in generating less-noisy polarity shifting training data. In addition, since our approach is language-independent, it is readily applicable to sentiment classification tasks in other languages.

For availability of the automatically generated polarity shifting training data, please contact the first author (for research purpose only).

Improving Corpus Comparability for Bilingual Lexicon Extraction from Comparable Corpora

Bo Li, Eric Gaussier
Laboratoire d'Informatique de Grenoble (LIG)
Université de Grenoble
firstname.lastname@imag.fr

Abstract

Previous work on bilingual lexicon extraction from comparable corpora aimed at finding a good representation for the usage patterns of source and target words and at comparing these patterns efficiently. In this paper, we try to work it out in another way: improving the quality of the comparable corpus from which the bilingual lexicon has to be extracted. To do so, we propose a measure of comparability and a strategy to improve the quality of a given corpus through an iterative construction process. Our approach, being general, can be used with any existing bilingual lexicon extraction method. We show here that it leads to a significant improvement over standard bilingual lexicon extraction methods.

1 Introduction

Bilingual dictionaries are an essential resource in many multilingual natural language processing (NLP) tasks such as machine translation (Och and Ney, 2003) and cross-language information retrieval (CLIR) (Ballesteros and Croft, 1997). Hand-coded dictionaries are of high quality, but expensive to build and researchers have tried, since the end of the 1980s, to automatically extract bilingual lexicons from parallel corpora (see (Chen, 1993; Kay and Röscheisen, 1993; Melamed, 1997a; Melamed, 1997b) for early work). Parallel corpora are however difficult to get at in several domains, and the majority of bilingual collections are comparable and not parallel. Due to their low cost of acquisition, several researchers have tried to exploit such comparable corpora for bilingual lexicon extraction (Fung and McKeown, 1997; Fung and Yee, 1998; Rapp, 1999; Déjean et al., 2002; Gaussier et al., 2004; Robitaille et al., 2006; Morin et al., 2007; Yu and Tsujii, 2009). The notion of comparability is however a loose one, and comparable corpora range from lowly comparable ones to highly comparable ones and parallel ones. For data-driven NLP techniques, using better corpora often leads to better results, a fact which should be true for the task of bilingual lexicon extraction. This point has largely been ignored in previous work on the subject. In this paper, we develop a well-founded strategy to improve the quality of a comparable corpus, so as to improve in turn the quality of the bilingual lexicon extracted. To do so, we first propose a measure of comparability which we then use in a method to improve the quality of the existing corpus.

The remainder of the paper is organized as follows: Section 2 introduces the experimental materials used for the different evaluations; comparability measures are then presented and evaluated in Section 3; in Section 4, we detail and evaluate a strategy to improve the quality of a given corpus while preserving its vocabulary; the method used for bilingual lexicon extraction is then described and evaluated in Section 5. Section 6 is then devoted to a discussion, prior to the conclusion given in Section 7.

2 Experimental Materials

For the experiments reported here, several corpora were used: the parallel English-French *Europarl* corpus (Koehn, 2005), the TREC

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 644–652,
Beijing, August 2010

(http://trec.nist.gov/) *Associated Press* corpus (*AP*, English) and the corpora used in the multilingual track of CLEF (http://www.clef-campaign.org) which includes the *Los Angeles Times* (*LAT94*, English), *Glasgow Herald* (*GH95*, English), *Le Monde* (*MON94*, French), *SDA French 94* (*SDA94*, French) and *SDA French 95* (*SDA95*, French). In addition to these existing corpora, two monolingual corpora from the Wikipedia dump[1] were built. For English, all the articles below the root category *Society* with a depth less than 4[2] were retained. For French, all the articles with a depth less than 7 below the category *Société* are extracted. As a result, the English corpus *Wiki-En* consists of 367,918 documents and the French one *Wiki-Fr* consists of 378,297 documents.

The bilingual dictionary used in our experiments is constructed from an online dictionary. It consists of 33,372 distinct English words and 27,733 distinct French words, which constitutes 75,845 translation pairs. Standard preprocessing steps: tokenization, POS-tagging and lemmatization are performed on all the linguistic resources. We will directly work on lemmatized forms of content words (nouns, verbs, adjectives, adverbs).

3 Measuring Comparability

As far as we can tell, there are no practical measures with which we can judge the degree of comparability of a bilingual corpus. In this paper, we propose a comparability measure based on the expectation of finding the translation for each word in the corpus. The measure is light-weighted and does not depend on complex resources like the machine translation system. For convenience, the following discussions will be made in the context of the English-French comparable corpus.

3.1 The Comparability Measure

For the comparable corpus $\mathcal{C}$, if we consider the translation process from the English part $\mathcal{C}_e$ to the French part $\mathcal{C}_f$, a comparability measure M_{ef} can be defined on the basis of the expectation of finding, for each English word w_e in the vocabulary $\mathcal{C}_e^v$ of $\mathcal{C}_e$, its translation in the vocabulary $\mathcal{C}_f^v$ of $\mathcal{C}_f$. Let σ be a function indicating whether a translation from the translation set $\mathcal{T}_w$ of w is found in the vocabulary $\mathcal{C}^v$ of a corpus $\mathcal{C}$, i.e.:

$$\sigma(w, \mathcal{C}^v) = \begin{cases} 1 & \text{iff } \mathcal{T}_w \cap \mathcal{C}^v \neq \emptyset \\ 0 & \text{else} \end{cases}$$

M_{ef} is then defined as:

$$\begin{aligned} M_{ef}(\mathcal{C}_e, \mathcal{C}_f) &= \mathbb{E}(\sigma(w, \mathcal{C}_f^v) | w \in \mathcal{C}_e^v) \\ &= \sum_{w \in \mathcal{C}_e^v} \underbrace{\sigma(w, \mathcal{C}_f^v) \cdot Pr(w \in \mathcal{C}_e^v)}_{A_w} \\ &= \frac{|\mathcal{C}_e^v|}{|\mathcal{C}_e^v \cap \mathcal{D}_e^v|} \sum_{w \in \mathcal{C}_e^v \cap \mathcal{D}_e^v} A_w \end{aligned}$$

where $\mathcal{D}_e^v$ is the English part of a given, independent bilingual dictionary $\mathcal{D}$, and where the last equality is based on the fact that, the comparable corpus and the bilingual dictionary being independent of one another, the probability of finding the translation in $\mathcal{C}_f^v$ of a word w is the same for w is in $\mathcal{C}_e^v \cap \mathcal{D}_e^v$ and in $\mathcal{C}_e^v \backslash \mathcal{D}_e^v$[3]. Furthermore, the presence of common words suggests that one should rely on a presence/absence criterion rather than on the number of occurrences to avoid a bias towards common words. Given the natural language text, our evaluation will show that the simple presence/absence criterion can perform very well. This leads to $Pr(w \in \mathcal{C}_e^v) = 1/|\mathcal{C}_e^v|$, and finally to:

$$M_{ef}(\mathcal{C}_e, \mathcal{C}_f) = \frac{1}{|\mathcal{C}_e^v \cap \mathcal{D}_e^v|} \sum_{w \in \mathcal{C}_e^v \cap \mathcal{D}_e^v} \sigma(w, \mathcal{C}_f^v)$$

This formula shows that M_{ef} is actually the proportion of English words translated in the French part of the comparable corpus. Similarly, the counterpart of M_{ef}, M_{fe}, is defined as:

$$M_{fe}(\mathcal{C}_e, \mathcal{C}_f) = \frac{1}{|\mathcal{C}_f^v \cap \mathcal{D}_f^v|} \sum_{w \in \mathcal{C}_f^v \cap \mathcal{D}_f^v} \sigma(w, \mathcal{C}_e^v)$$

[1] The Wikipedia dump files can be downloaded at http://download.wikimedia.org. In this paper, we use the English dump file on July 13, 2009 and the French dump file on July 7, 2009.

[2] There are several cycles in the category tree of Wikipedia. It is thus necessary to define a threshold on the depth to make the iterative process feasible.

[3] The fact can be reliable only when a substantial part of the corpus vocabulary is covered by the dictionary. Fortunately, the constraint is satisfied in most applications where the common but not the specialized corpora like the medical corpora are involved.

and measures the proportion of French words in $\mathcal{C}_f^v$ translated in the English part of the comparable corpus. A symmetric version of these measures is obtained by considering the proportion of the words (both English and French) for which a translation can be found in the corpus:

$$M(\mathcal{C}_e, \mathcal{C}_f) = \frac{\sum_{w \in \mathcal{C}_e^v \cap \mathcal{D}_e^v} \sigma(w, \mathcal{C}_f^v) + \sum_{w \in \mathcal{C}_f^v \cap \mathcal{D}_f^v} \sigma(w, \mathcal{C}_e^v)}{|\mathcal{C}_e^v \cap \mathcal{D}_e^v| + |\mathcal{C}_f^v \cap \mathcal{D}_f^v|}$$

We now present an evaluation of these measures on artificial test corpora.

3.2 Validation

In order to test the comparability measures, we developed gold-standard comparability scores from the *Europarl* and *AP* corpora. We start from the parallel corpus, *Europarl*, of which we degrade the comparability by gradually importing some documents from either *Europarl* or *AP*. Three groups (G_a, G_b, G_c) of comparable corpora are built in this fashion. Each group consists of test corpora with a gold-standard comparability ranging, arbitrarily, from 0 to 1 and corresponding to the proportion of documents in "parallel" translation. The first group G_a is built from *Europarl* only. First, the *Europarl* corpus is split into 10 equal parts, leading to 10 parallel corpora (P_1, P_2, ..., P_{10}) with a gold-standard comparability arbitrarily set to 1. Then for each parallel corpus, e.g. P_i, we replace a certain proportion p of the English part with documents of the same size from another parallel corpus $P_j (j \neq i)$, producing the new corpus P_i' with less comparability which is the gold-standard comparability $1 - p$. For each P_i, as p increases, we obtain several comparable corpora with a decreasing gold-standard comparability score. All the P_i and their descendant corpora constitute the group G_a. The only difference between G_b and G_a is that, in G_b, the replacement in P_i is done with documents from the *AP* corpus and not from *Europarl*. In G_c, we start with 10 final, comparable corpora P_i' from G_a. These corpora have a gold-standard comparability of 0 in G_a, and of 1 in G_c. Then each P_i' is further degraded by replacing certain portions with documents from the *AP* corpus.

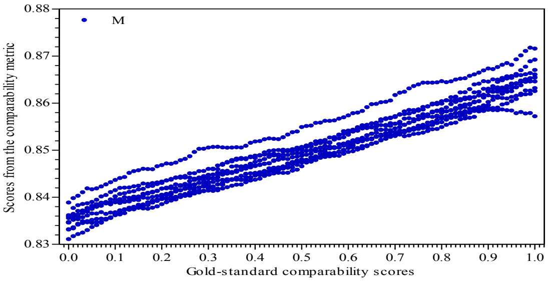

Figure 1: Evolution of M wrt gold-standard on the corpus group G_c (x-axis: gold-standard scores, y-axis: *M* scores)

We then computed, for each comparable corpus in each group, its comparability according to one of the comparability measures. Figure 1 plots the measure M for ten comparable corpora and their descendants from G_c, according to their gold-standard comparability scores. As one can note, the measure M is able to capture almost all the differences in comparability and is strongly correlated with the gold-standard. The correlation between the different measures and the gold-standard is finally computed with Pearson correlation coefficient. The results obtained are listed in Table 1. As one can note, M_{fe} performs worst among the three measures, the reason being that the process to construct G_b and G_c yields unbalanced bilingual corpora, the English section being larger than the French one. Translations of French words are still likely to be found in the English corpus, even though the corpora are not comparable. On all the 3 groups, M performs best and correlates very well with the gold standard, meaning that M was able to capture all the differences in comparability artificially introduced in the degradation process we have considered. This is the measure we will retain in the following parts.

	M_{ef}	M_{fe}	M
G_a	0.897	0.770	0.936
G_b	0.955	0.190	0.979
G_c	0.940	-0.595	0.960

Table 1: Correlation scores for the different comparability measures on the 3 groups of corpora

Having established a measure for the degree of comparability of bilingual corpora, we now turn to the problem of improving the quality of comparable corpora.

4 Improving Corpus Quality

We here try to improve the quality of a given corpus $\mathcal{C}$, which we will refer to as the *base corpus*, by extracting the highly comparable subpart $\mathcal{C}_H$ which is above a certain degree of comparability η (Step 1), and by enriching the lowly comparable part $\mathcal{C}_L$ with texts from other sources (Step 2). As we are interested in extracting information related to the vocabulary of the base corpus, we want the newly built corpus to contain a substantial part of the base corpus. This can be achieved by preserving in Step 1 as many documents from the base corpus as possible (e.g. by considering low values of η), and by using in step 2 sources close to the base corpus.

4.1 Step 1: Extracting $\mathcal{C}_H$

The strategy consisting of building all the possible sub-corpora of a given size from a given comparable corpora is not realistic as soon as the number of documents making up the corpora is larger than a few thousands. In such cases, better ways for extracting subparts have to be designed. The strategy we have adopted here aims at efficiently extracting a subpart of $\mathcal{C}$ above a certain degree of comparability and is based on the following property.

Property 1. *Let d_e^1 and d_e^2 (resp. d_f^1 and d_f^2) be two English (resp. French) documents from a bilingual corpus $\mathcal{C}$. We consider, as before, that the bilingual dictionary $\mathcal{D}$ is independent from $\mathcal{C}$. Let $(d_e^{1'}, d_f^{1'})$ be such that: $d_e^{1'} \subseteq d_e^1$, $d_f^{1'} \subseteq d_f^1$, which means $d_e^{1'}$ is a subpart of d_e^1 and $d_f^{1'}$ is a subpart of d_f^1.*
We assume:

$$\textit{(i)} \qquad \frac{|d_e^1 \cup d_e^2|}{|d_e^2|} = \frac{|d_f^1 \cup d_f^2|}{|d_f^2|}$$

$$\textit{(ii)} \quad M_{ef}(d_e^{1'}, d_f^1) \geq M_{ef}(d_e^2, d_f^2)$$

$$M_{fe}(d_e^1, d_f^{1'}) \geq M_{fe}(d_e^2, d_f^2)$$

Then:

$$M(d_e^2, d_f^2) \leq M(d_e^1 \cup d_e^2, d_f^1 \cup d_f^2)$$

Proof [sketch]: Let $B = (d_e^1 \cup d_e^2) \cap \mathcal{D}_e^v) \backslash (d_e^2 \cap \mathcal{D}_e^v)$. One can show, by exploiting condition (ii), that:

$$\sum_{w \in B} \sigma(w, d_f^1 \cup d_f^2) \geq |B| M_{ef}(d_e^2, d_f^2)$$

and similarly that:

$$\sum_{w \in d_e^2 \cap \mathcal{D}_e^v} \sigma(w, d_f^1 \cup d_f^2) \geq |d_e^2 \cap \mathcal{D}_e^v| M_{ef}(d_e^2, d_f^2)$$

Then exploiting condition (i), and the independence between the corpus and the dictionary, one arrives at:

$$\frac{\sum_{w \in (d_e^1 \cup d_e^2) \cap \mathcal{D}_e^v} \sigma(w, d_f^1 \cup d_f^2)}{|(d_e^1 \cup d_e^2) \cap \mathcal{D}_e^v| + |(d_f^1 \cup d_f^2) \cap \mathcal{D}_f^v|}$$
$$\geq \frac{|d_e^2 \cap \mathcal{D}_e^v| M_{ef}(d_e^2, d_f^2)}{|d_e^2 \cap \mathcal{D}_e^v| + |d_f^2 \cap \mathcal{D}_f^v|}$$

The same development on M_{fe} completes the proof. □

Property 1 shows that one can incrementally extract from a bilingual corpus a subpart with a guaranteed minimum degree of comparability η by iteratively adding new elements, provided (a) that the new elements have a degree of comparability of at least η and (b) that they are less comparable than the currently extracted subpart (conditions (ii)). This strategy is described in Algorithm 1. Since the degree of comparability is always above a certain threshold and since the new documents selected (d_e^2, d_f^2) are the most comparable among the remaining documents, condition (i) is likely to be satisfied, as this condition states that the increase in the vocabulary from the second documents to the union of the two is the same in both languages. Similarly, considering new elements by decreasing comparability scores is a necessary step for the satisfaction of condition (ii), which states that the current subpart should be uniformly more comparable than the element to be added. Hence, the conditions for property 1 to hold are met in Algorithm 1, which finally yields a corpus with a degree of comparability of at least η.

4.2 Step 2: Enriching $\mathcal{C}_L$

This step tries to absorb knowledge from other resources, which will be called *external corpus*,

```
Algorithm 1
Input:
    English document set $\mathcal{C}_e^d$ of $\mathcal{C}$
    French document set $\mathcal{C}_f^d$ of $\mathcal{C}$
    Threshold $\eta$
Output:
    $\mathcal{C}_H$, consisting of the English document set $\mathcal{S}_e$
    and the French document set $\mathcal{S}_f$
Initialize $\mathcal{S}_e = \emptyset, \mathcal{S}_f = \emptyset$, temp $= 0$;
repeat
    $(d_e, d_f) = \underset{d_e \in \mathcal{C}_e^d, d_f \in \mathcal{C}_f^d}{\arg\max} M(d_e, d_f)$;
    temp $= \max_{d_e \in \mathcal{C}_e^d, d_f \in \mathcal{C}_f^d} M(d_e, d_f)$;
    if temp $\geq \eta$ then
        Add $d_e$ into $\mathcal{S}_e$ and add $d_f$ into $\mathcal{S}_f$;
        $\mathcal{C}_e^d = \mathcal{C}_e^d \backslash d_e$, $\mathcal{C}_f^d = \mathcal{C}_f^d \backslash d_f$;
    end if
until $\mathcal{C}_e^d = \emptyset$ or $\mathcal{C}_f^d = \emptyset$ or temp $< \eta$
return $\mathcal{C}_H$;
```

to enrich the lowly comparable part $\mathcal{C}_L$ which is the left part in $\mathcal{C}$ during the creation of $\mathcal{C}_H$. One choice for obtaining the external corpus $\mathcal{C}_T$ is to fetch documents which are likely to be comparable from the Internet. In this case, we first extract representative words for each document in $\mathcal{C}_L$, translate them using the bilingual dictionary and retrieve associated documents via a search engine. An alternative approach is of course to use existing bilingual corpora. Once $\mathcal{C}_T$ has been constructed, the lowly comparable part $\mathcal{C}_L$ can be enriched in exactly the same way as in section 4.1: First, Algorithm 1 is used on the English part of $\mathcal{C}_L$ and the French part of $\mathcal{C}_T$ to get the high-quality document pairs. Then the French part of $\mathcal{C}_L$ is enriched with the English part of $\mathcal{C}_T$ by the same algorithm. All the high-quality document pairs are then added to $\mathcal{C}_H$ to constitute the final result.

4.3 Validation

We use here *GH95* and *SDA95* as the base corpus $\mathcal{C}^0$. In order to illustrate that the efficiency of the proposed algorithm is not confined to a specific external resource, we consider two external resources: (a) $\mathcal{C}_T^1$ made of *LAT94*, *MON94* and *SDA94*, and (b) $\mathcal{C}_T^2$ consisting of *Wiki-En* and *Wiki-Fr*. The number of documents in all the corpora after elimination of short documents (< 30 words) is listed in Table 2.

	$\mathcal{C}^0$	$\mathcal{C}_T^1$	$\mathcal{C}_T^2$
English	55,989	109,476	367,918
French	42,463	87,086	378,297

Table 2: The size of the corpora in the experiments

For the extraction of the highly comparable part $\mathcal{C}_H$ from the base corpus $\mathcal{C}^0$, we set η to 0.3 so as to extract a substantial subpart of $\mathcal{C}^0$. After this step, corresponding to Algorithm 1, we have 20,124 English-French document pairs in $\mathcal{C}_H$. The second step is to enrich the lowly comparable part $\mathcal{C}_L$ of the base corpus documents from the external resources $\mathcal{C}_T^1$ and $\mathcal{C}_T^2$. The final corpora we obtain consist of 46,996 document pairs for $\mathcal{C}^1$ (with $\mathcal{C}_T^1$) and of 54,402 document pairs for $\mathcal{C}^2$ (with $\mathcal{C}_T^2$), size similar to the one of $\mathcal{C}^0$. The proportion of documents (columns “D-e” and “D-f”), sentences (columns “S-e” and “S-f”) and vocabulary (columns “V-e” and “V-f”) of $\mathcal{C}^0$ found in $\mathcal{C}^1$ and $\mathcal{C}^2$ is given in Table 3. As one can note, the final corpora obtained through the method presented above preserve most of the information from the base corpus. Especially for the vocabulary, the final corpora cover nearly all the vocabulary of the base corpus. Considering the comparability scores, the comparability of $\mathcal{C}^1$ is 0.912 and the one of $\mathcal{C}^2$ is 0.916. Both of them are more comparable than the base corpus of which the comparability is 0.882.

From these results of the intrinsic evaluation, one can conclude that the strategy developed to improve the corpus quality while preserving most of its information is efficient: The corpora obtained here, $\mathcal{C}^1$ and $\mathcal{C}^2$, are more comparable than the base corpus $\mathcal{C}^0$ and preserve most of its information. We now turn to the problem of extracting bilingual lexicons from these corpora.

5 Bilingual Lexicon Extraction

Following standard practice in bilingual lexicon extraction from comparable corpora, we rely on the approach proposed by Fung and Yee (1998). In this approach, each word w is represented as a

	D-e	D-f	S-e	S-f	V-e	V-f
$\mathcal{C}^1$	0.669	0.698	0.821	0.805	0.937	0.981
$\mathcal{C}^2$	0.785	0.719	0.893	0.807	0.968	0.987

Table 3: Proportion of documents, sentences and vocabulary of $\mathcal{C}^0$ covered by the result corpora

context vector consisting of the weight $a(w^c)$ of each context word w^c, the context being extracted from a window running through the corpus. Once context vectors for English and French words have been constructed, a general bilingual dictionary $\mathcal{D}$ can be used to bridge them by accumulating the contributions from words that are translation of each other. Standard similarity measures, as the cosine or the Jaccard coefficient, can then be applied to compute the similarity between vectors. For example, the cosine leads to:

$$s_c(w_e, w_f) = \frac{\sum_{(w_e^c, w_f^c)\in\mathcal{D}} a(w_e^c)a(w_f^c)}{\|\overrightarrow{w_e}\| \cdot \|\overrightarrow{w_f}\|} \quad (1)$$

5.1 Using Algorithm 1 pseudo-Alignments

The process we have defined in the previous section to improve the quality of a given corpus while preserving its vocabulary makes use of highly comparable document pairs, and thus provides some loose alignments between the two corpora. One can thus try to leverage the above approach to bilingual lexicon extraction by re-weighting $s_c(w_e, w_f)$ by a quantity which is large if w_e and w_f appear in many document pairs with a high comparability score, and small otherwise. In this section, we can not use the alignments in algorithm 1 directly because the alignments in the comparable corpus should not be 1 to 1 and we did not try to find the precise 1 to 1 alignments in algorithm 1.

Let η be the threshold used in algorithm 1 to construct the improved corpus and let $\phi(d_e, d_f)$ be defined as:

$$\phi(d_e, d_f) = \begin{cases} 1 & \text{iff } M(d_e, d_f) \geq \eta \\ 0 & \text{else} \end{cases}$$

Let $\mathcal{H}_e$ (resp. $\mathcal{H}_f$) be the set of documents containing word w_e (resp. w_f). We define the joint probability of w_e and w_f as being proportional to the number of comparable document pairs they belong to, where two documents are comparable if their comparability score is above η, that is:

$$p(w_e, w_f) \propto \sum_{d_e \in \mathcal{H}_e, d_f \in \mathcal{H}_f} \phi(d_e, d_f)$$

The marginal probability $p(w_e)$ can then be written as:

$$\begin{aligned} p(w_e) &\propto \sum_{w_f \in \mathcal{C}_f^v} p(w_e, w_f) \\ &\propto \sum_{d_e \in \mathcal{H}_e} \sum_{d_f \in \mathcal{C}_f^d} |d_f| \cdot \phi(d_e, d_f) \end{aligned}$$

Assuming that all d_f in $\mathcal{C}_f^d$ have roughly the same vocabulary size and all d_e have the same number of comparable counterparts in $\mathcal{C}_f^d$, then the marginal probability can be simplified as: $p(w_e) \propto |\mathcal{H}_e|$. By resorting to the exponential of the point-wise mutual information, one finally obtains the following weight:

$$\begin{aligned} \pi(w_e, w_f) &= \frac{p(w_e, w_f)}{p(w_e) \cdot p(w_f)} \\ &\propto \frac{1}{|\mathcal{H}_e| \cdot |\mathcal{H}_f|} \sum_{d_e \in \mathcal{H}_e, d_f \in \mathcal{H}_f} \phi(d_e, d_f) \end{aligned}$$

which has the desired property: It is large if the two words appear in comparable document pairs more often than chance would predict, and small otherwise. We thus obtain the revised similarity score for w_e and w_f:

$$s_{cr}(w_e, w_f) = s_c(w_e, w_f) \cdot \pi(w_e, w_f) \quad (2)$$

5.2 Validation

In order to measure the performance of the bilingual lexicon extraction method presented above, we divided the original dictionary into 2 parts: 10% of the English words (3,338 words) together with their translations are randomly chosen and used as the evaluation set, the remaining words (30,034 words) being used to compute context vectors and similarity between them. In this study, the weight $a(w^c)$ used in the context vectors (see above) are taken to be the tf-idf score of w^c: $a(w^c)$ = tf-idf(w^c). English words not present in $\mathcal{C}_e^v$ or with no translation in $\mathcal{C}_f^v$ are excluded from the evaluation set. For each English word in the evaluation set, all the French words in $\mathcal{C}_f^v$ are then ranked according to their similarity with the English word (using either equation 1 or 2). To evaluate the quality of the lexicons extracted, we first retain for each English word its N first translations, and then measure the precision of the lists obtained, which amounts in this case to the proportion of lists containing the correct translation (in case of multiple translations, a list is deemed to contain the correct translation as soon as one of the possible translations is present). This evaluation procedure has been used in previous work (e.g. (Gaussier et al., 2004)) and is now standard for the evaluation of lexicons extracted from comparable corpora. In this study, N is set to 20. Furthermore, several studies have shown that it is easier to find the correct translations for frequent words than for infrequent ones (Pekar et al., 2006). To take this fact into account, we distinguished different frequency ranges to assess the validity of our approach for all frequency ranges. Words with frequency less than 100 are defined as low-frequency words (W_L), whereas words with frequency larger than 400 are high-frequency words (W_H), and words with frequency in between are medium-frequency words (W_M).

We then tested the standard method based on the cosine similarity (equation 1) on the corpora $\mathcal{C}^0$, $\mathcal{C}_H$, $\mathcal{C}'_H$, $\mathcal{C}^1$ and $\mathcal{C}^2$. The results obtained are displayed in Table 4, and correspond to columns 2-6. They show that the standard approach performs significantly better on the improved corpora $\mathcal{C}^1$/$\mathcal{C}^2$ than on the base corpus $\mathcal{C}^0$. The overall precision is increased by 5.3% on $\mathcal{C}^1$ (corresponding to a relative increase of 26%) and 9.5% on $\mathcal{C}^2$ (corresponding to a relative increase of 51%), even though the low-frequency words, which dominate the overall precision, account for a higher proportion in $\mathcal{C}^1$ (61.3%) and $\mathcal{C}^2$ (61.3%) than in $\mathcal{C}^0$ (56.2%). For the medium and high frequency words, the precision is increased by over 11% on $\mathcal{C}^1$ and 16% on $\mathcal{C}^2$. As pointed out in other studies, the performance for the low-frequency words is usually bad due to the lack of context information. This explains the relatively small improvement obtained here (only 2.2% on $\mathcal{C}^1$ and 6.7% on $\mathcal{C}^2$). It should also be noticed that the performance of the standard approach is better on $\mathcal{C}^2$ than on $\mathcal{C}^1$, which may be due to the fact that $\mathcal{C}^2$ is slightly larger than $\mathcal{C}^1$ and thus provides more information or to the actual content of these corpora. Lastly, if we consider the results on the corpus $\mathcal{C}_H$ which is produced by only choosing the highly comparable part from $\mathcal{C}^0$, the overall precision is increased by only 1.9%, which might come from the fact that the size of $\mathcal{C}_H$ is less than half the size of $\mathcal{C}^0$. We also notice the better results on $\mathcal{C}_H$ than on $\mathcal{C}'_H$ of the same size which consists of randomly choosing documents from $\mathcal{C}^0$.

The results obtained with the refined approach making use of the comparable document pairs found in the improved corpus (equation 2) are also displayed in Table 4 (columns "$\mathcal{C}^1$ new" and "$\mathcal{C}^2$ new"). From these results, one can see that the overall precision is further improved by 2.0% on $\mathcal{C}^1$ and 2.3% on $\mathcal{C}^2$, compared with the standard approach. For all the low, medium and high-frequency words, the precision has been improved, which demonstrates that the information obtained through the corpus enrichment process contributes to improve the quality of the extracted bilingual lexicons. Compared with the original base corpus $\mathcal{C}^0$, the overall improvement of the precision on both $\mathcal{C}^1$ and $\mathcal{C}^2$ with the refined approach is significant and important (respectively corresponding to a relative improvement of 35% and 62%), which also demonstrates that the efficiency of the refined approach is not confined to a specific external corpus.

6 Discussion

It is in a way useless to deploy bilingual lexicon extraction techniques if translation equivalents are not present in the corpus. This simple fact is at the basis of our approach which consists in constructing comparable corpora close to the original corpus and which are more likely to contain translation equivalents as they have a guaranteed degree of comparability. The pseudo-alignments identified in the construction process are then used to leverage state-of-the-art bilingual lexicon extraction methods. This approach to bilingual lexicon extraction from comparable corpora radically differs, to our knowledge, from previous approaches

	$\mathcal{C}^0$	$\mathcal{C}_H$	$\mathcal{C}'_H$	$\mathcal{C}^1$	$\mathcal{C}^2$	$\mathcal{C}^1$ new	$> \mathcal{C}^1, > \mathcal{C}^0$	$\mathcal{C}^2$ new	$> \mathcal{C}^2, > \mathcal{C}^0$
W_L	0.114	0.144	0.125	0.136	0.181	0.156	2.0%, 4.2%	0.205	2.4%, 9.1%

Table 4: Precision of the different approaches on different corpora

which are mainly variants of the standard method proposed in (Fung and Yee, 1998) and (Rapp, 1999). For example, the method developed in (Déjean et al., 2002) and (Chiao and Zweigenbaum, 2002) involves a representation of dictionary entries with context vectors onto which new words are mapped. Pekar et al. (2006) smooth the context vectors used in the standard approach in order to better deal with low frequency words. A nice geometric interpretation of these processes is proposed in (Gaussier et al., 2004), which furthermore introduces variants based on Fisher kernels, Canonical Correlation Analysis and a combination of them, leading to an improvement of the F1-score of 2% (from 0.14 to 0.16) when considering the top 20 candidates. In contrast, the approach we have developed yields an improvement of 7% (from 0.13 to 0.20) of the F-1 score on $\mathcal{C}^2$, again considering the top 20 candidates. More important, however, is the fact that the approach we have developed can be used in conjunction with any existing bilingual extraction method, as the strategies for improving the corpus quality and the re-weighting formula (equation 2) are general. We will assess in the future whether substantial gains are also attained with other methods.

Some studies have tried to extract subparts of comparable corpora to complement existing parallel corpora. Munteanu (2004) thus developed a maximum entropy classifier aiming at extracting those sentence pairs which can be deemed parallel. The step for choosing similar document pairs in this work resembles some of our steps. However their work focuses on high quality and specific documents pairs, as opposed to the entire corpus of guaranteed quality we want to build. In this latter case, the cross-interaction between documents impacts the overall comparability score, and new methods, as the one we have introduced, need to be proposed. Similarly, Munteanu and Marcu (2006) propose a method to extract subsentential fragments from non-parallel corpora. Again, the targeted elements are very specific (parallel sentences or sub-sentences) and limited, and the focus is put on a few sentences which can be considered parallel. As already mentioned, we rather focus here on building a new corpus which preserves most of the information in the original corpus. The construction process we have presented is theoretically justified and allows one to preserve ca. 95% of the original vocabulary.

7 Conclusion

We have first introduced in this paper a comparability measure based on the expectation of finding translation word pairs in the corpus. We have then designed a strategy to construct an improved comparable corpus by (a) extracting a subpart of the original corpus with a guaranteed comparability level, and (b) by completing the remaining subpart with external resources, in our case other existing bilingual corpora. We have then shown how the information obtained during the construction process could be used to improve state-of-the-art bilingual lexicon extraction methods. We have furthermore assessed the various steps of our approach and shown: (a) that the comparability measure we introduced captures variations in the degree of comparability between corpora, (b) that the construction process we introduced leads to an improved corpus preserving most of the original vocabulary, and (c) that the use of pseudo-alignments through simple re-weighting yields bilingual lexicons of higher quality.

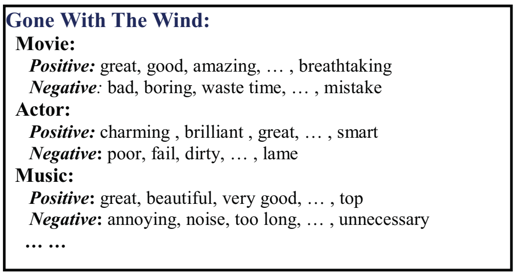
Abstract

In this paper, we focus on object feature[1] based review summarization. Different from most of previous work with linguistic rules or statistical methods, we formulate the review mining task as a joint structure tagging problem. We propose a new machine learning framework based on Conditional Random Fields (CRFs). It can employ rich features to jointly extract positive opinions, negative opinions and object features for review sentences. The linguistic structure can be naturally integrated into model representation. Besides linear-chain structure, we also investigate conjunction structure and syntactic tree structure in this framework. Through extensive experiments on movie review and product review data sets, we show that structure-aware models outperform many state-of-the-art approaches to review mining.

1 Introduction

With the rapid expansion of e-commerce, people are more likely to express their opinions and hands-on experiences on products or services they have purchased. These reviews are important for both business organizations and personal costumers. Companies can decide on their strategies for marketing and products improvement. Customers can make a better decision when purchasing products or services. Unfortunately, reading through all customer reviews is difficult, especially for popular items, the number of reviews can be up to hundreds or even thousands. Therefore, it is necessary to provide coherent and concise summaries for these reviews.



Gone With The Wind:
Movie:
Positive: great, good, amazing, … , breathtaking
Negative: bad, boring, waste time, … , mistake
Actor:
Positive: charming , brilliant , great, … , smart
Negative: poor, fail, dirty, … , lame
Music:
Positive: great, beautiful, very good, … , top
Negative: annoying, noise, too long, … , unnecessary
… …

Figure 1. Feature based Review Summarization

Inspired by previous work (Hu and Liu, 2004; Jin and Ho, 2009), we aim to provide object feature based review summarization. Figure 1 shows a summary example for movie "Gone with the wind". The object (movie) features, such as "movie", "actor", with their corresponding positive opinions and negative opinions, are listed in a structured way. The opinions are ranked by their frequencies. This provides a concise view for reviews. To accomplish this goal, we need to do three tasks: 1), extract all the object features and opinions; 2), determine the sentiment polarities for opinions; 3), for each object feature, determine the relevant opinions, i.e. object feature-opinion pairs.

For the first two tasks, most previous studies employ linguistic rules or statistical methods (Hu and Liu, 2004; Popescu and Etzioni 2005). They mainly use unsupervised learning methods, which lack an effective way to address infrequent object features and opinions. They are also hard to incorporate rich overlapping features.

[1] Note that there are two meanings for word "feature". We use "object feature" to represent the target entity, which the opinion expressed on, and use "feature" as the input for machine learning methods.

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 653–661,
Beijing, August 2010

Actually, there are many useful features, which have not been fully exploited for review mining. Meanwhile, most of previous methods extract object features, opinions, and determine the polarities for opinions separately. In fact, the object features, positive opinions and negative opinions correlate with each other.

In this paper, we formulate the first two tasks, i.e. object feature, opinion extraction and opinion polarity detection, as a joint structure tagging problem, and propose a new machine learning framework based on Conditional Random Fields (CRFs). For each sentence in reviews, we employ CRFs to jointly extract object features, positive opinions and negative opinions, which appear in the review sentence. This framework can naturally encode the linguistic structure. Besides the neighbor context with linear-chain CRFs, we propose to use Skip-chain CRFs and Tree CRFs to utilize the conjunction structure and syntactic tree structure. We also propose a new unified model, Skip-Tree CRFs to integrate these structures. Here, "structure-aware" refers to the output structure, which model the relationship among output labels. This is significantly different from the previous input structure methods, which consider the linguistic structure as heuristic rules (Ding and Liu, 2007) or input features for classification (Wilson et al. 2009). Our proposed framework has the following advantages: First, it can employ rich features for review mining. We will analyze the effect of features for review mining in this framework. Second, the framework can utilize the relationship among object features, positive opinions and negative opinions. It jointly extracts these three types of expressions in a unified way. Third, the linguistic structure information can be naturally integrated into model representation, which provides more semantic dependency for output labels. Through extensive experiments on movie review and product review, we show our proposed framework is effective for review mining.

The rest of this paper is organized as follows: In Section 2, we review related work. We describe our structure aware review mining methods in Section 3. Section 4 demonstrates the process of summary generation. In Section 5, we present and discuss the experiment results. Section 6 is the conclusion and future work.

2 Related Work

Object feature based review summary has been studied in several papers. Zhuang et al. (2006) summarized movie reviews by extracting object feature keywords and opinion keywords. Object feature-opinion pairs were identified by using a dependency grammar graph. However, it used a manually annotated list of keywords to recognize movie features and opinions, and thus the system capability is limited. Hu and Liu (2004) proposed a statistical approach to capture object features using association rules. They only considered adjective as opinions, and the polarities of opinions are recognized with WordNet expansion to manually selected opinion seeds. Popescu and Etzioni (2005) proposed a relaxation labeling approach to utilize linguistic rules for opinion polarity detection. However, most of these studies focus on unsupervised methods, which are hard to integrate various features. Some studies (Breck et al. 2007; Wilson et al, 2009; Kobayashi et al. 2007) have used classification based methods to integrate various features. But these methods separately extract object features and opinions, which ignore the correlation among output labels, i.e. object features and opinions. Qiu et al. (2009) exploit the relations of opinions and object features by adding some linguistic rules. However, they didn't care the opinion polarity. Our framework can not only employ various features, but also exploit the correlations among the three types of expressions, i.e. object features, positive opinions, and negative opinions, in a unified framework. Recently, Jin and Ho (2009) propose to use Lexicalized HMM for review mining. Lexicalized HMM is a variant of HMM. It is a generative model, which is hard to integrate rich, overlapping features. It may encounter sparse data problem, especially when simultaneously integrating multiple features. Our framework is based on Conditional Random Fields (CRFs). CRFs is a discriminative model, which can easily integrate various features.

These are some studies on opinion mining with Conditional Random Fields. For example, with CRFs, Zhao et al (2008) and McDonald et al. (2007) performed sentiment classification in sentence and document level; Breck et al (2007) identified opinion expressions from newswire documents; Choi et al. (2005) determined opinion holders to opinions also from newswire data. None of previous work focuses on jointly extracting object features, positive opinions and negative opinions simultaneously from review data. More importantly, we also show how to encode the linguistic structure, such as conjunction structure and syntactic tree structure, into model representation in our framework. This is significantly different from most of previous studies, which consider the structure information as heuristic rules (Hu and Liu, 2004) or input features (Wilson et al. 2009).

Recently, there are some studies on joint sentiment/topic extraction (Mei et al. 2007; Titov and McDonald, 2008; Snyder and Barzilay, 2007). These methods represent reviews as several coarse-grained topics, which can be considered as clusters of object features. They are hard to indentify the low-frequency object features and opinions. While in this paper, we will extract all the present object features and corresponding opinions with their polarities. Besides, the joint sentiment/topic methods are mainly based on review document for topic extraction. In our framework, we focus on sentence-level review extraction.

3 Structure Aware Review Mining

3.1 Problem Definition

To produce review summaries, we need to first finish two tasks: identifying object features, opinions, and determining the polarities for opinions. In this paper, we formulate these two tasks as a joint structure tagging problem. We first describe some related definitions:

Definition (Object Feature): is defined as whole target expression that the subjective expressions have been commented on. Object features can be products, services or their elements and properties, such as "character", "movie", "director" for movie review, and "battery", "battery life", "memory card" for product review.

Definition (Review Opinion): is defined as the whole subjective expression on object features. For example, in sentence "The camera is easy to use", "easy to use" is a review opinion. "opinion" is used for short.

Definition (Opinion Polarity): is defined as the sentiment category for review opinion. In this paper, we consider two types of polarities: positive opinion and negative opinion. For example, "easy to use" belongs to positive opinion.

For our review mining task, we need to represent three types of expressions: object features, positive opinions, and negative opinions. These expressions may be words, or whole phrases. We use BIO encoding for tag representation, where the non-opinion and neutral opinion words are represented as "O". With Negation (N), which is only one word, such as "not", "don't", as an independent tag, there are totally 8 tags, as shown in Table 1. The following is an example to denote the tags:

The*/O* camera*/FB* comes*/O* with*/O* a*/O* pitiful*/CB* 32mb*/FB* compact*/FI* flash*/FI* card*/FI ./O*

FB	Feature Beginning	CB	Negative Beginning
FI	Feature Inside	CI	Negative Inside
PB	Positive Beginning	N	Negation Word
PI	Positive Inside	O	Other

Table 1. Basic Tag Set for Review Mining

3.2 Structure Aware Model

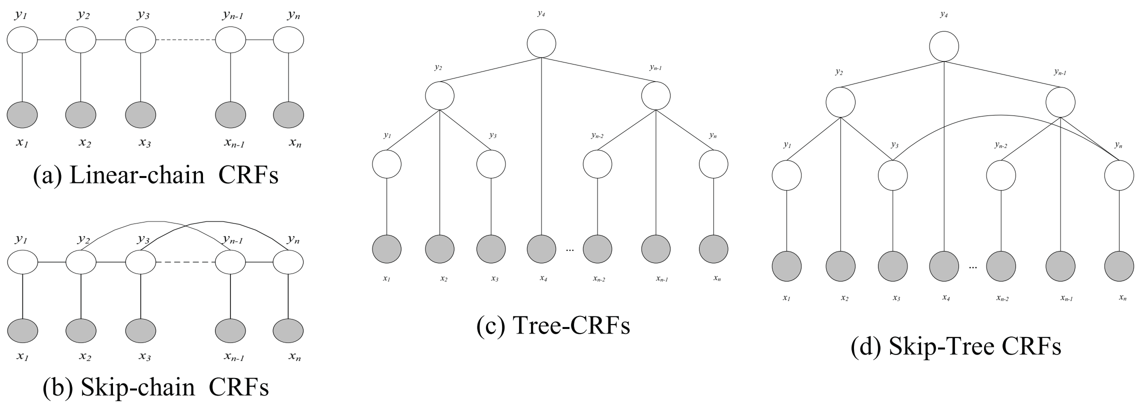
In this section, we describe how to encode different linguistic structure into model representation based on our CRFs framework.

3.2.1 Using Linear CRFs.

For each sentence in a review, our task is to extract all the object features, positive opinions and negative opinions. This task can be modeled as a classification problem. Traditional classification tools, e.g. Maximum Entropy model (Berger et al, 1996), can be employed, where each word or phrase will be treated as an instance. However, they independently consider each word or phrase, and ignore the dependency relationship among them.

Actually, the context information plays an important role for review mining. For example, given two continuous words with same part of speech, if the previous word is a positive opinion, the next word is more likely a positive opinion. Another example is that if the previous word is an adjective, and it is an opinion, the next noun word is more likely an object feature.

To this end, we formulate the review mining task as a joint structure tagging problem, and propose a general framework based on Conditional Random Fields (CRFs) (Lafferty et al., 2001) which are able to model the dependencies



y_1 y_2 y_3 y_{n-1} y_n
x_1 x_2 x_3 x_{n-1} x_n
y_4 y_2 y_{n-1} y_1 y_3 y_{n-2} y_n
x_1 x_2 x_3 x_4 x_{n-2} x_{n-1} x_n
...

(a) Linear-chain CRFs

(b) Skip-chain CRFs

(c) Tree-CRFs

(d) Skip-Tree CRFs

Figure 2 CRFs models

between nodes. (See Section 3.2.5 for more about CRFs)

In this section, we propose to use linear-chain CRFs to model the sequential dependencies between continuous words, as discussed above. It views each word in the sentence as a node, and adjacent nodes are connected by an edge. The graphical representation is shown in Figure 2(a). Linear CRFs can make use of dependency relationship among adjacent words.

3.2.2 Leveraging Conjunction Structure

We observe that the conjunctions play important roles on review mining: If the words or phrases are connected by conjunction "and", they mostly belong to the same opinion polarity. If the words or phrases are connected by conjunction "but", they mostly belong to different opinion polarity, as reported in (Hatzivassiloglou and McKeown, 1997; Ding and Liu, 2007). For example, "This phone has a very cool and useful feature – the speakerphone", if we only detect "cool", it is hard to determine its opinion polarity. But if we see "cool" is connected with "useful" by conjunction "and", we can easily acquire the polarity of "cool" as positive. This conjunction structure not only helps to determine the opinions, but also helps to recognize object features. For example, "I like the special effects and music in this movie", with word "music" and conjunction "and", we can easily detect that "special effects" as an object feature.

To model the long distance dependency with conjunctions, we use Skip-chain CRFs model to detect object features and opinions. The graphical representation of a Skip-chain CRFs, given in Figure 2(b), consists of two types of edges: linear-edge (y_{t-1} to y_t) and skip-edge (y_i to y_j). The linear-edge is described as linear CRFs. The skip-edge is imported as follows:

We first identify the conjunctions in the review sentence, with a collected conjunction set, including "and", "but", "or", "however", "although" etc. For each conjunction, we extract its connected two text sequences. The nearest two words with same part of speech from the two text sequences are connected with the skip-edge. Here, we just consider the noun, adjective, and adverb. For example, in "good pictures and beautiful music", there are two skip-edges: one connects two adjective words "good" and "beautiful"; the other connects two nouns "pictures" and "music". We also employ the general sentiment lexicons, SentiWordNet (Esuli and Sebastiani, 2006), to connect opinions. Two nearest opinion words, detected by sentiment lexicon, from two sequences, will also be connected by skip-edge. If the nearest distance exceeds the threshold, this skip edge will be discarded. Here, we consider the threshold as nine.

Skip-chain CRFs improve the performance of review mining, because it naturally encodes the conjunction structure into model representation with skip-edges.

3.2.3 Leveraging Syntactic Tree Structure

Besides the conjunction structure, the syntactic tree structure also helps for review mining. The tree denotes the syntactic relationship among words. In a syntactic dependency representation, each node is a surface word. For example, the corresponding dependency tree (Klein and Manning, 2003) for the sentence, "I really like this long movie", is shown in Figure 3.

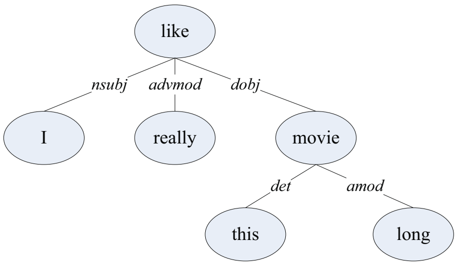


Figure 3. Syntactic Dependency Tree Representation

In linear-chain structure and skip-chain structure, “like” and “movie” have no direct edge, but in syntactic tree, “movie” is directly connected with “like”, and their relationship “dobj” is also included, which shows “movie” is an objective of “like”. It can provide deeper syntactic dependencies for object features, positive opinions and negative opinions. Therefore, it is important to consider the syntactic structure in the review mining task.

In this section, we propose to use Tree CRFs to model the syntactic tree structure for review mining. The representation of a Tree CRFs is shown in Figure 2(c). The syntactic tree structure is encoded into our model representation. Each node is corresponding to a word in the dependency tree. The edge is corresponding to dependency tree edge. Tree CRFs can make use of dependency relationship in syntactic tree structure to boost the performance.

3.2.4 Integrating Conjunction Structure and Syntactic Tree Structure

Conjunction structure provides the semantic relations correlated with conjunctions. Syntactic tree structure provides dependency relation in the syntactic tree. They represent different semantic dependencies. It is interesting to consider these two dependencies in a unified model. We propose Skip-Tree CRFs, to combine these two structure information. The graphical representation of a Skip-Tree CRFs, given in Figure 2(d), consists of two types of edges: tree edges and conjunction skip-edges. We hope to simultaneously model the dependency in conjunction structure and syntactic tree structure.

We also notice that there is a relationship “conj” in syntactic dependency tree. However, we find that it only connects two head words for a few coordinating conjunction, such as “and", “or", “but”. Our designed conjunction skip-edge provides more information for joint structure tagging. We analyze more conjunctions to connect not only two head words, but also the words with same part of speech. We also connect the words with sentiment lexicon. We will show that the skip-tree CRFs, which combine the two structures, is effective in the experiment section.

3.2.5 Conditional Random Fields

A CRFs is an undirected graphical model G of the conditional distribution $P(Y|X)$. Y are the random variables over the labels of the nodes that are globally conditioned on *X*, which are the random variables of the observations. The conditional probability is defined as:

$$\mathrm{P}(Y\,|X) = \frac{1}{Z(X)}\,exp\left(\sum_{e\in E,i} \gamma_i t_i(e, Y|e, X) + \sum_{v\in V,i} \mu_i s_i(v, Y|v, X)\right)$$

where *Z(x)* is the normalization factor, s_i is the state function on node, t_i is the transition functions on edge, and $\,_{,}r_i$ and μ_i are parameters to estimate (Sutton and McCallum, 2006).

Inference and Parameter Estimation. For Linear CRFs, dynamic programming is used to compute the maximum a posteriori (MAP) of *Y* given *X*. For more complicated graphs with cycles, we employ Tree Re-Parameterization (TRP) algorithm (Wainwright et al. 2001) for approximate inference.

Given the training Data $D = \{x^{(i)}, y^{(i)}\}_{i=1}^{n}$, the parameter estimation is to determine the parameters based on maximizing the log-likelihood $L_\theta = \sum_{i=1}^{n} log\, p(y^{(i)}|x^{(i)})$. In Linear CRFs model, dynamic programming and L-BFGS algorithm can be used to optimize objective function L_θ, while for complicated CRFs, TRP is used instead to calculate the marginal probability.

3.3 Feature Space

In this section, we describe the features used in the learning methods. All the features are listed in Figure 4. Word features include the word’s token, lemma, and part of speech. The adjacent words’ information is considered. We detect whether the negation words appear in the previous four words as a binary feature. We also detect whether this word is the superlative form, such as “best”, and comparative form, such as “better”, as binary features. Two types of dictionaries are employed. We use WordNet to acquire the synonyms and antonyms for each word. SentiWordNet (Esuli and Sebastiani, 2006) is used to acquire the prior polarity for each word. We use the words with positive or negative score

Word Feature:
- Word token
- Word lemma
- Word part of speech
- Previous word token, lemma, part of speech
- Next word token, lemma, part of speech
- Negation word appears in previous 4 words
- Is superlative degree
- Is comparative degree

Dictionary Feature
- WordNet Synonym
- WordNet Antonym
- SentiWordNet Prior Polarity

Sentence Feature
- Num of positive words in SentiWordNet
- Num of negative words in SentiWordNet
- Num of Negation word

Syntactic Features:
- Parent word
- Parent SentiWordnet Prior Polarity
- In subject
- In copular
- In object

Edge Feature
- Conjunction word
- Syntactic relationship

Figure 4. Features for learning Methods

above a threshold (0.6). Sentence Feature provides sentence level information. It includes the count of positive words and negative words, which are detected by SentiWordNet. We also incorporate the count of negation words as a feature. There are some syntactic features from dependency tree. Parent word and its polarity are considered. We also detect if the word is subject, object or copular. For edge features, the conjunction words are incorporated as corresponding skip-edge features. The syntactic relationship is considered as a feature for corresponding tree-edge. For classification and linear CRFs models, we just add this edge features as general features.

4 Review Summary Generation

After extracting the object features and opinions, we need to extract the relevant opinions for each feature. In this paper, we identify the nearest opinion word/phrase for each object feature as object feature-opinion pair, which is widely used in previous work (Hu and Liu, 2004; Jin and Ho, 2009). The review summary is generated as a list of structured object feature-opinion pairs, as shown in Figure 1.

5 Experiment

5.1 Experiment setup

Data Set: For our structure tagging task, we need to know the labels for all the words in reviews. In this paper, we manually annotate two types of these review data sets. One is movie review, which contains five movies with totally 500 reviews. The other is product review, which contains four products with totally 601 reviews. We need to label all object features, positive opinions, negative opinions, and the object feature-opinion pairs for all sentences. Each sentence is labeled by two annotators. The conflict is checked by the third person. Finally, we acquire 2207 sentences for movie review and 2533 sentences for product review. For each type, including movie and product, the data set is divided into five parts. We select four parts as training data, and the fifth part as testing data.

Evaluation Metric:

Precision, Recall and F measure are used to test our results, as Jin and Ho (2009).

5.2 Baselines

First word	Second Word	Third Word
JJ	NN or NNS	Anything
RB, RBR or RBS	JJ	NN or NNS
JJ	JJ	NN or NNS
NN or NNS	JJ	Not NN or NNS

Table 2. Rules in rule based method

Rule based Method:

The rule based method is used in Jin and Ho (2009), which is motivated by (Hu and Liu, 2004; Turney, 2002). The employed rules are shown in Table 2. The matching adjective is identified as opinion, and matching nouns are extracted as object features. To determine the polarities of the opinions, 25 positive adjectives and 25 negative adjectives are used as seeds, and then expanded by searching synonyms and antonyms in WordNet. The polarity of a word is detected by checking the collected lists.

Lexicon based Method:

The object features and opinions extraction is same as rule based method. The general sentiment lexicon SentiWordNet is employed to detect the polarity for each word.

Lexicalized HMM:

The object features and opinions are identified by Lexicalized HMM (L-HMM), as Jin and Ho (2009). L-HMM is a variant of HMM. It has two observations. The current tag is not only related

	Methods	Object Features			Positive Opinions			Negative Opinions			Overall		
		P(%)	*R(%)*	*F(%)*	*P(%)*	*R(%)*	*F(%)*	*P(%)*	*R(%)*	*F(%)*	*P(%)*	*R(%)*	*F(%)*

with the previous tag, but also correlates with previous observations. They use word token and part of speech as two features.

Classification based Method:

We also formulate the review mining as a classification task. Each word is considered as an instance. Maximum Entropy (MaxEnt) is used in this paper.

5.3 Experiment results

Since Lexicalized HMM employ word token and part of speech as features (Jin and Ho, 2009), we first conduct comparative experiments with these two features for learning methods. Table 3 shows the results. The rule based method is a little better than lexicon based method. SentiWordNet is designed for general opinion mining, which may be not suitable for domain specific review mining task. For rule based method, the seeds are selected in the review domain, which is more suitable for domain specific task. However, both methods achieve low performance. This because that they only employ simple linguistic rules to extract object features and opinions, which is not effective for infrequent cases and phrase cases. Lexicalized HMM is an extension of HMM. It uses word token and part of speech as two observations. The current tag is not only related with the previous tag, but also correlates with previous two observations. Lexicalized HMM can employ dependency relationship among adjacent words. However, it doesn't achieve the expected result. This is because that Lexicalized HMM is a generative model, which is hard to incorporate rich overlapping features. Even Lexicalized HMM uses linear interpolation smoothing technique. The data sparsity problem seriously hurt the performance. There are many sentences with zero probability. MaxEnt classifier is a discrimitive model, which can incorporate various features. However, it independently classifies each word, and ignores the dependency among successive words. The linear CRFs model achieves best performances for movie review, and product review in overall F-score. This is because that, in our joint structure tagging framework, linear CRFs can employs the global structure to make use of the adjacent dependency relation, and easily incorporate various features to boost the performance.

We also conduct the comparative experiments with all features. From Table 4, we can see that linear CRFs, which consider the chain structure,

Table 5. Feature Evaluations with Skip Tree CRFs (movie)

still achieve better results than MaxEnt classifier method. Skip-chain CRFs model the conjunction structure in the sentence. We can see that the Skip-chain CRFs achieve better results than linear CRFs. This shows that conjunction structure is really important for review mining. For example "although this camera takes great pictures, it is extremely fragile.", "fragile" is not correctly classified by MaxEnt and Linear CRFs. But the Skip-chain CRFs can correctly classify "fragile" as negative opinion, with conjunction "although", and the skip edge between "great" and "fragile". Tree CRFs encode the syntactic tree structure into model representation. Compared with linear-CRFs, the performances are improved for most of expression identification tasks, except for a little decline for product object feature, which may be because that the tags "FB" and "FI" are out of order when transferring to tree structure. These are no significant difference between Skip-Chain CRFs and Tree CRFs. Conjunction structure and syntactic structure represent the semantic dependency from different views. When integrating these two types of dependencies, the Skip-Tree CRFs achieve better overall results than both Skip-Chain CRFs and Tree CRFs.

Table 5 shows the movie review result for Skip Tree model for different types of features. The basic feature only employs word token as feature set. Other features are defined as shown in Figure 4. By adding different features, we find that they all achieve overall improvements than basic feature. The dictionary features are the most important features, especially for positive opinion and negative opinion identification, which shows the importance of prior word's sentiment. Word features also play important roles: Part of speech is reported useful in several papers (such as Jin and Ho, 2009); the superlative and comparative forms are good indicators for opinion words. Syntactic features acquire limited improvement in this experiment. They may overlap with CRF based structure model. We also find that sentence level features contribute to the review mining task. Edge feature is also important. It makes the skip edge and tree edge with the semantic representation. When combing all the features, the result is significantly improved compared with any single feature set, which shows that it is crucial to integrate various features for review mining.

A review summary example, generated by our methods, is shown in Figure 1.

6 Conclusion

In this paper, we formulate the review mining task as a joint structure tagging problem. A new framework based on Conditional Random Fields is proposed. The framework can employ rich features to simultaneously extract object features, positive opinions and negative opinions. With this framework, we investigate the chain structure, conjunction structure and syntactic tree structure for review mining. A new unified model, called skip tree CRFs, is proposed for review mining. Through extensive experiments, we show that our proposed framework is effective. It outperforms many state-of-the-art methods.

In future work, we will improve the object feature-opinion pair detection with other learning methods. We also want to cluster the related object features to provide more concise review summary.

Abstract

This paper addresses the problem of dynamic model parameter selection for log-linear model based statistical machine translation (SMT) systems. In this work, we propose a principled method for this task by transforming it to a test data dependent development set selection problem. We present two algorithms for automatic development set construction, and evaluated our method on several NIST data sets for the Chinese-English translation task. Experimental results show that our method can effectively adapt log-linear model parameters to different test data, and consistently achieves good translation performance compared with conventional methods that use a fixed model parameter setting across different data sets.

1 Introduction

In recent years, log-linear model (Och and Ney, 2002) has been a mainstream method to formulate statistical models for machine translation. Using this formulation, various kinds of relevant properties and data statistics used in the translation process, either on the monolingual-side or on the bilingual-side, are encoded and used as real-valued *feature functions*, thus it provides an effective mathematical framework to accommodate a large variety of SMT formalisms with different computational linguistic motivations.

Formally, in a log-linear SMT model, given a source sentence f, we are to find a translation e^* with largest posterior probability among all possible translations:

$$e^* = \operatorname*{argmax}_e \Pr(e|f)$$

and the posterior probability distribution $\Pr(e|f)$ is directly approximated by a log-linear formulation:

$$\Pr(e|f) = p_{\boldsymbol{\lambda}}(e|f) = \frac{\exp(\sum_{m=1}^{M} \lambda_m h_m(e,f))}{\sum_{e'} \exp(\sum_{m=1}^{M} \lambda_m h_m(e',f))} \quad (1)$$

in which h_m's are feature functions and $\boldsymbol{\lambda} = (\lambda_1, \ldots, \lambda_M)$ are model parameters (*feature weights*).

For a successful practical log-linear SMT model, it is usually a combined result of the several efforts:

- Construction of well-motivated SMT models
- Accurate estimation of feature functions
- Appropriate scaling of log-linear model features (feature weight tuning).

In this paper, we focus on the last mentioned issue – parameter tuning for log-linear model. In general, log-linear model parameters are optimized on a held-out development data set. Using this method, similarly to many machine learning tasks, the model parameters are solely tuned based on the development data, and the optimality of obtained model on unseen test data relies on the assumption that both development and test data observe identical probabilistic distribution,

[*]This work was done while the author was visiting Microsoft Research Asia.

which often does not hold for real-world data. The goal of this paper is to investigate novel methods for test data dependent model parameter selection. We begin with discussing the principle of parameter learning for log-linear SMT models, and explain the rationale of task transformation from parameter selection to development data selection. We describe two algorithms for automatic development set construction, and evaluated our method on several NIST MT evaluation data sets. Experimental results show that our method can effectively adapt log-linear model parameters to different test data and achieves consistent good translation performance compared with conventional methods that use a group of fixed model parameters across different data sets.

2 Model Learning for SMT with Log-linear Models

Model learning refers to the task to estimate a group of suitable log-linear model parameters $\boldsymbol{\lambda} = (\lambda_1, \ldots, \lambda_M)$ for use in Equation 1, which is often formulated as an optimization problem that finds the parameters maximizing certain *goodness* of the translations generated by the learnt model on a development corpus D. The goodness can be measured with either the translations' likelihood or specific machine translation evaluation metrics such as TER or BLEU.

More specifically, let e^* be the most probable translation of D with respect to model parameters $\boldsymbol{\lambda}$, and $E(e^*, \boldsymbol{\lambda}, D)$ be a score function indicating the goodness of translation e^*, then a parameter estimation algorithm will try to find the $\boldsymbol{\lambda}$ which satisfies:

$$\boldsymbol{\lambda}^* = \underset{\boldsymbol{\lambda}}{\operatorname{argmax}}\, E(e^*, \boldsymbol{\lambda}, D) \qquad (2)$$

Note when the goodness scoring function $E(\cdot)$ is specified, the parameter learning criterion in Equation 2 indicates that the derivation of model parameters $\boldsymbol{\lambda}^*$ only depends on development data D, and does not require any knowledge of test data T. The underlying rationale for this rule is that if the test data T observes the same distribution as D, $\boldsymbol{\lambda}^*$ will be optimal for both of them.

On the other side, however, when there are mismatches between development and test data, the translation performance on test data will be suboptimal, which is very common for real-world data. Due to the difference between data sets, generally there is no such $\boldsymbol{\lambda}^*$ that is optimal for multiple data sets at the same time. Table 1 shows some empirical evidences when two data sets are mutually used as development and test data. In this setting, we used a hierarchical phrase based decoder and 2 years' evaluation data of NIST Chinese-to-English machine translation task (for the year 2008 only the newswire subset was used because we want to limit both data sets within the same domain to show that data mismatch also exists even if there is no domain difference), and report results using BLEU scores. Model parameters were tuned using the MERT algorithm (Och, 2003) optimized for BLEU metric.

Dev data	MT05	MT08-nw
MT05	**0.402**	0.306
MT08-nw	0.372	**0.343**

Table 1: Translation performance of cross development/test on two NIST evaluation data sets.

In our work, we present a solution to this problem by using test data dependent model parameters for test data translation. As discussed above, since model parameters are solely determined by development data D, selection of log-linear model parameters is basically equivalent to selecting a set of development data D.

However, automatic development data selection in current SMT research remains a relatively open issue. Manual selection based on human experience and observation is still a common practice.

3 Adaptive Model Parameter Selection

An important heuristic behind manual development data selection is to use the dataset which is as similar to test set as possible in order to work around the data mismatch problem to maximal extent. There are also empirical evidences supporting this heuristics. For instance, it is generally perceived that data set MT03 is more similar to MT05, while MT06-nw is closer to MT08-nw. Table 2 shows experimental results using model parameters induced from MT03 and MT06-nw as development sets with the same settings as in Table 1. As expected, MT06-nw is far more suitable than MT03 as the development data for MT08-nw; yet for test set MT05, the situation is just the opposite.

Dev data	MT05	MT08-nw
MT03	**0.397**	0.306
MT06-nw	0.381	**0.337**

Table 2: Translation performance on different test sets of using different development sets.

In this work, this heuristic is further exploited for automatic development data selection when there is no prior knowledge of the test data available. In the following discussion, we assume the availability of a set of candidate source sentences together with translation references that are qualified for the log-linear model parameter learning task. Let D_F be the full candidate set, given a test set T, the task of selecting a set of development data which can optimize the translation quality on T can be transformed to searching for a suitable subset of D_F which is most similar to T:

$$D^* = \operatorname*{argmax}_{D \subseteq D_F} \mathrm{Sim}(D, T)$$

To achieve this goal, we need to address the following key issues:

- How to define and compute $\mathrm{Sim}(D, T)$, the similarity between different data sets;
- How to extract development data sets from a full candidate set for unseen test data.

3.1 Dataset Similarity

Computing document similarity is a classical task in many research areas such as information retrieval and document classification. However, typical methods for computing document similarity may not be suitable for our purpose. The reasons are two-fold:

1. The sizes of both development and test data are small in usual circumstances, and using similarity measures such as cosine or dice coefficient based on term vectors will suffer from severe data sparseness problems. As a result, the obtained similarity measure will not be statistically reliable.
2. More importantly, what we care about here is not the surface string similarity. Instead, we need a method to measure how similar two data sets are from the view of a log-linear SMT model.

Next we start with discussing the similarity between sentences. Given a source sentence f, we denote its possible translation space with $\mathcal{H}(f)$. In a log-linear SMT model, every translation $e \in \mathcal{H}(f)$ is essentially a feature vector $\boldsymbol{h}(e) = (h_1, \ldots, h_M)$. Accordingly, the similarity between two sentences f_1 and f_2 should be defined on the feature space of the model in use. Let $\boldsymbol{V}(f) = \{\boldsymbol{h}(e) : e \in \mathcal{H}(f)\}$ be the set of feature vectors for all translations in $\mathcal{H}(f)$, we have

$$\mathrm{Sim}(f_1, f_2) = \mathrm{Sim}\Big(\boldsymbol{V}(f_1), \boldsymbol{V}(f_2)\Big) \quad (3)$$

Because it is not practical to compute Equation 3 directly by enumerating all translations in $\mathcal{H}(f_1)$ and $\mathcal{H}(f_2)$ due to the huge search space in SMT tasks, we need to resort to some approximations. A viable solution to this is that if we can use a single feature vector $\tilde{\boldsymbol{h}}(f)$ to represent $\boldsymbol{V}(f)$, then Equation 3 can be simply computed using existing vector similarity measures.

One reasonable method to derive $\tilde{\boldsymbol{h}}(f)$ is to use a feature vector based on the *average* principle – each dimension of the vector is set to the expectation of its corresponding feature value over all translations:

$$\tilde{\boldsymbol{h}}(f) = \sum_{e \in \mathcal{H}(f)} P(e|f)\boldsymbol{h}(e) \quad (4)$$

An alternative and much simpler way to compute $\tilde{\boldsymbol{h}}(f)$ is to employ the *max* principle in which we just use the feature vector of the best translation in $\mathcal{H}(f)$:

$$\tilde{\boldsymbol{h}}(f) = \boldsymbol{h}(e^*) \quad (5)$$

where $e^* = \operatorname{argmax}_e P(e|f)$.

Note that in both Equation 4 and Equation 5 we make use of e's posterior probability $P(e|f)$.

Since the true distribution is unknown, a pre-learnt model $\mathcal{M}$ has to be used to assign approximate probabilities to translations, which indicates that the obtained similarity depends on a specific model. As a convention, we use $\mathrm{Sim}_{\mathcal{M}}(f_1, f_2)$ to denote the similarity between f_1 and f_2 based on $\mathcal{M}$, and call $\mathcal{M}$ the reference model of the computed similarity. To avoid unexpected bias caused by a single reference model, multiple reference models can be simultaneously used, and the similarity is defined to be the maximum of all model-dependent similarity values:

$$\mathrm{Sim}(f_1, f_2) = \max_{\mathcal{M}} \mathrm{Sim}_{\mathcal{M}}(f_1, f_2) \qquad (6)$$

where $\mathcal{M}$ belongs to $\{\mathcal{M}_1, \ldots, \mathcal{M}_n\}$, which is the set of reference models under consideration.

To generalize this method to data set level, we compute the vector $\tilde{\boldsymbol{h}}(S)$ for a data set $S = (f_1, \ldots, f_{|S|})$ as follows:

$$\tilde{\boldsymbol{h}}(S) = \sum_{i=1}^{|S|} \tilde{\boldsymbol{h}}(f_i) \qquad (7)$$

3.2 Development Sets Pre-construction

In the following, we sketch a method for automatically building a set of development data based on the full candidate set D_F before seeing any test data.

Theoretically, a subset of D_F containing randomly sampled sentences from D_F will not meet our requirement well because it is very probable that it will observe a distribution similar to D_F. What we expect is that the pre-built development sets can approximate as many as possible typical data distributions that can be estimated from subsets of D_F. Our solution is based on the assumption that D_F can be depicted by some mixture models, hence we can use classical clustering methods such as k-means to partition D_F into subsets with different distributions.

Let S_F be the set of extracted development data from D_F. The construction of S_{D_F} proceeds as following:

1. Train a log-linear model $\mathcal{M}_F$ using D_F as development data;
2. Compute a feature vector $\tilde{\boldsymbol{h}}(d)$[1] for each sentence $d \in D_F$ using $\mathcal{M}_F$ as reference model;
3. Cluster sentences in D_F using $\tilde{\boldsymbol{h}}(d)/|d|$ as feature vectors;
4. Add obtained sentence clusters to S_{D_F} as candidate development sets.

In the third step, since the feature vector $\tilde{\boldsymbol{h}}(d)$ is defined at sentence level, it is averaged by the number of words in d so that it is irrelevant to the length of a sentence. Considering the outputs of unsupervised data clustering methods are usually sensitive to initial conditions, we include in S_{D_F} sentence clusters based on different initialization configurations to remove related random effects. An initialization configuration for sentence clustering in our work includes starting point for each cluster and total number of clusters. In fact, the inclusion of more sentence clusters increases the diversity of the resulted S_{D_F} as well.

At decoding time, when a test set T is presented, we compute the similarity between T and each development set $D \in S_{D_F}$, and choose the one with largest similarity score as the development set for T:

$$D^* = \operatorname*{argmax}_{D \in S_{D_F}} \mathrm{Sim}(T, D) \qquad (8)$$

When a single reference model is used to compute $\mathrm{Sim}(T, D)$, $\mathcal{M}_F$ is a natural choice. In the multi-model setting as shown in Equation 6, models learnt from the development sets in S_{D_F} can serve this purpose.

Note in this method model learning is not required for every new test set because the model parameters for each development set in S_{D_F} can also be pre-learnt and ready to be used for decoding.

3.3 Dynamic Development Set Construction

In the previous method, test data T is only involved in the process of choosing a development set from a list of candidates but not in process of development set construction. Next we present a

[1] Throughout this paper, a development sentence d generally refers to the source part of it if there is no extra explanation.

method for building a development set on demand based on test data T.

Let $D_F = (d_1, \ldots, d_n)$ be the data set containing all candidate sentences for development data selection. The method is iterative process in which development data and learnt model are alternatively updated. Detailed steps are illustrated as follows:

1. Let $i = 0$, $D_0 = D_F$;
2. Train a model $\mathcal{M}_i$ based on D_i;
3. For each $d_k \in D_F$, compute the similarity score $\mathrm{Sim}_{\mathcal{M}_i}(T, d_k)$ between T and d_k based on model $\mathcal{M}_i$;
4. Select top n candidate sentences with highest similarity scores from D_F to form D_{i+1};
5. Repeat step 2 to step 4 until the similarity between T and latest selected development data converges (the increase in similarity measure is less than a specified threshold compared to last round) or the specified iteration limit is reached.

In step 4, D_{i+1} is greedily extracted from D_F, and there is no guarantee that $\mathrm{Sim}_{\mathcal{M}_i}(T, D_{i+1})$ will increase or decrease after a new sentence is added to D_{i+1}. Thereby the number of selected sentences n needs to be empirically determined. If n is too small, neither the selected data nor the learnt model parameters will be statistically reliable; while if n is too large, we may have to include some sentences that are not suitable for test data in the development data, and miss the opportunity to extract the most desirable development set.

One drawback of this method is the relatively high computational cost because it requires multiple parameter training passes when any test set is presented to the system for translation.

4 Experiments

4.1 Data

Experiments were conducted on the data sets used for NIST Chinese-English machine translation evaluation tasks. MT03 and MT06 data sets, which contain 919 and 1,664 sentences respectively, were used for development data in various settings. MT04, MT05 and MT08 data sets were used for test purpose. In some settings, we also used a test set MT0x, which containing 1,000 sentences randomly sampled from the above 3 data sets. All the translation performance results were measured in terms of case-insensitive BLEU scores.

For all experiments, all parallel corpora available to the constrained track of NIST 2008 Chinese-English MT evaluation task were used for translation model training, which consist of around 5.1M bilingual sentence pairs. GIZA++ was used for word alignment in both directions, which was further refined with the intersec-diag-grow heuristics.

We used a 5-gram language model which was trained from the Xinhua portion of English Gigaword corpus version 3.0 from LDC and the English part of parallel corpora.

4.2 Machine Translation System

We used an in-house implementation of the hierarchical phrase-based decoder as described in Chiang (2005). In addtion to the standard features used in Chiang (2005), we also used a lexicon feature indicating how many word paris in the translation found in a conventional Chinese-English lexicon. Phrasal rules were extracted from all the parallel data, but hierarchical rules were only extracted from the FBIS part of the parallel data which contains around 128,000 sentence pairs. For all the development data, feature weights of the decoder were tuned using the MERT algorithm (Och, 2003).

4.3 Results of Development Data Pre-construction

In the following we first present some overall results using the method of development data pre-construction, then dive into more detailed settings of the experiments.

Table 3 shows the results using 3 different data sets for log-linear model parameter tuning. Elements in the first column indicate the data sets used for parameter tuning, and other columns contain evaluation results on different test sets. In the

Tuning set	MT04	MT05	MT08	MT0x
MT03	0.399 / 0.392	0.395 / 0.390	0.241 / 0.258	0.319 / 0.322
MT06	0.381 / 0.388	0.382 / 0.391	0.275 / 0.283	0.343 / 0.342
MT03+MT06	0.391 / 0.401	0.392 / 0.397	0.265 / 0.281	0.336 / 0.345
Oracle cluster	0.401	0.398	0.293	0.345
Self-training	0.406	0.402	0.298	0.351

Table 3: Translation performance using different methods and data sets for parameter tuning.

third row of the table, MT03+MT06 means combining the data sets of MT03 and MT06 together to form a larger tuning set. The first number in each cell denotes the BLEU score using the tuning set as standard development set D, and the second for using the tuning set as a candidate set D_F.

For all experiment settings in the table, we used cosine value between feature vectors to measure similarity between data sets, and feature vectors were computed according to Equation 5 and Equation 7 using a reference model which is trained on the corresponding candidate set D_F as development set.[2] We adopted the k-means algorithm for data clustering with the number of clusters iterating from 2 to 5. In each iteration, we ran 4 passes of clustering using different initial values. Therefore, in total there are 56 sentence clusters generated in each S_{D_F}.[3]

From the table it can be seen that given the same set of sentences (MT03, MT06 and MT03+MT06), when they are used as the candidate set D_F for the development set preconstruction method, the translation performance is generally better than when they are just used as development sets as a whole. Using MT03 data set as D_F is an exception: there is slight performance drop on test sets MT04 and MT05, but it also helps reduce the performance *see-saw* problem on different test sets as shown in Table 1. Meanwhile, in the other two settings of D_F, we observed significant BLEU score increase on all test sets but MT0x (on which the performance almost kept unchanged). In addition, the fact that using MT03+MT06 as D_F achieves best (or almost best) performance on all test sets implies that it should be a better choice to include as diverse data as possible in D_F.

We also appended two oracle BLEU numbers for each test set in Table 3 for reference. One is denoted with *oracle cluster*, which is the highest possible BLEU that can be achieved on the test set when the development set must be chosen from the sentence clusters in $S_{MT03+MT06}$. The other is labeled as *self-training*, which is the BLEU score that can be obtained when the test data itself is used as development data. This number can serve as actual performance upper bound on the test set.

Next we investigated the impact of using different ways to compute feature vectors presented in Section 3.1. We re-ran some previous experiments on test sets MT04, MT05 and MT08 using MT03+MT06 as D_F. Most settings were kept unchanged except that the feature vector of each sentence was computed according to Equation 4. A 20-best translation list was used to approximate $\mathcal{H}(f)$. The results are shown in Table 4.

Test set	average	max
MT04	0.397	0.401
MT05	0.393	0.397
MT08	0.286	0.281

Table 4: Translation performance when using averaged feature values for similarity computation.

The numbers in the second column are based on Equation 4. Numbers based on Equation 5 are also listed in the third column for comparison. In all the experiment settings we did not observe consistent or significant advantage when using Equation 4 over using Equation 5. Since Equation 5

[2] For example, in all the experiments in the row of MT03 as D_F, we use the same reference model trained with MT03 as development set.

[3] Sometimes some clusters are empty or contain too few sentences, so the actual number may be smaller.

is much simpler, it is a good decision to use it in practice. So did we conduct all following experiments based on Equation 5.

We are also interested in the correlation between two measures: the similarity between development and test data and the actual translation performance on test data.

First we would like to echo the motivating experiment presented in Section 3. Table 5 shows the similarity between the data sets used in the experiment with $\mathcal{M}_{\mathrm{MT03+MT06}}$ as reference model. Obviously the results in Table 2 and Table 5 fit each other very well.

Dev data	MT05	MT08-nw
MT03	**0.99988**	0.99012
MT06-nw	0.99004	**0.99728**

Table 5: Similarity between NIST data sets.

Figure 1 shows the results of a set of more comprehensive experiments on MT05 data set concerning the similarity between development and test sets.

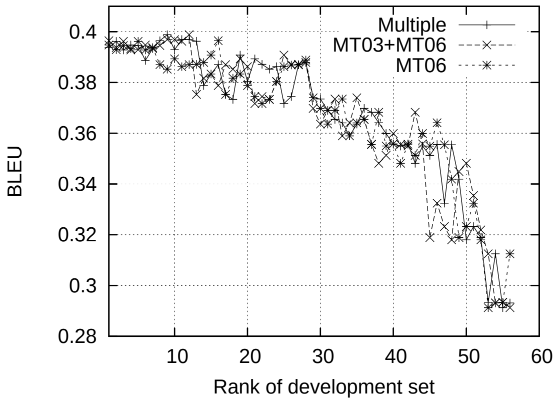

Figure 1: Correlation between similarity and BLEU on MT05 data set

In the figure, every data line shows how BLEU score changes when different pre-built development set in $S_{MT03+MT06}$ is used for model learning. The data points in each line are sorted by the rank of similarity between the development set in use and the MT05 data set. We also compared results based on 3 reference model settings. In the first one (multiple), the similarity was computed using Equation 6, and the reference model set contains all models learnt from the development sets in $S_{MT03+MT06}$. The other two settings use reference models learnt from MT06 and MT03+MT06 data sets respectively.

We can observe from the figure that the correlation between BLEU scores and data set similarity can only be identified on macro scales for all the three similarity settings. Although using data similarity may not be able to select the perfect development data set from S_{D_F}, by picking a development set with highest similarity score, we can usually (almost always) get good enough BLEU scores in our experiments.

4.4 Results of Development Data Dynamic Generation

We ran two sets of experiments for the method of development data dynamic construction.

The first one was designed to investigate how the size of extracted development data affects the translation performance. Using MT05 and MT08 as test sets and MT03+MT06 as D_F, we ran experiments for the algorithm presented in Section 3.3 with $n = 200$ to $n = 1,000$. In this experiment we did not observe significant enough changes in BLEU scores – the difference between the highest and lowest numbers is generally less than 0.005.

The second one aimed at examining how BLEU numbers changes when the extracted development data were iteratively updated. Figure 2 shows one set of results on test sets MT05 and MT08 using MT03+MT06 data set as D_F and n set to 400.

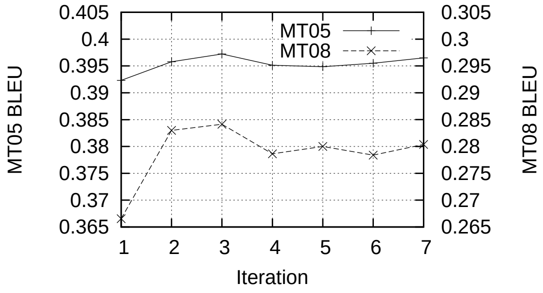

Figure 2: BLEU score as function of iteration in dynamic development data extraction.

The similarity usually converged after 2 to 3 iterations, which is consistent with trend of BLEU scores on test sets. However, in all our experimental settings, we did not observe any results significantly better than using the development set preconstruction method.

5 Discussions

Some of the previous work related to building adaptive SMT systems were discussed in the domain adaptation context, in which one fundamental idea is to estimate a more suitable domain-specific translation model or language model. When the target domain is already known, adding a small amount of domain data (both monolingual and bilingual) to the existing training corpora has been shown to be very effective in practice. But model adaptation is required in more scenarios other than explicitly defined domains. As shown by the results in Table 2, even for the data from the same domain, distribution mismatch can also be a problem.

There are also considerable efforts made to deal with the unknown distribution of text to be translated, and the research topics were still focused on translation and language model adaptation. Typical methods used in this direction include dynamic data selection (Lü et al., 2007; Zhao et al., 2004; Hildebrand et al., 1995) and data weighting (Foster and Kuhn, 2007; Matsoukas et al., 2009). All the mentioned methods use information retrieval techniques to identify relevant training data from the entire training corpora.

Our work presented here also makes no assumption about the distribution of test data, but it differs from the previous methods significantly from a log-linear model's perspective. Adjusting translation and language models based on test data can be viewed as *adaptation of feature values*, while our method is essentially *adaptation of feature weights*. This difference makes these two kinds of methods complementary to each other — it is possible to make further improvement by using both of them in one task.

To our knowledge, there is no dedicated discussion on principled methods to perform development data selection in previous research. In Lü et al. (2007), log-linear model parameters can also be adjusted at decoding time. But in their approach, the adjustment was based on heuristic rules and re-weighted training data distribution. In addition, compared with training data selection, the computational cost of development data selection is much smaller.

From machine learning perspective, both proposed methods can be viewed as certain form of transductive learning applied to the SMT task (Ueffing et al., 2007). But our methods do not rely on surface similarities between training and training/development sentences, and development/test sentences are not used to re-train SMT sub-models.

6 Conclusions and Future Work

In this paper, we addressed the data mismatch issue between training and decoding time of log-linear SMT models, and presented principled methods for dynamically inferring test data dependent model parameters with development set selection. We describe two algorithms for this task, development set pre-construction and dynamic construction, and evaluated our method on the NIST data sets for the Chinese-English translation task. Experimental results show that our methods are capable of consistently achieving good translation performance on multiple test sets with different data distributions without manual tweaking of log-linear model parameters. Though theoretically using the dynamic construction method could bring better results, the pre-construction method performs comparably well in our experimental settings. Considering the fact that the pre-consruction method is computationally cheaper, it should be a better choice in practice.

In the future, we are interested in two directions. One is to explore the possibility to perform data clustering on test set as well and choosing suitable model parameters for each cluster separately. The other involves dynamic SMT model selection – for example, some parts of the test data fit the phrase-based model better while other parts can be better translated using a syntax-based model.

Learning the Scope of Negation via Shallow Semantic Parsing

Junhui Li   Guodong Zhou[*]   Hongling Wang   Qiaoming Zhu

Abstract

In this paper we present a simplified shallow semantic parsing approach to learning the scope of negation (SoN). This is done by formulating it as a shallow semantic parsing problem with the negation signal as the predicate and the negation scope as its arguments. Our parsing approach to SoN learning differs from the state-of-the-art chunking ones in two aspects. First, we extend SoN learning from the chunking level to the parse tree level, where structured syntactic information is available. Second, we focus on determining whether a constituent, rather than a word, is negated or not, via a simplified shallow semantic parsing framework. Evaluation on the BioScope corpus shows that structured syntactic information is effective in capturing the domination relationship between a negation signal and its dominated arguments. It also shows that our parsing approach much outperforms the state-of-the-art chunking ones.

1 Introduction

Whereas negation in predicate logic is well-defined and syntactically simple, negation in natural language is much complex. Generally, learning the scope of negation involves two subtasks: negation signal finding and negation scope finding. The former decides whether the words in a sentence are negation signals (i.e., words indicating negation, e.g., *no*, *not*, *fail*, *rather than*), where the semantic information of the words, rather than the syntactic information, plays a critical role. The latter determines the sequences of words in the sentence which are negated by the given negation signal. Compared with negation scope finding, negation signal finding is much simpler and has been well resolved in the literature, e.g. with the accuracy of 95.8%-98.7% on the three subcorpora of the Bioscope corpus (Morante and Daelemans, 2009). In this paper, we focus on negation scope finding instead. That is, we assume golden negation signal finding.

Finding negative assertions is essential in information extraction (IE), where in general, the aim is to derive factual knowledge from free text. For example, Vincze et al. (2008) pointed out that the extracted information within the scopes of negation signals should either be discarded or presented separately from factual information. This is especially important in the biomedical domain, where various linguistic forms are used extensively to express impressions, hypothesized explanations of experimental results or negative findings. Szarvas et al. (2008) reported that 13.45% of the sentences in the abstracts subcorpus of the BioScope corpus and 12.70% of the sentences in the full papers subcorpus of the Bioscope corpus contain negative assertions. In addition to the IE tasks in the biomedical domain, SoN learning has attracted more and more attention in some natural language processing (NLP) tasks, such as sentiment classification (Turney, 2002). For example, in the sentence "*The chair is not comfortable but cheap*", although both the polarities of the words "*comfortable*" and "*cheap*" are positive, the polarity of "the chair" regarding the attribute "*cheap*" keeps positive while the polarity of "the chair" regarding the attribute "*comfortable*" is reversed due to the negation signal "*not*".

Most of the initial research on SoN learning focused on negated terms finding, using either some heuristic rules (e.g., regular expression), or machine learning methods (Chapman et al., 2001; Huang and Lowe, 2007; Goldin and Chapman, 2003). Negation scope finding has been largely ignored until the recent release of

Beijing, August 2010

the BioScope corpus (Szarvas et al., 2008; Vincze et al., 2008). Morante et al. (2008) and Morante and Daelemans (2009) pioneered the research on negation scope finding by formulating it as a chunking problem, which classifies the words of a sentence as being inside or outside the scope of a negation signal. However, this chunking approach suffers from low performance, in particular on long sentences, due to ignoring structured syntactic information. For example, given golden negation signals on the Bioscope corpus, Morante and Daelemans (2009) only got the performance of 50.26% in PCS (percentage of correct scope) measure on the full papers subcorpus (22.8 words per sentence on average), compared to 87.27% in PCS measure on the clinical reports subcorpus (6.6 words per sentence on average).

This paper explores negation scope finding from a parse tree perspective and formulates it as a shallow semantic parsing problem, which has been extensively studied in the past few years (Carreras and Màrquez, 2005). In particular, the negation signal is recast as the predicate and the negation scope is recast as its arguments. The motivation behind is that structured syntactic information plays a critical role in negation scope finding and should be paid much more attention, as indicated by previous studies in shallow semantic parsing (Gildea and Palmer, 2002; Punyakanok et al., 2005). Our parsing approach to negation scope finding differs from the state-of-the-art chunking ones in two aspects. First, we extend negation scope finding from the chunking level into the parse tree level, where structured syntactic information is available. Second, we focus on determining whether a constituent, rather than a word, is negated or not. Evaluation on the BioScope corpus shows that our parsing approach much outperforms the state-of-the-art chunking ones.

The rest of this paper is organized as follows. Section 2 reviews related work. Section 3 introduces the Bioscope corpus on which our approach is evaluated. Section 4 describes our parsing approach by formulating negation scope finding as a simplified shallow semantic parsing problem. Section 5 presents the experimental results. Finally, Section 6 concludes the work.

2 Related Work

While there is a certain amount of literature within the NLP community on negated terms finding (Chapman et al., 2001; Huang and Lowe, 2007; Goldin and Chapman, 2003), there are only a few studies on negation scope finding (Morante et al., 2008; Morante and Daelemans, 2009).

Negated terms finding

Rule-based methods dominated the initial research on negated terms finding. As a representative, Chapman et al. (2001) developed a simple regular expression-based algorithm to detect negation signals and identify medical terms which fall within the negation scope. They found that their simple regular expression-based algorithm can effectively identify a large portion of the pertinent negative statements from discharge summaries on determining whether a finding or disease is absent. Besides, Huang and Lowe (2007) first proposed some heuristic rules from a parse tree perspective to identify negation signals, taking advantage of syntactic parsing, and then located negated terms in the parse tree using a corresponding negation grammar.

As an alternative to the rule-based methods, various machine learning methods have been proposed for finding negated terms. As a representative, Goldin and Chapman (2003) adopted both Naïve Bayes and decision trees to distinguish whether an observation is negated by the negation signal "*not*" in hospital reports.

Negation scope finding

Morante et al. (2008) pioneered the research on negation scope finding, largely due to the availability of a large-scale annotated corpus, the Bioscope corpus. They approached the negation scope finding task as a chunking problem which predicts whether a word in the sentence is inside or outside of the negation scope, with proper post-processing to ensure consecutiveness of the negation scope. Morante and Daelemans (2009) further improved the performance by combing several classifiers.

Similar to SoN learning, there are some efforts in the NLP community on learning the scope of speculation. As a representative, Özgür and Radev (2009) divided speculation learning into two subtasks: speculation signal finding and speculation scope finding. In particular, they formulated speculation signal finding as a classification problem while employing some heuristic rules from the parse tree perspective on speculation scope finding.

3 Negation in the BioScope Corpus

This paper employs the BioScope corpus (Szarvas et al., 2008; Vincze et al., 2008)[1], a freely downloadable negation resource from the biomedical domain, as the benchmark corpus. In this corpus, every sentence is annotated with negation signals and speculation signals (if it has), as well as their linguistic scopes. Figure 1 shows a self-explainable example. In this paper, we only consider negation signals, rather than speculation ones. Our statistics shows that 96.57%, 3.23% and 0.20% of negation signals are represented by one word, two words and three or more words, respectively. Additional, adverbs (e.g., *not*, *never*) and determiners (e.g., *no*, *neither*) occupy 45.66% and 30.99% of negation signals, respectively.

<sentence id="S26.8">These findings <xcope id="X26.8.2"><cue type="**speculation**" ref="X26.8.2">indicate that</cue> <xcope id="X26.8.1">corticosteroid resistance in bronchial asthma <cue type="**negation**" ref="X26.8.1">can not</cue> be explained by abnormalities in corticosteroid receptor characteristics</xcope></xcope>.</sentence>

Figure 1: An annotated sentence in the BioScope corpus.

The Bioscope corpus consists of three subcorpora: the full papers and the abstracts from the GENIA corpus (Collier et al., 1999), and clinical (radiology) reports. Among them, the full papers subcorpus and the abstracts subcorpus come from the same genre, and thus share some common characteristics in statistics, such as the number of words in the negation scope to the right (or left) of the negation signal and the average scope length. In comparison, the clinical reports subcorpus consists of clinical radiology reports with short sentences. For detailed statistics about the three subcorpora, please see Morante and Daelemans (2009).

For preprocessing, all the sentences in the Bioscope corpus are tokenized and then parsed using the Berkeley parser[2] (Petrov and Klein, 2007) trained on the GENIA TreeBank (GTB) 1.0 (Tateisi et al., 2005)[3], which is a bracketed corpus in (almost) PTB style. 10-fold cross-validation on GTB1.0 shows that the parser achieves the performance of 86.57 in F1-measure. It is worth noting that the GTB1.0 corpus includes all the sentences in the abstracts subcorpus of the Bioscope corpus.

4 Negation Scope Finding via Shallow Semantic Parsing

In this section, we first formulate the negation scope finding task as a shallow semantic parsing problem. Then, we deal with it using a simplified shallow semantic parsing framework.

4.1 Formulating Negation Scope Finding as a Shallow Semantic Parsing Problem

Given a parse tree and a predicate in it, shallow semantic parsing recognizes and maps all the constituents in the sentence into their corresponding semantic arguments (roles) of the predicate. As far as negation scope finding considered, the negation signal can be regarded as the predicate[4], while the scope of the negation signal can be mapped into several constituents which are negated and thus can be regarded as the arguments of the negation signal. In particular, given a negation signal and its negation scope which covers $word_m$, …, $word_n$, we adopt the following two heuristic rules to map the negation scope of the negation signal into several constituents which can be deemed as its arguments in the given parse tree.

1) The negation signal itself and all of its ancestral constituents are non-arguments.
2) If constituent *X* is an argument of the given negation signal, then *X* should be the highest constituent dominated by the scope of $word_m$, …, $word_n$. That is to say, *X*'s parent constituent must cross-bracket or include the scope of $word_m$, …, $word_n$.

[1] http://www.inf.u-szeged.hu/rgai/bioscope

[2] http://code.google.com/p/berkeleyparser/

[3] http://www-tsujii.is.s.u-tokyo.ac.jp/GENIA

[4] If a negation signal consists of multiply words (e.g., rather than), the last word (e.g., than) is chosen to represent the negation signal.

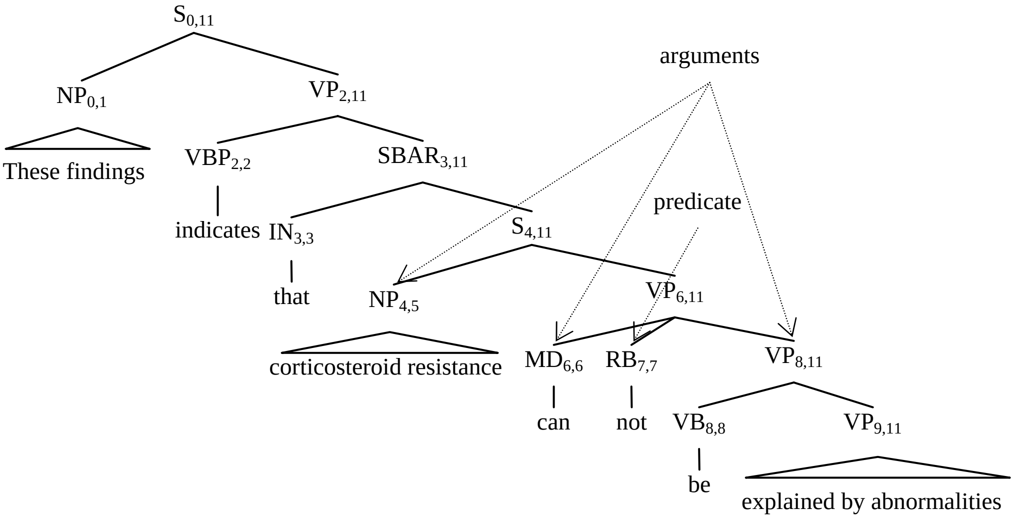

Figure 2: An illustration of a negation signal and its arguments in a parse tree.

The first rule ensures that no argument covers the negation signal while the second rule ensures no overlap between any two arguments. For example, in the sentence "*These findings indicate that corticosteroid resistance can not be explained by abnormalities*", the negation signal "*can not*" has the negation scope "*corticosteroid resistance can not be explained by abnormalities*". As shown in Figure 2, the node "$RB_{7,7}$" (i.e., *not*) represents the negation signal "*can not*" while its arguments include three constituents {$NP_{4,5}$, $MD_{6,6}$, and $VP_{8,11}$}. It is worth noting that according to the above rules, negation scope finding via shallow semantic parsing, i.e. determining the arguments of a given negation signal, is robust to some variations in parse trees. This is also empirically justified by our later experiments. For example, if the $VP_{6,11}$ in Figure 2 is incorrectly expanded by the rule $VP_{6,11} \rightarrow MD_{6,6}+RB_{7,7}+VB_{8,8}+VP_{9,11}$, the negation scope of the negation signal "*can not*" can still be correctly detected as long as {$NP_{4,5}$, $MD_{6,6}$, $VB_{8,8}$, and $VP_{9,11}$} are predicted as the arguments of the negation signal "*can not*".

Compared with common shallow semantic parsing which needs to assign an argument with a semantic label, negation scope finding does not involve semantic label classification and thus could be divided into three consequent phases: argument pruning, argument identification and post-processing.

4.2 Argument Pruning

Similar to the predicate-argument structures in common shallow semantic parsing, the negation signal-scope structures in negation scope finding can be also classified into several certain types and argument pruning can be done by employing several heuristic rules to filter out constituents, which are most likely non-arguments of a negation signal. Similar to the heuristic algorithm as proposed in Xue and Palmer (2004) for argument pruning in common shallow semantic parsing, the argument pruning algorithm adopted here starts from designating the negation signal as the current node and collects its siblings. It then iteratively moves one level up to the parent of the current node and collects its siblings. The algorithm ends when it reaches the root of the parse tree. To sum up, except the negation signal and its ancestral constituents, any constituent in the parse tree whose parent covers the given negation signal will be collected as argument candidates. Taking the negation signal node "$RB_{7,7}$" in Figure 2 as an example, constituents {$MD_{6,6}$, $VP_{8,11}$, $NP_{4,5}$, $IN_{3,3}$, $VBP_{2,2}$, and $NP_{0,1}$} are collected as its argument candidates consequently.

4.3 Argument Identification

Here, a binary classifier is applied to determine the argument candidates as either valid arguments or non-arguments. Similar to argument identification in common shallow semantic parsing, the structured syntactic information plays a critical role in negation scope finding.

Basic Features

Table 1 lists the basic features for argument identification. These features are also widely used in common shallow semantic parsing for both verbal and nominal predicates (Xue, 2008; Li et al., 2009).

Feature	Remarks
b1	Negation: the stem of the negation signal, e.g., not, rather_than. (*can_not*)
b2	Phrase Type: the syntactic category of the argument candidate. (*NP*)
b3	Path: the syntactic path from the argument candidate to the negation signal. (*NP<S>VP>RB*)
b4	Position: the positional relationship of the argument candidate with the negation signal. "left" or "right". (*left*)

Table 1: Basic features and their instantiations for argument identification in negation scope finding, with $NP_{4,5}$ as the focus constituent (i.e., the argument candidate) and "*can not*" as the given negation signal, regarding Figure 2.

Additional Features

To capture more useful information in the negation signal-scope structures, we also explore various kinds of additional features. Table 2 shows the features in better capturing the details regarding the argument candidate and the negation signal. In particular, we categorize the additional features into three groups according to their relationship with the argument candidate (AC, in short) and the given negation signal (NS, in short).

Some features proposed above may not be effective in argument identification. Therefore, we adopt the greedy feature selection algorithm as described in Jiang and Ng (2006) to pick up positive features incrementally according to their contributions on the development data. The algorithm repeatedly selects one feature each time which contributes most, and stops when adding any of the remaining features fails to improve the performance. As far as the negation scope finding task concerned, the whole feature selection process could be done by first running the selection algorithm with the basic features (b1-b4) and then incrementally picking up effective features from (ac1-ac6, AC1-AC2, ns1-ns4, NS1-NS2, nsac1-nsac2, and NSAC1 -NSAC7).

Feature	Remarks
argument candidate (AC) related	
ac1	the headword (ac1H) and its POS (ac1P). (*resistance*, *NN*)
ac2	the left word (ac2W) and its POS (ac2P). (*that*, *IN*)
ac3	the right word (ac3W) and its POS (ac3P). (*can*, *MD*)
ac4	the phrase type of its left sibling (ac4L) and its right sibling (ac4R). (*NULL*, *VP*)
ac5	the phrase type of its parent node. (*S*)
ac6	the subcategory. (*S:NP+VP*)
combined features (AC1-AC2)	
b2&fc1H, b2&fc1P	
negation signal (NS) related	
ns1	its POS. (*RB*)
ns2	its left word (ns2L) and right word (ns2R). (*can*, *be*)
ns3	the subcategory. (*VP:MD+RB+VP*)
ns4	the phrase type of its parent node. (*VP*)
combined features (NS1-NS2)	
b1&ns2L, b1&ns2R	
NS-AC-related	
nsac1	the compressed path of b3: compressing sequences of identical labels into one. (*NP<S>VP>RB*)
nsac2	whether AC and NS are adjacent in position. "yes" or "no". (*no*)
combined features (NSAC1-NSAC7)	
b1&b2, b1&b3, b1&nsac1, b3&NS1, b3&NS2, b4&NS1, b4&NS2	

Table 2: Additional features and their instantiations for argument identification in negation scope finding, with $NP_{4,5}$ as the focus constituent (i.e., the argument candidate) and "*can not*" as the given negation signal, regarding Figure 2.

4.4 Post-Processing

Although a negation signal in the BioScope corpus always has only one continuous block as its negation scope (including the negation signal itself), the negation scope finder may result in discontinuous negation scope due to independent prediction in the argument identification phase. Given the golden negation signals, we observed that 6.2% of the negation scopes predicted by our negation scope finder are discontinuous.

Figure 3 demonstrates the projection of all the argument candidates into the word level. According to our argument pruning algorithm in Section 4.2, except the words presented by the negation signal, the projection covers the whole sentence and each constituent (*LAC_i* or *RAC_j* in Figure 3) receives a probability distribution of being an argument of the given negation signal in the argument identification phase.

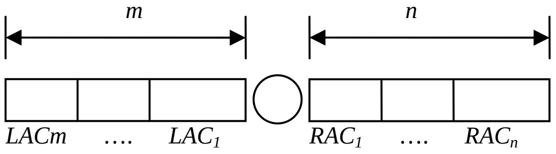

Figure 3: Projecting the left and the right argument candidates into the word level.

Since a negation signal is deemed inside of its negation scope in the BioScope corpus, our post-processing algorithm first includes the negation signal in its scope and then starts to identify the left and the right scope boundaries, respectively.

As shown in Figure 3, the left boundary has *m+1* possibilities, namely the negation signal itself, the leftmost word of constituent *LAC_i* (*1<=i<=m*). Supposing *LAC_i* receives probability of *P_i* being an argument, we use the following formula to determine *LAC_{k*}* whose leftmost word represents the boundary of the left scope. If *k*=0*, then the negation signal itself represents its left boundary.

$$k^* = \arg\max_k \prod_{i=1}^{k} P_i * \prod_{i=k+1}^{m} (1-P_i)$$

Similarly, the right boundary of the given negation signal can be decided.

5 Experimentation

We have evaluated our shallow semantic parsing approach to negation scope finding on the BioScope corpus.

5.1 Experimental Settings

Following the experimental setting in Morante and Daelemans (2009), the abstracts subcorpus is randomly divided into 10 folds so as to perform 10-fold cross validation, while the performance on both the papers and clinical reports subcorpora is evaluated using the system trained on the whole abstracts subcorpus. In addition, SVMLight[5] is selected as our classifier. In particular, we adopt the linear kernel and the training parameter C is fine-tuned to 0.2.

The evaluation is made using the accuracy. We report the accuracy using three measures: *PCLB* and *PCRB*, which indicate the percentages of correct left boundary and right boundary respectively, *PCS*, which indicates the percentage of correct scope as a whole.

5.2 Experimental Results on Golden Parse Trees

In order to select beneficial features from the additional features proposed in Section 4.3, we randomly split the abstracts subcorpus into training and development datasets with proportion of 4:1. After performing the greedy feature selection algorithm on the development data, features {NSAC5, ns2R, NS1, ac1P, ns3, NSAC7, ac4R} are selected consecutively for argument identification. Table 3 presents the effect of selected features in an incremental way on the development data. It shows that the additional features significantly improve the performance by 11.66% in PCS measure from 74.93% to 86.59% ($\chi^2; p < 0.01$).

Feature	PCLB	PCRB	PCS
Baseline	84.26	88.92	74.93
+NSAC5	90.96	88.92	81.34
+ns2R	91.55	88.92	81.92
+NS1	92.42	89.50	83.09
+ac1P	93.59	89.50	84.26
+ns3	93.88	90.09	84.84
+NSAC7	94.75	89.80	85.42
+ac4R	95.04	90.67	86.59

Table 3: Performance improvement (%) of including the additional features in an incremental way on the development data (of the abstracts subcorpus).

However, Table 3 shows that the additional features behave quite differently in terms of PCLB and PCRB measures. For example, PCLB measure benefits more from features NSAC5, ns2R, NS1, ac1P, and NSAC7 while PCRB measure benefits more from features NS1 and ac4R. It also shows that the features (e.g., NSAC5, ns2R, NS1, NSAC7) related to neighboring words of the negation signal play a critical role in recognizing both left and right boundaries. This may be due to the fact that neighboring words usually imply sentential information. For example, "*can not be*" indicates a passive clause while "*did not*" indicates an active clause. Table 3 also shows that the recognition of left boundaries is much easier than that of right boundaries. This may be due

[5] http://svmlight.joachims.org/

to the fact that 83.6% of negation signals have themselves as the left boundaries in the abstracts subcorpus.

Table 4 presents the performance on the abstracts subcorpus by performing 10-fold cross-validation. It shows that the additional features significantly improve the performance over the three measures ($\chi^2; p < 0.01$).

Feature	PCLB	PCRB	PCS
Baseline	84.29	87.82	74.05
+selected features	93.06	88.96	83.10

Table 4: Performance (%) of negation scope finding on the abstracts subcorpus using 10-fold cross-validation.

5.3 Experimental Results on Automatic Parse Trees

The GTB1.0 corpus contains 18,541 sentences in which 11,850 of them (63.91%) overlap with the sentences in the abstracts subcorpus[6]. In order to get automatic parse trees for the sentences in the abstracts subcorpus, we train the Berkeley parser with the remaining 6,691 sentences in GTB1.0. The Berkeley parser trained on 6,691 sentences achieves the performance of 85.22 in F1-measure on the other sentences in GTB1.0. For both the full papers and clinical reports subcorpora, we get their automatic parse trees by using two Berkeley parsers: one trained on 6,691 sentences in GBT1.0, and the other trained on all the sentences in GTB1.0.

To test the performance on automatic parse trees, we employ two different configurations. First, we train the argument identification classifier on the abstracts subcorpus using *automatic parse trees* produced by Berkeley parser trained on 6,691 sentences. The experimental results are presented in the rows of *autoparse(t&t)* in Table 5 and Table 6. Then, we train the argument identification classifier on the abstracts subcorpus using *golden parse trees*. The experimental results are presented in the rows of *autoparse(test)* in Table 5 and Table 6.

We also report an oracle performance to explore the best possible performance of our system by assuming that our negation scope finder can always correctly determine whether a candidate is an argument or not. That is, if an argument candidate is outside or cross-brackets with the golden negation scope, then it is a non-argument. The oracle performance is presented in the rows of *oracle* in Table 5 and Table 6.

Table 5 and Table 6 show that:

1) Automatic syntactic parsing lowers the performance of negation scope finding on the abstracts subcorpus in all three measures (e.g. from 83.10 to 81.84 in PCS). As expected, the parser trained on the whole GTB1.0 corpus works better than that trained on 6,691 sentences (e.g. 64.02 Vs. 62.70, and 89.79 Vs. 85.21 in PCS measure on the full papers and the clinical reports subcorpora, respectively). However, the performance decrease shows that negation scope finding is not as sensitive to automatic syntactic parsing as common shallow semantic parsing, whose performance might decrease by about ~10 in F1-measure (Toutanova et al., 2005). This indicates that negation scope finding via shallow semantic parsing is robust to some variations in the parse trees.
2) *autoparse(test)* consistently outperforms *autoparse(t&t)* on both the abstracts and the full papers subcorpora. However, it is surprising to find that *autoparse(t&t)* achieves better performance on the clinical reports subcorpus than *autoparse(test)*. This may be due to the special characteristics of the clinical reports subcorpus, which mainly consists of much shorter sentences with 6.6 words per sentence on average, and better adaptation of the argument identification classifier to the variations in the automatic parse trees.
3) The performance on all three subcorpora indicates that the recognition of right boundary is much harder than that of left boundary. This may be due to the longer right boundary on an average. Our statistics shows that the average left/right boundaries are 1.1/6.9, 0.1/3.7, and 1.2/6.5 words on the abstracts, the full papers and the clinical reports subcorpora, respectively.
4) The oracle performance is less sensitive to automatic syntactic parsing. In addition, given the performance gap between the performance of our negation scope finder and the oracle performance, there is still much room for further performance improvement.

[6] There are a few cases where two sentences in the abstracts subcorpus map into one sentence in GTB.

	Abstracts			Papers			Clinical		
	PCLB	PCRB	PCS	PCLB	PCRB	PCS	PCLB	PCRB	PCS
autoparse(t&t)	91.97	87.82	80.88	85.45	67.20	59.26	97.48	88.30	85.89
autoparse(test)	92.71	88.33	81.84	87.57	68.78	62.70	97.48	87.73	85.21
oracle	99.72	94.59	94.37	98.94	84.13	83.33	99.89	98.39	98.39

Table 5: Performance (%) of negation scope finding on the three subcorpora by using automatic parser trained with 6,691 sentences in GTB1.0.

	Papers			Clinical		
	PCLB	PCRB	PCS	PCLB	PCRB	PCS
autoparse(t&t)	85.98	67.99	60.32	97.48	92.66	90.48
autoparse(test)	87.83	70.11	64.02	97.36	92.20	89.79
oracle	98.94	83.86	83.07	99.77	97.94	97.82

Table 6: Performance (%) of negation scope finding on the two subcorpora by using automatic parser trained with all the sentences in GTB1.0.

Method	Abstracts	Papers	Clinical
M et al. (2008)	57.33	n/a	n/a
M & D (2009)	73.36	50.26	87.27
Our baseline	73.42	53.70	88.42
Our final system	81.84	64.02	89.79

Table 7: Performance comparison over the PCS measure (%) of our system with other state-of-the-art ones.

Table 7 compares our performance in PCS measure with related work. It shows that even our baseline system with four basic features as presented in Table 1 performs better than Morante et al. (2008) and Morante and Daelemans(2009). This indicates the appropriateness of our simplified shallow semantic parsing approach and the effectiveness of structured syntactic information on negation scope finding. It also shows that our final system significantly outperforms the state-of-the-art ones using a chunking approach, especially on the abstracts and full papers subcorpora. However, the improvement on the clinical reports subcorpus is less apparent, partly due to the fact that the sentences in this subcorpus are much simpler (with average length of 6.6 words per sentence) and thus a chunking approach can achieve high performance. Following are two typical sentences from the clinical reports subcorpus, where the negation scope covers the whole sentence (except the period punctuation). Such sentences account for 57% of negation sentences in the clinical reports subcorpus.

(1) No evidence of focal pneumonia .

(2) No findings to account for symptoms .

6 Conclusion

In this paper we have presented a simplified shallow semantic parsing approach to negation scope finding by formulating it as a shallow semantic parsing problem, which has been extensively studied in the past few years. In particular, we regard the negation signal as the predicate while mapping the negation scope into several constituents which are deemed as arguments of the negation signal. Evaluation on the Bioscope corpus shows the appropriateness of our shallow semantic parsing approach and that structured syntactic information plays a critical role in capturing the domination relationship between a negation signal and its negation scope. It also shows that our parsing approach much outperforms the state-of-the-art chunking ones. To our best knowledge, this is the first research on exploring negation scope finding via shallow semantic parsing.

Future research will focus on joint learning of negation signal and its negation scope findings. Although Morante and Daelemans (2009) reported the performance of 95.8%-98.7% on negation signal finding, it lowers the performance of negation scope finding by about 7.29%-16.52% in PCS measure.

Filtered Ranking for Bootstrapping in Event Extraction

grishman@cs.nyu.edu

Abstract

Several researchers have proposed semi-supervised learning methods for adapting event extraction systems to new event types. This paper investigates two kinds of bootstrapping methods used for event extraction: the document-centric and similarity-centric approaches, and proposes a filtered ranking method that combines the advantages of the two. We use a range of extraction tasks to compare the generality of this method to previous work. We analyze the results using two evaluation metrics and observe the effect of different training corpora. Experiments show that our new ranking method not only achieves higher performance on different evaluation metrics, but also is more stable across different bootstrapping corpora.

1 Introduction

The goal of event extraction is to identify instances of a class of events in text, along with the arguments of the event (the participants, place, and time). In this paper we shall focus on the sub-problem of identifying the events themselves.

Event extraction systems from the early and mid 90s relied primarily on hand-coded rules, which must be written anew for every task. Since then, supervised and semi-supervised methods have been developed in order to build systems for new scenarios more easily. Supervised methods can perform quite well with enough training data, but annotating sufficient data may require months of labor. Semi-supervised methods aim to reduce the annotated data required, ideally to a small set of seeds.

Most semi-supervised event extractors seek to learn sets of *patterns* consisting of a predicate and some lexical or semantic constraints on its arguments. The semi-supervised learning was based primarily on one of two assumptions: the document-centric approach, which assumes that relevant patterns should appear more frequently in relevant documents (Riloff 1996; Yangarber et al. 2000; Yangarber 2003; Surdeanu et al 2006); and the similarity-centric approach, which assumes that relevant patterns should have lexically related terms (Stevenson and Greenwood 2005, Greenwood and Stevenson 2006).

An effective semi-supervised extractor will have good performance over a range of extraction tasks and corpora. However, many of the learning procedures just cited have been tested on only one or two extraction tasks, so their generality is uncertain. To remedy this, we have tested learners based on both assumptions, targeting both a MUC (Message Understanding Conference) scenario and several ACE (Automatic Content Extraction) event types. We identify shortcomings of the prior bootstrapping methods, propose a more effective and stable ranking method, and consider the effect of different corpora and evaluation metrics.

2 Related Work

The basic assumption of the document-centric approach is that documents containing a large number of patterns already identified as relevant to a particular IE scenario are likely to contain further relevant patterns. Riloff (1996) initiated

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 680–688,
Beijing, August 2010

this approach and claimed that if a corpus can be divided into documents involving a certain event type and those not involving that type, patterns can be evaluated based on their frequency in relevant and irrelevant documents. Yangarber et al. (2000) incorporated Riloff's metric into a bootstrapping procedure, which started with several seed patterns but required no manual document classification or corpus annotation. The seed patterns were used to identify some relevant documents, and the top-ranked patterns (based on their distribution in relevant and irrelevant documents) were added to the seed set. This process was repeated, assigning a relevance score to each document based on the relevance of the patterns it contains and gradually growing the set of relevant patterns. This approach was further refined by Surdeanu et al. (2006), who used a co-training strategy in which two classifiers seek to classify documents as relevant to a particular scenario. Patwardhan and Riloff (2007) presented an information extraction system that find relevant regions of text and applies extraction patterns within those regions. They created a self-trained relevant sentence classifier to identify relevant regions, and use a semantic affinity measure to automatically learn domain-relevant extraction patterns. They also distinguish primary patterns from secondary patterns and apply the patterns selectively in the relevant regions.

Stevenson and Greenwood (2005) (henceforth 'S&G') suggested an alternative method for ranking the candidate patterns. Their approach relied on the assumption that useful patterns will have similar lexical items to the patterns that have already been accepted. They used WordNet to calculate word similarity. They chose to represent each pattern as a vector consisting of the lexical items and used a version of the cosine metric to determine the similarity between pairs of patterns. Later, Greenwood and Stevenson (2006) introduced a structural similarity measure that could be applied to extraction patterns consisting of linked dependency chains.

3 Ranking Methods in Bootstrapping

Most semi-supervised event extraction systems are based on patterns with variables which have semantic type constraints. A simple example is "*organization* appoints *person* as *position*"; if this pattern matches a passage in a test document, a hiring event will be instantiated with the items matching the variables being the arguments of the event. So training an event extractor becomes primarily a task of acquiring these patterns. In a semi-supervised setting, this involves ranking candidate patterns and accepting the top-ranked patterns at each iteration. Our goal was to create a more robust learner through improved pattern ranking.

3.1 Problems of Document-centric Bootstrapping

Document-centric bootstrapping tries to find patterns with high frequency in relevant documents and low frequency in irrelevant documents. The assumption is that descriptions of the same event or the same type of event may occur multiple times in a document, and so a document containing a relevant pattern is more likely to contain more such patterns. This approach may end up extracting patterns for related events; for example, *start-position* often comes with *end-position* events. This effect may be salutary if the extraction scenario includes these related events (as in MUC-6), but will pose a problem if the goal is to extract individual event types. Also, because an extra corpus for bootstrapping is needed, different corpora might perform quite differently (see Figure 2).

3.2 Problems of Similarity-centric Bootstrapping

Similarity-centric bootstrapping tries to find patterns with high lexical similarities. The most crucial issue is how to evaluate the similarity of two patterns, which is based on the similarity of two words. In this strategy, no extra corpus is needed, which eliminates the effort to find a good bootstrapping corpus, but a semantic dictionary that can provide word similarity is required. S&G used WordNet[1] to provide word similarity information. However, in the similarity-centric approach, lexical polysemy can lead the bootstrapping down false paths. For example, for *start-position (hire)* events, "*name*" and "*charge*" are in the same *Synset* as *appoint*, but including these words is quite dangerous because they contain other common senses

[1] http://wordnet.princeton.edu/

unrelated to *start-position* events. For *die* events, we might have words like "*go*" and "*pass*", which are also used in very specific contexts when they refer to "*die*". If similarity-centric ranking extracts patterns including these words, performance will deteriorate very quickly, because most of the time, these words do not predicate the proper event, and more and more wrong patterns will be extracted.

3.3 Our Approach

We propose a new ranking method, which constrains the document-centric and similarity-centric assumptions, and makes a more restricted assumption: patterns that appear in relevant documents *and* are lexically similar are most likely to be relevant. This method limits the effect of ambiguous patterns by narrowing the search to relevant documents, and limits irrelevant patterns in relevant documents by word similarity restriction. For example, although "charge" has high word similarity to "appoint", its document relevance score is very low, and we will not include this word in bootstrapping starting from "appoint".

Many different combinations are possible; we propose one that uses the word similarity as a filter. The document relevance score is first applied to rank the patterns in relevant documents, then the patterns with lexical similarity scores below a similarity threshold will be removed from the ranking; only patterns above threshold will be added to the seeds. However, if in the current iteration, no pattern meets the threshold, the threshold will be lowered until new patterns can be found. We call this ranking method *filtered ranking*[2]:

$$Filter(p) = \begin{cases} Yangarber(p) & Stevenson(p) >= t \\ 0 & otherwise \end{cases}$$

where t is the threshold, which is initialized to 0.9 in our experiments.

4 System Description

Our approach is similar to that for document-centric bootstrapping, but the ranking function is changed to incorporate lexical similarity information. For our experiments bootstrapping was terminated after a fixed number of iterations; in practice, we would monitor performance on a held-out (dev-test) sample and stop when it declines for k iterations.

4.1 Pre-processing

Instead of limiting ourselves to surface syntactic relations, we want to get more general and meaningful patterns. To this end, we used semantic role labeling (Gildea and Jurafsky, 2002) to generate the logical grammatical and predicate-argument representation automatically from a parse tree (Meyers et al. 2009). The output of the semantic labeling is the dependency representation of the text, where each sentence is a graph consisting of nodes (corresponding to words) and arcs. Each arc captures up to three relations between two words: (1) a SURFACE relation, the relation between a predicate and an argument in the parse tree of a sentence; (2) a LOGIC1 (grammatical logical) relation which regularizes for lexical and syntactic phenomena like passive, relative clauses, and deleted subjects; and (3) a LOGIC2 (predicate-argument) relation corresponding to relations in PropBank (Palmer et al. 2005) and NomBank

In constructing extraction patterns from this graph, we take each dependency link along with its predicate-argument role; if that role is null, we use its logical grammatical role, and finally, its surface role. For example, for the sentence:

```
John is hit by Tom's brother.
```

we generate the patterns:

<Arg1 hit John>
<Arg0 hit brother>
<T-pos brother Tom>

where the first two represent LOGIC2 relations and the third a SURFACE relation. To reduce data sparseness, all inflected words are changed to their root form (e.g. "attackers"→"attacker"), and all names are replaced by their ACE type (*person, organization, location, etc.*), so the first pattern would become

<Arg1 hit PERSON>

4.2 Document-based Ranking

The document-centric method employs a

[2] We also tried using the product of the document relevance score and word similarity score, and found the results to be quite similar. Due to space limitations, we do not report these results here.

re-implementation of the procedure described in (Yangarber et al. 2000), using the disjunctive voting scheme for document relevance. At each iteration *i* we compute a precision score *Prec^i(p)* for each pattern *p* and a relevance score *Rel^i(d)* for each document *d*. Initially the seed patterns have precision 1 and all other patterns precision 0. These are updated by

$$\mathrm{Re}\,l^i(d) = 1 - \prod_{p \in K(d)} (1 - \mathrm{Pr}\,ec^i(p))$$

where *K(d)* is the set of accepted patterns that match document *d*, and

$$\mathrm{Pr}\,ec^{i+1}(p) = \frac{1}{|H(p)|} \bullet \sum_{d \in H(p)} \mathrm{Re}\,l^i(d)$$

where *H(p)* is the set of documents matching pattern *p*. Patterns are then ranked by

$$RankFun_{Yangarber}(p) = \frac{Sup(p)}{|H(p)|} * \log Sup(p)$$

where

$$Sup(p) = \sum_{d \in H(p)} \mathrm{Re}\,l(d)$$

(a generalization of Yangarber's metric), and the top-ranked candidates are added to the set of accepted patterns.

4.3 Pattern Similarity

For two words, there are several ways to measure their similarity using WordNet, which can be roughly divided into two categories: distance-based, including Leacock and Chodorow (1998), Wu and Palmer (1994); and information content based, including Resnik (1995), Lin (1998), and Jiang and Conrath (1997). We follow S&G (2005)'s method and use the semantic similarity of concepts based on Information Content (IC).

Every pattern consists of a predicate and a constraint ("argument") on its local syntactic context, and so the similarity of two patterns depends on the similarity of the predicates and the similarity of the arguments. We modified S&G's structural similarity measure to reflect some differences in pattern structure: first, S&G only focus on patterns headed by verbs, while we include verbs, nouns and adjectives; second, they only record the subject and object to a verb, while we record all argument relations; third, our patterns only contain a predicate and a single constraint (argument), while their pattern might contain two arguments, subject and object. With two arguments, many more patterns are possible and the vector similarity calculation over all patterns in a large corpus becomes very time consuming.

We do not limit ourselves to verb patterns because nouns and (occasionally) adjectives can also represent an event. For example, "Stevenson's promotion is a signal …" expresses a *start-position* event. Moreover, in our pattern, we assume that the predicate is more important than constraint, because it is the root (head) of the pattern in the semantic graph structure, and place different weights on predicate and constraint. Finally, the similarity of two patterns p_1 and p_2 is computed as follows:

$$\begin{aligned} &Sim(p_1,p_2) \\ &\quad = \alpha * Sim(f_1,f_2) + \beta * Sim(r_1,r_2) * Sim(a_1,a_2) \end{aligned}$$

where $\alpha+\beta=1$, *f* represents a predicate, *r* represent a role, and *a* represent an argument. In our experiment, α is set to 0.6 and β is set to 0.4. The role similarity is 1 for identical roles and for roles which generally correspond at the syntactic and predicate-argument level (arg0 ↔ subj; arg1 ↔ obj); selected other role pairs are assigned a small positive similarity (0.1 or 0.2), and others 0.

As with the document-centric method, bootstrapping begins by accepting a set of seed patterns. At each iteration, the procedure computes the similarity between all patterns in the training corpus and the currently accepted patterns and accepts the most similar pattern(s). In S&G's experiments the evaluation corpus also served as the training corpus.

5 Experiments

There have been two types of event extraction tasks. One involved several 'elementary' event types, such as "attack", "die", "injure" etc.; for example, the ACE 2005 evaluation[3] used a set of 33 event types and subtypes. The other type involved a *scenario* – a set of related events, like "attacks and the damage, injury, and death they cause", or "arrest, trial, sentencing etc.". The

[3] See http://projects.ldc.upenn.edu/ace/docs/English-Events-Guidelines_v5.4.3.pdf for a description of this task.

MUC evaluations included two scenarios that have been the subject of considerable research on learning methods: *terrorist incidents* (MUC-3/4) and *executive succession* (MUC-6).

We conducted experiments on the MUC-6 task to make a comparison to previous work. We also did experiments on ACE 2005 data, because it provides many distinct event types; we conducted experiments on three disparate event types: *attack*, *die*, and *start-position*. Note that MUC-6 identifies a scenario while ACE identifies specific event types, and types which are in the same MUC scenario might represent different ACE events. For example, the *executive succession* scenario (MUC-6) includes the *start-position* and *end-position* events in ACE.

5.1 Data Description

There are four corpora used in the experiments:

MUC-6 corpora

- **Bootstrapping:** pre-selected data from the Reuters corpus (Rose et al. 2002) from 1996 and 1997, including 3000 related documents and 3000 randomly chosen unrelated documents
- **Evaluation:** MUC-6 annotated data, including 200 documents (official training and test). We were guided by the MUC-6 key file in annotating every document and sentence as relevant or irrelevant.

ACE corpora

- **Bootstrapping:** untagged data from the Gigaword corpus from January 2006, including 14,171 English newswire articles from Agence France-Presse (AFP).
- **Evaluation:** ACE 2005 annotated (training) data, including 589 documents

5.2 Parameters used in Experiments

In our bootstrapping process, we only extract patterns appearing more than 2 times in the corpus, and the similarity filter threshold is originally set to 0.9. If no patterns are found, it is reduced by 0.1 until new patterns are found.

In each iteration, the top 3 patterns in the ranking function will be added to the seeds.

For the similarity-centric method, only patterns appearing more than 2 times and in less than 30% of the documents will be extracted, which is the same as S&G's approach.

5.3 MUC-6 Experiments

Our overall goal was to demonstrate that filtered ranking was in all cases competitive with and in at least some cases clearly superior to the earlier methods, over a range of extraction tasks and bootstrapping corpora. We began with the MUC-6 task, where the efficacy of the earlier methods had already been demonstrated.

< Arg0 resign Person >
< Arg1 appoint Person >
< Arg0 appoint Org_commercial>
<Arg1 succeed Person >

Table 1. Seeds for MUC-6 evaluation

For MUC-6 evaluation, we follow S&G's approach and assess extraction patterns by their ability to identify event-relevant sentences.[4] The system treats a sentence as relevant if it matches an extraction pattern. Bootstrapping starts from four seeds which yield 80% precision and 24% recall for sentence filtering.

To compare with previous work, we tested the filtered ranking method on two corpora: the first is the Reuters corpus used in S&G's recreation of Yangarber's experiment (Filter1), to compare with their results for the document-centric method; the second uses the test corpus as S&G did (Filter2), to compare with their results for the similarity-centric method. We compare methods based on peak F score; in practice, this would mean controlling the bootstrapping using a held-out test sample.

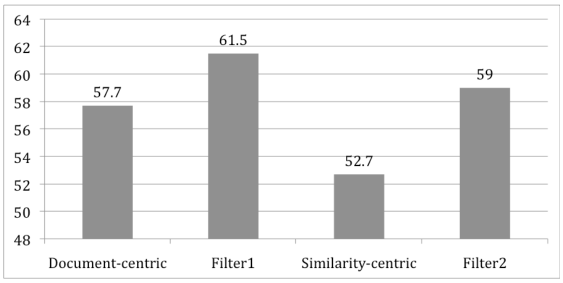

Figure 1. F score for different ranking methods on MUC-6 evaluation

Figure 1 showed that the filtered ranking

[4] We also tried the document filtering evaluation introduced by Yangarber but, as S&G observed, this metric is too insensitive because over 50% of the documents in the MUC-6 test set are relevant.

methods edge out both document and similarity-centric methods. Our scores are comparable to S&G's, although they report somewhat better performance for similarity-centric than for document-centric (55 vs. 51) whereas document-centric did better for us. This difference may reflect differences in pattern generation (discussed above) and possibly differences in the specific corpora used.

However, document-centric bootstrapping needs an extra corpus for bootstrapping; S&G used a pre-selected corpus that contains approximately same number of relevant and irrelevant documents[5]. We wanted to check if such a corpus is essential for the document-centric method, and if the need for pre-selection can be reduced through filtered ranking. Thus, we set up another experiment to see if the document-centric method is stable or sensitive to different corpora. We used two additional corpora for MUC-6 evaluation: one is a subset of the Wall Street Journal (WSJ) 1991 corpus, which contains 18,734 untagged documents; the other is the Gigaword AFP corpus described in section 5.1. Both corpora are much larger than the Reuters corpus, and while we do not have precise information about relevant document density, the WSJ contains quite a few *start-position* events because it is primarily business news; the Gigaword corpus (AFP newswire) has fewer *start-position* events because it contains a wider variety of news.

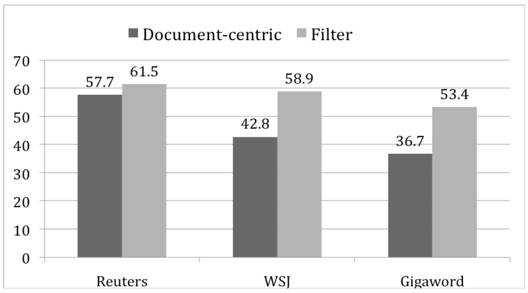

Figure 2. Document-centric and Filtered ranking results on different corpora for MUC-6

Figure 2 showed that the document-centric method performs quite differently on different corpora, which indicates that a pre-selected corpus plays an important role in document-centric ranking. It suggests that the percentage of relevant documents may be more important than the overall corpus size. The figure also shows that filtered ranking is much more stable across different corpora. Richer corpora still have better peak performance, but the difference is not quite as great; also, peak performance on a given corpus is consistently better than the document-centric method.

From the above experiments, we conclude that our filtering method is better in two aspects: first, bootstrapping on the same corpus performs better than either document or similarity-centric methods; second, if we can not get a corpus with an assured high density of relevant documents, it is safer to use filtered ranking because it is more stable across different corpora.

5.4 ACE2005 Experiments

The ACE2005 corpus includes annotations for 33 different event types and subtypes, offering us an opportunity to assess the generality of our methods across disparate event types. We selected 3 event types to report on here:

- **Die:** "occurs whenever the life of a PERSON Entity ends. It can be accidental, intentional or self-inflicted." This event appears 535 times in the corpus.
- **Attack:** "is defined as a violent physical act causing harm or damage." Attack events include a variety of sub-events like "person attack person", "country invade country", and "weapons attack locations". This event type appears 1120 times.
- **Start-Position:** "occurs whenever a PERSON Entity begins working for (or changes offices within) an ORGANIZATION or GPE. This includes government officials starting their terms, whether elected or appointed". It appears 116 times in the corpus.

We choose these three event types because they reflect the diversity of events ACE annotated: *die* events appear frequently in the ACE corpus and its definition is very clear; *attack* events also appear frequently, but its definition is rather complicated and contains several different sub-events; *start-position*'s definition is clear, but it is relatively infrequent in the corpus.

Based on the observations from the MUC-6 corpus, we eschewed corpus pre-selection for

[5] The pre-selection of relevant and irrelevant documents is based on document meta-data provided as part of the Reuters Corpus Volume I (Rose et al., 2002).

two reasons: first, building a different corpus for training each event type is an extra burden in developing a system for handling multiple events; second, we want to demonstrate that filtered ranking would work without pre-selection, while the document-centric method does not. As a result, we used the Gigaword AFP corpus for all event types.

In the ACE 2005 corpus, for every event, the annotators recorded a trigger, which is the main word that most clearly expresses an event occurrence. This added information allowed us to conduct dual evaluations: one based on sentence relevance - following S&G - presented in section 5.4.2, and one based on trigger identification, presented in section 5.4.3.

5.4.1 ACE2005 Supervised Model

To provide a benchmark for our semi-supervised learners, we built a very simple pattern-based supervised learning model. For training, for every pattern, we count how many times it contains an event trigger and how many times it does not. If more than 50% of the time it contains an event trigger, we treat it as a positive pattern.

For sentence level evaluation, if there is a positive pattern in a sentence, we tag this sentence as relevant; otherwise not. For word level evaluation, if the word is the predicator of a positive pattern, we tag it as a trigger; otherwise not[6].

We did a 5-fold cross-validation on the ACE 2005 data, report the average results and compare it to the semi-supervised learning method (see figure 3 & 4).

5.4.2 Sentence level ACE Event Evaluation[7]

Different event types have quite different performance (see figure 3): for the *die* event, the peak performance of all methods is quite good, and quite close to the supervised result; for the *attack* event, filtered ranking performs much better than both document and similarity-centric methods, but still worse than the supervised method; for *start-position* events, the semi-supervised method beats the supervised method. The reason might be as follows:

Die events appear frequently in ACE 2005, and most instances correspond to a small number of forms, so it is easy to find the correct patterns both from WordNet or related documents. As a result, filtered ranking provides no apparent benefit.

Attack is a more complicated event including several sub-events, which also have a lot of related events like *die* and *injure*. As a result, the document-centric method's performance goes down much faster, because patterns for related event types get drawn in; while the similarity-centric method performs worse than filtered ranking because some ambiguous words are introduced. For example, "hit" is an *attack* trigger, but words in the same Synset, such as "reach", "make", "attain", "gain" are quite dangerous because most of the time, these words do not refer to an attack event.

Start-position events do not appear frequently in ACE 2005, and supervised learning cannot achieve good performance because it can't collect enough training samples. The similarity-centric and Filter2 methods, which also depend on the ACE 2005 corpus, do not perform well either. Filter1 performs quite well because the Gigaword AFP corpus is quite large and contains more relevant documents, although the percentage is very small. This confirms our assumption that filtered ranking can achieve reasonable performance on a large unselected corpus, which is especially useful when the event is rare in the evaluation corpus.

<Arg1 kill Person>
<Arg1 slay Person>
<Arg1 death Person>

Table 2. Seeds for Ace 2005 *Die* evaluation

<Arg0 hire ORG>
<Arg1 hire Person>
<Arg1 appoint Person>
<Arg0 appoint ORG>

Table 3. Seeds for Ace 2005 *Start-Position* evaluation

[6] For word-level evaluation, we only consider trigger words with at least one semantic argument such as subject, object or a preposition; for that reason the performance is quite different from sentence level evaluation. We did the same for the word-level evaluation of semi-supervised learning.

[7] We do not list *Attack* seed patterns here as there are 34 patterns used.

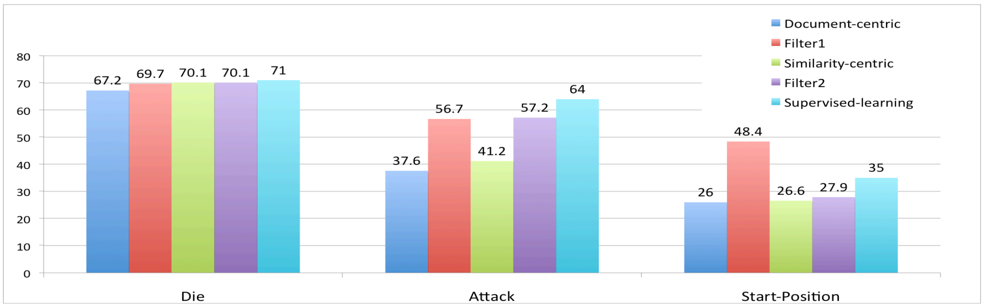

Figure 3. Performance on different ranking methods on ACE2005 sentence level evaluation

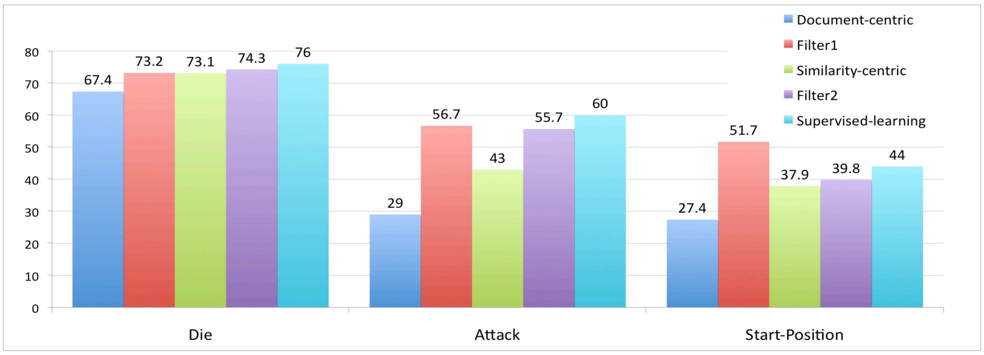

Figure 4. Performance on different ranking methods on ACE2005 word level evaluation

5.4.3 Word-level ACE Event Evaluation

Word-level evaluation is different from sentence-level evaluation because patterns which appear around an event but do not predicate an event are penalized in this evaluation. For example, the pattern <*Sbj chairman PERSON*>, which arises from a phrase like "*PERSON was the chairman of COMPANY*", appears much more in relevant *start-position* sentences than irrelevant sentences, and adding this pattern to the seeds will improve performance using the relevant-sentence metric. We would prefer a metric which discounted such patterns.

As noted above, ACE event annotations contain triggers, which are more specific event locators than a sentence, and we use this as the basis for a more specific evaluation. Extracted patterns are used to identify event triggers instead of identifying relevant sentences. For every word *w* in the ACE corpus, we extract all the patterns whose predicate is *w*. If the event extraction patterns include one of these patterns, we tag *w* as a trigger.

In word level evaluation, document-centric performs worse than the other methods. The reason is that some patterns appear often in the context of an event and are positive patterns for sentence level evaluation, but they do not actually predicate an event and are negative patterns in word level evaluation. In this situation, the document-centric method performs worse than the similarity-centric method, because it extracts many such patterns. For example, of the sentences which contain *die* events, 29% also contain *attack* events.

Thus in word level evaluation, filtered ranking continues to outperform either document- or similarity-centric methods, and its advantage over document-centric methods is accentuated.

6 Conclusions

In this paper, we propose a new ranking method in bootstrapping for event extraction and investigate the performance on different bootstrapping corpora with different ranking methods. This new method can block some irrelevant patterns coming from relevant documents, and, by preferring patterns from relevant documents, can eliminate some lexical ambiguity. Experiments show that this new ranking method performs better than previous ranking methods and is more stable across different corpora.

Exploring variation across biomedical subdomains

Abstract

Previous research has demonstrated the importance of handling differences between domains such as "newswire" and "biomedicine" when porting NLP systems from one domain to another. In this paper we identify the related issue of *subdomain variation*, i.e., differences between subsets of a domain that might be expected to behave homogeneously. Using a large corpus of research articles, we explore how subdomains of biomedicine vary across a variety of linguistic dimensions and discover that there is rich variation. We conclude that an awareness of such variation is necessary when deploying NLP systems for use in single or multiple subdomains.

1 Introduction

One of the most noticeable trends in the past decade of Natural Language Processing (NLP) research has been the deployment of language processing technology to meet the information retrieval and extraction needs of scientists in other disciplines. This meeting of fields has proven mutually beneficial: scientists increasingly rely on automated tools to help them cope with the exponentially expanding body of publications in their field, while NLP researchers have been spurred to address new conceptual problems in theirs. Among the fundamental advances from the NLP perspective has been the realisation that tools which perform well on textual data from one source may fail to do so on another unless they are tailored to the new source in some way. This has led to significant interest in the idea of contrasting *domains* and the concomitant problem of *domain adaptation*, as well as the production of manually annotated domain-specific corpora.[1]

One definition of *domain variation* associates it with differences in the underlying probability distributions from which different sets of data are drawn (Daumé III and Marcu, 2006). The concept also mirrors the notion of variation across thematic subjects and the corpus-linguistic notions of *register* and *genre* (Biber, 1988). In addition to the differences in vocabulary that one would expect to observe, domains can vary in many linguistic variables that affect NLP systems. The scientific domain which has received the most attention (and is the focus of this paper) is the biomedical domain. Notable examples of corpus construction projects for the biomedical domain are PennBioIE (Kulick et al., 2004) and GENIA (Kim et al., 2003). These corpora have been used to develop systems for a range of processing tasks, from entity recognition (Jin et al., 2006) to parsing (Hara et al., 2005) to coreference resolution (Nguyen and Kim, 2008).

An implicit assumption in much previous work on biomedical NLP has been that particular subdomains of biomedical literature – typically molecular biology – can be used as a model of biomedical language in general. For example, GENIA consists of abstracts dealing with a specific set of subjects in molecular biology, while PennBioIE covers abstracts in two specialised domains, cancer genomics and the behaviour of a particular class of enzymes. This assumption of representativeness is understandable because linguistic annotation is labour-intensive and it may not be worthwhile to produce annotated corpora for multiple subdomains within a single discipline if there is lit-

[1] A workshop dedicated to domain adaptation is collocated with ACL 2010.

tle task-relevant variation across those subdomains. However, such conclusions should not be made before studying the actual degree of difference between the subdomains of interest.

One of the principal goals of this paper is to map how the concept of "biomedical language", often construed as a monolithic entity, is composed of diverse patterns of behaviour at more fine-grained topical levels. Hence we study linguistic variation in a broad biomedical corpus of abstracts and full papers, the PMC Open Access Subset.[2] We select a range of lexical and structural phenomena for quantitative investigation. The results indicate that common subdomains for resource development are not representative of biomedical text in general and furthermore that different linguistic features often partition the subdomains in quite different ways.

2 Related Work

A number of researchers have explored the differences between non-technical and scientific language. Biber and Gray (2010) describe two distinctive syntactic characteristics of academic writing which set it apart from general English. Firstly, in academic writing additional information is most commonly integrated by pre- and post-modification of phrases rather than by the addition of extra clauses. Secondly, academic writing places greater demands on the reader by omitting non-essential information, through the frequent use of passivisation, nominalisation and noun compounding. Biber and Gray also show that these tendencies towards "less elaborate and less explicit" language have become more pronounced in recent history.

We now turn to corpus studies that focus on biomedical writing. Verspoor et al. (2009) use measurements of lexical and structural variation to demonstrate that Open Access and subscription-based journal articles in a specific domain (mouse genomics) are sufficiently similar that research on the former can be taken as representative of the latter. While their primary goal is different from ours and they do not consider variation across multiple domains, they do compare their mouse genomics corpus with small reference corpora drawn from newswire and general biomedical sources. This analysis unsurprisingly finds differences between the domain and newswire corpora across many linguistic dimensions; more interestingly for our purposes, the comparison of domain text to the broader biomedical superdomain shows a more complex picture with similarities in some aspects (e.g., passivisation and negation) and dissimilarities in others (e.g., sentence length, semantic features).

Friedman et al. (2002) document the "sublanguages" associated with two biomedical domains: clinical reports and molecular biology articles. They set out restricted ontologies and frequent co-occurrence templates for the two domains and discuss the similarities and differences between them, but they do not perform any quantitative analysis.

Other researchers have focused on specific phenomena, rather than cataloguing a broad scope of variation. Cohen et al. (2008) carry out a detailed analysis of argument realisation with respect to verbs and nominalisations, using the GENIA and PennBioIE corpora. Nguyen and Kim (2008) compare the behaviour of anaphoric pronouns in newswire and biomedical corpora; they improve the performance of a pronoun resolver by incorporating their observations, thus demonstrating the importance of capturing domain-specific phenomena. Nguyen and Kim's findings are discussed in more detail in Section 5.4 below.

3 Subdomains in the OpenPMC Corpus

The Open Access Subset of PubMed (OpenPMC) is the largest publicly available corpus of full-text articles in the biomedical domain. OpenPMC is comprised of 169,338 articles drawn from 1233 medical journals, totalling approximately 400 million words. The NIH maintains a one-to-many mapping from journals to 122 subject areas (NIH, 2009b). This covers about 400 of the OpenPMC journals, but these account for over 70% of the database by byte size and word count. Journals are assigned up to five subject areas with the majority assigned one (69%) or two (26%) subjects. In this paper we adopt the OpenPMC subject areas (e.g. "Pulmonary Medicine", "Genetics", "Psychiatry") as the basis for subdomain comparison.

[2] http://www.ncbi.nlm.nih.gov/pmc/about/openftlist.html

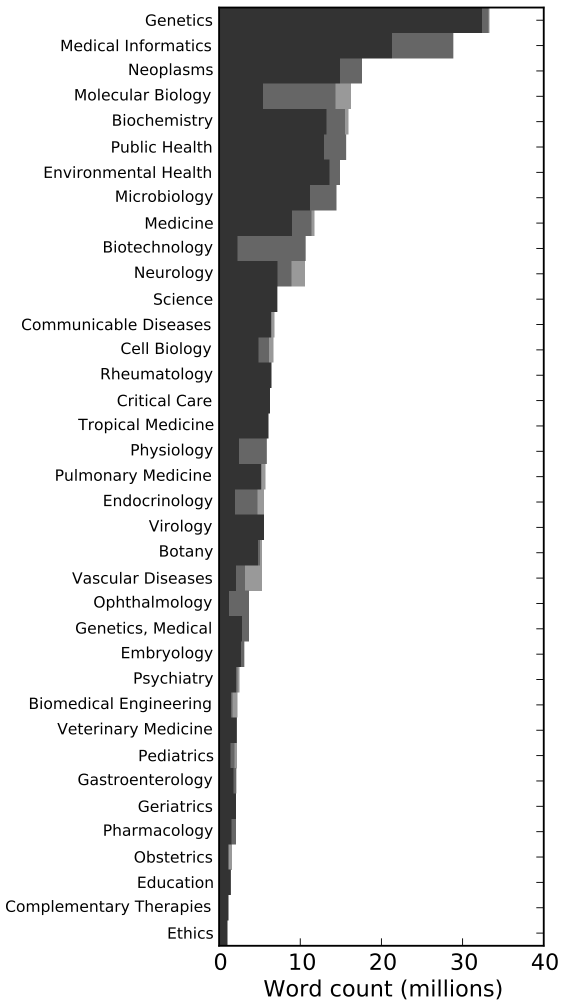

Figure 1: OpenPMC word count by subdomain, dark colouring indicates data assigned single subdomain, each lighter shade indicates an additional overlapping subdomain

4 Methodology

4.1 Data selection and preprocessing

An important initial question was how to treat data with multiple classifications: we only consider journals assigned a single subdomain, to avoid the added complexity of interactions in data from overlapping subdomains. To ensure sufficient data for comparing a variety of linguistic features, we discard the subdomains with less than one million words meeting the single-subdomain criterion. After review, we also drop the "Biology" subdomain, which appears to function as a catch-all for many loosely related areas. Figure 1 shows the distribution of data across the subjects we use, by word-count, with lighter-coloured areas representing data that is assigned multiple subjects. These subjects provide a convenient starting point for dividing the corpus into subdomains (hereafter, "subdomain" will be used rather than "subject"). We also add a reference subdomain, "Newswire", composed of a 6 million word random sample from the English Gigaword corpus (Graff et al., 2005). The final data set has a total of 39 subdomains.

Articles in the OpenPMC corpus are formatted according to a standard XML tag set (NIH, 2009a). We first convert each article to plain text, ignoring "non-content" elements such as tables and formulas, and split the result into sentences, aggregating the results by subdomain.

4.2 Feature extraction

We investigate subdomain variation in our corpus across a range of lexical, syntactic, sentential and discourse features. The corpus is lemmatised, tagged and parsed using the C&C pipeline (Curran et al., 2007) with the adapted part-of-speech and lexical category tagging models produced by Rimell and Clark (2009) for biomedical parsing.

From this output we count occurrences of noun, verb, adjective and adverb lemmas, part-of-speech (POS) tags, grammatical relations (GRs), chunks, and lexical categories. The lemma features are Zipfian-distributed items from an open class, so we have experimented with filtering low-frequency items at various thresholds to reduce noise and improve processing speed. The other feature sets can be viewed as closed classes, where filtering is unnecessary.

Since verbs are central to the meaning and structure of sentences, we consider their special behavior by constructing features for each verb's distribution over other grammatical properties. Several grammatical properties are captured by pairing each verb with its POS (indicating e.g. tense, such as present, past, and present participle). Voice is determined from additional annotation output by the C&C parser. Table 1 shows the POS-distribution for the verb "restrict", in two subdomains from the corpus. Finally, we record distributions over verb subcategorization frames (SCFs) taken by each verb, and over the GRs it participates in.

Subdomain	VB	VBG	VBN	VBP	VBZ
Medical Informatics	.35	.29	.06	.09	.21
Cell Biology	.14	.43	.05	.10	.29

Table 1: Distribution over POS tags for verb "restrict", in two subdomains

SCFs were extracted using a system of Preiss et al. (2007).

To facilitate a more robust and interpretable analysis of vocabulary differences, we estimate a "topic model" of the corpus with Latent Dirichlet Analysis (Blei et al., 2003) using the MALLET toolkit.[3] As preprocessing we divide the corpus into articles, removing stopwords and words shorter than 3 characters. The Gibbs sampling procedure is parameterised to induce 100 topics, each giving a coherent cluster of related words learned from the data, and to run for 1000 iterations. We collate the predicted distribution over topics for each article in a subdomain, weighted by article wordcount, to produce a topic distribution for the subdomain.

4.3 Measurements of divergence

Our goal is to illustrate the presence or absence of differences between the feature sets, and to do so we calculated the Jensen-Shannon divergence and the Pearson correlation. Jensen-Shannon divergence is a finite symmetric measurement of the divergence between probability distributions, while Pearson correlation quantifies the linear relationship between two real-valued samples.

The count-features are weighted, for a given subdomain, by the feature's log-likelihood between the subdomain's data and the rest of the corpus. Log-likelihood has been shown to perform well when comparing counts of potentially low-frequency features (Rayson and Garside, 2000) such as found in Zipfian-distributed data. This serves to place more weight in the comparison on items that are distinctive of the subdomain with respect to the entire corpus.

While the count-features are treated as a single distribution for the purposes of JSD, the verbwise-features are composed of many distributions, one for each verb lemma. Our approach is to combine the JSD of the verbs, weighted by the log-likelihood of the verb lemma between the two subdomains in question, and normalize the distances to the interval [0, 1]. Using the lemma's log-likelihood assumes that, when a verb's distribution behaves differently in a subdomain, its frequency changes as well.

We present the results as dendrograms and heat maps. Dendrograms are tree structures that illustrate the results of hierarchical clustering. We perform hierarchical clustering on the inter-subdomain divergences for each set of features. The algorithm begins with each instance (in our case, subdomains) as a singleton cluster, and repeatedly joins the two most similar clusters until all the data is clustered together. The order of these merges is recorded as a tree structure that can be visualized as a dendrogram in which the length of a branch represents the distance between its child nodes. Similarity between clusters is calculated using average distance between all members, known as "average linking".

Heat maps show the pairwise calculation of a metric in a grid of squares, where square (x, y) is shaded according to the value of $metric(sub_x, sub_y)$. For our measurements of JSD, black represents 0 (i.e. identical distributions) and white represents the metric's theoretical maximum of 1. We also inscribe the actual value inside each square. Dendrograms are tree structures that illustrate the hierarchical clustering procedure described above. The dendrograms present all 39 subdomains, while for readability the heatmaps present 12 subdomains selected for representativeness.

5 Results

Different thresholds for filtering low-frequency terms had little effect on the divergence measures, and served mainly to improve processing time. We therefore report results using a cutoff of 150 occurrences (over the entire 234 million word data set) and log-likelihood weights. The results of Pearson correlation and JSD show similar trends, and due to its specific design for comparing distributions we only report the latter.

[3] http://mallet.cs.umass.edu

5.1 Vocabulary and lexical features

Differences in vocabulary are what first comes to mind when describing subdomains. Word features are fundamental components for systems such as POS taggers and lexicalised parsers; one therefore expects that these systems will be affected by variation in lexical distributions. Figure 2a uses JSD calculated on each subdomain's distribution over 100 LDA-induced topics to compare vocabulary distributions. Subdomains related to molecular biology (Genetics, Molecular Biology) show the smallest divergences, an interesting fact since these are heavily used in building resources for BioNLP. The dendrogram shows a rough division into "public policy", "patient-centric", "applied" and "microscopic" subdomains, with the distance between unrelated subdomains such as Biochemistry and Pediatrics almost as large as their respective differences from Newswire.

We omit figures for variation over noun, verb and adjective lemmas due to space restrictions; in general, these correlate with the variation in LDA topics though there are some differences. Figure 2b shows JSD calculated on distributions over adverb lemmas. Part of the variation is due to characteristic markers of scientific argument ("therefore", "significantly", "statistically"). A more interesting factor is the coining of domain-specific adverbs, an example of the tendency in scientific text to use complex lexical items and premodifiers rather than additional clauses. This also has the effect of moving subdomain-specific objects and processes from verbs and nouns to adverbs. This behavior seems non-continuous, in that subdomains either make heavy, or almost no, use of it: for example, Pediatrics has no subdomain-specific items among the its ten top adverbs by log-likelihood, while Neoplasms has "histologically", "immunohistochemically" and "subcutaneously". These information-dense terms could prove useful for tasks like automatic curation of subdomain vocabularies, where they imply relationships between their components, the items they modify, etc.

5.2 Verb distributional behavior

Modelling verb behavior is important for both syntactic (Collins, 2003) and semantic (Korhonen et al., 2008) processing, and subdomains are known to conscript verbs into specific roles that change the distributions of their syntactic properties (Roland and Jurafsky, 1998). The four properties we considered verbs' distributions over (SCF, POS, GR and voice) produced similar inter-subdomain JSD values. Figure 2c demonstrates how verbs differ between subdomains with respect to SCFs. For example, while the Pediatrics subdomain uses the verb "govern" in a single SCF among its 12 possibilities, the Genetics subdomain distributes its usage over 7 of them. Two subdomains may both use "restrict" with high frequency (e.g. Molecular Biology and Ethics), but with different frequency distributions over SCFs.

5.3 Syntax

It is difficult to measure syntactic complexity accurately without access to a hand-annotated treebank, but it is well-known that sentence length correlates strongly with processing difficulty (Collins, 1996). The first column of Table 2 gives average sentence lengths (excluding punctuation and "sentences" of fewer than three words) for selected domains. All standard errors are < 0.1. It is clear that all biomedical subdomains typically use longer sentences than newswire, though there is also variation within biomedicine, from an average length of 27 words in Molecular Biology to 24.5 words in Pediatrics.

"Packaging" information in complex pre- and/or post-modified noun phrases is a characteristic feature of academic writing (Biber and Gray, 2010). This increases the information density of a sentence but brings with it syntactic and semantic ambiguities. For example, the difficulty of resolving the internal structure of noun-noun compounds and strings of prepositional phrases has been the focus of ongoing research in NLP; these phenomena have also been identified as significant challenges in biomedical language processing (Rosario and Hearst, 2001; Schuman and Bergler, 2006). The second and third columns of Table 2 present average lengths for full noun phrases, defined as every word dominated by a head noun in the grammatical relation graph for a sentence, and for base nominals, defined as nouns plus premodifying adjectives and nouns only. All standard errors are ≤ 0.01. Newswire text uses the simplest noun

phrase structures; there is notable variation across PMC domains. Full NP and base nominal lengths do not always correlate; for example, Cell Biology uses relatively long base NPs (nominalisations and multitoken names in particular) but relatively simple full NP structures.

5.4 Coreference

Resolving coreferential terms is a crucial and challenging task when extracting information from texts in any domain. Nguyen and Kim (2008) compare the use of pronouns in the newswire and biomedical domains, using the GENIA corpus as representative of the latter. Among the differences observed between the domains were the absence of any personal pronouns other than third-person neuter pronouns in the GENIA corpus, and a greater proportion of demonstrative pronouns in GENIA than in the ACE or MUC newswire corpora. Corroborating the importance of domain modelling, Nguyen and Kim demonstrate that tailoring a pronoun resolution system to specific properties of the biomedical domain improves performance.

As our corpus is not annotated for coreference we restrict our attention to types that are reliably coreferential: masculine/feminine personal pronouns (*he*, *she* and case variations), neuter personal pronouns (*they*, *it* and variations) and definite NPs with demonstrative determiners such as *this* and *that*. To filter out pleonastic pronouns we used a combination of the C+C parser's pleonasm tag and heuristics based on Lappin and Leass (1994). To filter out the most common class of non-anaphoric demonstrative NPs we simply discarded any matching the pattern *this*...*paper*|*study*|*article*.

Table 3 presents statistics for selected types of coreferential noun phrases in a number of domains. The results generally agree with the findings of Nguyen and Kim (2008): biomedical text is on average 200 times less likely than news text to use gendered pronouns and twice as likely to use anaphoric definite noun phrases. At the domain level, however, there is clear variation within the biomedical corpus. In contrast to Nguyen and Kim's observations about GENIA some domains do make non-negligible use of gendered pronouns, most notably Ethics (usually to refer to other scholars) and domains such as Psychiatry and Pediatrics where studies of actual patients are common. All biomedical domains use demonstrative NPs more frequently than newswire and only one (Ethics) matches newswire for frequent use of neuter 3rd-person pronouns.

6 Conclusion

In this paper we have explored the phenomenon of linguistic variation at a finer-grained level than previous NLP research, focusing on subdomains

Table 3: Frequency of coreferential types (proportion of all NPs) across domains

rather than traditional domains such as “newswire” and “biomedicine”. We have identified patterns of variation across dimensions of vocabulary, syntax and discourse that are known to be of importance for NLP applications. While the magnitude of variation between subdomains is unsurprisingly less pronounced than between coarser domains, subdomain variation clearly does exist and should be taken into account when considering the generalisability of systems trained and evaluated on specific subdomains, for example molecular biology.

Future work includes directly evaluating the effect of subdomain variation on practical tasks, investigating further dimensions of variation such as nominalisation usage and learning alternative subdomain taxonomies directly from the corpus text. Ultimately, we expect that a more nuanced understanding of subdomain effects will have tangible benefits for many applications of scientific language processing.

Abstract

News tweets that report what is happening have become an important real-time information source. We raise the problem of Semantic Role Labeling (SRL) for news tweets, which is meaningful for fine grained information extraction and retrieval. We present a self-supervised learning approach to train a domain specific SRL system to resolve the problem. A large volume of training data is automatically labeled, by leveraging the existing SRL system on news domain and content similarity between news and news tweets. On a human annotated test set, our system achieves state-of-the-art performance, outperforming the SRL system trained on news.

1 Introduction

Tweets are text messages up to 140 characters. Every day, more than 50 million tweets are generated by millions of Twitter users. According to the investigation by Pear Analytics (2009), about 4% tweets are related to news[1].

We divide news related tweets into two categories: those excerpted from news articles and those not. The former kind of tweets, hereafter called news excerpt, is formally written while the latter, hereafter called news tweet, varies in style and often is not grammatically correct. To understand the proportion of news tweets, we randomly selected 1000 tweets related to news, and got 865 news tweets. Following is an example of anews tweet, containing *oh, yea,* which usually appear in spoken language, and *:-(,* an emoticon.

oh yea and Chile earthquake the earth off it's axis according to NASA and shorten the day by a wee second :-((S1)

News tweets arean important information source because they keep reporting what is happening in real time. For example, the earthquake near Los Angeles that happened on Tuesday, July 29, 2008 was first reported through news tweets only seconds later than the outbreak of the quake. Official news did not emerge about this event until four minutes later. By then, "Earthquake" was trending on Twitter Search with thousands of updates[2].

However, it is a daunting task for people to find out information they are interested in from such a huge number of news tweets, thus motivating us to conduct some kind of information

extraction such as event mining, where SRL plays a crucial role (Surdeanu et al., 2003). Considering Sentence 1, suppose the agent *earthquake* and the patient *day* for the predicate *shorten* are identified. Then it is straightforward to output the event *Chile earthquake shorten the day*, which captures the essential information encoded in this tweet.

Following Màrquez (2009), we define SRL for news tweets as the task of identifying the arguments of a given verb as predicate in a news tweet and assigning them semantic labels describing the roles they play for the predicate. To make our method applicable to general information extraction tasks, rather than only to some special scenarios such as arresting event extraction, we adopt general semantic roles, i.e., Agent(*A0*), Patient(*A1*), Location(*AM-LOC*), Temporal(*AM-TMP*),etc., instead of situation-specific roles (Fillmore et al., 2004) such as Suspect, Authorities, and Offense in an arrest frame.

Our first attempt is to directly apply the state-of-art SRL system (Meza-Ruiz and Riedel, 2009) that trained on the CoNLL 08 shared task dataset(Surdeanu et al., 2008), hereafter called SRL-BS, to news tweets. Not surprisingly, we observe its F1 score drops sharply from 75.5% on news corpus to 43.3% on our human annotated news tweets, owing much to the informal written style of news tweets.

Therefore, we have to build a domain specific SRL system for news tweets. Given the diversified styles of news tweets, building such a system requires a larger number of annotated news tweets, which are not available, and are not affordable for human labeling. We propose a novel method to automatically annotate news tweets, which leverages the existing resources of SRL for news domain, and content similarity between news and news tweets. We argue that the same event is likely to be reported by both news and news tweets, which results in content similarity between the news and news tweet. Further, we argue that the news and news tweets reporting the same event tend to have similar predicate-argument structures. We tested our assumptions on the event *Chile earthquake* that happened on Match 2nd, 2010. We got 261 news and 722 news tweets published on the same day that described this event. Sentence 2 and 3 are two examples of the news excerpts and Sentence 1 is one example of news tweets for this event.

Chile Earthquake Shortened Earth Day (S2)

Chile Earthquake Shortened Day (S3)

Obviously Sentence 1, 2 and 3 all have predicate "*shortened*" with the same A0 and A1 arguments. Our manually checking showed that in average each news tweet in those 993 samples had 2.4 news excerpts that had the same predicate-argument structures.

Our news tweet annotation approach consists of four steps. First, we submit hot queries to Twitter and for each query we obtain a list of tweets. Second, for each list of tweets, we single out news excerpts using heuristic rules and remove them from the list, conduct SRL on news excerpts using SRL-BS, and cluster them in terms of the similarity in content and predicate-argument structures. Third, for each list of tweets, we try to merge every remaining tweet into one news excerpt cluster according to its content similarity to the cluster. Those that can be put into one news group are regarded as news tweet. Finally, semantic structures of news excerpts are passed to the news tweet in the same group through word alignment.

Our domain specific SRL system is then trained on automatically constructed training data using the Conditional Random Field (CRF: Lafferty et al., 2001) learning framework. Our system is evaluated on a human labeled dataset, and achieves state-of-the-art performance, outperforming the baseline SRL-BS.

Our contributions can be summarized as follows:

1) We propose to conduct SRL for news tweets for fine grained information extraction and retrieval;
2) We present a semi-supervised learning approach to train a domain specific SRL system for news tweets, which outperforms SRL-BS and achieves the state-of-the-art performance on a human labeled dataset.

The rest of this paper is organized as follows: In the next section, we review related work. In Section 3 we detail key components of our approach. In Section 4, we setup experiments and evaluate the effectiveness of our method. Finally, Section 5 concludes and presents the future work.

2 Related Work

Our related work falls into two categories: SRL on news and domain adaption.

As for SRL on news, most researchers used the pipelined approach, i.e., dividing the task into several phases such as argument identification, argument classification, global inference, etc., and conquering them individually (Xue and Palmer, 2004; Koomen et al., 2005; Cohn and Blunsom, 2005; Punyakanok et al., 2008; Toutanova et al., 2005; Toutanova et al., 2008). Exceptions to the pipelined approach exist. Màrquez et al. (2005) sequentially labeled the words according to their positions relative to an argument (i.e., inside, outside or at the beginning of it). Carreras et al. (2004) and Surdeanu et al. (2007) jointly labeled all the predicates. Vickrey and Koller(2008) simplified the input sentence by hand-written and machine learnt rules before conducting SRL. Some other approaches simultaneously resolved all the sub-tasks by integrating syntactic parsing and SRL into a single model (Musillo and Merlo, 2006; Merlo and Musillo, 2008), or by using Markov Logic Networks (MLN, Richardson and Domingos, 2005) as the learning framework (Riedel and Meza-Ruiz, 2008; Meza-Ruiz and Riedel, 2009).

All the above approaches focus on sentences from news articles or other formal documents, and depend on human annotated corpus for training. To our knowledge, little study has been carried out on SRL for news tweets.

As for domain adaption, some researchers regarded the out-of-domain data as "prior knowledge" and estimated the model parameters by maximizing the posterior under this prior distribution, and successfully applied their approach to language modeling (Bacchiani and Roark, 2003) and parsing (Roark and Bacchiani, 2003). Daumé III and Marcu (2006) presented a novel framework by defining a "general domain" between the "truly in-domain" and "truly out-of-domain".

Unlike existing domain adaption approaches, our method is about adapting SRL system on news domain to the news tweets domain, two domains that differ in writing style but are linked through content similarity.

3 Our Method

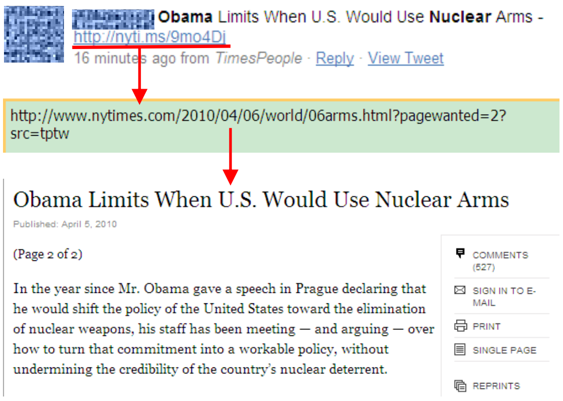
Our method of SRL for news tweets is to train a domain specific SRL on automatically annotated training data as briefed in Section 1.

In this section we present details of the five crucial components of our method, i.e., news excerpt identification, news excerpt clustering, news tweets identification, semantic structure mapping, and the domain specific SRL system constructing.

3.1 News Excerpt Identification

We use one heuristic rule to decide whether or not a tweet is news excerpt: if a tweet has a link to a news article and its text content is included by the news article, it is news excerpt, otherwise not.

Given a tweet, to apply this rule, we first extract the content link and expand it, if any, into the full link with the unshorten service[3]. This step is necessary because content link in tweet is usually shortened to reduce the total amount of characters. Next, we check if the full link points to any of the pre-defined news sites, which, in our experiments, are 57 English news websites. If yes, we download the web page and check if it exactly contains the text content of the input tweet. Figure 1 illustrates this process.



[redacted] **Obama** Limits When U.S. Would Use **Nuclear** Arms - http://nyti.ms/9mo4Dj

Obama Limits When U.S. Would Use Nuclear Arms

Published: April 5, 2010

(Page 2 of 2)

In the year since Mr. Obama gave a speech in Prague declaring that he would shift the policy of the United States toward the elimination of nuclear weapons, his staff has been meeting — and arguing — over how to turn that commitment into a workable policy, without undermining the credibility of the country's nuclear deterrent.

Figure 1. An illustration of news excerpt identification.

To test the precision of this approach, while preparing for the training data for the experiments, we checked 100 tweets that were identified as news excerpt by this rule to find out they all are excerpted from news.

[3] http://unshort.me

3.2 News Excerpt Clustering

Given as input a list of news excerpts concerning the same query and published in the same time scope, this component uses the hierarchical agglomerative clustering algorithm (Manning et al., 2008) to divide news excerpts into groups in terms of the similarity in content and predicate-argument structures.

Before clustering, for every news excerpt, we remove the content link and other metadata such as author, retweet marks (starting with RT @), reply marks (starting with @ immediately after the author), hash tags (starting with #), etc., and keep only the text content; then it is further parsed into tokens, POS tags, chunks and syntactic tree using the OpenNLP toolkit[4]. After that, SRL is conducted with SRL-BS to get predicate-argument structures. Finally, every news excerpt is represented as frequency a vector of terms, including tokens, POS tagger, chunks, predicate-argument structures, etc. A news cluster is regarded as a "macro" news excerpt and is also represented as a term frequency vector, i.e., the sum of all the term vectors in the cluster. Noisy terms, such as numbers and predefined stop words are excluded from the frequency vector. To reduce data sparseness, words are stemmed by Porter stemmer (Martin F. Porter, 1980).

The cosine similarity is used to measure the relevance between two clusters, as defined in Formula 1.

$$CS\left(C,C^{'}\right)=\frac{CV\cdot CV^{'}}{\left\|CV\right\|\times\left\|CV^{'}\right\|} \tag{1}$$

Where *C, C'* denote two clusters, *CV, CV'* denote the term frequency vectors of *C* and *C'* respectively, and *CS(C, C')* stands for the cosine similarity between *C* and *C'*.

Initially, one news excerpt forms one cluster. Then the clustering process repeats merging the two most similar clusters into one till the similarity between any pair of clusters is below a threshold, which is experimentally set to 0.7 in our experiments.

During the training data preparation process, we randomly selected 100 clusters, each with 3.2 pieces of news in average. For every pair of news excerpts in the same cluster, we checked if they shared similar contents and semantic structures, and found out that 91.1% were the cases.

3.3 News Tweets Identification

After news excerpts are identified and removed from the list, every remaining tweet is checked if it is a news tweet. Here we group news excerpts and news tweets together in two steps because 1) news excerpts count for only a small proportion of all the tweets in the list, making our two-step clustering algorithm more efficient; and 2) one-step clustering tends to output meaningless clusters that include no news tweets.

Intuitively, news tweet, more often than not, have news counterparts that report similar contents. Thus we use the following rule to identify news tweets: if the content similarity between the tweet and any news excerpt cluster is greater than a threshold, which is experimentally set to 0.7 in our experiments, the tweet is a news tweet, otherwise it is not. Furthermore, each news tweet is merged into the cluster with most similar content. Finally, we re-label any news tweet as news excerpt, which is then process by SRL-BS, if its content similarity to the cluster exceeds a threshold, which is experimentally set to 0.9 in our experiments.

Again, the cosine similarity is used to measure the content similarity between tweet and news excerpt cluster. Each tweet is repressed as a term frequency vector. Before extracting terms from tweet, tweet metadata is removed and a rule-based normalization process is conducted to restore abnormal strings, say "&apos;", into their human friendly form, say ‘' '. Next, stemming tools and OpenNLP are applied to get lemmas, POS tags, chunks, etc., and noisy terms are filtered.

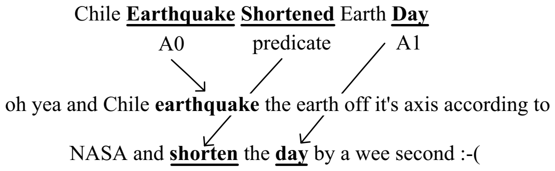
We evaluated the performance of this approach when preparing for the training data. We randomly sampled 500 tweets that were identified as news tweets, to find that 93.8% were true news tweets.

3.4 Semantic Structure Mapping

Semantic structure mapping is formed as the task of word alignment from news excerpt to news tweet. A HMM alignment model is trained with GIZA++ (Franz and Hermann, 2000) on all (news excerpt, news tweet) pairs in the same cluster. After word alignment is done, semantic

[4] http://opennlp.sourceforge.net/

information attached to a word in a news excerpt is passed to the corresponding word in the news tweet as illustrated in Figure 2.



Chile **Earthquake** **Shortened** Earth **Day**
A0
predicate
A1
oh yea and Chile **earthquake** the earth off it's axis according to
NASA and **shorten** the **day** by a wee second :-(

Figure 2. An example of mapping semantic structures from news excerpts to news tweets.

In Figure 2, *shorten*, *earthquake* and *day* in two sentences are aligned, respectively; and two predicate-argument structures in the first sentence, i.e., *(shortened, earthquake, A0), (shortened, day, A1)*, are passed to the second.

News tweets may receive no semantic information from related news excerpts after mapping, because of word alignment errors or no news excerpt in the cluster with similar semantic structures. Such tweets are dropped.

Mapping may also introduce cases that violate the following two structural constraints in SRL (Meza-Ruiz and Riedel, 2009): 1) one (predicate, argument) pair has only one role label in one sentence; and 2) for each predicate, each of the proper arguments *(A0~A5)* can occur at most once. Those conflicts are largely owing to the noisy outputs of SRL trained on news and to the alignment errors. While preparing for the training data for our experiments, we found 38.9% of news tweets had such conflicts.

A majority voting schema and the structural constrains are used to resolve the conflicts as described below.

1) Step 1, for every cluster, each (*predicate*, *argument*, *role*) is weighted according to its frequency in the cluster;
2) Step 2, for every cluster, detect conflicts using the structural constrains; if no conflicts exist, stop; otherwise go to Step 3;
3) Step 3, for every cluster, keep the one with higher weight in each conflicting (*predicate*, *argument*, *role*) pair; if the weights are equal, drop both;

Here is an example to show the conflicting resolution process. Consider the cluster including Sentence 1, 2 and 3, where *(shorten, earthquake, A0), (shorten, earthquake, A1), (shorten, axis, A0),* and *(shorten, day, A1)* occur 6, 4, 1 and 3 times, respectively. This cluster includes three conflicting pairs:

1) *(shorten, earthquake, A0) vs. (shorten, earthquake, A1);*
2) *(shorten, earthquake, A1) vs. (shorten, day, A1);*
3) *(shorten, earthquake, A0) vs. (shorten, axis, A0);*

The first pair is first resolved, causing *(shorten, earthquake, A0)* to be kept and *(shorten, earthquake, A1)* removed, which leads to the second pair being resolved as well; then we process the third pair resulting in *(shorten, earthquake, A0)* being kept and *(shorten, axis, A0)* dropped; finally *(shorten, earthquake, A0)* and *(shorten, day, A1)* stay in the cluster.

The conflicting resolution algorithm is sensitive to the order of conflict resolution in Step 3. Still consider the three conflicting pairs listed above. If the second pair is first processed, only *(shorten, earthquake, A0)* will be left. Our strategy is to first handle the conflict resolving which leads to most conflicts resolved.

We tested the performance of this semantic structure mapping strategy while preparing for the training data. We randomly selected 56 news tweets with conflicts and manually annotated them with SRL. After the conflict resolution method was done, we observed that 38 news tweets were resolved correctly, 9 resolved but incorrectly, and 9 remain unresolved, suggesting the high precision of this method, which fits our task. We leave it to our future work to study more advanced approach for semantic structure mapping.

3.5 SRL System for News Tweets

Following Màrquez et al. (2005), we regard SRL for tweets as a sequential labeling task, because of its joint inference ability and its openness to support other languages.

We adopt conventional features for each token defined in Màrquez et al.(2005), such as the lemma/POS tag of the current/previous/next token, the lemma of predicate and its combination with the lemma/POS tag of the current token, the voice of the predicate (active/passive), the distance between the current token and the predicate, the relative position of the current token to the predicate, and so on. We do not use features related to syntactic parsing trees, to allow our system not to rely on any syntactic parser, whose performance depends on style and language of text, which limits the generality of our system.

Before extracting features, we perform a preprocessing step to remove tweet metadata and normalize tweet text content, as described in Section 3.3. The OpenNLP toolkit is used for feature extraction, and the CRF++ toolkit[5] is used to train the model.

4 Experiments

In this section, we evaluate our SRL system on a gold-standard dataset consisting of 1,110 human annotated news tweets and show that our system achieves the state-of-the-art performance compared with SRL-BS that is trained on news. Furthermore, we study the contribution of automatically generated training data.

4.1 Evaluation Metric

We adopt the widely used precision (Pre.), recall (Rec.) and F-score (F., the harmonic mean of precision and recall) as evaluation metrics.

4.2 Baseline System

We use SRL-BS as our baseline because of its state-of-art performance on news domain, and its readiness to use as well.

4.3 Data Preparation

We restrict to English news tweets to test our method. Our method can label news tweets of other languages, given that the related tools such as the SRL system on news domain, the word alignment tool, OpenNLP, etc., can support other languages.

We build two corpora for our experiments: one is the training dataset of 10,000 news tweets with semantic roles automatically labeled; the other is the gold-standard dataset of 1,110 news tweets with semantic roles manually labeled.

Training Dataset

We randomly sample 80 queries from 300 English queries extracted from the top stories of Bing news, Google news and Twitter trending topics from March 1, 2010 to March 4, 2010.

Submitting the 80 queries to Twitter search, we retrieve and download 512,000 tweets, from which we got 4,785 news excerpts and 11,427 news tweets, which were automatically annotated using the method described in Section 3.

Furthermore, 10,000 tweets are randomly selected from the automatically annotated news tweets, forming the training dataset, while the other 1,427 news tweets are used to construct the gold-standard dataset.

Gold-standard Dataset

We ask two people to annotate the 1,427 news tweets, following the Annotation guidelines for PropBank[6] with one exception: for phrasal arguments, only the head word is labeled as the argument, because our system and SRL-BS conduct word level SRL.

317 news tweets are dropped because of inconsistent annotation, and the remaining 1,110 news tweets form the gold-standard dataset.

Quality of Training dataset

Since the news tweets in the gold-standard dataset are randomly sampled from the automatically labeled corpus and are labeled by both human and machine, we use them to estimate the quality of training data, i.e., to which degree the automatically generated results are similar to humans'.

We find that our method achieves 75.6% F1 score, much higher than the baseline, suggesting the relatively high quality of the training data.

4.4 Result and Analysis

Table 1 reports the experimental results of our system (SRL-TS) and the baseline on the gold-standard dataset.

	Precision	Recall	F-Score
SRL-BS	36.0 %	54.5%	43.3%
SRL-TS	78.0%	57.1%	66.0%

Table 1. Performances of our system and the baseline on the gold-standard dataset.

As shown in Table 1, our system performs much better than the baseline on the gold-standard dataset in terms of all metrics. We observe two types of errors that are often made by

[5] http://crfpp.sourceforge.net/

[6] http://verbs.colorado.edu/~mpalmer/projects/ace/PBguidelines.pdf

SRL-BS but not so often by our system, which largely explains the difference in performance.

The first type of errors, which accounts for 25.3% of the total errors made by SRL-BS, is caused by the informal written style, such as ellipsis, of news tweets. For instance, for the example Sentence 1 listed in Section 1, the SRL-BS incorrectly identify earth as the A0 argument of the predicate shorten. The other type of errors, which accounts for 10.2% of the total errors made by SRL-BS, is related to the discretionary combination of news snippets. For example, consider the following news tweet:

The Chile earthquake shifted the earth's axis, "shortened the length of an Earth day by 1.26 miliseconds". (S4)

We analyze the errors made by our system and find that 12.5% errors are attributed to the complex syntactic structures, suggesting that combining our system with systems on news domain is a promising direction. For example, our system cannot identify the A0 argument of the predicate *shortened*, because of its blindness of attributive clause; in contrast, SRL-BS works on this case.

wow..the earthquake that caused the 2004 Indian Ocean tsunami shortened the day by almost 3 microseconds..what does that even mean?! HOW? (S5)

We also find that 32.3% of the errors made by our system are more or less related to the training data, which has noise and cannot fully represent the knowledge of SRL on news tweets. For instance, our system fails to label the following sentence, partially because the predicate *strike* does not occur in the training set.

8.8-Magnitude-Earthquake-Strikes-Chile (S6)

We further study how the size of automatically labeled training data affects our system's performance, as illustrated in Figure 3. We conduct two sets of experiments: in the first set, the training data is automatically labeled and the testing data is the gold-standard dataset; in the second set, half of the news tweets from the gold-standard dataset are added to the training data, the remaining half forms the testing dataset. Curve 1 and 2 represent the experimental results of set 1 and 2, respectively.

From Curve 1, we see that our system's performance increases sharply when the training data size varies from 5,000 to 6,000; then increases relatively slowly with more training data; and finally reaches the highest when all training data is used. Curve 2 reveals a similar trend.

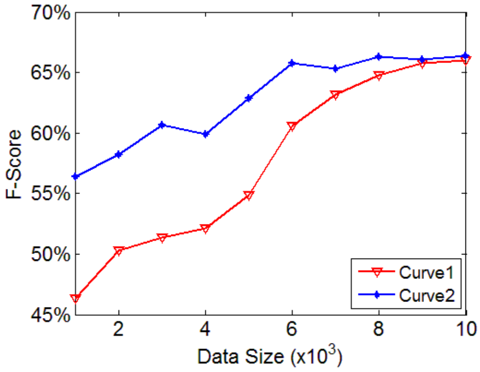


Figure 3. Performance on training data of varying size.

This phenomenon is largely due to the competing between two forces: the noise in the training data, and the knowledge of SRL encoded in the training data.

Interestingly, from Figure 3, we observe that the contribution of human labeled data is no longer significant after 6,000 automatically labeled training data is used, reaffirming the effectiveness of the training data.

5 Conclusions and Future Work

We propose to conduct SRL on news tweets for fine grained information extraction and retrieval. We present a self-supervised learning approach to train a domain specific SRL system for news tweets. Leveraging the SRL system on news domain and content similarity between news and news tweets, our approach automatically labels a large volume of training data by mapping SRL-BS generated results of news excerpts to news tweets. Experimental results show that our system outperforms the baseline and achieves the state-of-the-art performance.

In the future, we plan to enlarge training data size and test our system on a larger dataset; we also plan to further boost the performance of our system by incorporating tweets specific features such as hash tags, reply/re-tweet marks into our

CRF model, and by combining our system with SRL systems trained on news.

Joint Parsing and Translation

Abstract

Tree-based translation models, which exploit the linguistic syntax of source language, usually separate decoding into two steps: parsing and translation. Although this separation makes tree-based decoding simple and efficient, its translation performance is usually limited by the number of parse trees offered by parser. Alternatively, we propose to parse and translate jointly by casting tree-based translation as parsing. Given a source-language sentence, our joint decoder produces a parse tree on the source side and a translation on the target side simultaneously. By combining translation and parsing models in a discriminative framework, our approach significantly outperforms a forest-based tree-to-string system by 1.1 absolute BLEU points on the NIST 2005 Chinese-English test set. As a parser, our joint decoder achieves an F_1 score of 80.6% on the Penn Chinese Treebank.

1 Introduction

Recent several years have witnessed the rapid development of syntax-based translation models (Chiang, 2007; Galley et al., 2006; Shen et al., 2008; Quirk et al., 2005; Liu et al., 2006; Huang et al., 2006; Eisner, 2003; Zhang et al., 2008; Chiang, 2010), which incorporate formal or linguistic syntax into translation process. Depending on whether modeling the linguistic syntax of source language or not, we divide them into two categories: *string-based* and *tree-based* models. [1]

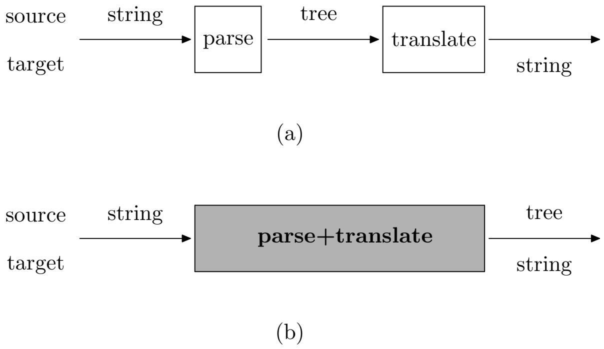

Figure 1: Tree-based decoding: (a) separate parsing and translation versus (b) joint parsing and translation.

String-based models include *string-to-string* (Chiang, 2007) and *string-to-tree* (Galley et al., 2006; Shen et al., 2008). Regardless of the syntactic information on the source side, they treat decoding as a parsing problem: the decoder parses a source-language sentence using the source projection of a synchronous grammar while building the target sub-translations in parallel.

Tree-based models include *tree-to-string* (Liu et al., 2006; Huang et al., 2006) and *tree-to-tree* (Quirk et al., 2005; Eisner, 2003; Zhang et al., 2008; Chiang, 2010). These models explicitly use source parse trees and divide decoding into two separate steps: parsing and translation. A parser first parses a source-language sentence into a parse tree, and then a decoder converts the tree to a translation on the target side (see Figure 1(a)).

Figure 2 gives a training example for tree-to-string translation, which consists of a Chinese tree, an English sentence, and the word alignment between them. Romanized Chinese words are given to facilitate identification. Table 1 shows

[1] Mi et al. (2008) also distinguish between string-based and tree-based models but depending on the type of input.

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 707–715,
Beijing, August 2010

(6)	NPB(NN(*huitan*))→*meeting*

Table 1: Tree-to-string rules extracted from Figure 2.

a set of tree-to-string rules obtained from Figure 2. The source side of a rule is a tree fragment and the target side is a string. We use x to denote non-terminals and the associated subscripts indicate the correspondence between non-terminals on both sides.

Conventionally, decoding for tree-to-string translation is cast as a *tree parsing* problem (Eisner, 2003). The tree parsing algorithm visits each node in the input source tree in a top-down order and tries to match each translation rule against the local sub-tree rooted at the node. For example, the first rule in Table 1 matches a sub-tree rooted at $\mathrm{IP}_{0,6}$ in Figure 2. The descendent nodes of $\mathrm{IP}_{0,6}$ (i.e., $\mathrm{NPB}_{0,1}$, $\mathrm{PP}_{1,3}$, and $\mathrm{VPB}_{3,6}$) can be further matched by other rules in Table 1. The matching procedure runs recursively until the entire tree is covered. Finally, the output on the target side can be taken as a translation.

Compared with its string-based counterparts, tree-based decoding is simpler and faster: there is no need for *synchronous binarization* (Huang et al., 2009b; Zhang et al., 2006) and tree parsing generally runs in linear time (Huang et al., 2006).

While separating parsing and translation makes tree-based decoding simple and efficient, its search space is limited by the number of parse trees offered by parser. Studies reveal that tree-based systems are prone to produce degenerate translations due to the propagation of parsing mistakes (Quirk and Corston-Oliver, 2006). This problem can be alleviated by offering more alternatives to the pipeline. An elegant solution is to replace 1-best trees with packed forests that encode exponentially many trees (Mi et al., 2008; Liu et al., 2009). Mi et al. (2008) present an efficient algorithm to match tree-to-string rules against packed forests that encode millions of trees. They prove that offering more alternatives to tree parsing improves translation performance substantially.

In this paper, we take a further step towards the direction of offering multiple parses to translation by proposing *joint parsing and translation*. As shown in Figure 1(b), our approach parses and translates jointly as it finds a parse tree and a translation of a source-language sentence simultaneously. We integrate the tree-to-string model (Liu et al., 2006; Huang et al., 2006), n-gram language model, probabilistic context-free grammar (PCFG), and Collins' Model 1 (Collins, 2003) in a discriminative framework (Och, 2003). Allowing parsing and translation to interact with each other, our approach obtains an absolute improvement of 1.1 BLEU points over a forest-based tree-to-string translation system (Mi et al., 2008) on the 2005 NIST Chinese-English test set. As a parser, our joint decoder achieves an F_1 score of 80.6% on the Penn Chinese Treebank.

2 Joint Parsing and Translation

2.1 Decoding as Parsing

We propose to integrate parsing and translation into a single step. To achieve joint parsing and translation, we cast tree-to-string decoding as a monolingual parsing problem (Melamed, 2004; Chiang, 2007; Galley et al., 2006): the decoder takes a source-language string as input and parses it using the source-projection of SCFG while building the corresponding sub-translations simultaneously.

For example, given the Chinese sentence *bushi yu sha long juxing le huitan* in Figure 2, the derivation in Table 1 explains how a Chinese tree, an English string, and the word alignment between them are generated synchronously. Unlike the string-based systems as described in (Chiang, 2007; Galley et al., 2006; Shen et al., 2008), we exploit the linguistic syntax on the source side explicitly. Therefore, the source parse trees produced by our decoder are meaningful from a linguistic point of view.

As tree-to-string rules usually have multiple non-terminals that make decoding complexity generally exponential, synchronous binarization (Huang et al., 2009b; Zhang et al., 2006) is a key technique for applying the CKY algorithm to parsing with tree-to-string rules. [2] Huang et al. (2009b) factor each tree-to-string rule into two SCFG rules: one from the root nonterminal to the subtree, and the other from the subtree to the leaves. In this way, one can uniquely reconstruct the original tree using a two-step SCFG derivation.

For example, consider the first rule in Table 1:

$$\mathrm{IP}(x_1\mathrm{:NPB\ VP}(x_2\mathrm{:PP}\ x_3\mathrm{:VPB}))\rightarrow x_1\ x_3\ x_2$$

We use a specific non-terminal, say, T, to uniquely identify the left-hand side subtree and produce two SCFG rules: [3]

$$\mathrm{IP} \rightarrow \langle \mathrm{T}_{\boxed{1}}, \mathrm{T}_{\boxed{1}} \rangle \quad (1)$$

$$\mathrm{T} \rightarrow \langle \mathrm{NPB}_{\boxed{1}}\mathrm{PP}_{\boxed{2}}\mathrm{VPB}_{\boxed{3}}, \mathrm{NPB}_{\boxed{1}}\mathrm{VPB}_{\boxed{3}}\mathrm{PP}_{\boxed{2}} \rangle \quad (2)$$

where the boxed numbers indicate the correspondence between nonterminals.

Then, the rule (2) can be further binarized into two rules that have at most two non-terminals:

$$\mathrm{T} \rightarrow \langle \mathrm{NPB}_{\boxed{1}}\ \mathrm{PP\text{-}VPB}_{\boxed{2}}, \mathrm{NPB}_{\boxed{1}}\ \mathrm{PP\text{-}VPB}_{\boxed{2}} \rangle \quad (3)$$

$$\mathrm{PP\text{-}VPB} \rightarrow \langle \mathrm{PP}_{\boxed{1}}\mathrm{VPB}_{\boxed{2}}, \mathrm{VPB}_{\boxed{2}}\mathrm{PP}_{\boxed{1}} \rangle \quad (4)$$

where $\mathrm{PP\text{-}VPB}$ is an intermediate *virtual non-terminal.*

We call rules the tree roots of which are virtual non-terminals *virtual rules* and others *natural rules*. For example, the rule (1) is a natural rule and the rules (3) and (4) are virtual rules. We follow Huang et al. (2009b) to keep the probabilities of a natural rule unchanged and set those of a virtual rule to 1. [4]

After binarizing tree-to-string rules into SCFG rules that have at most two non-terminals, we can use the CKY algorithm to parse a source sentence and produce its translation simultaneously as described in (Chiang, 2007; Galley et al., 2006).

2.2 Adding Parsing Models

As our decoder produces "genuine" parse trees during decoding, we can integrate parsing models as features together with translation features such as the tree-to-string model, n-gram language model, and word penalty into a discriminative framework (Och, 2003). We expect that parsing and translation could interact with each other: parsing offers linguistically motivated reordering to translation and translation helps parsing resolve ambiguity.

2.2.1 PCFG

We use the probabilistic context-free grammar (PCFG) as the first parsing feature in our decoder. Given a PCFG, the probability for a tree is the product of probabilities for the rules that it contains. That is, if a tree π is a context-free derivation that involves K rules of the form $\alpha_k \rightarrow \beta_k$, its probability is given by

$$\mathcal{P}(\pi) = \prod_{k=1...K} \mathcal{P}_{pcfg}(\alpha_k \rightarrow \beta_k) \quad (5)$$

For example, the probability for the tree in Figure 2 is

$$\begin{aligned}\mathcal{P}(\pi) \quad = \quad & \mathcal{P}_{pcfg}(\mathrm{IP} \rightarrow \mathrm{NPB\ VP}) \times \\ & \mathcal{P}_{pcfg}(\mathrm{NPB} \rightarrow \mathrm{NR}) \times \\ & \mathcal{P}_{pcfg}(\mathrm{NR} \rightarrow \textit{bushi}) \times \\ & \ldots \end{aligned} \quad (6)$$

[2] But CKY is not the only choice. The Earley algorithm can also be used to parse with tree-to-string rules (Zhao and Al-Onaizan, 2008). As the Earley algorithm binarizes multi-nonterminal rules implicitly, there is no need for synchronous binarization.

[3] It might look strange that the node VP disappears. This node is actually stored in the monolithic node T. Please refer to page 573 of (Huang et al., 2009b) for more details about how to convert tree-to-string rules to SCFG rules.

[4] This makes the scores of hypotheses in the same chart cell hardly comparable because some hypotheses are covered by a natural non-terminal and others covered by a virtual non-terminal. To alleviate this problem, we follow Huang et al. (2009b) to separate natural and virtual hypotheses in different beams.

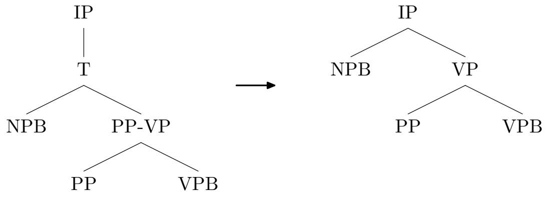

Figure 3: Reconstructing original tree from virtual rules. We first construct the tree on the left by substituting the trees of the rules (1), (3), and (4) and then restore the original tree on the right via the monolithic node T.

There are 13 PCFG rules involved. We omit the remaining 10 rules.

We formalize the decoding process as a deductive system to illustrate how to include a PCFG. Given a natural rule

$$\mathrm{VP} \rightarrow \langle \mathrm{PP}_{\boxed{1}}\ \mathrm{VPB}_{\boxed{2}}, \mathrm{VPB}_{\boxed{2}}\ \mathrm{PP}_{\boxed{1}} \rangle \tag{7}$$

the following deductive step grows an item in the chart by the rule

$$\frac{(\mathrm{PP}_{1,3}) : (w_1, e_1) \quad (\mathrm{VPB}_{3,6}) : (w_2, e_2)}{(\mathrm{VP}_{1,6}) : (w, e_2 e_1)} \tag{8}$$

where $\mathrm{PP}_{1,3}$ denotes the recognition of the non-terminal PP spanning from the substring from position 1 through 3 (i.e., *yu shalong* in Figure 2), w_1 and e_1 are the score and translation of the first antecedent item, respectively, and the resulting item score is calculated as: [5]

$$w = w_1 + w_2 + \log \mathcal{P}_{pcfg}(\mathrm{VP} \rightarrow \mathrm{PP\ VPB}) \tag{9}$$

As the PCFG probabilities of natural rules are fixed during decoding, they can be pre-computed and stored in the rule table. Therefore, including PCFG for natural rules hardly increases decoding complexity.

However, calculating the PCFG probabilities for virtual rules is quite different due to the presence of virtual non-terminals. For instance, using the rule (4) in Section 2.1 to generate an item leads to the following deductive step:

$$\frac{(\mathrm{PP}_{1,3}) : (w_1, e_1) \quad (\mathrm{VPB}_{3,6}) : (w_2, e_2)}{(\text{PP-VPB}_{1,6}) : (w, e_2 e_1)} \tag{10}$$

As PP-VPB is a virtual non-terminal, the subtree it dominates is a virtual tree, for which we cannot figure out its PCFG probability. Therefore, we have to postpone the calculation of PCFG probabilities until reaching a natural non-terminal such as IP. In other words, only when using the rule (1) to produce an item, the decoding algorithm can update PCFG probabilities because the original tree can be restored from the special node T now. Figure 3 shows how to reconstruct the original tree from virtual rules. We first construct the tree on the left by substituting the trees of the rules (1), (3), and (4) and then restore the original tree on the right via T. Now, we can calculate the PCFG probability of the original tree. [6] In practice, we pre-compute this PCFG probability and store it in the rule (1) to reduce computational overhead.

2.2.2 Lexicalized PCFG

Although widely used in natural language processing, PCFGs are often criticized for the lack of lexicalization, which is very important to capture the lexical dependencies between words. Therefore, we use Collins' Model 1 (Collins, 2003), a simple and effective lexicalized parsing model, as the second parsing feature in our decoder.

Following Collins (2003), we first lexicalize a tree by associating a *headword* h with each non-terminal. Figure 4 gives the lexicalized tree corresponding to Figure 2. The left-hand side of a rule in a lexicalized PCFG is $P(h)$ and the right-hand side has the form:

$$L_n(l_n) \dots L_1(l_1) H(h) R_1(\tau_1) \dots R_m(\tau_m) \tag{11}$$

where H is the head-child that inherits the headword h from its parent P, $L_1 \dots L_n$ and $R_1 \dots R_m$ are left and right modifiers of H, and $l_1 \dots l_n$ and $\tau_1 \dots \tau_m$ are the corresponding headwords. Either n or m may be zero, and $n = m = 0$ for unary rules. Collins (2003) extends the left and right sequences to include a terminating STOP symbol. Thus, $L_{n+1} = R_{m+1} = \mathrm{STOP}$.

[5] The logarithmic form of probability is used to avoid manipulating very small numbers for practical reasons. w_1 and w_2 take the PCFG probabilities of the two antecedent items into consideration.

[6] Postponing the calculation of PCFG probabilities also leads to the "hard-to-compare" problem mentioned in footnote 4 due to the presence of virtual non-terminals. We still maintain multiple beams for natural and virtual hypotheses (i.e., items) to alleviate this prblem.

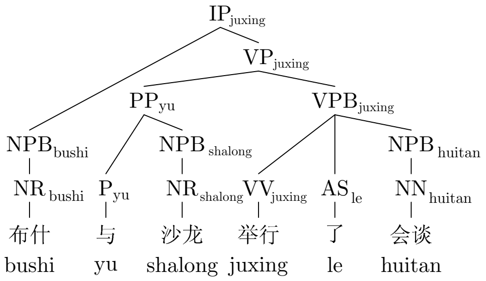

Figure 4: The lexicalized tree corresponding to Figure 2.

Collins (2003) breaks down the generation of the right-hand side of a rule into a sequence of smaller steps. The probability of a rule is decomposed as:

$$\begin{aligned}&\mathcal{P}_h(H|P(h)) \times \\ &\prod_{i=1...n+1} \mathcal{P}_l(L_i(l_i)|P(h),H,t,\Delta) \times \\ &\prod_{j=1...m+1} \mathcal{P}_r(R_j(\tau_j)|P(h),H,t,\Delta)\end{aligned} \quad (12)$$

where t is the POS tag of of the headword h and Δ is the distance between words that captures head-modifier relationship.

For example, the probability of the lexicalized rule $\text{IP}(\textit{juxing}) \rightarrow \text{NPB}(\textit{bushi})\ \text{VP}(\textit{juxing})$ can be computed as [7]

$$\begin{aligned}&\mathcal{P}_h(\text{VP}|\text{IP},\ \textit{juxing}) \times \\ &\mathcal{P}_l(\text{NPB}(\textit{bushi})|\text{IP},\text{VP},\ \textit{juxing}) \times \\ &\mathcal{P}_l(\text{STOP}|\text{IP},\text{VP},\ \textit{juxing}) \times \\ &\mathcal{P}_r(\text{STOP}|\text{IP},\text{VP},\ \textit{juxing})\end{aligned} \quad (13)$$

We still use the deductive system to explain how to integrate the lexicalized PCFG into the decoding process. Now, Eq. (8) can be rewritten as:

$$\frac{(\text{PP}^{\text{yu}}_{1,3}) : (w_1, e_1) \quad (\text{VPB}^{\text{juxing}}_{3,6}) : (w_2, e_2)}{(\text{VP}^{\text{juxing}}_{1,6}) : (w, e_2 e_1)} \quad (14)$$

where *yu* and *juxing* are the headwords attached to $\text{PP}_{1,3}$, $\text{VPB}_{3,6}$, and $\text{VP}_{1,6}$. The resulting item score is given by

$$\begin{aligned} w \;=\; & w_1 + w_2 + \log\mathcal{P}_h(\text{VPB}|\text{VP},\ \textit{juxing}) + \\ & \log\mathcal{P}_l(\text{PP}(\textit{yu})|\text{VP},\text{VPB},\ \textit{juxing}) + \\ & \log\mathcal{P}_l(\text{STOP}|\text{VP},\text{VPB},\ \textit{juxing}) + \\ & \log\mathcal{P}_r(\text{STOP}|\text{VP},\text{VPB},\ \textit{juxing})\end{aligned} \quad (15)$$

Unfortunately, the lexicalized PCFG probabilities of most natural rules cannot be pre-computed because the headword of a non-terminal must be determined on the fly during decoding. Consider the third rule in Table 1

$$\text{PP}(\text{P}(\textit{yu})\ x_1\text{:NPB}) \rightarrow \textit{with}\ x_1$$

It is impossible to know what the headword of NPB is in advance, which depends on the actual sentence being translated. However, we could safely say that the headword attached to PP is always *yu* because PP should have the same headword with its child P.

Similar to the PCFG scenario, calculating lexicalized PCFG for virtual rules is different from natural rules. Consider the rule (4) in Section 2.1, the corresponding deductive step is

$$\frac{(\text{PP}^{\text{yu}}_{1,3}) : (w_1, e_1) \quad (\text{VPB}^{\text{juxing}}_{3,6}) : (w_2, e_2)}{(\text{PP-VPB}^{-}_{1,6}) : (w, e_2 e_1)} \quad (16)$$

where "$-$" denotes that the headword of $\text{PP-VPB}_{1,6}$ is undefined.

We still need to postpone the calculation of lexicalized PCFG probabilities until reaching a natural non-terminal such as IP. In other words, only when using the rule (1) to produce an item, the decoding algorithm can update the lexicalized PCFG probabilities. After restoring the original tree from T, we need to visit backwards to frontier nodes of the tree to find headwords and calculate lexicalized PCFG probabilities. More specifically, updating lexicalized PCFG probabilities for the rule the rule (1) involves the following steps:

1. Reconstruct the original tree from the rules (1), (3), and (4) as shown in Figure 3;

2. Attach headwords to all nodes;

3. Calculate the lexicalized PCFG probabilities according to Eq. (12).

[7] For simplicity, we omit POS tag and distance in the presentation. In practice, we implemented the Collins' Model 1 exactly as described in (Collins, 2003).

Back-off level	$\mathcal{P}_h(H\|\dots)$	$\mathcal{P}_l(L_i(l_i)\|\dots)$ $\mathcal{P}_r(R_j(\tau_j)\|\dots)$
1	P, h, t	P, H, h, t, Δ
2	P, t	P, H, t, Δ
3	P	P, H, Δ

Table 2: The conditioning variables for each level of back-off.

As suggested by Collins (2003), we use back-off smoothing for sub-model probabilities during decoding. Table 2 shows the various levels of back-off for each type of parameter in the lexicalized parsing model we use. For example, $\mathcal{P}_h$ estimation p interpolates maximum-likelihood estimates $p_1 = \mathcal{P}_h(H|P, h, t)$, $p_2 = \mathcal{P}_h(H|P, t)$, and $p_3 = \mathcal{P}_h(H|P)$ as follows:

$$p_1 = \lambda_1 p_1 + (1 - \lambda_1)(\lambda_2 p_2 + (1 - \lambda_2) p_3) \quad (17)$$

where λ_1, λ_2, and λ_3 are smoothing parameters.

3 Experiments

In this section, we try to answer two questions:

1. Does tree-based translation by parsing outperform the conventional tree parsing algorithm? (Section 3.1)

2. How about the parsing performance of the joint decoder? (Section 3.2)

3.1 Translation Evaluation

We used a bilingual corpus consisting of 251K sentences with 7.3M Chinese words and 9.2M English words to extract tree-to-string rules. The Chinese sentences in the bilingual corpus were parsed by an in-house parser (Xiong et al., 2005), which obtains an F_1 score of 84.4% on the Penn Chinese Treebank. After running GIZA++ (Och and Ney, 2003) to obtain word alignments, we used the GHKM algorithm (Galley et al., 2004) and extracted 11.4M tree-to-string rules from the source-side parsed, word-aligned bilingual corpus. Note that the bilingual corpus does not contain the bilingual version of Penn Chinese Treebank. In other words, all tree-to-string rules were learned from noisy parse trees and alignments. We used the SRILM toolkit (Stolcke, 2002) to train a 4-gram language model on the Xinhua portion of the GIGAWORD corpus, which contains 238M English words. We trained PCFG and Collins' Model 1 on the Penn Chinese Treebank.

We used the 2002 NIST MT Chinese-English test set as the development set and the 2005 NIST test set as the test set. Following Huang (2008), we modified our in-house parser to produce and prune packed forests on the development and test sets. There are about 105M parse trees encoded in a forest of a sentence on average. We also extracted 1-best trees from the forests.

As the development and test sets have many long sentences ($\geq$ 100 words) that make our decoder prohibitively slow, we divided long sentences into short sub-sentences simply based on punctuation marks such as comma and period. The source trees and target translations of sub-sentences were concatenated to form the tree and translation of the original sentence.

We compared our parsing-based decoder with the tree-to-string translation systems based on the tree parsing algorithm, which match rules against either 1-best trees (Liu et al., 2006; Huang et al., 2006) or packed forests (Mi et al., 2008). All the three systems used the same rule set containing 11.4M tree-to-string rules. Given the 1-best trees of the test set, there are 1.2M tree-to-string rules that match fragments of the 1-best trees. For the forest-based system (Mi et al., 2008), the number of filtered rules increases to 1.9M after replacing 1-best trees with packed forests, which contain 105M trees on average. As our decoder takes a string as input, 7.7M tree-to-string rules can be used to parse and translate the test set. We binarized 99.6% of tree-to-string rules into 16.2M SCFG rules and discarded non-binarizable rules. As a result, the search space of our decoder is much larger than those of the tree parsing counterparts.

Table 3 shows the results. All the three systems used the conventional translation features such as relative frequencies, lexical weights, rule count, n-gram language model, and word count. Without any parsing models, the tree-based system achieves a BLEU score of 29.8. The forest-based system outperforms the tree-based system by $+1.8$ BLEU points. Note that each hyperedge

Algorithm	Input	Parsing model	# of rules	BLEU (%)	Time (s)
tree parsing	tree	-	1.2M	29.8	0.56
	forest	PCFG	1.9M	31.6	9.49
parsing	string	-	7.7M	32.0	51.41
		PCFG		32.4	55.52
		Lex		32.6	89.35
		PCFG + Lex		**32.7**	91.72

Table 3: Comparison of tree parsing and parsing for tree-to-string translation in terms of *case-insensitive* BLEU score and average decoding time (second per sentence). The column "parsing model" indicates which parsing models were used in decoding. We use "-" to denote using only translation features. "Lex" represents the Collins' Model 1. We excluded the extra parsing time for producing 1-best trees and packed forests.

Forest size	Exact match (%)	Precision (%)
1	0.55	41.5
390	0.74	47.7
5.8M	0.92	54.1
66M	1.48	62.0
105M	2.22	65.9

Table 4: Comparison of 1-best trees produced by our decoder and the parse forests produced by the monolingual Chinese parser. Forest size represents the average number of trees stored in a forest.

in a parse forest is assigned a PCFG probability. Therefore, the forest-based system actually includes PCFG as a feature (Mi et al., 2008). Without incorporating any parsing models as features, our joint decoder achieves a BLEU score of 32.0. Adding PCFG and Collins' Model 1 (i.e., "Lex" in Table 2) increases translation performance. When both PCFG and Collins' Model 1 are used, our joint decoder outperforms the tree parsing systems based on 1-best trees ($+2.9$) and packed forests ($+1.1$) significantly ($p < 0.01$). This result is also better than that of using only translation features significantly (from 32.0 to 32.7, $p < 0.05$).

Not surprisingly, our decoder is much slower than pattern matching on 1-best trees and packed forests (with the same beam size). In particular, including Collins' Model 1 increases decoding time significantly because its sub-model probabilities requires back-off smoothing on the fly.

How many 1-best trees produced by our decoder are included in the parse forest produced by a standard parser? We used the Chinese parser to generate five pruned packed forests with different sizes (average number of trees stored in a forest). As shown in Table 4, only 2.22% of the trees produced by our decoder were included in the biggest forest. One possible reason is that we used sub-sentence division to reduce decoding complexity. To further investigate the matching rate, we also calculated labeled precision, which indicates how many brackets in the parse match those in the packed forest. The labeled precision on the biggest forest is 65.9%, suggesting that the 1-best trees produced by our decoder are significantly different from those in the packed forests produced by a standard parser. [8]

3.2 Parsing Evaluation

We followed Petrov and Klein (2007) to divide the Penn Chinese Treebank (CTB) version 5 as follows: Articles 1-270 and 400-1151 as the training set, Articles 301-325 as the development set, and Articles 271-300 as the test set. We used max-F_1 training (Och, 2003) to train the feature weights. We did not use sub-sentence division as the sentences in the test set have no more than 40 words.

[8] The packed forest produced by our decoder ("rule" forest) might be different from the forest produced by a monolingual parser ("parser" forest). While tree-based and forest-based decoders search in the intersection of the two forests (i.e., matched forest), our decoder directly explores the "rule" forest, which represents the true search space of tree-to-string translation. This might be the key difference of our approach from forest-based translation (Mi et al., 2008). As sub-sentence division makes direct comparison of the two forests quite difficult, we leave this to future work.

Parsing model	F_1 (%)	Time (s)
-	62.7	23.9
PCFG	65.4	24.7
Lex	79.8	48.8
PCFG + Lex	$\mathbf{80.6}$	50.4

Table 5: Effect of parsing models on parsing performance ($\leq$ 40 words) and average decoding time (second per sentence). We use "-" to denote only using translation features.

Table 5 shows the results. Translation features were used for all configurations. Without parsing models, the F_1 score is 62.7. Adding Collins' Model 1 results in much larger gains than adding PCFG. With all parsing models integrated, our joint decoder achieves an F_1 score of 80.6 on the test set. Although lower than the F_1 score of the in-house parser that produces the noisy training data, this result is still very promising because the tree-to-string rules that construct trees in the decoding process are learned from noisy training data.

4 Related Work

Charniak et al. (2003) firstly associate lexicalized parsing model with syntax-based translation. They first run a string-to-tree decoder (Yamada and Knight, 2001) to produce an English parse forest and then use a lexicalized parsing model to select the best translation from the forest. As the parsing model operates on the target side, it actually serves as a syntax-based language model for machine translation. Recently, Shen et al. (2008) have shown that dependency language model is beneficial for capturing long-distance relations between target words. As our approach adds parsing models to the source side where the source sentence is fixed during decoding, our decoder does parse the source sentence like a monolingual parser instead of a syntax-based language model. More importantly, we integrate translation models and parsing models in a discriminative framework where they can interact with each other directly.

Our work also has connections to joint parsing (Smith and Smith, 2004; Burkett and Klein, 2008) and bilingually-constrained monolingual parsing (Huang et al., 2009a) because we use another language to resolve ambiguity for one language. However, while both joint parsing and bilingually-constrained monolingual parsing rely on the target sentence, our approach only takes a source sentence as input.

Blunsom and Osborne (2008) incorporate the source-side parse trees into their probabilistic SCFG framework and treat every source-parse PCFG rule as an individual feature. The difference is that they parse the test set before decoding so as to exploit the source syntactic information to guide translation.

More recently, Chiang (2010) has shown that ("exact") tree-to-tree translation as parsing achieves comparable performance with Hiero (Chiang, 2007) using much fewer rules. Xiao et al. (2010) integrate tokenization and translation into a single step and improve the performance of tokenization and translation significantly.

5 Conclusion

We have presented a framework for joint parsing and translation by casting tree-to-string translation as a parsing problem. While tree-to-string rules construct parse trees on the source side and translations on the target side simultaneously, parsing models can be integrated to improve both translation and parsing quality.

This work can be considered as a final step towards the continuum of tree-to-string translation: from single tree to forest and finally to the integration of parsing and translation. In the future, we plan to develop more efficient decoding algorithms, analyze forest matching systematically, and use more sophisticated parsing models.

Semantic Role Features for Machine Translation

Abstract

We propose semantic role features for a Tree-to-String transducer to model the reordering/deletion of source-side semantic roles. These semantic features, as well as the Tree-to-String templates, are trained based on a conditional log-linear model and are shown to significantly outperform systems trained based on Max-Likelihood and EM. We also show significant improvement in sentence fluency by using the semantic role features in the log-linear model, based on manual evaluation.

1 Introduction

Syntax-based statistical machine translation (SSMT) has achieved significant progress during recent years (Galley et al., 2006; May and Knight, 2007; Liu et al., 2006; Huang et al., 2006), showing that deep linguistic knowledge, if used properly, can improve MT performance. Semantics-based SMT, as a natural extension to SSMT, has begun to receive more attention from researchers (Liu and Gildea, 2008; Wu and Fung, 2009). Semantic structures have two major advantages over syntactic structures in terms of helping machine translation. First of all, semantic roles tend to agree better between two languages than syntactic constituents (Fung et al., 2006). This property motivates the approach of using the consistency of semantic roles to select MT outputs (Wu and Fung, 2009). Secondly, the set of semantic roles of a predicate models the *skeleton* of a sentence, which is crucial to the readability of MT output. By skeleton, we mean the main structure of a sentence including the verbs and their arguments. In spite of the theoretical potential of the semantic roles, there has not been much success in using them to improve SMT systems.

Liu and Gildea (2008) proposed a semantic role based Tree-to-String (TTS) transducer by adding semantic roles to the TTS templates. Their approach did not differentiate the semantic roles of different predicates, and did not always improve the TTS transducer's performance. Wu and Fung (2009) took the output of a phrase-based SMT system Moses (Koehn et al., 2007), and kept permuting the semantic roles of the MT output until they best matched the semantic roles in the source sentence. This approach shows the positive effect of applying semantic role constraints, but it requires re-tagging semantic roles for every permuted MT output and does not scale well to longer sentences.

This paper explores ways of tightly integrating semantic role features (SRFs) into an MT system, rather than using them in post-processing or n-best re-ranking. Semantic role labeling (SRL) systems usually use sentence-wide features (Xue and Palmer, 2004; Pradhan et al., 2004; Toutanova et al., 2005); thus it is difficult to compute target-side semantic roles incrementally during decoding. Noticing that the source side semantic roles are easy to compute, we apply a compromise approach, where the target side semantic roles are generated by projecting the source side semantic roles using the word alignments between the source and target sentences. Since this approach does not perform true SRL on the target string, it cannot fully evaluate whether the source and target semantic structures are consistent. However, the approach does capture the semantic-level re-ordering of the sentences. We assume here that the MT system is capable of providing word alignment (or equivalent) information during decoding, which is generally true for current statistical MT systems.

Specifically, two types of semantic role features are proposed in this paper: a semantic role reordering feature designed to capture the skeleton-level permutation, and a semantic role deletion fea-

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 716–724,
Beijing, August 2010

ture designed to penalize missing semantic roles in the target sentence. To use these features during decoding, we need to keep track of the semantic role sequences (SRS) for partial translations, which can be generated based on the source-side semantic role sequence and the corresponding word alignments. Since the SRL system and the MT system are separate, a translation rule (e.g., a phrase pair in phrase-based SMT) could cover two partial source-side semantic roles. In such cases partial SRSs must be recorded in such a way that they can be combined later with other partial SRSs. Dealing with this problem will increase the complexity of the decoding algorithm. Fortunately, Tree-to-String transducer based MT systems (Liu et al., 2006; Huang et al., 2006) can avoid this problem by using the same syntax tree for both SRL and MT. Such an arrangement guarantees that a TTS template either covers parts of one source-side semantic role, or a few complete semantic roles. This advantage motivates us to use a TTS transducer as the MT system with which to demonstrate the use of the proposed semantic role features. Since it is hard to design a generative model to combine both the semantic role features and the TTS templates, we use a log-linear model to estimate the feature weights, by maximizing the conditional probabilities of the target strings given the source syntax trees. The log-linear model with latent variables has been discussed by Blunsom et al. (2008); we apply this technique to combine the TTS templates and the semantic role features.

The remainder of the paper is organized as follows: Section 2 describes the semantic role features proposed for machine translation; Section 3 describes how semantic role features are used and trained in a TTS transducer; Section 4 presents the experimental results; and Section 5 gives the conclusion.

2 Semantic Role Features for Machine Translation

2.1 Defining Semantic Roles

There are two semantic standards with publicly available training data: PropBank (Palmer et al., 2005) and FrameNet (Johnson et al., 2002). PropBank defines a set of semantic roles for the verbs in the Penn TreeBank using numbered roles. These roles are defined individually for each verb. For example, for the verb *disappoint*, the role name *arg1* means *experiencer*, but for the verb *wonder*, role name *arg1* means *cause*. FrameNet is motivated by the idea that a certain type of verbs can be gathered together to form a *frame*, and in the same frame, a set of semantic roles is defined and shared among the verbs. For example, the verbs *boil*, *bake*, and *steam* will be in frame *apply_heat*, and they have the semantic roles of *cook*, *food*, and *heating_instrument*. Of these two semantic standards, we choose PropBank over FrameNet for the following reasons:

1. PropBank has a simpler semantic definition than FrameNet and thus is easier for automatic labeling.

2. PropBank is built upon the Penn TreeBank and is more consistent with statistical parsers, most of which are trained on the Penn TreeBank.

3. PropBank is a larger corpus than FrameNet.

Note that the semantic standard/corpus is not crucial in this paper. Any training corpus that can be used to automatically obtain the set of semantic roles of a verb could be used in our approach.

2.2 Semantic Role Features

Ideally, we want to use features based on the true semantic roles of the MT candidates. Considering there is no efficient way of integrating SRL and MT, accurate target-side semantic roles can only be used in post-processing and re-ranking the MT outputs, where a limited number of MT candidates are considered. On the other hand, it is much easier to obtain reliable semantic roles for the source sentences. This paper uses a compromise approach, where the target-side semantic roles are projected from the source-side semantic roles using the word alignment derived from the translation process. More specifically, we define two types of semantic role features:

1. **Semantic Role Re-ordering (SRR)** This feature describes re-ordering of the source-side

semantic roles (including the predicate) in the target side. It takes the following form:

$$SrcPred : SrcRole_1, ..., SrcRole_n \Rightarrow TarRole_1, ..., TarRole_n$$

where $SrcPred$ and $SrcRole$ denotes the central verb and semantic roles in the source side, and $TarRole$ denotes the target-side roles. The source/target SRSs do not need be continuous, but there should be a one-to-one alignment between the roles in the two sides. Compared to the general re-ordering models used in statistical MT systems, this type of feature is capable of modeling skeleton-level re-ordering, which is crucial to the fluency of MT output. Because a predicate can have different semantic role sequences in different voices, *passive/active* are tagged for each occurrence of the verbs based on their POS and preceding words. Figure 1 shows examples of the feature SRR.

2. **Deleted Roles (DR)** are the individual source-side semantic roles which are deleted in the MT outputs, taking the form of:

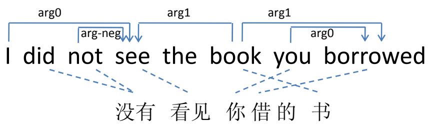
$$SrcPred : SrcRole \Rightarrow deleted$$

DR is meant to penalize the deletion of the semantic roles. Though most statistical MT systems have penalties for word deletion, it is still useful to make separate features for the deletion of semantic roles, which is considered more harmful than the deletion of non-core components (e.g., modifiers) and deserves more serious penalty. Examples of the deletion features can be found in Figure 1.

Both types of features can be made non-lexicalized by removing the actual verb but retaining its voice information in the features. Non-lexicalized features are used in the system to alleviate the problem of sparse verbs.

3 Using Semantic Role Features in Machine Translation

This section describes how to use the proposed semantic role features in a Tree-to-String transducer, assuming that the semantic roles have been tagged for the source sentences. We first briefly describe the basic Tree-to-String translation model used in our experiments, and then describe how to modify it to incorporate the semantic role features.



SRR:
see-active: arg-neg verb ➔ arg-neg verb
borrowed-active: arg1 arg0 ➔ arg0 arg1
borrowed-active: arg1 verb ➔ verb arg1
borrowed-active: arg0 verb ➔ arg0 verb
borrowed-active: arg1 arg0 verb ➔ arg0 verb arg1
DR:
see-active: arg0 ➔ deleted

Figure 1: Examples of the semantic role features

3.1 Basic Tree-to-String Transducer

A Tree-to-String transducer receives a syntax tree as its input and, by recursively applying TTS templates, generates the target string. A TTS template is composed of a left-hand side (LHS) and a right-hand side (RHS), where the LHS is a subtree pattern and the RHS is a sequence of variables and translated words. The variables in the RHS of a template correspond to the bottom level non-terminals in the LHS's subtree pattern, and their relative order indicates the permutation desired at the point where the template is applied to translate one language to another. The variables are further transformed, and the recursive process goes on until there are no variables left. The formal description of a TTS transducer is given by Graehl and Knight (2004), and our baseline approach follows the *Extended Tree-to-String Transducer* defined by Huang et al. (2006). For a given derivation (decomposition into templates) of a syntax tree, the translation probability is computed as the product of the templates which generate both the source syntax trees and the target translations.

$$Pr(S \mid T, D^*) = \prod_{t \in D^*} Pr(t)$$

Here, S denotes the target sentence, T denotes the source syntax tree, and D^* denotes the derivation of T. In addition to the translation model, the

```
function DECODE($T$)
    for tree node $v$ of $T$ in bottom-up order do
        for template $t$ applicable at $v$ do

            $\{c_1, c_2\}$=match($v, t$);
            $s.leftw = c_1.leftw$;
            $s.rightw = c_2.rightw$;
            $s.val = c_1.val \times c_2.val$;
            $s.val \times= Pr(t)$;
            $s.val \times= Pr(c_2.leftw|c_1.rightw)$;
            add $s$ to $v$'s beam;
```

Figure 2: Decoding algorithm for the standard Tree-to-String transducer. $leftw$/$rightw$ denote the left/right boundary word of s. c_1, c_2 denote the descendants of v, ordered based on RHS of t.

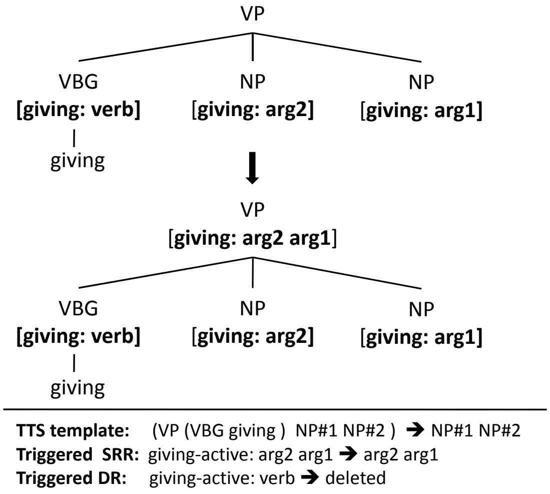
TTS system includes a trigram language model, a deletion penalty, and an insertion bonus. The bottom-up decoding algorithm for the TTS transducer is sketched in Figure 2. To incorporate the n-gram language model, states in the algorithm denote a tree node's best translations with different left and right boundary words. We use standard beam-pruning to narrow the search space. To simplify the description, we assume in Figure 2 that a bigram language model is used and all the TTS templates are binarized. It is straightforward to generalize the algorithm for larger n-gram models and TTS templates with any number of children in the bottom using target-side binarized combination (Huang et al., 2006).

3.2 Modified Tree-to-String Transducer with Semantic Role Features

Semantic role features can be used as an auxiliary translation model in the TTS transducer, which focuses more on the skeleton-level permutation. The model score, depending on not only the input source tree and the derivation of the tree, but also the semantic roles of the source tree, can be formulated as:

$$Pr(S \mid T, D^*) = \prod_{f \in F(S, T.role, D^*)} Pr(f)$$

where T denotes the source syntax tree with semantic roles, $T.role$ denotes the semantic role sequence in the source side and $F(S.role, T.role, D^*)$ denotes the set of defined semantic role features over $T.role$ and the target side semantic role sequence $S.role$. Note that given $T.role$ and the derivation D^*, $S.role$ can be easily derived. Now we show how to incorporate the two types of semantic role features into a TTS transducer. To use the semantic role re-ordering feature SRR, the states in the decoding algorithm need to be expanded to encode the target-side SRSs. The SRSs are initially attached to the translation states of the source tree con-



TTS template: (VP (VBG giving) NP#1 NP#2) → NP#1 NP#2
Triggered SRR: giving-active: arg2 arg1 → arg2 arg1
Triggered DR: giving-active: verb → deleted

Figure 3: An example showing the combination of the semantic role sequences of the states. Above/middle is the state information before/after applying the TTS template, and bottom is the used TTS template and the triggered SRFs during the combination.

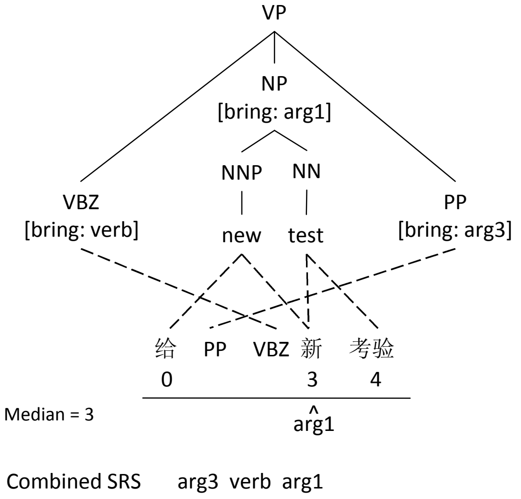


Figure 4: An example showing how to compute the target side position of a semantic role by using the median of its aligning points.

stituents which are labeled as semantic roles for some predicate. These semantic roles are then accumulated with re-ordering and deletion operations specified by the TTS templates as the decoding process goes bottom-up. Figure 5 shows the decoding algorithm incorporating the SRR features. The model component corresponding to the feature SRR is computed when combining two translation states. I.e., the probabilities of the SRR features composed based on the semantic roles of the two combining states will be added into the combined state. See Figure 3 for examples. The theoretical upper bound of the decoding complexity is $O(NM^{4(n-1)}R(\sum_{i=0}^{C} \frac{C!}{i!})^V)$, where N is the number of nodes in the source syntax tree, M is the vocabulary size of the target language, n is the order of the n-gram language model, R is the maximum number of TTS templates which can be matched at a tree node, C is the maximum number of roles of a verb, and V is the maximum number of verbs in a sentence. In this formula, $\sum_{i=0}^{C} \frac{C!}{i!}$ is the number of role sequences obtained by first choosing i out of C possible roles and then permuting the i roles. This theoretical upper bound is not reached in practice, because the number of possible TTS templates applicable at a tree node is very limited. Furthermore, since we apply beam pruning at each tree node, the running time is controlled by the beam size, and is linear in the size of the tree.

The re-ordering of the semantic roles from source to target is computed for each TTS template as part of the template extraction process, using the word-level alignments between the LHS/RHS of the TTS template (e.g., Figure 3). This is usually straightforward, with the exception of the case where the words that are aligned to a particular role's span in the source side are not continuous in the target side, as shown in Figure 4. Since we are primarily interested in the relative order of the semantic roles, we approximate each semantic role's target side position by the median of the word positions that is aligned to. If more than one semantic role is mapped to the same position in the target side, their source side order will be used as their target side order, i.e., monotonic translation is assumed for those semantic roles. Figure 4 shows an example of calculating the target side SRS based on a complicated TTS template. The word alignments in the TTS templates are also used to compute the deletion feature DR. Whenever a semantic role is deleted in a TTS template's RHS, the corresponding deletion penalty will be applied.

```
function DECODE($T$)
    for tree node $v$ of $T$ in bottom-up order do
        for template $t$ applicable at $v$ do
            $\{c_1, c_2\}$=match($v, t$);
            $s.leftw = c_1.leftw$;
            $s.rightw = c_2.rightw$;
            $s.role$ = concatenate($c_1.role$, $c_2.role$);
            if $v$ is a semantic role then
                set $s.role$ to $v.role$;
            $s.val = c_1.val \times c_2.val$;
            $s.val \times= Pr(t)$;
            $s.val \times= Pr(c_2.leftw|c_1.rightw)$;
▷ Compute the probabilities associated with semantic roles
            $s.val \times= \prod_{f \in Sema(c_1.role, c_2.role, t)} Pr(f)$;
            add $s$ to $v$'s beam;
```

Figure 5: Decoding algorithm using semantic role features. $Sema(c_1.role, c_2.role, t)$ denotes the triggered semantic role features when combining two children states, and examples can be found in Figure 3.

3.3 Training

We describe two alternative methods for training the weights for the model's features, including both the individual TTS templates and the semantic role features. The first method maximizes data likelihood as is standard in EM, while the second method maximizes conditional likelihood for a log-linear model following Blunsom et al. (2008).

3.3.1 Maximizing Data Likelihood

The standard way to train a TTS translation model is to extract the minimum TTS templates using GHKM (Galley et al., 2004), and then normalize the frequency of the extracted TTS templates (Galley et al., 2004; Galley et al., 2006; Liu et al., 2006; Huang et al., 2006). The probability of the semantic features SRR and DR can be computed similarly, given that SRR and DR can be derived from the paired source/target sentences and the word alignments between them. We refer to this model as max-likelihood training and normalize the counts of TTS templates and semantic features based on their roots and predicates respectively.

We wish to overcome noisy alignments from GIZA++ and learn better TTS rule probabilities by re-aligning the data using EM within the TTS

```
E-step:
for all pair of syntax tree $T$ and target string $S$ do
    for all TTS Template $t$, semantic features $f$ do
        $EC(t)$ += $\frac{\sum_{D:t\in D} Pr(S,T,D)}{\sum_{D'} Pr(S,T,D')}$;
        $EC(f)$ += $\frac{\sum_{D:f\in D} Pr(S,T,D)}{\sum_{D'} Pr(S,T,D')}$;
M-step:
for all TTS Template $t$, semantic features $f$ do
    $Pr(t) = \frac{EC(t)}{\sum_{t':t'.root=t.root} EC(t')}$;
    $Pr(f) = \frac{EC(f)}{\sum_{f':f'.predicate=t.predicate} EC(f')}$;
```

Figure 6: EM Algorithm For Estimating TTS Templates and Semantic Features

```
function COMPUTE_PARTITION($T$)
    for tree node $v$ of $T$ in bottom-up order do
        for template $t$ applicable at $v$ do
            for $\{s_1, s_2\}$=Match($v$, $t$) do
                $s.sum$ += $s_1.sum \times s_2.sum \times$
$exp(\lambda_t + \sum_{f\in Sema(s_1,s_2,t)} \lambda_f)$;
                $s.role$ = concatenate($s_1.role$, $s_2.role$);
                add $s$ to $v$;
    for state $s$ in $root$ do $res$ += $s.sum$;
    return $res$;
```

Figure 7: Computing the partition function of the conditional probability $Pr(S|T)$. $Sema(s_1, s_2, t)$ denotes all the semantic role features generated by combining s_1 and s_2 using t.

framework (May and Knight, 2007). We can estimate the expected counts of the TTS templates and the semantic features by formulating the probability of a pair of source tree and target string as:

$$\sum_D Pr(S,T,D) = \sum_D \left(\prod_{t\in D} Pr(t) \prod_{f\in F(S,T.role,D)} Pr(f) \right)$$

Though the above formulation, which makes the total probability of all the pairs of trees and strings less than 1, is not a strict generative model, we can still use the EM algorithm (Dempster et al., 1977) to estimate the probability of the TTS templates and the semantic features, as shown in Figure 6.

The difficult part of the EM algorithm is the *E-step*, which computes the expected counts of the TTS templates and the semantic features by summing over all possible derivations of the source trees and target strings. The standard inside-outside algorithm (Graehl and Knight, 2004) can be used to compute the expected counts of the TTS templates. Similar to the modification made in the TTS decoder, we can add the target-side semantic role sequence to the dynamic programming states of the inside-outside algorithm to compute the expected counts of the semantic features. This way each state (associated with a source tree node) represents a target side span and the partial SRSs. To speed up the training, a beam is created for each target span and only the top rated SRSs in the beam are kept.

3.3.2 Maximizing Conditional Likelihood

A log-linear model is another way to combine the TTS templates and the semantic features together. Considering that the way the semantic role features are defined makes it impossible to design a sound generative model to incorporate these features, a log-linear model is also a theoretically better choice than the EM algorithm. If we directly translate the EM algorithm into the log-linear model, the problem becomes maximizing the data likelihood represented by feature weights instead of feature probabilities:

$$Pr(S,T) = \frac{\sum_D \exp \sum_i \lambda_i f_i(S,T,D)}{\sum_{S',T'} \sum_{D'} \exp \sum_i \lambda_i f_i(S',T',D')}$$

where the features f include both the TTS templates and the semantic role features. The numerator in the formula above can be computed using the same dynamic programming algorithm used to compute the expected counts in the EM algorithm. However, the partition function (denominator) requires summing over all possible source trees and target strings, and is infeasible to compute. Instead of approximating the partition function using methods such as sampling, we change the objective function from the data likelihood to the conditional likelihood:

$$Pr(S \mid T) = \frac{\sum_D \exp \sum_i \lambda_i f_i(S,T,D)}{\sum_{S'\in all(T)} \sum_{D'} \exp \sum_i \lambda_i f_i(S',T,D')}$$

where $all(T)$ denotes all the possible target strings which can be generated from the source tree T. Given a set of TTS templates, the new partition function can be efficiently computed using the dynamic programming algorithm shown in Figure 7. Again, to simplify the illustration, only binary TTS templates are used. Using the conditional probability as the objective function not only reduces the computational cost, but also corresponds better to the TTS decoder, where the best MT output is selected only among the possible candidates which can be generated from the input source tree using TTS templates.

The derivative of the logarithm of the objective function (over the entire training corpus) w.r.t. a feature weight can be computed as:

$$\frac{\partial \log \prod_{S,T} Pr(S \mid T)}{\partial \lambda_i} = \sum_{S,T} \{EC_{D|S,T}(f_i) - EC_{S'|T}(f_i)\}$$

where $EC_{D|S,T}(f_i)$, the expected count of a feature over all derivations given a pair of tree and string, can be computed using the modified inside-outside algorithm described in Section 3.2, and $EC_{S'|T}(f_i)$, the expected count of a feature over all possible target strings given the source tree, can be computed in a similar way to the partition function described in Figure 7. With the objective function and its derivatives, a variety of optimization methods can be used to obtain the best feature weights; we use LBFGS (Zhu et al., 1994) in our experiments. To prevent the model from overfitting the training data, a weighted Gaussian prior is used with the objective function. The variance of the Gaussian prior is tuned based on the development set.

4 Experiments

We train an English-to-Chinese translation system using the FBIS corpus, where 73,597 sentence pairs are selected as the training data, and 500 sentence pairs with no more than 25 words on the Chinese side are selected for both the development and test data.[1] Charniak (2000)'s parser, trained on the Penn Treebank, is used to generate the English syntax trees. To compute the semantic roles for the source trees, we use an in-house max-ent classifier with features following Xue and Palmer (2004) and Pradhan et al. (2004). The semantic role labeler is trained and tuned based on sections 2–21 and section 24 of PropBank respectively. The standard role-based F-score of our semantic role labeler is 88.70%. Modified Kneser-Ney trigram models are trained using SRILM (Stolcke, 2002) on the Chinese portion of the training data. The model (n-gram language model, TTS templates, SRR, DR) weights of the transducer are tuned based on the development set using a grid-based line search, and the translation results are evaluated based on a single Chinese reference using BLEU-4 (Papineni et al., 2002). Huang et al. (2006) used character-based BLEU as a way of normalizing inconsistent Chinese word segmentation, but we avoid this problem as the training, development, and test data are from the same source.

The baseline system in our experiments uses the TTS templates generated by using GHKM and the union of the two single-direction alignments generated by GIZA++. Unioning the two single-direction alignments yields better performance for the SSMT systems using TTS templates (Fossum et al., 2008) than the two single-direction alignments and the heuristic diagonal combination (Koehn et al., 2003). The two single-direction word alignments as well as the union are used to generate the initial TTS template set for both the EM algorithm and the log-linear model. The initial TTS templates' probabilities/weights are set to their normalized counts based on the root of the TTS template (Galley et al., 2006). To test semantic role features, their initial weights are set to their normalized counts for the EM algorithm and to 0 for the log-linear model. The performance of these systems is shown in Table 1. We can see that the EM algorithm, based only on TTS templates, is slightly better than the baseline system. Adding semantic role features to the EM algorithm actually hurts the performance, which is not surprising since the combination of the TTS templates and semantic role features does not yield a sound generative model. The log-linear model based on TTS templates achieves significantly better results than both the baseline system and the EM algorithm. Both improvements are significant at $p < 0.05$ based on 2000 iterations of paired bootstrap resampling of the test set (Koehn, 2004).

Adding semantic role features to the log-linear model further improves the BLEU score. One problem in our approach is the sparseness of the verbs, which makes it difficult for the log-linear model to tune the lexicalized semantic role features. One way to alleviate this problem is to make features based on verb classes. We first tried using the verb

[1] The total 74,597 sentence pairs used in experiments are those in the FBIS corpus whose English part can be parsed using Charniak (2000)'s parser.

classes in VerbNet (Dang et al., 1998). Unfortunately, VerbNet only covers about 34% of the verb tokens in our training corpus, and does not improve the system's performance. We then resorted to automatic clustering based on the aspect model (Hofmann, 1999; Rooth et al., 1999). The training corpus used in clustering is the English portion of the selected FBIS corpus. Though automatically obtained verb clusters lead to further improvement in BLEU score, the total improvement from the semantic role features is not statistically significant. Because BLEU-4 is biased towards the adequacy of the MT outputs and may not effectively evaluate their fluency, it is desirable to give a more accurate evaluation of the sentence's fluency, which is the property that semantic role features are supposed to improve. To do this, we manually compare the outputs of the two log-linear models with and without the semantic role features. Our evaluation focuses on the completeness and ordering of the semantic roles, and *better*, *equal*, *worse* are tagged for each pair of MT outputs indicating the impact of the semantic role features. Table 2 shows the manual evaluation results based on the entire test set, and the improvement from SRF is significant at $p < 0.005$ based on a t-test. To illustrate how SRF impacts the translation results, Figure 8 gives 3 examples of the MT outputs with and without the SRFs.

5 Conclusion

This paper proposes two types of semantic role features for a Tree-to-String transducer: one models the reordering of the source-side semantic role sequence, and the other penalizes the deletion of a source-side semantic role. These semantic features and the Tree-to-String templates, trained based on a conditional log-linear model, are shown to significantly improve a basic TTS transducer's performance in terms of BLEU-4. To avoid BLEU's bias towards the adequacy of the MT outputs, manual evaluation is conducted for sentence fluency and significant improvement is shown by using the semantic role features in the log-linear model. Considering our semantic features are the most basic ones, using more sophisticated features (e.g., the head words and their translations of the source-side semantic roles) provides a possible direction for further experimentation.

TimeML Events Recognition and Classification: Learning CRF Models with Semantic Roles

Hector Llorens, Estela Saquete, Borja Navarro-Colorado

University of Alicante
{hllorens,stela,borja}@dlsi.ua.es

Abstract

This paper analyzes the contribution of semantic roles to TimeML event recognition and classification. For that purpose, an approach using conditional random fields with a variety of morphosyntactic features plus semantic roles features is developed and evaluated. Our system achieves an F1 of 81.4% in recognition and a 64.2% in classification. We demonstrate that the application of semantic roles improves the performance of the presented system, especially for nominal events.

1 Introduction

Event recognition and classification has been pointed out to be very important to improve complex natural language processing (NLP) applications such as automatic summarization (Daniel et al., 2003) and question answering (QA) (Pustejovsky, 2002). Natural language (NL) texts often describe sequences of events in a time line. In the context of summarization, extracting such events may aid in obtaining better summaries when these have to be focused on specific happenings. In the same manner, the access to such information is crucial for QA systems attempting to address questions about events.

The analysis of events as well as the classification of the different forms they adopt in NL text is not a new issue (Vendler, 1967). It relates not only to linguistics but different scientific areas such as philosophy, psychology, etc.

In NLP, different definitions of event can be found regarding the target application.

On the one hand, in topic detection and tracking (Allan, 2002), event is defined as an instance of a topic identified at document level describing something that happen (e.g., "wars"). The aim of this task is to cluster documents on the same topic, that is to say, the same event.

On the other hand, information extraction (IE) provides finer granularity event definitions. IE proposes standard schemes to annotate the individual events within the scope of a document. STAG scheme (2000) was aimed to identify events in news and their relationship with points in a temporal line. More recently, TimeML (Pustejovsky et al., 2003a) presented a rich specification for annotating events in NL text extending the features of the previous one.

This paper is focused on the TimeML view of events. TimeML defines events as situations that *happen or occur*, or elements describing *states or circumstances* in which something obtains or holds the truth. These events are generally expressed by tensed or untensed verbs, nominalizations, adjectives, predicative clauses or prepositional phrases. TimeML guidelines define seven classes of events:

- *Reporting*. Action of a person or organization declaring or narrating an event (e.g., "say")
- *Perception*. Physical perception of another event (e.g., "see", "hear")
- *Aspectual*. Aspectual predication of another event (e.g., "start", "continue")
- *I_Action*. Intensional action (e.g., "try")
- *I_State*. Intensional state (e.g., "feel", "hope")
- *State*. Circumstance in which something holds the truth (e.g., "war", "in danger")
- *Occurrence*. Events that describe things that happen (e.g., "erupt", "arrive")

The following sentence shows an example of an occurrence event and a state event.

```
It's <EVENT class="OCCURRENCE">turning</EVENT>
out to be another <EVENT class="STATE">bad</EVENT>
financial week.
```

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 725–733,
Beijing, August 2010

The automatic annotation of events has been addressed with different data-driven approaches. Current approaches are mainly based on morphosyntactic information. Our hypothesis is that semantic roles, as higher language level analysis information, may be useful as additional feature to improve the performance of such approaches.

Within this setting, the main objective of this paper is to analyze (1) the contribution of semantic roles, as additional feature, and (2) the influence of conditional random fields (CRFs), as machine learning (ML) technique, in the events automatic recognition and classification task.

This paper is structured as follows. Firstly, related work in the task is reviewed in Section 2. The next section provides a detailed description of our proposal to address event recognition and classification. After that, Section 4 includes an evaluation of the proposal, and a comparative analysis of the results. Finally, conclusions are drawn in Section 5.

2 Related Work

There is only one corpus available annotated with TimeML events: TimeBank (Pustejovsky et al., 2003b). Hence, all the approaches regarding TimeML events extraction have been evaluated using this corpus.

EVITA system (Saurí et al., 2005) recognizes events by combining linguistic and statistical techniques. The main features used to manually encode event recognition rules are the following: part-of-speech (PoS) tagging, lemmatizing, chunking, lexical lookup and contextual parsing. Furthermore, WordNet information combined with Bayesian learned disambiguation was used to identify nominal events. EVITA obtained 74.03% precision, 87.31% recall, and 80.12% $F_{\beta=1}$ in event recognition over TimeBank.

Boguraev and Ando (2005) present an evaluation on automatic TimeML events annotation. They set out the task as a classification problem and used a robust risk minimization (RRM) classifier to solve it. The $F_{\beta=1}$ results obtained by a 5-fold cross validation over TimeBank were 78.6% for recognition and 61.3% for classification. Moreover, they evaluated the impact of applying word-profiling techniques over their approach to exploit unannotated data. Using this additional information, the $F_{\beta=1}$ results improved to 80.3% and 64.0%. In this evaluation, neither precision nor recall were given.

STEP (Bethard and Martin, 2006) is a system for TimeML event recognition and classification. This approach uses a rich set of textual, morphological, dependency and WordNet hypernymy features to build a Support Vector Machine (SVM) model. The model was trained using 9/10 of the TimeBank. The test, carried out using the remaining 1/10 of the corpus, obtained a 82.0% precision, 70.6% recall and 75.9% $F_{\beta=1}$ for recognition and a 66.7% precision, 51.2% recall and 57.9% $F_{\beta=1}$ for classification.

Finally, March and Baldwin (2008) present an evaluation on event recognition using a multiclass classifier (BSVM). The main features used to train the classifier are word and PoS context window, stop words removal and feature generalization through words grouping (numbers, named entities, etc.). The result for the best feature combination in a 10-fold cross validation over TimeBank was 76.4% $F_{\beta=1}$.

It is worth mentioning that there are two versions of the TimeBank corpus, 1.1 and 1.2. The latest version is the current gold standard. Both versions consist of the same documents[1], mainly news articles and transcribed broadcast news from different domains. EVITA is the only reference which used TimeBank 1.2 while the rest of reviewed references used TimeBank 1.1.

3 Our proposal: semantic roles enhancing a CRF model

In this section, the motivation for our proposal, and our specific approach are presented.

3.1 Motivation

The next two subsections describe the main feature (semantic roles) and the ML algorithm (CRFs) we selected to address event recognition and classification; and the reasons why we think they could be useful in that task.

[1] Except 3 documents removed in TimeBank 1.2

3.1.1 Semantic roles

Semantic role labeling (SRL) has achieved important results in the last years (Gildea and Jurafsky, 2002). For each predicate in a sentence, semantic roles identify all constituents, determining their arguments (agent, patient, etc.) and their adjuncts (locative, temporal, etc.). Currently, there exist different role sets aimed to cover opposed requirements. They range from more specific, such as FrameNet (Baker et al., 1998), to more general like PropBank (Palmer et al., 2005). Figure 1 illustrates a semantic role labeled sentence.

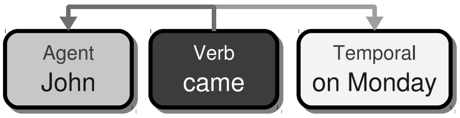

Figure 1: Semantic roles example

Many research efforts into the application of semantic roles demonstrated that this information is useful for different NLP purposes (Melli et al., 2006). Focusing on TimeML, semantic roles have been applied to temporal expressions recognition (Llorens et al., 2009), and temporal links classification (Hagège and Tannier, 2007). However, they have not been used to recognize and classify TimeML events.

Semantic roles provide structural relations of the predicates in which events may participate. Beyond syntactic relations expressed by means of the different types of phrases, semantic roles give further information about semantic relations between the arguments of a predicate. Therefore, as richer information, roles may better distinguish tokens to be candidate events. In addition, different semantic role settings may represent specific event classes.

Example 1 shows four sentences annotated with PropBank semantic roles (in square brackets) in which the noun "control" participates. In the sentences 1 and 2, "control" does not represent an event, while in the sentences 3 and 4, it represents an *state* event. It can be seen that the noun "control", when it is contained by A1 role it may represent an event. However, it is not an event when contained by A0 or AM-MNR roles. The analysis may also take into account the governing verb. In the example, we could specify that "control" represents an event when contained by A1 role of "seek" and "obtain" verbs; and the opposite for the A0 role of "emerge" and the AM-MNR of "had".

(1) 1. "[Control procedures A0] will emerge"
2. "[Iraq A0] had [thousands of Americans A1] [under its control AM-MNR]"
3. "[Crane Co. A0] may obtain [control of Milton Roy Corp. A1]"
4. "[Pattison's A0] decided to seek [control A1]"

Our hypothesis is that semantic roles, as additional information, may help in the recognition and classification of events. The information about the role of a token and the verb it depends on, or the set of roles of the sentence, could be useful for determining whether a token or a sequence of tokens is an event or not. Due to the fact that roles represent high level information in NL text, they are more independent from word tokens. Hence, roles may aid in learning more general models that could improve the results of approaches focused on lower level information.

3.1.2 CRF probabilistic model

Conditional Random Fields is a popular and efficient ML technique for supervised sequence labeling (Lafferty et al., 2001). CRFs are undirected graphical models, a special case of conditionally-trained finite state machines. A key advantage of CRFs is their flexibility to include a wide variety of arbitrary, non-independent features of the input.

We see the task set out in this paper as a sequence labeling problem. Assume X is a random variable over data sequences to be labeled, and Y is a random variable over the corresponding label sequences (hidden), being all Y components (Y_i) members of a finite label alphabet γ. X might range over NL sentences and Y range over event annotations of those sentences, with γ the set of possible event IOB2[2] labels. The following example illustrates the event recognition problem.

(2)

X	Y		
was	?		
another	?		B-EVENT
bad	?	? =	I-EVENT
week	?		O

[2] IOB2 format: (B)egin, (I)nside, and (O)utside

The variables X and Y are jointly distributed over both label and observation sequences. However, unlike Hidden Markov Models (generative) in which $p(X,Y)$, CRFs (discriminative) construct a conditional model from paired observation and label sequences: $p(Y|X)$. Graphically, CRFs are represented by undirected graphs, $G = (V,E)$ such that $Y = (Y_v),\ v \epsilon V$, so that Y is indexed by the vertices of G. Then (X,Y) is a *conditional random field* if Y_v variables obey the *Markov property* with respect to the graph when conditioned on X:

$$P(Y_v|X,Y_w,v \neq w) = P(Y_v|X,Y_w,v \sim w),$$

where $v \sim w$ means that Y_v and Y_w are connected neighbors in G.

To extend the problem to event classification, the alphabet γ must be extended with the event classes (state, aspectual, etc.).

CRFs have been successfully applied to many sequence labeling tasks (Sha and Pereira, 2003; McCallum and Li, 2003).

From our point of view, the task addressed in this paper is well suited for this ML technique. Events may depend on structural properties of NL sentences. Not only the word sequence, but morphological, syntactic and semantic information is related with the event structure (Tenny and Pustejovsky, 2000).

For example, sequences of verbs may represent *i_action+occurrence* or *aspectual+occurrence* events (see Example 3).

(3) "The president will <EVENT class="i_action"> try </EVENT> to <EVENT class="occurrence"> assist </EVENT> to the <EVENT class="occurrence"> conference </EVENT>"

"Saddam will <EVENT class="aspectual"> begin </EVENT> <EVENT class="occurrence"> withdrawing </EVENT> troops from Iranian territory on Friday"

In addition, for instance, many *state* event instances are represented by "to be" plus a variable quality (see Example 4).

(4) "It is <EVENT class="occurrence"> turning </EVENT> out to be another <EVENT class="state"> bad </EVENT> financial week."

Given this analysis, our hypothesis is that CRFs will be useful in the recognition of events in which the sequential and structural properties are relevant.

3.2 Approach description

This paper proposes CRFs as learning method to infer an event recognition and classification model. Our system includes CRF++ toolkit[3] for training and testing our approach. The learning process was done using *CRF-L2* algorithm and hyper-parameter C=1.

The definition of the features is crucial for the architecture of the system. The features used in our approach are grouped in two feature sets. On the one hand, general features, which comprise morphosyntactic and ontological information. On the other hand, semantic roles features, which are the main focus of this paper.

The general features used to train our CRF model are described regarding each language analysis level.

- **Morphological**: The lemma and PoS context, in a 5-window (-2,+2), was employed. This basic linguistic feature showed good results in different NLP tasks, as well as in event recognition and classification (March and Baldwin, 2008). Tokenization, PoS and lemmatization were obtained using TreeTagger (Schmid, 1994).

- **Syntactic**: Different events are contained in particular types of phrases and syntactic dependencies. This feature tries to tackle this by considering syntactic information. Charniak parser (Charniak and Johnson, 2005) was used to obtain the syntactic tree.

- **Lexical semantics**: WordNet (Fellbaum, 1998) top ontology classes have been widely used to represent word meaning at ontological level, and demonstrated its worth in many tasks. We obtained the four top classes for each word.

The specific semantic roles features used to enhance the training framework of the CRF model were developed considering PropBank role set. PropBank was applied in our system due to the high coverage it offers in contrast to FrameNet. In order to get PropBank semantic roles, the CCG

[3] http://crfpp.sourceforge.net/

SRL tool (Punyakanok et al., 2004) was used for labeling the corpus.

- **Role**: For each token, we considered the role regarding the verb the token depends on. Semantic roles information may be useful for distinguish particular lemmas that are events only when appearing under a precise role.
- **Governing verb**: The verb to which the current token holds a particular role. This may distinguish tokens appearing under the influence of different verbs.
- **Role+verb combination**: The previous two features were combined to capture the relation between them. This introduces new classification information by distinguishing roles depending on different verbs. The importance of this falls especially on the numbered roles of PropBank (A0, A1, ...) holding different meanings when depending on different verbs.
- **Role configuration**: This consists of the set of roles depending on the verb the token depends on. This may be particularly useful for distinguish different sentence settings and thus, whether a token denotes an event in a particular sentence type.

The system consists of two main processes. Firstly, given TimeML annotated text, it obtains the defined features plus the IOB2 tags of the annotated events. Then, using this data the system learns (trains) a model for event recognition and a model for event classification. Secondly, given plain text, it automatically gets the defined features using the described tools. With this data, the system applies the learned models to recognize and classify TimeML events.

4 Evaluation

In this section, firstly, the corpus, criteria and measures are defined. Secondly, the results obtained by our approach are presented. After that, the contribution of our approach is measured through different experiments: (1) general contribution, (2) semantic roles contribution, and (3) CRFs contribution. And finally, our approach is compared to the state of the art systems.

4.1 Corpus, criteria and measures

For the evaluation, the TimeBank 1.2 corpus (7881 events) was used without modification. All the results reported in this evaluation were obtained using a 5-fold cross validation. The n-fold train-test sets were built sorting the corpus files alphabetically and then sequentially select each set regarding the documents size. It is important to highlight the latter because if the n-folds were made regarding the number of documents, the sets had not been homogeneous due to the differences in TimeBank document sizes.

Only annotations matching the exact event span were considered as *correct* in recognition and classification, requiring also the class matching in the second case.

The following measures were used to score the evaluated approaches.

- Precision $\frac{correct\_annotations}{total\_approach\_annotations}$
- Recall $\frac{correct\_annotation}{total\_corpus\_annotations}$
- $F_{\beta=1}$ $\frac{2 * precision * recall}{precision + recall}$

4.2 Our approach results

Table 1 shows the results obtained by our approach for both recognition and classification of events. The last column (BF) indicates the best $F_{\beta=1}$ results obtained in the individual folds.

	Precision	**Recall**	$\mathbf{F}_{\beta=1}$	BF
Recognition	83.43	79.54	**81.40**	82.43
Classification	68.84	60.15	**64.20**	69.68

Table 1: Our approach (CRF+Roles) results

The results show a high $F_{\beta=1}$ score in both recognition and classification, showing a good balance between precision and recall. This indicates that our approach is appropriate to address this task.

Focusing on classification task, Table 2 shows the detailed scores for each event class.

Looking at the specific class results, *reporting* obtained the best results. This is due to the fact that 80% of *reporting* events are represented by lemmas “say” and “report” with PoS “VBD” and “VBZ”. *Occurrence, perception, aspectual* and *i_state* obtained classification results over 50%.

Class (instances)	**Precision**	**Recall**	**F$_{\beta=1}$**
Reporting (1021)	91.90	89.18	90.51
Perception (48)	65.93	66.83	66.37
Aspectual (258)	81.35	47.00	59.57
I_Action (673)	51.40	29.30	37.32
I_State (582)	68.44	43.70	53.34
State (1107)	50.01	24.84	33.19
Occurrence (4192)	66.73	72.07	69.29

Table 2: CRF+Roles 5-fold detailed results

Although *perception* and *aspectual* are quite restricted to some lemmas, they obtained results below *reporting*. This is due to the fact that TimeBank contains very few examples of these classes. *I_action* and *state* show poorer results. In the case of the former, this is because some nonintensional verbs (e.g., "look") appear in the corpus as *i_action* under certain conditions, for example, when there is modality or these verbs appear in conditional sentences. This suggests the necessity of incorporating a word sense disambiguation (WSD) technique. Our approach did not take into account this information and thus the results are lower for this event class. In the case of *state*, the reasons for the low performance are the richness of this event class by means of lemmas, PoS, and phrases.

Finally, Table 3 shows the results of our approach by word class.

		Precision	**Recall**	**F$_{\beta=1}$**
Recognition	*Verb*	91.56	92.15	91.33
	Noun	72.67	48.26	58.42
	Adj.	66.78	38.09	48.35
Classification	*Verb*	73.86	74.21	73.51
	Noun	62.73	41.33	49.53
	Adj.	55.69	31.12	40.41

Table 3: CRF+Roles 5-fold word class results

It may be seen that the best results in both recognition and classification are obtained in verb events, followed by noun and adjective.

4.3 Contribution analysis

This subsection details the contribution of each aspect of our approach through three comparative experiments.

First experiment: general contribution

This experiment measures the general contribution of our approach by comparing its results with a baseline. TimeBank was analyzed to find a basic general rule to annotate events. The events are mainly denoted by verbs, pertaining to *occurrence* class. Hence, we propose a baseline that annotates all verbs as *occurrence* events. Table 4 shows results obtained by this baseline for both recognition and classification of events.

		Prec.	**Recall**	**F$_{\beta=1}$**
Our approach	*Recog.*	83.43	79.54	81.40
	Class.	68.84	60.15	64.20
Baseline	*Recog.*	72.50	65.20	68.60
	Class.	46.01	53.19	49.34

Table 4: Our approach vs Baseline results

Given the simplicity of the baseline, the results obtained are quite high. However, our approach F$_{\beta=1}$ significantly improves baseline by 19% for recognition and 30% for classification.

Second experiment: roles contribution

The main objective of this paper is to determine the impact of semantic roles in this task. To quantify it, a non-roles version of our approach was evaluated. This version only uses the general features described in section 3. Table 5 shows the results obtained.

		Precision	**Recall**	**F$_{\beta=1}$**
Our approach	*Recog.*	83.43	79.54	81.40
	Class.	68.84	60.15	64.20
Non-roles	*Recog.*	82.96	74.81	78.67
	Class.	67.53	54.80	60.50

Table 5: Our approach vs Non-roles results

Comparing these results with the ones obtained by our full featured approach, the application of roles improved especially the recall. Specifically, recall improved by 6% and 10% for recognition and classification respectively. The main improvement was achieved by *state* and *occurrence* classes (60% of the total improvement), especially, nominal events of that classes that concentrate around the 70% of the total contribution.

To illustrate corpus examples that have been improved by roles, Example 5 shows two sentences containing state events that were correctly tagged by the roles approach and missed by the non-roles. In the examples, the TimeML events annotation and below the semantic roles annotation is reported.

(5) "There are still few buyers and the mood is `<EVENT class=STATE>gloomy</EVENT>`"
"[There A0] are [still AM-TMP] [few buyers A1] and [the mood A0] is [gloomy AM-MNR]"

"Security is now `<EVENT>better</EVENT>`"
"[Security A0] is [now AM-TMP] [better AM-MNR]"

In these cases, AM-MNR role information lead to a correct *state* event recognition.

Third experiment: CRFs contribution

In order to measure the CRFs contribution to this task, an extra experiment was carried out. This consisted of comparing, under the same setting, CRFs with a popular learning technique: support vector machines (SVM). As in Bethard and Martin (2006), YamCha[4] software was used (parameters: C=1 and polynomial_degree=2).

Table 6 shows the results obtained by the SVM-based approach in recognition and Table 7 reports the improvement (CRFs over SVM) distribution in the different word classes.

	Precision	**Recall**	**$F_{\beta=1}$**
Our approach (CRF)	83.43	79.54	81.40
SVM	80.00	75.10	77.40

Table 6: Our approach (CRF) vs SVM results

	Verb	**Noun**	**Adj.**	**Adv.**	**Prep.**
General	22%	71%	5%	1%	1%

Table 7: CRF improvement distribution among the word classes

These results verify that CRF improves SVM $F_{\beta=1}$ by 5% in this task. Furthermore, especially noun events take advantage of using CRF.

Finally, Figure 2 illustrates the results of our approach over the described experiments.

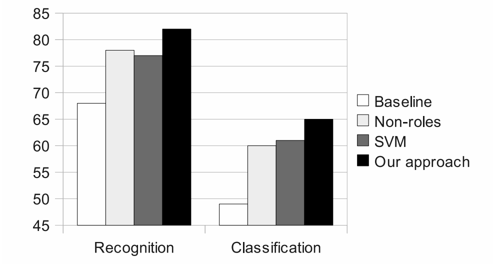

Figure 2: $F_{\beta=1}$ Results

4.4 Comparison with the state of the art

Most systems found in the literature are data-driven approaches using morphosyntactic features. SVM based approaches (Bethard and Martin, 2006; March and Baldwin, 2008) achieved, approximately, 76% and 58% $F_{\beta=1}$ in event recognition and classification respectively. Boguraev and Ando (2005) used a robust risk minimization classifier to address this task and obtained 78.6% and 61% (without exploiting unannotated data). These results are very similar to the ones obtained by our non-roles approach. This suggests that using, apart from morphosyntactic features, additional features based on semantic roles could improve the approaches.

EVITA system (Saurí et al., 2005) combines linguistic and statistical techniques. On the one hand, it consists of a set of manually encoded rules based on morphosyntactic information. On the other hand, it includes a Bayesian learned disambiguation module to identify nominal events. The later was trained and tested using the whole corpus, therefore, the results could be inflated by this fact. For that reason, Bethard and Martin (2006) presented an EVITA implementation (Sim-Evita) to compare the results. Sim-Evita obtains an 73% and 51% $F_{\beta=1}$ in event recognition and classification respectively. These results suggest that data-driven improve rule-based approaches.

Only STEP evaluation showed detailed classification results. We agree that *state* events are the most complex and heterogeneous ones. Focusing on such events, our $F_{\beta=1}$ results (33%) improve Bethard's (25%) by 32%. Regarding the results obtained for each word class. Bethard's results presented good performance on classifying verb events (71%), but lower results in noun events (34%). Our approach results for noun events (49%) improve theirs by 44%. This suggests that the application of semantic roles enables our approach on making more general predictions. In this manner, our system may recog-

[4] http://chasen.org/˜taku/software/YamCha/

nize unseen nominal event instances as long as they share, with the seen instances, some semantic roles features.

5 Conclusions and Further Work

This paper presented an approach for the recognition and classification of TimeML events consisting of a CRF model learned using semantic roles as main feature. In addition to morphosyntactic features, the model was enhanced including extra semantic information, semantic role labeling, used for other applications with satisfactory results, but never employed before for this purpose. Our proposal was evaluated using the gold standard corpus, TimeBank 1.2, and the results obtained were analyzed and compared to measure the impact of both semantic roles and CRFs in the described task.

The obtained $F_{\beta=1}$ results demonstrated that semantic roles are useful to recognize (81.43%) and classify (64.20%) TimeML events, improving the presented baseline by 19% for recognition and 30% for classification. Specifically, Semantic roles employed as additional feature improved the recall of the non-roles version by 6% and 10% for recognition and classification respectively. This indicates that roles features led to more general models capable of better annotating unseen instances. The roles contribution was more significant in *state* and *occurrence* classes of noun events, concentrating around the 70% of the improvement.

Furthermore, it was verified that CRFs achieve higher results than models learned using other ML techniques such as SVM (5% improvement), contributing especially to nominal events. This demonstrated that CRF models are appropriate to face the task.

Finally, to the extent our results are comparable to state of the art evaluations, ours outperform the $F_{\beta=1}$ scores in both recognition and classification. Especially, our approach showed better performance than related works in *state* (32% improvement) and nominal events (44% improvement). Hence, the extension of the current approaches with semantic roles features could benefit their performance.

The main difficulties found in the task addressed in this paper are related to *i_action* and *state* events. In the former, we detected that modality and the word senses are important and must be treated to distinguish such events. In the later, although they were improved by our approach, *state* events are still the most complex class of events due to their richness in contrast to the reduced size of the training data. We agree with related literature that event classification results are still below other tasks performance, which indicates that this task is inherently complex and more training data may lead to significant improvements.

As further work we propose, firstly, improving the *i_action* results by taking into account the modality considering the *AM-MOD* role, and the word senses using a WSD technique. Secondly, the application of FrameNet role set (finer granularity) to determine which kind of roles are better to improve the current event annotation systems.

Exploiting Structured Ontology to Organize Scattered Online Opinions

{yuelu2,duan9,wang296,czhai}@illinois.edu

Abstract

We study the problem of integrating scattered online opinions. For this purpose, we propose to exploit structured ontology to obtain well-formed relevant aspects to a topic and use them to organize scattered opinions to generate a structured summary. Particularly, we focus on two main challenges in implementing this idea, (1) how to select the most useful aspects from a large number of aspects in the ontology and (2) how to order the selected aspects to optimize the readability of the structured summary. We propose and explore several methods for solving these challenges. Experimental results on two different data sets (US Presidents and Digital Cameras) show that the proposed methods are effective for selecting aspects that can represent the major opinions and for generating coherent ordering of aspects.

1 Introduction

The explosive growth of online opinions raises interesting challenges for opinion integration and summarization. It is especially interesting to integrate and summarize scattered opinions in blog articles and forums as they tend to represent the general opinions of a large number of people and get refreshed quickly as people dynamically generate new content, making them valuable for understanding the current views of a topic.

However, opinions in blogs and forums are usually fragmental, scattered around, and buried among other off-topic content, so it is quite challenging to organize them in a meaningful way. Traditional text summarization techniques generate an unstructured list of sentences as a summary, which cannot reveal representative opinions on different aspects of a topic or effectively facilitate navigation into the huge opinion space. To address this limitation, recent work has shown the usefulness of generating a structured summary of opinions, in which related opinions are grouped into topical aspects with explicit labeling of all the aspects. A major challenge in producing such a structured summary is how to generate these aspects for an arbitrary topic (e.g., products, political figures, policies, etc.). Intuitively, the aspects should be concise phrases that can both be easily interpreted in the context of the topic under consideration and capture the major opinions. However, where can we find such phrases and which phrases should we select as aspects? Furthermore, once we selected aspects, how should we order them to improve the readability of a structured summary? One way to generate aspects is to cluster all the opinion sentences and then identify representative phrases in each cluster. Although aspects selected in this way can effectively capture the major opinions, a major limitation is that it is generally hard to ensure that the selected phrases are well connected with the given topic (Chen and Dumais, 2000).

In this paper, we propose a novel approach to generating aspects by leveraging the ontologies with structured information that are available online, such as open domain knowledge base in Freebase[1]. Such kind of ontology data is not in small scale by any measure. For example, Freebase alone contains more than 10 million topics, 3000 types, and 30,000 properties; moreover, it is constantly growing as people collaboratively contribute. Freebase provides different properties for different types of topics such as personal information for a “US President” and product features for a “Digital Camera”. Since this kind of resources can provide related entities/relations for a

[1] http://www.freebase.com

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 734–742,
Beijing, August 2010

wide range of topics , our general idea is to leverage them as guidance for more informed organization of scattered online opinions, and in particular, to select the most important properties of a topic from such structured ontology as aspects to generate a structured opinion summary. A significant advantage of this approach to aspect generation is that the selected aspects are guaranteed to be very well connected with the topic, but it also raises an additional challenge in selecting the aspects to best capture the major opinions from a large number of aspects provided for each topic in the ontology. Different from some existing work on exploiting ontologies, e.g., (Sauper and Barzilay, 2009), which relies on training data, we focus on exploring *unsupervised* approaches, which can be applied to a larger scope of topics.

Specifically, given a topic with entries in an ontology and a collection of scattered online opinions about the topic, our goal is to generate a structured summary where representative major opinions are organized with well aligned aspects and in an order easy for human to follow. We propose the following general approach: First, retrieval techniques are employed to align opinions to relevant aspects. Second, a subset of most interesting aspects are selected. Third, we will further order the selected aspects to present them in a reasonable order. Finally, for the opinions uncovered by the selected aspects from the ontology, we use a phrase ranking method to suggest new aspects to add to the ontology for increasing its coverage.

Implementing the second and third steps involves special challenges. In particular, without any training data, it is unclear how we should show the most interesting aspects in ontology with major opinions aligned and which presentation order of aspects is natural and intuitive for human. Solving these two challenges is the main focus of this paper. We propose three methods for aspect selection, i.e., size-based, opinion coverage-based, and conditional entropy-based methods, and two methods for aspect ordering, i.e., ontology-ordering and coherence ordering. We evaluate our methods on two different types of topics: US Presidents and Digital Cameras. Qualitative results demonstrate the utility of integrating opinions based on structured ontology as well as the generalizability of proposed methods. Quantitative evaluation is also conducted to show the effectiveness of our methods.

Note that we use the term ”opinion” to broadly refer to any discussion in opinionated sources such as blogs and reviews. This allows us to formulate and solve the problem in a general way. Indeed, the main goal of our work is to extract and organize the major opinions about a topic that are buried in many scattered opinionated sources rather than perform deeper understanding of opinions (e.g., distinguishing positive from negative opinions), which can be done by using any existing sentiment analysis technique as an orthogonal post-processing step after applying our method.

2 Related Work

Aspect summarization, i.e., structured opinion summarization over topical aspects, has attracted much attention recently. Existing work identifies aspects using frequent-pattern/association-rule mining, e.g. (Liu et al., 2005; Popescu and Etzioni, 2005), sentence clustering, e.g. (Gamon et al., 2005; Leouski and Croft, 1996), or topic modeling, e.g. (Mei et al., 2006; Titov and McDonald, 2008). After that, meaningful and prominent phrases need to be selected to represent the aspects, e.g. (Zhao and He, 2006; Mei et al., 2007). However, these methods suffer from the problem of producing trivial aspects. Consequently, some of the aspects generated are very difficult to interpret (Chen and Dumais, 2000). In this paper, we propose a different kind of approach that is to use aspects provided by ontology which are known to be relevant and easy to interpret.

Ontology is used in (Carenini et al., 2005) but only for mapping product features. The closest work to ours are (Lu and Zhai, 2008; Sauper and Barzilay, 2009); both try to use well-written articles for summarization. However, (Lu and Zhai, 2008) assumes the well-written article is structured with explicit or implicit aspect information, which does not always hold in practice, while (Sauper and Barzilay, 2009) needs a relatively large amount of training data in the given domain. In comparison, our work only needs the ontology information for the given topic which is much easier to obtain from resources such as Freebase.

3 Methods

Given (1) an input topic T, (2) a large number of aspects/properties $A = \{A_1, ..., A_m\}$ from an ontology that are related to T, and (3) a huge collection of scattered opinion sentences about the topic $D_T = \{s_1, \ldots, s_n\}$, our goal is to generate a structured organization of opinions that are both aligned well with the interesting aspects and representative of major opinions about the topic.

The envisioned structured organization consists of a sequence of selected aspects from ontology ordered to optimize readability and a set of sentences matching each selected aspect. Once we obtain a set of sentences in each aspect, we can easily apply a standard text summarization method to further summarize these sentences, thus the unique challenges related to our main idea of exploiting ontology are the following, which are also the main focus of our study:

Aspect Selection: How can we select a subset of aspects $A' \subset A$ to capture the *major* opinions in our opinion set D_T?

Aspect Ordering: How can we order a subset of selected aspects A' so as to present them in an order $\pi(A')$ that is most natural with respect to human perception?

New Aspects Suggestion: Can we exploit the opinions in D_T to suggest new aspects to be added to the ontology?

3.1 Aspect Selection

In order to align the scattered opinions to the most relevant aspects, we first use each aspect label $A_i \in A$ as a query to retrieve a set of relevant opinions in the collection $S_i \subseteq D_T$ with a standard language modeling approach, i.e., the KL-divergence retrieval model (Zhai and Lafferty, 2001). Up to 1000 opinion sentences are retrieved for each aspect; each opinion sentence can be potentially aligned to several aspects. In this way, scattered online discussion are linked to the most relevant aspects in the ontology, which enables a user to use aspects as "semantic bridges" to navigate into the opinion space..

However, there are usually a lot of candidate aspects in an ontology, and only some are heavily commented in online discussions, so showing all the aspects is not only unnecessary, but also overwhelming for users. To solve this problem, we propose to utilize the aligned opinions to further select a subset of the most interesting aspects $A' \subset A$ with size k. Several approaches are possible for this subset selection problem.

Size-based: Intuitively, the selected subset A' should reflect the major opinions. So a straightforward method is to order the aspects A_i by the size of the aligned opinion sentences S_i, i.e., the number of relevant opinion sentences, and then select the top k ones.

Opinion Coverage-based: The previous method does not consider possible redundancy among the aspects. A better approach is to select the subset that covers as many *distinct* opinion sentences as possible. This can be formulated as a maximum coverage problem, for which a greedy algorithm is known to be a good approximation: we select one aspect at a time that is aligned with the largest number of uncovered sentences.

Conditional Entropy-based: Aspects from a structured ontology are generally quite meaningful, but they are not designed specifically for organizing the opinions in our data set. Thus, they do not necessarily correspond well to the natural clusters in scattered opinions. To obtain aspects that are aligned well with the natural clusters in scattered opinions, we can first cluster D_T into l clusters $C = \{C_1, \ldots, C_l\}$ using K-means with $TF \times IDF$ as features, and then choose the subset of aspects that minimize Conditional Entropy of the cluster label given the aspect:

$$\begin{aligned} A' &= \arg\min H(C|A') = \arg\min \\ &\left[- \sum_{A_i \in A', C_i \in C} p(A_i, C_i) \log \frac{p(A_i, C_i)}{p(A_i)} \right] \end{aligned}$$

This Conditional Entropy measures the uncertainty about the cluster label of a sentence given the knowledge of its aspect. Intuitively, if the aspects are aligned well with the clusters, we would be able to predict well the cluster label of a sentence if we know its aspect, thus there would be less uncertainty about the cluster label. In the extreme case when the cluster label can be completely determined by the aspect, the conditional entropy would reach its minimum (i.e., 0). Intuitively, the conditional entropy-based method essentially selects the most appropriate aspects from

Algorithm 1 Greedy Algorithm for Conditional Entropy Based Aspect Selection

```
Input: $A = \{A_1, ..., A_m\}$
Output: $k$-sized $A' \subseteq A$
$A' = \{\cup_{i=1}^{m} A_i\}$
for j=1 to $k$ do
    $bestH = \infty$; $bestA = A_0$
    for each $A_i$ in $A$ do
        $tempA' = \{A_i, A' \setminus A_i\}$
        if $H(C|tempA') < bestH$ then
            $bestH = H(C|tempA')$
            $bestA = A_i$
    $A' = \{bestA, A' \setminus bestA\}$
output $A'$
```

the ontology to label clusters of opinions.

The exact solution of this combinatorial optimization problem is NP-complete, so we employ a polynomial time greedy algorithm to approximate it: in the i-th iteration, we select the aspect that can minimize the conditional entropy given the previous $i - 1$ selected aspects. Pseudo code is given in Algorithm 1.

3.2 Aspect Ordering

In order to present the selected aspects to users in a most natural way, it is important to obtain a coherent order of them, i.e., generating an order consistent with human perception. To achieve this goal, our idea is to use human written articles on the topic to learn how to organize the aspects automatically. Specifically, we would order aspects so that the relative order of the sentences in all the aspects would be as consistent with their order in the original online discussions as possible.

Formally, the input is a subset of selected aspects A'; each $A_i \in A'$ is aligned with a set of relevant opinion sentences $S_i = \{S_{i,1}, S_{i,2}, ...\}$. We define a coherence measurement function over sentence pairs $Co(S_{i,k}, S_{j,l})$, which is set to 1 iff $S_{i,k}$ appears before $S_{j,l}$ in the same article. Otherwise, it is set to 0. Then a coherence measurement function over an aspect pair can be calculated as

$$Co(A_i, A_j) = \frac{\sum_{S_{i,k} \in S_i, S_{j,l} \in S_j} Co(S_{i,k}, S_{j,l})}{|S_i||S_j|}$$

As an output, we would like to find a permutation $\hat{\pi}(A')$ that maximizes the coherence of all pairwise aspects, i.e.,

$$\hat{\pi}(A') = \arg\max_{\pi(A')} \sum_{A_i, A_j \in A', A_i \prec A_j} Co(A_i, A_j)$$

Algorithm 2 Greedy Algorithm for Coherence Based Aspect Ordering

```
Input: $A$
Output: $\pi(A)$
for each $A_i, A_j$ in $A$ do
    calculate $Co(A_i, A_j)$
for $p = 1$ to $len = A.size()$ do
    $Max = A[1]$
    for each aspect $A_i$ in $A$ do
        $A_i.coherence = 0$
        for each aspect $A_j$ in $\pi(A)$ do
            $A_i.coherence+ = Co(A_j, A_i)$
        for each aspect $A_j$ in $A, j \neq i$ do
            $A_i.coherence+ = Co(A_i, A_j)$
        if $A_i.coherence > Max.coherence$ then
            $Max = A_i$
    remove $Max$ from $A$; add $Max$ to $\pi(A)$
output $\pi(A)$
```

where $A_i \prec A_j$ means that A_i is before A_j. It is easy to prove that the problem is NP-complete. Therefore, we resort to greedy algorithms to find approximations of the solution. Particularly we view the problem as a ranking problem. The algorithm proceeds by finding at each ranking position an aspect that can maximize the coherence measurement, starting from the top of the rank list. The detailed algorithm is given in Algorithm 2.

3.3 New Aspects Suggestion

Finally, if the opinions cover more aspects than in the ontology, we also want to identify informative phrases to label such extra aspects; such phrases can also be used to further augment the ontology with new aspects.

This problem is similar to existing work on generating labels for clusters (Zeng et al., 2004) or topic models (Mei et al., 2007). Here we employ a simple but representative technique to demonstrate the feasibility of discovering interesting new aspects for augmenting the ontology. We first extract named entities from scattered opinions D_T using Stanford Named Entity Recognizer (Finkel et al., 2005). After that, we rank the phrases by pointwise Mutual Information (MI):

$$MI(T, ph) = \log \frac{P(T, ph)}{P(T)P(ph)}$$

where T is the given topic and ph refers to a candidate entity phrase. $P(T, ph)$ is proportional to the number of opinion sentences they co-occur; $P(T)$ or $P(ph)$ are proportional to the number of times T or ph appears. A higher MI value indicates a

Table 1: Statistics of Data Sets

stronger association. We can then suggest the top ranked entity phrases that are not in the selected aspects as new aspects.

4 Experiments

4.1 Data Sets

To examine the generalizability of our methods, we test on two very different categories of topics: *US Presidents* and *Digital Cameras*.[2] For the ontology, we leverage Freebase, downloading the structured ontology for each topic. For the opinion corpus, we use blog data for US Presidents and customer reviews for Digital Cameras. The blog entries for US Presidents were collected by using Google Blog Search[3] with the name of a president as the query. Customer reviews for Digital Cameras were crawled from CNET[4]. The basic statistics of our data sets is shown in Table 1. For all the data collections, Porter stemmer (Porter, 1997) is applied and stop words are removed.

4.2 Sample Results

We first show sample results of automatic organization of online opinions. We use the opinion coverage-based algorithm to select 10 aspects (10-20 aspects were found to be optimal in (Käki, 2005)) and then apply the coherence-based aspect ordering method. The number of clusters is set so that there are on average 15 opinions per cluster.

Opinion Organization: Table 2 and Table 3 present sample results for President Ronald Reagan and Sony Cybershot DSC-W200 camera respectively[5]. We can see that (1) although Freebase aspects provide objective and accurate information about the given topics, extracted opinion sentences offer additional subjective information; (2) aligning scattered opinion sentences to most relevant aspects in the ontology helps digestion and navigation; and (3) the support number, which is the number of opinion sentences aligned to an aspect, can show the popularity of the aspect in the online discussions.

Adaptability of Aspect Selection: Being unsupervised is a significant advantage of our methods over most existing work. It provides flexibility of applying the methods in different domains without the requirement of training data, benefiting from both the ontology based template guidance as well as data-driven approaches. As a result, we can generate different results for different topics even in the same domain. In Table 4, we show the top three selected and ordered aspects for Abraham Lincoln and Richard Nixon. Although they belong to the same category, different aspects are picked up due to the differences in online opinions. People talk a lot about Lincoln's role in American Civil War and his famous quotation, but when talking about Nixon, people focus on ending the Vietnam war and the Watergate scandal. “Date of birth” and “Government position” are ranked first because people tend to start talking from these aspects, which is more natural than starting from aspects like “Place of death”.

Baseline Comparison: We also show below the aspects for Lincoln generated by a representative approach using clustering method (e.g. (Gamon et al., 2005)). i.e., we label the largest clusters by selecting phrases with top mutual information. We can see that although some phrases make sense, not all are well connected with the given topic; using aspects in ontology circumvents this problem. This example confirms the finding in previous work that the popular existing clustering-based approach to aspects generation cannot generate meaningful labels (Chen and Dumais, 2000).

```

Gettysburg
John F.
```

New Aspect Discovery: Finally, in Table 5 we show some phrases ranked among top 10 using the method described in Section 3.3. They reveal additional aspects covered in online discussions and serve as candidate new aspects to be added to Freebase. Interestingly, John Wilkes Booth, who assassinated President Lincoln, is not explicitly

listed in Freebase, but we can find it in people's online discussion using mutual information.

4.3 Evaluation of Aspect Selection

Measures: Aspect selection is a new challenge, so there is no standard way to evaluate it. It is also very hard for human to read all of the aspects and opinions and then select a gold standard subset. Therefore, we opt to use indirect measures capturing different characteristics of the aspect selection problem (1) *Aspect Coverage* (AC): we first assign each aspect A_i to the cluster C_j that has the most overlapping sentences with A_i, approximating the cluster that would come into mind when a reader sees A_i. Then AC is defined as the percentage of the clusters covered by at least one aspect. (2) *Aspect Precision* (AP): for each covered cluster C_i, AP measures the Jaccard similarity between C_i as a set of opinions and the union of all aspects assigned to C_i. (3) *Average Aspect Precision* (AAP): defines averaged AP for all clusters where an uncovered C_i has a zero AP; it essentially combines AC and AP. We also report *Sentence Coverage* (SC), i.e., how many distinct opinion sentences can be covered by the selected aspects and *Conditional Entropy* (H), i.e., how well the selected aspects align with the natural clusters in the opinions; a smaller H value indicates a better alignment.

Results: We summarize the evaluation results in Table 6. In addition to the three methods described in Section 3.1, we also include one baseline of averaging 10 runs of random selection. The best performance by each measure on each data set is highlighted in bold font. Not surprisingly, opinion coverage-based approach has the best sentence coverage (SC) performance and conditional entropy-based greedy algorithm achieves the lowest H. Size-based approach is best in aspect precision but at the cost of lowest aspect coverage. The trade-off between AP and AC is comparable to that between precision and recall as in information retrieval while AAP summarizes the combination of these two. The greedy algorithm based on conditional entropy outperforms all other approaches in AC and also in AAP, suggesting that it can provide a good balance between AP and AC.

4.4 Evaluation of Aspect Ordering

Human Annotation: In order to quantitatively evaluate the effectiveness of aspect ordering, we conduct user studies to establish gold standard ordering. Three users were each given k selected aspects and asked to perform two tasks for each US President: (1) identify clusters of aspects that are more natural to be presented together (*cluster constraints*) and (2) identify aspect pairs where one aspect is preferred to appear before the other from the viewpoint of readability. (*order constraints*). We did not ask them to provide a full order of the k aspects, because we suspect that there are usually more than one "perfect" order. Instead, identifying partial orders or constraints is easier for human to perform, thus provides more robust gold standard.

Human Agreement: After obtaining the human annotation results, we first study human consensus on the ordering task. For both types of human identified constraints, we convert them into pairwise relations of aspects, e.g., "A_i and A_j should be presented together" or "A_i should be displayed before A_j". Then we calculate the agreement percentage among the three users. In Table 7, we can see that only a very small percentage of pair-wise partial orders (15.92% of the cluster constraints and none of the order constraints) are agreed by all the three users, though the agreement of clustering is much higher than that of ordering. This indicates that ordering the aspects is a subjective and difficult task.

AgreedBy	**Cluster Constraint**	**Order Constraint**
1	37.14%	89.22%
2	46.95%	10.78%
3	15.92%	0.00%

Table 7: Human Agreement on Ordering

Measures: Given the human generated gold standard of partial constraints, we use the following measures to evaluate the automatically generated full ordering of aspects: (1) *Cluster Precision* (pr_c): for all the aspect pairs placed in the same cluster by human, we calculate the percentage of them that are also placed together in the system output. (2) *Cluster Penalty* (p_c): for each aspect pair placed in the same cluster by human, we give a linear penalty proportional to the number of aspects in between the pair that the system places; p_c can be interpreted as the average number of aspects between aspect pairs that should be presented together in the case of misordering. Smaller penalty corresponds to better ordering performance. (3) *Order Precision* (pr_o): the percentage of correctly predicted aspect pairs compared with human specified order.

Results: In Table 8, we report the ordering performance based on two selection algorithms: opinion coverage-based and conditional entropy-based. Different selection algorithms provide different subsets of aspects for the ordering algorithms to operate on. For comparison with our coherence-based ordering algorithm, we include a random baseline and Freebase ontology ordering. Note that Freebase order is a very strong baseline because it is edited by human even though the purpose was not for organizing opinions. To take into account the variation of human annotation, we use four versions of gold standard: three are from the individual annotators and one from the union of their annotation. We did not include the gold stan-

Table 8: Evaluation Results on Aspect Ordering

dard that is the intersection of three annotators because that would leave us with too little overlap.

We have several observations: (1) In general, results show large variations when using different versions of gold standard, indicating the subjective nature of the ordering task. (2) Coherence-based ordering shows similar performance to Freebase order-based in cluster precision (pr_c), but when we take into consideration the distance-based penalty (p_c) of separating aspects pairs in the same cluster, coherence-based ordering is almost always significantly better except in one case. This shows that our method can effectively learn the coherence of aspects based on how their aligned opinion sentences are presented in online discussions. (3) Order precision (pr_o) can hardly distinguish different ordering algorithm. This indicates that people vary a lot in their preferences as which aspects should be presented first. However, in cases when the random baseline outperforms others the margin is fairly small, while Freebase order and coherence-based order have a much larger margin of improvement when showing superior performance.

5 Conclusions and Future Work

A major challenge in automatic integration of scattered online opinions is how to organize all the diverse opinions in a meaningful way for any given topic. In this paper, we propose to solve this challenge by exploiting related aspects in structured ontology which are guaranteed to be meaningful and well connected to the topic. We proposed three different methods for selecting a subset of aspects from the ontology that can best capture the major opinions, including size-based, opinion coverage-based, and conditional entropy-based methods. We also explored two ways to order aspects, i.e., ontology-order and coherence optimization. In addition, we also proposed appropriate measures for quantitative evaluation of both aspect selection and ordering.

Experimental evaluation on two data sets (US President and Digital Cameras) shows that by exploiting structured ontology, we can generate interesting aspects to organize scattered opinions. The conditional entropy method is shown to be most effective for aspect selection, and the coherence optimization method is more effective than ontology-order in optimizing the coherence of the aspect ordering, though ontology-order also appears to perform reasonably well. In addition, by extracting salient phrases from the major opinions that cannot be covered well by any aspect in an existing ontology, we can also discover interesting new aspects to extend the existing ontology.

Complementary with most existing summarization work, this work proposes a new direction of using structured information to organize and summarize unstructured opinions, opening up many interesting future research directions. For instance, in order to focus on studying aspect selection and ordering, we have not tried to optimize sentences matching with aspects in the ontology; it would be very interesting to further study how to accurately retrieve sentences matching each aspect. Another promising future work is to organize opinions using both structured ontology information and well-written overview articles.

Abstract

We propose an unsupervised approach utilizing only raw corpora to enhance morphological alignment involving highly inflected languages. Our method focuses on *closed-class morphemes*, modeling their influence on nearby words. Our language-independent model recovers important links missing in the IBM Model 4 alignment and demonstrates improved end-to-end translations for English-Finnish and English-Hungarian.

1 Introduction

Modern statistical machine translation (SMT) systems, regardless of whether they are word-, phrase- or syntax-based, typically use the word as the atomic unit of translation. While this approach works when translating between languages with limited morphology such as English and French, it has been found inadequate for morphologically-rich languages like Arabic, Czech and Finnish (Lee, 2004; Goldwater and McClosky, 2005; Yang and Kirchhoff, 2006). As a result, a line of SMT research has worked to incorporate morphological analysis to gain access to information encoded within individual words.

In a typical MT process, word aligned data is fed as training data to create a translation model. In cases where a highly inflected language is involved, the current word-based alignment approaches produce low-quality alignment, as the statistical correspondences between source and target words are diffused over many morphological forms. This problem has a direct impact on end translation quality.

Our work addresses this shortcoming by proposing a morphologically sensitive approach to word alignment for language pairs involving a highly inflected language. In particular, our method focuses on a set of *closed-class morphemes* (CCMs), modeling their influence on nearby words. With the model, we correct erroneous alignments in the initial IBM Model 4 runs and add new alignments, which results in improved translation quality.

After reviewing related work, we give a case study for morpheme alignment in Section 3. Section 4 presents our four-step approach to construct and incorporate our CCM alignment model into the grow-diag process. Section 5 describes experiments, while Section 6 analyzes the system merits. We conclude with suggestions for future work.

2 Related Work

MT alignment has been an active research area. One can categorize previous approaches into those that use language-specific syntactic information and those that do not. Syntactic parse trees have been used to enhance alignment (Zhang and Gildea, 2005; Cherry and Lin, 2007; DeNero and Klein, 2007; Zhang et al., 2008; Haghighi et al., 2009). With syntactic knowledge, modeling long distance reordering is possible as the search space is confined to plausible syntactic variants. However, they generally require language-specific tools and annotated data, making such approaches infeasible for many languages. Works that follow non-syntactic approaches, such as (Matusov et al.,

Figure 1: **Sample English-Finnish IBM Model 4 alignments**: (a) word-level and (b) morpheme-level. Solid lines indicate intersection alignments, while the exhaustive asymmetric alignments are listed below. In (a), translation glosses for Finnish are given; the dash-dot line is the incorrect alignment. In (b), bolded texts are closed-class morphemes (CCM), while bolded indices indicate alignments involving CCMs. The dotted lines are correct CCM alignments not found by IBM Model 4.

2004; Liang et al., 2006; Ganchev et al., 2008), which aim to achieve symmetric word alignment during training, though good in many cases, are not designed to tackle highly inflected languages.

Our work differs from these by taking a middle road. Instead of modifying the alignment algorithm directly, we preprocess asymmetric alignments to improve the input to the symmetrizing process later. Also, our approach does not make use of specific language resources, relying only on unsupervised morphological analysis.

3 A Case for Morpheme Alignment

The notion that morpheme based alignment would be useful in highly inflected languages is intuitive. Morphological inflections might indicate tense, gender or number that manifest as separate words in largely uninflected languages. Capturing these subword alignments can yield better word alignments that otherwise would be missed.

Let us make this idea concrete with a case study of the benefits of morpheme based alignment. We show the intersecting alignments of an actual English (source) → Finnish (target) sentence pair in Figure 1, where (a) word-level and (b) morpheme-level alignments are shown. The morpheme-level alignment is produced by automatically segmenting words into morphemes and running IBM Model 4 on the resulting token stream.

Intersection links (*i.e.*, common to both direct and inverse alignments) play an important role in creating the final alignment (Och and Ney, 2004). While there are several heuristics used in the symmetrizing process, the *grow-diag(onal)* process is common and prevalent in many SMT systems, such as Moses (Koehn et al., 2007). In the grow-diag process, intersection links are used as seeds to find other new alignments within their neighborhood. The process continues iteratively, until no further links can be added.

In our example, the morpheme-level intersection alignment is better as it has no misalignments and adds new alignments. However it misses some key links. In particular, the alignments of closed-class morphemes (CCMs; later formally defined) as indicated by the dotted lines in (b) are overlooked in the IBM Model 4 alignment. This difficulty in aligning CCMs is due to:

1. Occurrences of *garbage-collector* words (Moore, 2004) that attract CCMs to align to them. Examples of such links in (b) are 1–23 or 11–21 with the occurrences of rare words $\texttt{adjourn+}_{11}$ and $\texttt{avatuksi}_{23}$. We further characterize such errors in Section 6.1.

2. Ambiguity among CCMs of the same surface that causes incorrect matchings. In (b), we observe multiple occurrence of `the` and `n` on the source and target sides respectively. While the link 8–6 is correct, 5–4 is not as $\texttt{i}_1$ should be aligned to $\texttt{n}_4$ instead. To resolve such ambiguity, context information should be considered as detailed in Section 4.3.

The fact that rare words and multiple affixes often occur in highly inflected languages exacerbates this problem, motivating our focus on improving CCM alignment. Furthermore, having access to the correct CCM alignments as illustrated in Figure 1 guides the grow-diag process in finding the remaining correct alignments. For example, the addition of CCM links $\texttt{i}_1$–$\texttt{n}_4$ and $\texttt{d}_4$–$\texttt{lle}_{21}$ helps to identify $\texttt{declare}_2$–$\texttt{julist}_2$ and $\texttt{resume}_3$–$\texttt{avatuksi}_{23}$ as admissible alignments, which would otherwise be missed.

4 Methodology

Our idea is to enrich the standard IBM Model 4 alignment by modeling closed-class morphemes (CCMs) more carefully using global statistics and context. We realize our idea by proposing a four-step method. First, we take the input parallel corpus and convert it into morphemes before training the IBM Model 4 morpheme alignment. Second, from the morpheme alignment, we induce automatically bilingual CCM pairs. The core of our approach is in the third and fourth steps. In Step 3, we construct a *CCM alignment model*, and apply it on the segmented input corpus to obtain an automatic CCM alignment. Finally, in Step 4, we incorporate the CCM alignment into the symmetrizing process via our *modified grow-diag process*.

4.1 Step 1: Morphological Analysis

The first step presupposes morphologically segmented input to compute the IBM Model 4 morpheme alignment. Following Virpioja et al. (2007), we use *Morfessor*, an unsupervised analyzer which learns morphological segmentation from raw tokenized text (Creutz and Lagus, 2007).

The tool segments input words into labeled morphemes: `PRE` (prefix), `STM` (stem), and `SUF` (suffix). Multiple affixes can be proposed for each word; word compounding is allowed as well, e.g., `uncarefully` is analyzed as `un/PRE+ care/STM+ ful/SUF+ ly/SUF`. We append a "+" sign to each nonfinal tag to distinguish word-internal morphemes from word-final ones, e.g., "x/STM" and "x/STM+" are considered different tokens. The "+" annotation enables the restoration of the original words, a key point to enforce word boundary constraints in our work later.

4.2 Step 2: Bilingual CCM Pairs

We observe that low and highly inflected languages, while intrinsically different, share more in common at the morpheme level. The many-to-one relationships among words on both sides is often captured better by one-to-one correspondences among morphemes. We wish to model such bilingual correspondence in terms of closed-class morphemes (CCM), similar to Nguyen and Vogel (2008)'s work that removes nonaligned affixes during the alignment process. Let us now formally define CCM and an associative measure to gauge such correspondence.

Table 1: **English(en)-Finnish(fi) Bilingual CCM pairs** (N=128). Shown are the top 19 and last 10 of 168 bilingual CCM pairs extracted. Subscript i indicates the i^{th} most frequent morpheme in each language. ‡ marks exact correspondence linguistically, whereas † suggests rough correspondence w.r.t `http://en.wiktionary.org/wiki/`.

Definition 1. *Closed-class Morphemes (CCM)* are a *fixed set of stems and affixes* that exhibit grammatical functions just like closed-class words. In highly inflected languages, we observe that grammatical meanings may be encoded in morphological stems and affixes, rather than separate words. While we cannot formally identify valid CCMs in a language-independent way (as by definition they manifest language-dependent grammatical functions), we can devise a good approximation. Following Setiawan et al. (2007), we induce the set of CCMs for a language as the top N frequent stems together with all affixes[1].

Definition 2. *Bilingual Normalized PMI (biPMI)* is the averaged normalized PMI computed on the asymmetric morpheme alignments. Here, normalized PMI (Bouma, 2009), known to be less biased towards low-frequency data, is defined as: $\mathit{nPMI}(x, y) = \ln \frac{p(x,y)}{p(x)p(y)})/\text{-}\ln p(x, y)$, where $p(x)$, $p(y)$, and $p(x, y)$ follow definitions in the standard PMI formula. In our case, we only

[1] Note that we employ length and vowel sequence heuristics to filter out corpus-specific morphemes.

compute the scores for x, y being morphemes frequently aligned in both asymmetric alignments.

Given these definitions, we now consider a pair of source and target CCMs related and termed a **bilingual CCM pair** (CCM pair, for short) if they exhibit positive correlation in their occurrences (*i.e.*, positive nPMI[2] and frequent cooccurrences).

We should note that relying on a hard threshold of N as in (Setiawan et al., 2007) is brittle as the CCM set varies in sizes across languages. Our method is superior in the use of N as a starting point only; the bilingual correspondence of the two languages will ascertain the final CCM sets.

Take for example the *en* and *fi* CCM sets with 154 and 214 morphemes initially (each consisting of N=128 stems). As morphemes not having their counterparts in the other language are spurious, we remove them by retaining only those in the CCM pairs. This effectively reduces the respective sizes to 91 and 114. At the same time, these final CCMs cover a much larger range of top frequent morphemes than N, up to 408 *en* and 391 *fi* morphemes, as evidenced in Table 1.

4.3 Step 3: The CCM Alignment Model

The goal of this model is to predict when appearances of a CCM pair should be deemed as linking.

With an identified set of CCM pairs, we know when source and target morphemes correspond. However, in a sentence pair there can be many instances of both the source and target morphemes. In our example, the `the`–`n` pair corresponds to definite nouns; there are two `the` and three -`n` instances, yielding 2 × 3=6 possible links.

Deciding which instances are aligned is a decision problem. To solve this, we inspect the IBM Model 4 morpheme alignment to construct a CCM alignment model. The CCM model labels whether an instance of a CCM pair is deemed semantically related (linked). We cast the modeling problem as supervised learning, where we choose a maximum entropy (ME) formulation (Berger et al., 1996).

We first discuss sample selection from the IBM Model 4 morpheme alignment, and then give details on the features extracted. The processes described below are done per sentence pair with f_1^m, e_1^n and U denoting the source, target sentences and the union alignments, respectively.

Class labels. We base this on the initial IBM Model 4 alignment to label each CCM pair instance as a positive or negative example: *Positive examples* are simply CCM pairs in U. To be precise, links j–i in U are positive examples if f_j–e_i is a CCM pair. To find *negative examples*, we inventory other potential links that share the same lexical items with a positive one. That is, a link j'–i' not in U is a negative example, if a positive link j–i such that $f_j = f'_j$ and $e_i = e'_i$ exists.

We stress that our collection of positive examples contains high-precision but low-recall IBM Model 4 links, which connect the reliable CCM pairs identified before. The model then generalizes from these samples to detect incorrect CCM links and to recover the correct ones, enhancing recall. We later detail this process in §4.4.

Feature Set. Given a CCM pair instance, we construct three feature types: lexical, monolingual, and bilingual (See Table 2). These features capture the global statistics and contexts of CCM pairs to decide if they are true alignment links.

• **Lexical features** reflect the tendency of the CCM pair being aligned to themselves. We use *biPMI*, which aggregates the global alignment statistics, to determine how likely source and target CCMs are associated with each other.

• **Monolingual context features** measure the association among tokens of the same language, capturing what other stems and affixes co-occur with the source/target CCM:

1. within the same word (*intra*). The aim is to disambiguate affixes as necessary in highly inflected languages where same stems could generate different roles or meanings.
2. outside the CCM's word boundary (*inter*). This potentially capture cues such as tense, or number agreement. For example, in English, the 3sg agreement marker on verbs `-s` often co-occurs with nearby pronouns e.g., `he`, `she`, `it`; whereas the same marker on nouns (`-s`), often appears with plural determiners e.g., `these`, `those`, `many`.

To accomplish this, we compute two monolingual nPMI scores in the same spirit as biPMI, but using the morphologically segmented input from

[2] *nPMI* has a bounded range of $[-1, 1]$ with values 1 and 0 indicating perfect positive and no correlation, respectively.

Feature Description	Examples
Lexical — *biPMI*: None $[-1, 0]$, Low $(0, 1/3]$, Medium $(1/3, 2/3]$, High $(2/3, 1]$	pmi$_{d-lle}$=Low
Monolingual Context — Capture morpheme cooccurrence with the src/tgt CCM	
Intra – **W**ithin the same word	srcW$_{d-lle}$=resume, tgtW$_{d-lle}$=en, tgtW$_{d-lle}$=uude
Inter – To the **L**eft & **R**ight, in different words	srcL$_{d-lle}$=i, srcR$_{d-lle}$=the, tgtR$_{d-lle}$=avatuksi
Bilingual context — Capture neighbor links' cooccurrence with the CCM pair link	
bi0 – Most descriptive, capturing in terms of surface forms only → maybe sparse	bi0$_{d-lle}$=resume–avatuksi
bi1 – Generalizes morphemes into relative locations (**L**eft, **W**ithin, **R**ight)	bi1$_{d-lle}$=W–avatuksi, bi1$_{d-lle}$=resume–R
bi2 – Most general, coupling token types (**C**lose, **O**pen) /w relative positions	bi2$_{d-lle}$=O–WR

Table 2: **Maximum entropy feature set.** Shown are feature types, descriptions and examples. Most examples are given for the alignment d$_4$–lle+$_{21}$ of the same running example in §3. Note that we only partially list the bilingual context features.

each language separately. Two morphemes are "linked" if within a context window of w_c words.

- **Bilingual context features** model cross-lingual reordering, capturing the relationships between the CCM pair link and its neighbor[3] links. Consider a simple translation between an English phrase of the form we ⟨verb⟩ and the Finnish one ⟨verb⟩ -mme, where -mme is the 1pl verb marker. We aim to capture movements such as "the open-class morphemes on the right of we and on the left of -mme are often aligned". These will function as evidence for the ME learner to align the CCM pair (we, -mme). We encode the bilingual context at three different granularities, from most specific to most general ones (cf Table 2).

4.4 Step 4: Incorporate CCM Alignment

At test time, we apply the trained CCM alignment model to all CCM pairs occurring in each sentence pair to find CCM links. On our running example in Figure 1, the CCM classifier tests 17 CCM pairs, identifying 6 positive CCM links of which 4 are true positives (dotted lines in (b)).

Though mostly correct, we note that some of the predicted links conflict: (d$_4$–lle$_{21}$, ed$_{12}$–neen$_{17}$ and ed$_{12}$–lle$_{21}$) share alignment endpoints. Such sharing in CCM alignments is rare and we believe should be disallowed. This motivates us to resolve all CCM link conflicts before incorporating them into the symmetrizing process.

Resolving link conflicts. As CCM pairs are classified independently, they possess classification probabilities which we use as evidence to resolve the conflicts. In our example, the classification probabilities for (d$_4$–lle$_{21}$, ed$_{12}$–neen$_{17}$, ed$_{12}$–lle$_{21}$) are $(0.99, 0.93, 0.79)$ respectively.

We use a simple, "best-first" greedy approach to determine which links are kept and which are dropped to satisfy our assumption. In our case, we pick the most confident link, d$_4$–lle$_{21}$ with probability 0.99. This precludes the incorrect link, ed$_{12}$–lle$_{21}$, but admits the other correct one ed$_{12}$–neen$_{17}$, probability 0.93. As a result, this resolution successfully removes the incorrect link.

Modifying grow-diag. We incorporate the set of conflict-resolved CCM links into the grow-diag process. This step modifies the input alignments as well as the growing process. U and I denote the IBM Model 4 union and intersection alignments.

In our view, the resolved CCM links can serve as a quality mark to "upgrade" links before input into the grow-diag process. We upgrade resolved CCM links: (a) those $\in U \rightarrow$ part of I, treating them as alignment seeds; (b) those $\notin U \rightarrow$ part of U, using them for exploration and growing. To reduce spurious alignments, we discarded links in U that conflict with the resolved CCM links.

In the usual grow-diag, links immediately adjacent to a seed link l are considered candidates to be appended into the alignment seeds. While suitable for word-based alignment, we believe it is too small a context when the input are morphemes.

For morpheme alignment, the candidate context makes more sense in terms of word units. We thus *enforce word boundaries* in our modified grow-diag. We derive word boundaries for end points in l using the morphological tags and the "+" word-end marker mentioned in §4.1. Using such boundaries, we can then extend the grow-diag to consider candidate links within a neighborhood of w_g words; hence, enhancing the candidate coverage.

5 Experiments

We use English-Finnish and English-Hungarian data from past shared tasks (WPT05 and WMT09)

[3] Within a context window of w_c words as in monolingual.

to validate our approach. Both Finnish and Hungarian are highly inflected languages, with numerous verbal and nominal cases, exhibiting agreement. Dataset statistics are given in Table 3.

	en-fi	#	en-hu	#
Train	Europarl-v1	714K	Europarl-v4	1,510K
LM	Europarl-v1-fi	714K	News-hu	4,209K
Dev	wpt05-dev	2000	news-dev2009	2051
Test	wpt05-test	2000	news-test2009	3027

Table 3: **Dataset Statistics:** the numbers of parallel sentences for training, LM training, development and test sets.

We use the Moses SMT framework for our work, creating both our CCM-based systems and the baselines. In all systems built, we obtain the IBM Model 4 alignment via GIZA++ (Och and Ney, 2003). Results are reported using case-insensitive BLEU (Papineni et al., 2001).

Baselines. We build two SMT baselines:

w-system: This is a standard phrase-based SMT, which operates at the word level. The system extracts phrases of maximum length 7 words, and uses a 4-gram word-based LM.

w_m-system: This baseline works at the word level just like the w-system, but differs at the alignment stage. Specifically, input to the IBM Model 4 training is the morpheme-level corpus, segmented by *Morfessor* and augmented with "+" to provide word-boundary information (§4.1). Using such information, we constrain the alignment symmetrization to extract phrase pairs of 7 words or less in length. The morpheme-based phrase table is then mapped back to word forms. The process continues identically as in the w-system.

CCM-based systems. Our CCM-based systems are similar in spirit to the w_m system: train at the morpheme, but decode at the word level. We further enhance the w_m-system at the alignment stage. First, we train our CCM model based on the initial IBM Model 4 morpheme alignment, and apply it to the morpheme corpus to obtain CCM alignment, which are input to our modified grow-diag process. The CCM approach defines the setting of three parameters: $\langle N, w_c, w_g\rangle$ (Section 4). Due to our resource constraints, we set N=128, similar to (Setiawan et al., 2007), and w_c=1 experimentally. We only focus on the choice of w_g, testing w_g=$\{1, 2\}$ to explore the effect of enforcing word boundaries in the grow-diag process.

5.1 English-Finnish results

We test the translation quality of both directions (*en-fi*) and (*fi-en*). We present results in Table 4 for 7 systems, including: our baselines, three CCM-based systems with word-boundary knowledge w_g=$\{0, 1, 2\}$ and two w_m-systems w_g=$\{1, 2\}$.

Results in Table 4 show that our CCM approach effectively improves the performance. Compared to the w_m-system, it chalks up a gain of 0.46 BLEU points for *en-fi*, and a larger improvement of 0.93 points for the easier, reverse direction.

Further using word boundary knowledge in our modified grow-diag process demonstrates that the additional flexibility consistently enhances BLEU for $w_g = 1, 2$. We achieve the best performance at $w_g = 2$ with improvements of 0.67 and 1.22 BLEU points for *en-fi* and *fi-en*, respectively.

	en-fi	fi-en
w-system	14.58	23.56
w_m-system	14.47	22.89
w_m-system + CCM	$14.93_{+0.46}$	$23.82_{+0.93}$
w_m-system + CCM + $w_g = 1$	15.01	23.95
w_m-system + CCM + $w_g = 2$	$\mathbf{15.14}_{+0.67}$	$\mathbf{24.11}_{+1.22}$
w_m-system + $w_g = 1$	14.44	22.92
w_m-system + $w_g = 2$	14.28	23.01
(Ganchev, 2008) - Base	14.72	22.78
(Ganchev, 2008) - Postcat	14.74	$23.43_{+0.65}$
(Yang, 2006) - Base	N/A	22.0
(Yang, 2006) - Backoff	N/A	$22.3_{+0.3}$

Table 4: **English/Finnish results.** Shown are BLEU scores (in %) with subscripts indicating absolute improvements with respect to the w_m-system baseline.

Interestingly, employing the word boundary heuristic alone in the original grow-diag does not yield any improvement for *en-fi*, and even worsens as w_g is enlarged (as seen in Rows 6–7). There are only slight improvements for *fi-en* with larger w_g.This attests to the importance of combining the CCM model and the modified grow-diag process.

Our best system outperforms the w-system baseline by 0.56 BLEU points for *en-fi*, and yields an improvement of 0.55 points for *fi-en*.

Compared to works experimenting *en/fi* translation, we note the two prominent ones by Yang and Kirchhoff (2006) and recently by Ganchev et al. (2008). The former uses a simple back-off method experimenting only *fi-en*, yielding an improvement of 0.3 BLEU points. Work in the opposite direction (*en-fi*) is rare, with the latter paper extending the EM algorithm using posterior constraints, but showing no improvement; for *fi-en*, they demonstrate a gain of 0.65 points. Our CCM method compares favorably against both approaches, which use the same datasets as ours.

5.2 English-Hungarian results

To validate our CCM method as language-independent, we also perform preliminary experiments on *en-hu*. Table 5 shows the results using the same CCM setting and experimental schemes as in *en/fi*. An improvement of 0.35 BLEU points is shown using the CCM model. We further improve by 0.44 points with word boundary w_g=1, but performance degrades for the larger window. Due to time constraints, we leave experiments for the reverse, easier direction as future work. Though modest, the best improvement for *en-hu* is statistical significant at p<0.01 according to Collins' sign test (Collins et al., 2005).

System	**BLEU**
w-system	9.63
w$_m$-system	9.47
w$_m$-system + CCM	9.82 $_{+0.35}$
w$_m$-system + CCM + $w_g = 1$	**9.91** $_{+0.44}$
w$_m$-system + CCM + $w_g = 2$	9.87

Table 5: **English/Hungarian results.** Subscripts indicate absolute improvements with respect to the w$_m$-system.

We note that MT experiments for *en/hu* [4] are very limited, especially for the *en* to *hu* direction. Novák (2009) obtained an improvement of 0.22 BLEU with no distortion penalty; whereas Koehn and Haddow (2009) enhanced by 0.5 points using monotone-at-punctuation reordering, minimum Bayes risk and larger beam size decoding.

While not directly comparable in the exact settings, these systems share the same data source and splits similar to ours. In view of these community results, we conclude that our CCM model does perform competitively in the *en-hu* task, and indeed seems to be language independent.

6 Detailed Analysis

The macroscopic evaluation validates our approach as improving BLEU over both baselines, but how do the various components contribute? We first analyze the effects of Step 4 in producing the CCM alignment, and then step backward to examine the contribution of the different feature classes in Step 3 towards the ME model.

6.1 Quality of CCM alignment

To evaluate the quality of the predicted CCM alignment, we address the following questions:

Q1: What is the portion of CCM pairs being misaligned in the IBM Model 4 alignment?

Q2: How does the CCM alignment differ from the IBM Model 4 alignment?

Q3: To what extent do the new links introduced by our CCM model address Q1?

Given that we do not have linguistic expertise in Finnish or Hungarian, it is not possible to exhaustively list all misaligned CCM pairs in the IBM Model 4 alignment. As such, we need to find other form of approximation in order to address Q1.

We observe that correct links that do not exist in the original alignment could be entirely missing, or mistakenly aligned to neighboring words. With morpheme input, we can also classify mistakes with respect to intra- or inter-word errors. Figure 2 characterizes errors T_1, T_2 and T_3, each being a more severe error class than the previous. Focusing on e_i in the figure, links connecting e_i to $f_{j'}$ or $f_{j''}$ are deemed T_1 errors (misalignments happen on one side). A T_2 error aligns f''_j within the same word, while a T_3 error aligns it outside the current word but still within its neighborhood. This characterization is automatic, cheap and has the advantage of being language-independent.

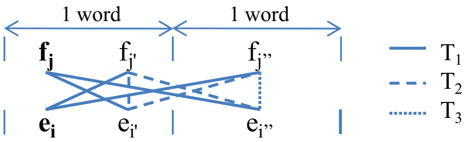

Figure 2: **Categorization of CCM missing links.** Given that a CCM pair link (f_j–e_i) is not present in the IBM Model 4, occurrences of any nearby link of the types T$_{[1-3]}$ can be construed as evidence of a potential misalignment.

Statistics in Table 6(ii) answers Q1, suggesting a fairly large number of missing CCM links: $3,418K$ for *en/fi* and $6,216K$ for *en/hu*, about 12.35% and 12.06% of the IBM Model 4 union alignment respectively. We see that T_1 errors con-

[4] Hungarian was used in the ACL shared task 2008, 2009.

stitute the majority, a reasonable reflection of the *garbage- collector*[5] effect discussed in Section 3.

	General (i)		Missing CCM links (ii)		
	en/fi	en/hu		en/fi	en/hu
Direct	17,632K	34,312K	T_1	2,215K	3,487K
Inverse	18,681K	34,676K	T_2	358K	690K
$D \cap I$	8,643K	17,441K	T_3	845K	2,039K
$D \cup I$	27,670K	51,547K	**Total**	**3,418K**	**6,216K**

Table 6: **IBM Model 4 alignment statistics.** (i) General statistics. (ii) Potentially missing CCM links.

Q2 is addressed by the last column in Table 7. Our CCM model produces about 11.98% (1,035K/8,643K) new CCM links as compared to the size of the IBM Model 4 intersection alignment for en/fi, and similarly, 9.52% for en/hu.

	Orig.	Resolved	I	U\I	New
en/fi	5,299K	3,433K	1065K	1,332K	**1,035K**
en/hu	9,425K	6,558K	2,752K	2,146K	**1,660K**

Table 7: **CCM vs IBM Model 4 alignments.** *Orig.* and *Resolved* give # CCM links predicted in Step 4 before and after resolving conflicts. Also shown are the number of resolved links present in the **I**ntersection, Union excluding I (**U****I**) of the IBM Model 4 alignment and **New** CCM links.

Lastly, figures in Table 8 answer Q3, revealing that for *en/fi*, 91.11% (943K/1,035K) of the new CCM links effectively cover the missing CCM alignments, recovering 27.59% (943K/3,418K) of all missing CCM links. Our modified *grow-diag* realizes a majority 76.56% (722K/943K) of these links in the final alignment.

We obtain similar results in the *en/hu* pair for link recovery, but a smaller percentage 22.59% (330K/1,461K) are realized through the modified symmetrization. This partially explains why improvements are modest for *en/hu.*

	New CCM Links (i)		Modified grow-diag (ii)	
	en/fi	en/hu	en/fi	en/hu
T_1	707K	1,002K	547K	228K
T_2	108K	146K	79K	22K
T_3	128K	313K	96K	80K
Total	**943K**	**1,461K**	**722K**	**330K**

Table 8: **Quality of the newly introduced CCM links**. Shown are # new CCM links addressing the three error types before (i) and after (ii) the modified grow-diag process.

6.2 Contributions of ME Feature Classes

We also evaluate the effectiveness the ME features individually through ablation tests. For brevity, we only examine the more difficult translation direction, *en* to *fi*. Results in Table 9 suggest that all our features are effective, and that removing any feature class degrades performance. Balancing specificity and generality, `bi1` is the most influential feature in the bilingual context group. For monolingual context, `inter`, which captures larger monolingual context, outperforms `intra`. The most important feature overall is `pmi`, which captures global alignment preferences. As feature groups, bilingual and monolingual context features are important sources of information, as removing them drastically decreases system performance by 0.23 and 0.16 BLEU, respectively.

System			BLEU
all (w_m-system+CCM)			14.93
−bi2	14.90	−intra	14.89
−bi1	$14.84^{*}_{-0.09}$	−pmi	$14.81^{*}_{-0.12}$
−bi0	14.89	−bi{2/1/0}	$14.70^{*}_{-0.23}$
−inter	14.85	−in{ter/tra}	$14.77^{*}_{-0.16}$

Table 9: **ME feature ablation tests for English-Finnish experiments.** $*$ mark results statistically significant at $p < 0.05$, differences are subscripted.

7 Conclusion and Future Work

In this work, we have proposed a language-independent model that addresses morpheme alignment problems involving highly inflected languages. Our method is unsupervised, requiring no language specific information or resources, yet its improvement on BLEU is comparable to much semantically richer, language-specific work. As our approach deals only with input word alignment, any downstream modifications of the translation model also benefit.

As alignment is a central focus in this work, we plan to extend our work over different and multiple input alignments. We also feel that better methods for the incorporation of CCM alignments is an area for improvement. In the en/hu pair, a large proportion of discovered CCM links are discarded, in favor of spurious links from the union alignment. Automatic estimation of the correctness of our CCM alignments may improve end translation quality over our heuristic method.

[5] E.g., e_i prefers f'_j or f''_j (garbage collectors) over f_j.

Automatic analysis of semantic similarity in comparable text through syntactic tree matching

Erwin Marsi
TiCC, Tilburg University
e.c.marsi@uvt.nl

Emiel Krahmer
TiCC, Tilburg University
e.j .krahmer@uvt.nl

Abstract

We propose to analyse semantic similarity in comparable text by matching syntactic trees and labeling the alignments according to one of five semantic similarity relations. We present a Memory-based Graph Matcher (MBGM) that performs both tasks simultaneously as a combination of exhaustive pairwise classification using a memory-based learner, followed by global optimization of the alignments using a combinatorial optimization algorithm. The method is evaluated on a monolingual treebank consisting of comparable Dutch news texts. Results show that it performs substantially above the baseline and close to the human reference.

1 Introduction

Natural languages allow us to express essentially the same underlying meaning as many alternative surface forms. In other words, there are often many similar ways to say the same thing. This characteristic poses a problem for many natural language processing applications. Automatic summarizers, for example, typically rank sentences according to their informativity and then extract the top n sentences, depending on the required compression rate. Although the sentences are essentially treated as independent of each other, they typically are not. Extracted sentences may have substantial semantic overlap, resulting in unintended redundancy in the summaries. This is particularly problematic in the case of multi-document summarization, where sentences extracted from related documents are very likely to express similar information in different ways (Radev and McKeown, 1998). Therefore, if semantic similarity between sentences could be detected automatically, this would certainly help to avoid redundancy in summaries.

Similar arguments can be made for many other NLP applications. Automatic duplicate and plagiarism detection beyond obvious string overlap requires recognition of semantic similarity. Automatic question-answering systems may benefit from clustering semantically similar candidate answers. Intelligent document merging software, which supports a minimal but lossless merge of several revisions of the same text, must handle cases of paraphrasing, restructuring, compression, etc. Recognizing textual entailments (Dagan et al., 2005) could arguably be seen as a specific instance of detecting semantic similarity.

In addition to merely *detecting* semantic similarity, we can ask to what extent two expressions share meaning. For instance, the meaning of one sentence can be fully contained in that of another, the meaning of one sentence can overlap only partly with that of another, etc. This requires an *analysis* of the semantic similarity between a pair of expressions. Like detection, automatic analysis of semantic similarity can play an important role in NLP applications. To return to the case of multi-document summarization, analysing the semantic similarity between sentences extracted from different documents provides the basis for *sentence fusion*, a process where a new sentence is generated that conveys all common information from both sentences without introducing redundancy (Barzilay and McKeown, 2005; Marsi and Krahmer, 2005b).

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 752–760,
Beijing, August 2010

Analysis of semantic similarity can be approached from different angles. A basic approach is to use string similarity measures such as the Levenshtein distance or the Jaccard similarity coefficient. Although cheap and fast, this fails to account for less obvious cases such as synonyms or syntactic paraphrasing. At the other extreme, we can perform a deep semantic analysis of two expressions and rely on formal reasoning to derive a logical relation between them. This approach suffers from issues with coverage and robustness commonly associated with deep linguistic processing. We therefore think that the middle ground between these two extremes offers the best option. In this paper we present a new method for analysing semantic similarity in comparable text. It relies on a combination of morphological and syntactic analysis, lexical resources such as word nets, and machine learning from examples. We propose to analyse semantic similarity between sentences by aligning their syntax trees, where each node is matched to the most similar node in the other tree (if any). In addition, we label these alignments according to the type of similarity relation that holds between the aligned phrases. The labeling supports further processing. For instance, Marsi & Krahmer (2005b; 2008) describe how to generate different types of sentence fusions on the basis of this relation labeling.

In the next Section we provide a more formal definition of the task of matching syntactic trees and labeling alignments, followed by a discusion of related work in Section 3. Section 4 describes a parallel, monolingual treebank used for developing and testing our approach. In Section 5 we propose a new algorithm for simultaneous node alignment and relation labeling. The results of several evaluation experiments are presented in Section 6. We finish with a conclusion.

2 Problem statement

Aligning a pair of similar syntactic trees is the process of pairing those nodes that are most similar. More formally: let v be a node in the syntactic tree T of sentence S and v' a node in the syntactic tree T' of sentence S'. A *labeled node alignment* is a tuple $< v, v', r >$ where r is a label from a set of relations. A *labeled tree alignment* is a set of labeled node alignments. A *labeled tree matching* is a tree alignment in which each node is aligned to at most one other node.

For each node v, its terminal *yield* $\textsc{str}(v)$ is defined as the sequence of all terminal nodes reachable from v (i.e., a substring of sentence S). Aligning node v to v' with label r indicates that relation r holds between their yields $\textsc{str}(v)$ and $\textsc{str}(v')$. We label alignments according to a small set of *semantic similarity relations*. As an example, consider the following Dutch sentences:

(1) a. Dagelijks koffie vermindert risico op
Daily coffee diminishes risk on
Alzheimer en Dementie.
Alzheimer and Dementia.

b. Drie koppen koffie per dag reduceert
Three cups coffee a day reduces
kans op Parkinson en Dementie.
chance on Parkinson and Dementia.

The corresponding syntax trees and their (partial) alignment is shown in Figure 1. We distinguish the following five mutually exclusive similarity relations:

1. v **equals** v' iff lower-cased $\textsc{str}(v)$ and lower-cased $\textsc{str}(v')$ are identical – example: *Dementia* equals *Dementia*;
2. v **restates** v' iff $\textsc{str}(v)$ is a proper paraphrase of $\textsc{str}(v')$ – example: *diminishes* restates *reduces*;
3. v **generalizes** v' iff $\textsc{str}(v)$ is more general than $\textsc{str}(v')$ – example: *daily coffee* generalizes *three cups of coffee a day*;
4. v **specifies** v' iff $\textsc{str}(v)$ is more specific than $\textsc{str}(v')$ – example: *three cups of coffee a day* specifies *dailly coffee*;
5. v **intersects** v' iff $\textsc{str}(v)$ and $\textsc{str}(v')$ share meaning, but each also contains unique information not expressed in the other – example: *Alzheimer and Dementia* intersects *Parkinson and Dementia*.

Our interpretation of these relations is one of common sense rather than strict logic, akin to the definition of entailment employed in the RTE challenge (Dagan et al., 2005). Note also that relations are prioritized: *equals* takes precedence

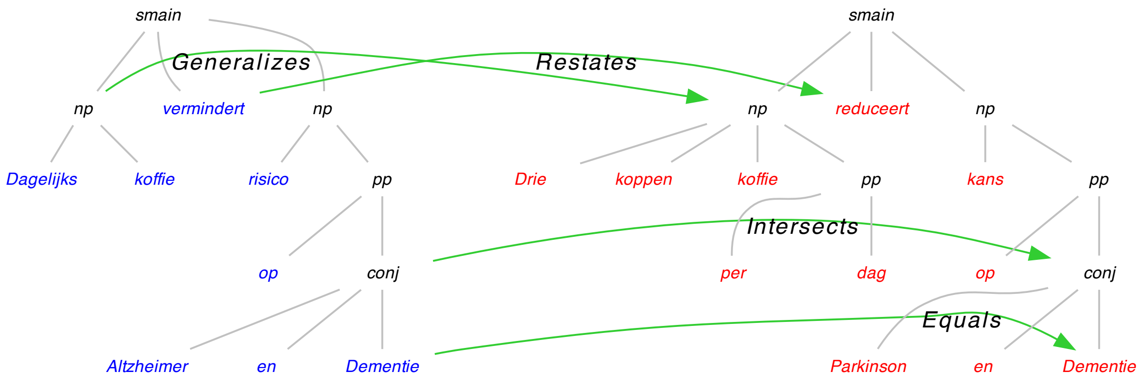

Figure 1: Example of two aligned and labeled syntactic trees. For expository reasons the alignment is not exhaustive.

over *restates*, etc. Furthermore, *equals*, *restates* and *intersects* are symmetrical, whereas *generalizes* is the inverse of *specifies*. Finally, nodes containing unique information, such as *Alzheimer* and *Parkinson*, remain unaligned.

3 Related work

Many syntax-based approaches to machine translation rely on bilingual treebanks to extract transfer rules or train statistical translation models. In order to build bilingual treebanks a number of methods for automatic tree alignment have been developed, e.g., (Gildea, 2003; Groves et al., 2004; Tinsley et al., 2007; Lavie et al., 2008). Most related to our approach is the work on discriminative tree alignment by Tiedemann & Kotzé (2009). However, these algorithms assume that source and target sentences express the same information (i.e. *parallel* text) and cannot cope with comparable text where parts may remain unaligned. See (MacCartney et al., 2008) for further arguments and empirical evidence that MT alignment algorithms are not suitable for aligning parallel monolingual text.

MacCartney, Galley, and Manning (2008) describe a system for monolingual phrase alignment based on supervised learning which also exploits external resources for knowledge of semantic relatedness. In contrast to our work, they do not use syntactic trees or similarity relation labels. Partly similar semantic relations are used in (MacCartney and Manning, 2008) for modeling semantic containment and exclusion in natural language inference. Marsi & Krahmer (2005a) is closely related to our work, but follows a more complicated method: first a dynamic programming-based tree alignment algorithm is applied, followed by a classification of similarity relations using a supervised-classifier. Other differences are that their data set is much smaller and consists of parallel rather than comparable text. A major drawback of this algorithmic approach it that it cannot cope with crossing alignments. We are not aware of other work that combines alignment with semantic relation labeling, or algorithms which perform both tasks simultaneously.

4 Data collection

For developing our alignment algorithm we use the DAESO corpus[1]. This is a Dutch parallel monolingual treebank of 1 million words, half of which were manually annotated. The corpus consists of pairs of sentences with different levels of semantic overlap, ranging from high (different Dutch translations of books from Darwin, Montaigne and Saint-Exupéry) to low (different press releases from the two main news agencies in The Netherlands, ANP and NOVUM). For this paper, we concentrate on the latter part of the DAESO corpus, where the proportion of Equals and Restates is relatively low. This corpus segment consists of 8,248 pairs of sentences, containing 162,361 tokens (ignoring punctuation). All sentences were tokenized and tagged, and subsequently parsed by the Alpino dependency parser for Dutch (Bouma et al., 2001). Two annota-

Table 1: Average F-scores (in percentages, with Standard Deviations) for the six human annotators on alignment and semantic relation labeling, for words and for full syntactic trees.

tors determined which sentences in the comparable news reports contained semantic overlap. Six other annotators produced manual alignments of words and phrases in matched sentence pairs, which resulted in 86,227 aligned pairs of nodes.

A small sample of 10 similar press releases comprising a total of 48 sentence pairs was independently annotated by all six annotators to determine inter-annotator agreement. We used precision, recall and F-score on alignment. To calculate these scores for relation labeling, we simply restrict the set of alignments to those labeled with a particular relation, ignoring all others. Likewise, we restrict these sets to terminal node alignments in order to get scores on word alignment.

Given the six annotations $\mathrm{A}_1, \ldots, \mathrm{A}_6$, we repeatedly took one as the $True$ annotation against which the five other annotations were evaluated. We then computed the average scores over these $6 * 5 = 30$ scores (note that with this procedure, precision, recall and F score end up being equal). Table 1 summarizes the results, both for word alignments and for full syntactic tree alignment. It can be seen that for alignment of words an average F-score of over 95 % was obtained, while alignment for full syntactic trees results in an F-score of 88%. For relation labeling, the scores differed per relation, as is to be expected: the average F-score for Equals was over 95% for both word and full tree alignment[2], and for the other relations average F-scores between 0.6 and 0.7 were obtained. The exception to note is Intersects on word level, which only occurred a few times according to a few of the annotators. The macro and micro (weighted) F-score averages on labeled alignment are 62.11% and 88.72% for words, and 71.36% and 81.92% for full syntactic trees.

5 Memory-based Graph Matcher

In order to automatically perform the alignment and labeling tasks described in Section 2, we cast these tasks simultaneously as a combination of exhaustive pairwise classification using a supervised machine learning algorithm, followed by global optimization of the alignments using a combinatorial optimization algorithm. Input to the tree matching algorithm is a pair of syntactic trees consisting of a source tree T_s and a target tree T_t.

Step 1: Feature extraction For each possible pairing of a source node n_s in tree T_s and a target node n_t in tree T_t, create an instance consisting of feature values extracted from the input trees. Features can represent properties of individual nodes, e.g. the category of the source node is NP, or relations between nodes, e.g. source and target node share the same part-of-speech.

Step 2: Classification A generic supervised classifier is used to predict a class label for each instance. The class is either one of the semantic similarity relations or the special class *none*, which is interpreted as *no alignment*. Our implementation employs the memory-based learner TiMBL (Daelemans et al., 2009), a freely available, efficient and enhanced implementation of k-nearest neighbour classification. The classifier is trained on instances derived according to Step 1 from a parallel treebank of aligned and labeled syntactic trees.

[2] At first sight, it may seem that labeling Equals is a trivial and deterministic task, for which the F-score should always be close to 100%. However, the same word may occur multiple times in the source or target sentences, which introduces ambiguity. This frequently occurs with function words such as determiners and prepositions. Moreover, choosing among several equivalent Equals alignments may sometimes involve a somewhat arbitrary decision. This situation arises, for instance, when a proper noun is mentioned just once in the source sentence but twice in the target sentence.

Step 3: Weighting Associate a cost with each prediction so that high costs indicate low confidence in the predicted class and vice versa. We use the normalized entropy of the class labels in the set of nearest neighbours (H) defined as

$$H = -\frac{\sum_{c \in C} p(c)\, log_2\, p(c)}{log_2 |C|} \quad (1)$$

where C is the set of class labels encountered in the set of nearest neighbours (i.e., a subset of the five relations plus *none*), and $p(c)$ is the probability of class c, which is simply the proportion of instances with class label c in the set of nearest neighbours. Intuitively this means that the cost is zero if all nearest neighbours are of the same class, whereas the cost goes to 1 if the nearest neighbours are equally distributed over all possible classes.

Step 4: Matching The classification step will usually give rise to one-to-many alignment of nodes. In order to reduce this to just one-to-one alignments, we search for a node matching which minimizes the sum of costs over all alignments. This is a well-known problem in combinatorial optimization known as the *Assignment Problem*. The equivalent in graph-theoretical terms is a *minimum weighted bipartite graph matching*. This problem can be solved in polynomial time ($O(n^3)$) using e.g., the *Hungarian algorithm* (Kuhn, 1955). The output of the algorithm is the labeled tree matching obtained by removing all node alignments labeled with the special *none* relation.

6 Experiments

6.1 Experimental setup

Word alignment and full tree alignments are conceptually different tasks, which require partly different features and may have different practical applications. These are therefore addressed in separate experiments.

Table 2 summarizes the respective sizes of development and the held-out test set in terms of number of aligned graph pairs, number of aligned node pairs and number of tokens. The percentage of aligned nodes over all graphs is calculated relative to the number of nodes over all graphs. Since alignments involving non-terminal nodes are ignored in the task of word alignment, the number of aligned node pairs and the percentage of aligned nodes is lower in the word develop and word test sets. Table 3 gives the distribution of semantic relations in the development and test set, for word and tree alignment. It can be observed that the distribution if fairly skewed with Equals being the majority class, even more so for word alignments. Another thing to notice is that Intersects are much more frequent at the level of non-terminal alignments.

Data	**Graph pairs**	**Node pairs**	**Tokens**	**Aligned nodes (%)**
word develop	2 664	13 027	45 149	15.71
word test	547	2 858	10 005	14.96
tree develop	2 664	22 741	45 149	47.20
tree test	547	4 894	10 005	47.05

Table 2: Properties of develop and test data sets

Data	**Eq**	**Re**	**Spec**	**Gen**	**Int**
word develop	84.92	6.15	2.10	1.77	5.07
word test	85.62	6.09	2.17	1.99	4.13
tree develop	56.61	6.57	7.52	6.38	22.91
tree test	58.40	7.11	7.40	6.38	20.72

Table 3: Distribution of semantic similarity relations for word alignment and for full tree alignments in both develop and test data sets

Development was carried out using 10-fold cross validation on the development data and consequently reported scores on the development data are averages over 10 folds. Only two parameters were coarsely optimized on the development set. First, the amount of downsampling of the *none* class varied between 0.1 or 0.5. Second, the parameter k of the memory-based classifier – the number of nearest neighbours taken into account during classification – ranged from 1 to 15. Optimal settings were finally applied when testing on the held-out data.

A simple greedy alignment procedure served as baseline. For word alignment, identical words are aligned as Equals and identical roots as Restates. For full tree alignment, this is extended to the level of phrases so that phrases with identical words are aligned as Equals and phrases with identical roots as Restates. The baseline does not predict Specifies, Generalizes or Intersects relations, as that would require a more involved, knowledge-based approach.

All features used are described in Table 4. The word-based features rely on pure string processing and require no linguistic preprocessing. The morphology-based features exploit the limited amount of morphological analysis provided by the Alpino parser (Bouma et al., 2001). For instance, it provides word roots and decomposes compound words. Likewise the part-of-speech-based features use the coarse-grained part-of-speech tags assigned by the Alpino parser. The lexical-semantic features rely on the Cornetto database (Vossen et al., 2008), a recent extension to the Dutch WordNet, to look-up synonym and hypernym relations among source and target lemmas. Unfortunately there is no word sense disambiguation module to identify the correct senses. In addition, a background corpus of over 500M words of (mainly) news text provides the word counts required to calculate the Lin similarity measure (Lin, 1998). The syntax-based features use the syntactic structure, which is a mix of phrase-based and dependency-based analysis. The phrasal features express similarity between the terminal yields of source and target nodes. With the exception of *same-parent-lc-phrase*, these features are only used for full tree alignment, not for word alignment.

6.2 Results on word alignment

We evaluate our alignment model in two steps: first focussing on word alignment and then on full tree alignment. Table 5 summarizes the results for MBGM on word alignment (50% downsampling and $k = 3$), which we compare statistically to the baseline performance, and informally with the human scores reported in Table 1 in Section 4 (note that the human scores are only for a subset of the data used for automatic evaluation).

The first thing to observe is that the MBGM scores on the development and tests sets are very similar throughout. For predicting word alignments, the MBGM system performs significantly better than the baseline system ($t(18) = 17.72, p < .0001$). On the test set, MBGM obtains an F-score of nearly 89%, which is almost exactly halfway between the scores of the baseline system and the human scores. In a similar vein, the performance of the MBGM system on relation labeling is considerably better than that of the baseline system. For all semantic relations, MBGM performs significantly better than the baseline ($t(18) > 9.4138, p < .0001$ for each relation, trivially so for the Specifies, Generalizes and Intersects relations, which the baseline system never predicts).

The macro scores are plain averages over the 5 scores on each relation, whereas the micro scores are weighted averages. As the Equals is the majority class and at the same time easiest to predict, the micro scores are higher. The macro scores, however, better reflect performance on the real challenge, that is, correctly predicting the relations other than Equals. The MBGM macro average is 27.37% higher than the baseline (but still some 10% below the human top line), while the micro average is 5.83% higher and only 0.75% below the human top line. Macro scores on the test set are overall lower than those on the develop set, presumably because of tuning on the development data.

6.3 Results on tree alignment

Table 6 contains the results of full tree alignment (50% downsampling and $k = 5$); here both terminal and non-terminal nodes are aligned and classified in one pass. Again scores on the development and test set are very similar, the latter being slightly better. For full tree alignment, MBGM once again performs significantly better than the baseline, $t(18) = 25.68, p < .0001$. With an F-score on the test set of 86.65, MBGM scores almost 20 percent higher than the baseline system. This F-score is less than 2% lower than the average F-score obtained by our human annotators on full tree alignment, albeit not on exactly the same sample. The picture that emerges for semantic relation labeling is closely related to the one we saw for word alignments. MBGM significantly outperforms the baseline, for each semantic relation ($t(18) > 12.6636, p < .0001$). MBGM scores a macro average F-score of 52.24% (an increase of 30.05% over the baseline) and a micro average of 80.03% (12.68% above the base score). It is inter-

Feature	Type	Description
Word		
word-subsumption	string	indicate if source word equals, has as prefix, is a prefix of, has a suffix, is a suffix of, has as infix or is an infix of target word
shared-pre-/in-/suffix-len	int	length of shared prefix/infix/suffix in characters
source/target-stop-word	bool	test if source/target word is in a stop word list of frequent function words
source/target-word-len	int	length of source/target word in characters
word-len-diff	int	word length difference in characters
source/target-word-uniq	bool	test if source/target word is unique in source/target sentence
same-words-lhs/rhs	int	no. of identical preceding/following words in source and target word contexts
Morphology		
root-subsumption	string	indicate if source root equals, has as prefix, is a prefix of, has a suffix, is a suffix of, has as infix or is an infix of target root
roots-share-pre-/in-/suffix	bool	source and target root share a prefix/infix/suffix
Part-of-speech		
source/target-pos	string	source/target part-of-speech
same-pos	bool	test if source and target have same part-of-speech
source/target-content-word	bool	test if source/target word is a content word
both-content-word	bool	test if both source and target word are content words
Lexical-semantic using Cornetto		
cornet-restates	float	1.0 if source and target words are synonyms and 0.5 if they are near-synonyms, zero otherwise
cornet-specifies	float	Lin similarity score if source word is a hyponym of target word, zero otherwise
cornet-generalizes	float	Lin similarity score if source word is a hypernym of target word, zero otherwise
cornet-intersects	float	Lin similarity score if source word share a common hypernym, zero otherwise
Syntax		
source/target-cat	string	source/target syntactic category
same-cat	bool	test if source and target have same syntactic category
source/target-parent-cat	string	source/target syntactic category of parent node
source/target-deprel	string	source/target dependency relation
same-deprel	bool	test if source and target have same dependency relation
same-dephead-root	bool	test if the dependency heads of the source and target have same root
Phrasal		
word-prec/rec	float	precision/recall on the yields of source and target nodes
same-lc-phrase	bool	test if lower-cased yields of source and target nodes are identical
same-parent-lc-phrase	bool	test if lower-cased yields of parents of source and target nodes are identical
source/target-phrase-len	int	length of source/target phrase in words
phrase-len-diff	int	phrase length difference in words

Table 4: Features (where slashes indicate multiple versions of the same feature, e.g. *source/target-pos* represents the two features *source-pos* and *target-pos*)

esting to observe that MBGM obtains *higher* F-scores on Equals and on Intersects (the two most frequent relations) than the human annotators obtained. As a result of this, the micro F-score of the automatic full tree alignment is less than 2% lower than the human reference score.

Tree alignment can also be implemented as a two-step procedure, where in the first step alignments and semantic relation classifications at the word level are produced, while in the second step these are used to predict alignments and semantic relations for non-terminals. We experimented with such a two-step procedure as well, in one version using the actual word alignments and in the other the predicted word alignments. The scores of the two-step prediction are only marginally different from those of one step prediction, both for alignment and for relation classification, giving improvements in the order of about 1% for both subtasks. As is to be expected, the scores with true word alignments are much better than those with predicted word alignments. They are interesting though, because they suggest that a fairly good full tree alignment can be automatically ob-

tained given a manually checked word alignment.

7 Conclusions

We have proposed to analyse semantic similarity between comparable sentences by aligning their syntax trees, matching each node to the most similar node in the other tree (if any). In addition, alignments are labeled with a semantic similarity relation. We have presented a Memory-based Graph Matcher (MBGM) that performs both tasks simultaneously as a combination of exhaustive pairwise classification using a memory-based learning algorithm, and global optimization of alignments using a combinatorial optimization algorithm. It relies on a combination of morphological/syntactic analysis, lexical resources such as word nets, and machine learning using a parallel monolingual treebank. Results on aligning comparable news texts from a monolingual parallel treebank for Dutch show that MBGM consistently and significantly outperforms the baseline, both for alignment and labeling. This holds both for word alignment and tree alignment.

In future research we will test MBGM on other data, as the DAESO corpus contains sub-corpora with various degrees of semantic overlap. In addition, we intend to explore alternative features from word space models. Finally, we plan to evaluate MBGM in the context of NLP applications such as multi-document summarization. This includes work on how to define similarity at the sentence level in terms of the proportion of aligned constituents. Both MBGM and the annotated data set will be publicly released.[2]

Abstract

This paper investigates how to automatically create a dialogue control component of a listening agent to reduce the current high cost of manually creating such components. We collected a large number of listening-oriented dialogues with their user satisfaction ratings and used them to create a dialogue control component using partially observable Markov decision processes (POMDPs), which can learn a policy to satisfy users by automatically finding a reasonable reward function. A comparison between our POMDP-based component and other similarly motivated systems using human subjects revealed that POMDPs can satisfactorily produce a dialogue control component that can achieve reasonable subjective assessment.

1 Introduction

Although task-oriented dialogue systems have been actively researched (Hirshman, 1989; Ferguson et al., 1996; Nakano et al., 1999; Walker et al., 2002), recently non-task-oriented functions are starting to attract attention, and systems without a specific task that deal with more casual dialogues, such as chats, are being actively investigated from their social and entertainment aspects (Bickmore and Cassell, 2001; Higashinaka et al., 2008; Higuchi et al., 2008).

In the same vein, we have been working on listening-oriented dialogues in which one conversational participant attentively listens to the other (hereafter, listening-oriented dialogue). Our aim is to build listening agents that can implement such a listening process so that users can satisfy their desire to speak and be heard. Figure 1 shows an excerpt from a typical listening-oriented dialogue. In the literature, dialogue control components for less (or non-) task-oriented dialogue systems, such as listening agents, have typically used hand-crafted rules for dialogue control, which can be problematic because completely covering all dialogue states by hand-crafted rules is difficult when the dialogue has fewer task restrictions (Wallace, 2004; Isomura et al., 2009).

To solve this problem, this paper aims to automatically build a dialogue control component of a listening agent using partially observable Markov decision processes (POMDPs). POMDPs, which make it possible to learn a policy that can maximize the averaged reward in partially observable environments (Pineau et al., 2003), have been successfully adopted in task-oriented dialogue systems for learning a dialogue control module from data (Williams and Young, 2007). However, no work has attempted to use POMDPs for less (or non-) task-oriented dialogue systems, such as listening agents, because user goals are not as well-defined as task-oriented ones, complicating the finding of a reasonable reward function.

We apply POMDPs to listening-oriented dialogues by having the system learn a policy that simultaneously maximizes how well users feel that they are being listened to (hereafter, user satisfaction) and how smoothly the system generates dialogues (hereafter, smoothness). This formulation is new; no work has considered both user satisfaction and smoothness using POMDPs. We collected a large amount of listening-oriented dialogues and annotated them with dialogue acts and also obtained subjective evaluation results for them. From them, we calculated the rewards and learned the POMDP policies. We evaluated the dialogue-act tag sequences of our POMDPs using human subjects.

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 761–769,
Beijing, August 2010

Utterance	Dialogue act
S: Good evening.	Greeting
The topic is “food,” nice to meet you.	Greeting
L: Nice to meet you, too.	Greeting
S: I had curry for dinner.	S-Disc (sub: fact)
Do you like curry?	Question (sub: pref)
L: Yes, I do.	Sympathy
S: Really?	Repeat
Me, too.	Sympathy
L: Do you usually go out to eat?	Question (sub: habit)
S: No, I always cook at home.	S-Disc (sub: habit)
I don’t use any special spices, but I sometimes cook noodles using soup and curry.	S-Disc (sub: habit)
L: That sounds good!	S-Disc (sub: pref (positive))

Figure 1: Excerpt of a typical listening-oriented dialogue. Dialogue topic is “food.” Dialogue acts corresponding to utterances are shown in parentheses (See Table 1 for meanings): S-Disc stands for Self-disclosure; pref for preference; S for speaker; and L for listener. The dialogue was translated from Japanese by the authors.

The next section introduces related work. Section 3 describes our approach. Section 4 describes our collection of listening-oriented dialogues. This is followed in Section 5 by an evaluation experiment that compared our POMDP-based dialogue control with other similarly motivated systems. The last section summarizes the main points and mentions future work.

2 Related work

With increased attention on social dialogues and senior peer counseling, work continues to emerge on listening-oriented dialogues. One early work is (Maatman et al., 2005), which showed that virtual agents can give users the sense of being heard using such gestures as nodding and head shaking. Recently, Meguro et al. (2009a) analyzed the characteristics of listening-oriented dialogues. They compared listening-oriented dialogues and casual conversations between humans, revealing that the two types of dialogues have significantly different flows and that listeners actively question with frequently inserted self-disclosures; the speaker utterances were mostly concerned with self-disclosure.

Shitaoka et al. (2010) also investigated the functions of listening agents, focusing on their response generation components. Their system takes the confidence score of speech recognition into account and changes the system response accordingly; it repeats the user utterance or makes an empathic utterance for high-confidence user utterances and makes a backchannel when the confidence is low. The system’s empathic utterances can be “I’m happy” or “That’s too bad,” depending on whether a positive or negative expression is included in the user utterances. Their system’s response generation only uses the speech recognition confidence and the polarity of user utterances as cues to choose its actions. Currently, it does not consider the utterance content or the user intention.

In order for listening agents to achieve high smoothness, a switching mechanism between the “active listening mode,” in which the system is a listener, and the “topic presenting mode,” in which the system is a speaker, has been proposed (Yokoyama et al., 2010; Kobayashi et al., 2010). Here, the system uses a heuristic function to maintain a high user interest level and to keep the system in an active listening mode. Dialogue control is done by hand-crafted rules. Our motivation bears some similarity to theirs in that we want to build a listening agent that gives users a sense of being heard; however, we want to automatically make such an agent from dialogue data.

POMDPs have been introduced for robot action control (Pineau et al., 2003). Here, the system learns to make suitable movements for completing a certain task. Over the years, POMDPs have been actively studied for applications to spoken dialogue systems. Williams et al. (2007) successfully used a POMDP for dialogue control in a ticket-buying domain in which the objective was to fix the departure and arrival places for tickets. Recent work on POMDPs indicates that it is possible to train a dialogue control module in task-oriented dialogues when the user goal is obvious. In contrast, in this paper, we aim to verify whether POMDPs can be applied to less task-oriented dialogues (i.e., listening-oriented dialogues) where user goals are not as obvious.

In a recent study, Minami et al. (2009) applied POMDPs to non-task-oriented man-machine interaction. Their system learned suitable action control of agents that can act smoothly by obtaining rewards from the statistics of artificially generated data. Our work is different because we use real human-human dialogue data to train POMDPs for dialogue control in listening-oriented dialogues.

3 Approach

A typical dialogue system has utterance understanding, dialogue control, and utterance generation modules. The utterance understanding module comprehends user natural-language utterances, whose output (i.e., a user dialogue act) is passed to the dialogue control module. The dialogue control module chooses the best system dialogue act at every dialogue point using the user dialogue act as input. The utterance generation module generates natural-language utterances and says them to users by realizing the system dialogue acts as surface forms.

This paper focuses on the dialogue control module of a listening agent. Since a listening-oriented dialogue has a characteristic conversation flow (Meguro et al., 2009a), focusing on this module is crucial because it deals with the dialogue flow. Our objective is to train from data a dialogue control module that achieves a smooth dialogue flow that makes users feel that they are being listened to attentively.

3.1 Dialogue control using POMDPs

The purpose of our dialogue control is to simultaneously create situations in which users feel listened to (i.e., user satisfaction) and to generate smooth action sequences (i.e., smoothness). To do this, we automatically and statistically train the reward and the policy of the POMDP using a large amount of listening-oriented dialogue data. POMDP is a reinforcement learning framework that can learn a policy to select an action sequence that maximizes average future rewards. Setting a reward is crucial in POMDPs.

For our purpose, we introduce two different rewards: one for user satisfaction and the other for smoothness. Before creating a POMDP structure, we used the dynamic Bayesian network (DBN) structure (Fig. 2) to obtain the statistical structure of the data and the two rewards.

The random values in the DBN are as follows: s_o and s_a are the dialogue state and action state, o is a speaker observation, a is a listener action, and d is a random variable for an evaluation score that indicates the degree of the user being listened to. This evaluation score can be obtained by questionnaires, and the variable is used for calculating a user satisfaction reward for the POMDP. The DBN arcs in Fig. 2 define the emission and transition probabilities. $\Pr(o'|s'_o)$ is the emission probability of o' given s'_o. $\Pr(d|s_o)$ is the emission probability of d given s_o. $\Pr(s'_o|s_o, a)$ is a transition probability from s_o to s'_o given a. The DBN is trained using the EM algorithm. Using the obtained variables, we calculate the two reward functions as follows:

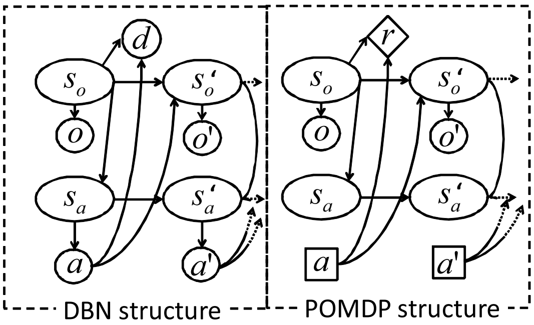

Figure 2: DBN and POMDP structures employed in this paper. Note that a in the POMDP is isolated from other states because it is decided by a learned policy.

(1) Reward for user satisfaction This reward is obtained from the d variable by

$$r_1((s_o, *), a) = \sum_{d=min}^{max} d \times \Pr(d|s_o, a),$$

where * is arbitrary s_a and min and max are minimum and maximum evaluation scores.

(2) Reward for smoothness For smoothness, we maximize the action predictive probability given the history of actions and observations. The probability is calculated from listening-oriented dialogue data. s_a is introduced for estimating the predictive probability of action a and for selecting a to maximize the predictive probability.

We set $\Pr(a|s_a) = 1$ when $a = s_a$ so that s_a corresponds one-on-one with a. Then, if $a_t = s_a$ at time t is given, we obtain

$$\begin{aligned}&\Pr(a_t|o_1, a_1, \ldots, a_{t-1}, o_t)\\&\quad= \sum_{s'_a} \Pr(a_t|s'_a) \Pr(s'_a|o_1, a_1, \ldots, a_{t-1}, o_t)\\&\quad= \Pr(s_a|o_1, a_1, \ldots, o_{t-1}, a_{t-1}, o_t)\end{aligned}$$

Consequently, maximizing the predictive probability of a equals maximizing that of s_a. If we set 1.0 to reward $r_2((*, s_a), a)$ when $s_a = a$, the POMDP will generate actions that maximize their predictive probabilities. We believe that this reward should increase the smoothness of a system action sequence since the sequence is generated according to the statistics of human-human dialogues.

Converting a DBN into a POMDP The DBN is converted into a POMDP (Fig. 2), while maintaining the transition and output probabilities. We convert d to r as described above.

The system is in a partially observed state. Since the state is not known exactly, we use a distribution called "belief state" b_t with which we obtain the average reward that will be gained in the future at time t by:

$$V_t = \sum_{\tau=0}^{\infty} \gamma^{\tau} \sum_{s} b_{\tau+t}((s_o, s_a)) r((s_o, s_a), a_{\tau+t}),$$

where τ is a discount factor; namely, the future reward is decreased by τ. A policy is learned by value iteration so that the action that maximizes V_t can be chosen. We define $r((s_o, s_a), a)$ as follows:

$$r((s_o, s_a), a) = r_1((s_o, *), a) + r_2((*, s_a), a).$$

By balancing these two rewards, we can choose an action that satisfies both user satisfaction and smoothness.

4 Data collection

We collected listening-oriented dialogues using human subjects who consisted of ten listeners (five males and five females) and 37 speakers (18 males and 19 females). The listeners and speakers ranged from 20 to 60 years old and were all native Japanese speakers. Listeners and speakers were matched to form a listener-speaker pair and communicated over the Internet with our chat interface. They used only text; they were not allowed to use voice, video, or facial expressions. The speakers chose their own listener and freely participated in dialogues from 7:00 pm to midnight for a period of 15 days. One conversation was restricted to about ten minutes. The subjects talked about a topic chosen by the speaker. There were 20 predefined topics: money, sports, TV and radio, news, fashion, pets, movies, music, housework and childcare, family, health, work, hobbies, food, human relationships, reading, shopping, beauty aids, travel, and miscellaneous. The listeners were instructed to make it easy for the speakers to say what the speakers wanted to say. We collected 1260 listening-oriented dialogues.

4.1 Dialogue-act annotation

We labeled the collected dialogues using the dialogue-act tag set shown in Table 1. We made these tags by selecting, extending, and modifying those from previous studies that concerned human listening behaviors in some way (Meguro et al., 2009a; Jurafsky et al., 1997; Ivey and Ivey, 2002). In our tag set, only question and self-disclosure tags have sub-category tags. Two annotators (not the authors) labeled each sentence of our collected dialogues using these 32 tags. In dialogue-act annotation, since there can be several sentences in one utterance, one annotator first split the utterances into sentences, and then both annotators labeled each sentence with a single dialogue act.

4.2 Obtaining evaluation scores

POMDPs need evaluation scores (i.e., d) for dialogue acts (i.e., a) for training a reward function. Therefore, we asked a third-party participant, who was neither a listener nor a speaker in our dialogue data collection, to evaluate the user satisfaction levels of the collected dialogues. She rated each dialogue in terms of how she would have felt "being heard" after the dialogue if she had been the speaker of the dialogue in question. She provided ratings on the 7-point Likert scale for each dialogue. Since she rated the whole dialogue with a single rating, we set the evaluation score of each action within a dialogue using the evaluation score for that dialogue.

We used a third-person's evaluation and not the original person's to avoid the fact that the evaluative criterion is too different between humans; identical evaluation scores from two people do not necessarily reflect identical user satisfaction levels. We highly valued the reliability and consistency of the third-person scores. This way, at least, we can train a policy that maximizes its average reward function for the rater, which we need to verify first before considering adaptation to two or more individuals.

5 Experiment

5.1 Experimental setup

The experiment followed three steps.

GREETING	Greeting and confirmation of dialogue theme. e.g., Hello. Let's talk about lunch.
INFORMATION	Delivery of objective information. e.g., My friend recommended a restaurant.
SELF-DISCLOSURE	Disclosure of preferences and feelings.
sub: fact	e.g., I live in Tokyo.
sub: experience	e.g., I had a hamburger for lunch.
sub: habit	e.g., I always go out for dinner.
sub: preference (positive)	e.g., I like hamburgers.
sub: preference (negative)	e.g., I don't really like hamburgers.
sub: preference (neutral)	e.g., Its taste is near my homemade taste.
sub: desire	e.g., I want to try it.
sub: plan	e.g., I'm going there next week.
sub: other	
ACKNOWLEDGMENT	Encourage the conversational partner to speak. e.g., Well. Aha.
QUESTION	Utterances that expect answers.
sub: information	e.g., Please tell me how to cook it.
sub: fact	e.g., What kind of curry?
sub: experience	e.g., What did you have for dinner?
sub: habit	e.g., Did you cook it yourself?
sub: preference	e.g., Do you like it?
sub: desire	e.g., Don't you want to eat rice?
sub: plan	e.g., What are you going to have for dinner?
sub: other	
SYMPATHY	Sympathetic utterances and praises. e.g., Me, too.
NON-SYMPATHY	Negative utterances. e.g., Not really.
CONFIRMATION	Confirm what the conversation partner said. e.g., Really?
PROPOSAL	Encourage the partner to act. e.g., Try it.
REPEAT	Repeat the partner's utterance.
PARAPHRASE	Paraphrase the partner's utterance.
APPROVAL	Broach or show goodwill toward the partner. e.g., Absolutely!
THANKS	Express thanks e.g., Thank you.
APOLOGY	Express regret e.g., I'm sorry.
FILLER	Filler between utterances. e.g., Uh. Let me see.
ADMIRATION	Express affection. e.g., Ha-ha.
OTHER	Other utterances.

Table 1: Definition and example of dialogue acts

	All	Food (subset of All)
# dialogues	1260	250
# words	479881	94867
# utterances per dialogue	28.2	29.1
# dialogues per listener	126	25
# dialogues per speaker	34	6.8
# dialogue acts	67801	13376
inter-annotator agreement	0.57	0.55

Table 2: Statistics of collected dialogues and dialogue-act annotation. Inter-annotator agreement means agreement of dialogue-act annotation using Cohen's κ.

In the first step, we created our POMDP system using our approach (See Section 3.1). We also made five other systems for comparison that we describe in Section 5.2. Each system outputs dialogue-act tag sequences for evaluation. The dialogue theme was "food" because it was the most frequent theme and accounted for 20% of our data (See Table 2 for the statistics); we trained our POMDP using the "food" dialogues. We restricted the dialogue topic to verify that our approach at least works with a small set. Since there is no established measure for automatically evaluating a dialogue-act tag sequence, we evaluated our dialogue control module using human subjective evaluations. However, this is very difficult to do because dialogue control modules only output dialogue acts, not natural language utterances.

In the second step, we recruited participants who created natural language utterances from dialogue-act tag sequences. In their creating dialogues, we provided them with situations to stimulate their imaginations. Table 3 shows the situations, which were deemed common in everyday Japanese life; we let the participants create utterances that fit the situations. These situations were necessary because, without restrictions, the evaluation scores could be influenced by dialogue content rather than by dialogue flow.

For this dialogue-imagining exercise, we recruited 16 participants (eight males and eight females) who ranged from 19 to 39 years old. Each participant made twelve dialogues using two situations. For assigning the situations, we first created four conditions: (1) a student and living with family, (2) working and living with family, (3) a student and living alone, and (4) working and living alone. Then the participants were categorized into one of these conditions on the basis of their actual lifestyle and assigned two of the situations matching the condition.

For each situation, each participant created six imaginary dialogues from the six dialogue-act sequences output by the six systems: our POMDP and the other five systems for comparison. This process produced such dialogues as shown in Figs. 5 and 6. The dialogue in Fig. 5 was made from a dialogue-act tag sequence of a human-human conversation using No. 1 of Table 3. The dialogue in Fig. 6 was made from the sequence of our POMDP using No. 2 of Table 3.

In the third step, we additionally recruited three judges (one male and two females) to evaluate the imagined 192 (16 × 2 × 6) dialogues. The judges were neither the participants who made dialogues nor those who rated the collected listening-oriented dialogues. Six dialogues made from one situation were randomly shown to the judges one-by-one, who then filled out questionnaires to indicate their user satisfaction levels by answering this question on a 7-point Likert scale: “If you had been the speaker, would you have felt that you were listened to?”

5.2 Systems for comparison

We created our POMDP-based dialogue control and five other systems for comparison.

POMDP We learned a policy based on our approach. We used “food” dialogues (See Section 4), and the evaluation scores were those described in Section 4.2. This system used the policy to generate sequences of dialogue-act tags by simulation; user observations were generated based on emission probability, and system actions were generated based on the policy.

In this paper, the total number of observations and actions was 33 because we have 32 dialogue-act tags (See Table 1) plus a “skip” tag. In learning the policy, an observation and an action must individually take turns, but our data can include multiple dialogue-act tags in one utterance. Therefore, if there is more than one dialogue-act tag in one utterance, a “skip” is inserted between the tags. The state numbers for S_o and S_a were 16 and 33, respectively. In this experiment, we set 10 to $r_2((*, s_a), a)$.

EvenPOMDP We arranged a POMDP using only the smoothness reward (hereafter, EvenPOMDP) by creating a POMDP system with a fixed evaluation score; hence user satisfaction is not incorporated in the reward. When using fixed (even) evaluation scores for all dialogues, the effect of the user satisfaction reward is denied, and the system only generates highly frequent sequences. We have EvenPOMDP to clarify whether user satisfaction is necessary. The other conditions are identical as in the POMDP system.

HMM We modeled our dialogue-act tag sequences using a Speaker HMM (SHMM) (Meguro et al., 2009a), which has been utilized to model two-party listening-oriented dialogues. In a SHMM, half the states emit listener dialogue acts, and the other half emit speaker dialogue acts. All states are connected to each other. We modeled the “food” dialogues using an SHMM, and made the model generate the most probable dialogue-act tag sequences. More specifically, first, a dialogue-act tag was generated randomly based on the initial state. If the state was that of a listener, we generated a maximum likelihood action and the state was randomly transited based on the transition probability. If the state was that of a speaker, we randomly generated an action based on the emission probability and the state was transited using the maximum likelihood transition probability.

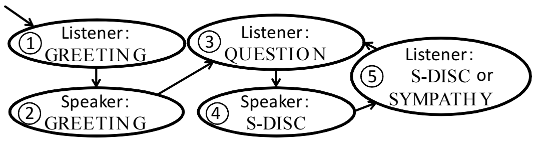

Figure 3: Structure of rule-based system

Rule-based system This system creates dialogue-act tag sequences using hand-crafted rules that are based on the findings in (Meguro et al., 2009a) and are realized as shown in Fig. 3. A sequence begins at state ① in Fig. 3, and one dialogue act is generated at each state. At state ③, a sub-category tag under QUESTION is chosen randomly, and at state ④, a matched sub-category tag under SELF-DISCLOSURE is chosen. At state ⑤, the listener’s SELF-DISCLOSURE or SYMPATHY is generated randomly.

Human dialogue sequence This system created dialogue-act tag sequences by randomly choosing dialogues between humans from the collected data and used their annotated tag sequences.

Random This system simply created dialogue-act tag sequences at random.

5.3 Experimental results

Figure 4 shows the average subjective evaluation scores. Except between HMM and EvenPOMDP, there was a significant difference (p<0.01) between all systems in a non-parametric multiple comparison test (Steel-Dwass test). The dialogues shown in Figs. 5 and 6 were generated by the systems. The dialogue in Fig. 5 was made from human dialogue sequences, and the one in Fig. 6 was made from POMDP.

	With whom	What day	What time	What	Where	Who made
1	family	weekday	around 6:00 pm	grilled salmon	home	mother
2	family	weekend	around 7:00 pm	potato and meat	home	mother
3	co-workers	weekday	at noon	boiled seaweed	lunch box	myself
⋮	⋮	⋮	⋮	⋮	⋮	⋮
32	friend	weekday	at noon	hamburger	school cafeteria	N/A

Table 3: Dialogue situations relating to everyday Japanese life

We qualitatively analyzed the dialogues of each system and observed the following characteristics:

POMDP At a dialogue's beginning, the system greets several times and shifts to a different phase in which listeners ask questions and self-disclose to encourage speakers to reciprocate.

Rule-based The output of this system seems very natural and easy to read. The dialogue-act tags followed reasonable rules, making it easier for the participants to create natural utterances from them.

Human conversation The dialogues between humans were obviously natural before they were changed to tags from the natural-language utterances. However, human dialogues have randomness, which makes it difficult for the participants to create natural-language utterances from the tags. Hence, the evaluation score for this system was lower than the "Rule-based."

HMM, EvenPOMDP Since these systems continually output the same action tags, their output was very unnatural. For example, greetings never stopped because GREETING is most frequently followed by GREETING in the data. These systems have no mechanism to stop this loop.

POMDP successfully avoided such continuation because its actions have more varied rewards. For example, GREETING is repeated in EvenPOMDP because its smoothness reward is high; however, in POMDP, although the smoothness reward remains high, its user satisfaction reward is not that high. This is because greetings appear in all dialogues and their user satisfaction reward converges to the average. Therefore, such actions as greetings do not get repeated in POMDP. In POMDP, some states have high user satisfaction rewards, and the POMDP policy generated actions to move to such states.

Random Since this system has more variety of tags than HMM, its evaluation scores outperformed HMM, but were outperformed by POMDP, which learned statistically from the data.

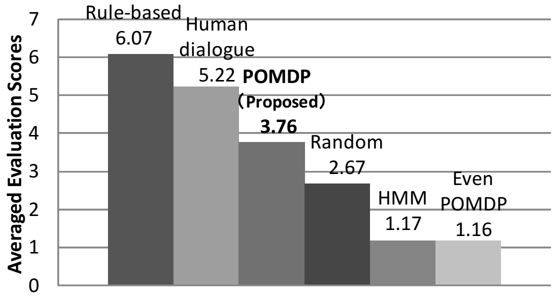

Figure 4: System scores. Except between POMDP and EvenPOMDP, significant differences exist among all systems (p<0.01).

From our qualitative analysis, we found that POMDP can generate more satisfying sequences than HMM/EvenPOMDP because it does not fall into the loop of frequent dialogue-act tag sequences. This suggests the usefulness of incorporating two kinds of rewards into the policy and that our approach for setting a reward is promising.

However, with the proposed POMDP, unnatural sequences remain; for example, the system suddenly output THANKS, as shown in Fig. 6. The number of states may have been too small. We plan to investigate what caused this in the future.

In our qualitative analysis, we observed that randomness in dialogues might hold a clue for improving evaluation scores. Therefore, we measured the perplexity of each system output using dialogue-act trigrams and obtained 72.8 for "Random," 27.4 for "Human dialogue," 7.4 for "POMDP," 3.2 for "HMM," 2.5 for "EvenPOMDP," and 1.7 for "Rule-based."

The perplexity of the human dialogues is less than that of the random system, but humans also exhibit a certain degree of freedom. On the other hand, POMDP's perplexity is less than the human dialogues; they still have some freedom, which probably led to their reasonable evaluation scores. Considering that HMM and EvenPOMDP, which continually output the same dialogue acts, had low

	Utterance	Dialogue act
S:	Hello.	Greeting
L:	Nice to meet you	Greeting
S:	I had dinner at home today.	S-Disc (sub: fact)
	Do you like grilled salmon?	Question, pref
L:	Yes, I think so.	Sympathy
	I sometimes want to have a fancy meal.	S-Disc (sub: desire)
S:	Deluxe.	Repeat
	Me too.	Sympathy
L:	Do you usually do your own cooking?	Question (sub: habit)
S:	No, I don't.	S-Disc, habit
	I always buy my meals at the convenience store.	S-Disc (sub: habit)
L:	I like the lunch boxes of convenience stores	S-Disc (sub: pref (positive))

Figure 5: Excerpt of listening-oriented dialogue that participant imagined from tag sequences of human conversations. Dialogue was translated from Japanese by the authors.

	Utterance	Dialogue act
L:	Nice to meet you.	Greeting
	Where and who did you have dinner with today?	Question (sub: fact)
S:	I had "niku-jaga" (meat and beef) with my family at home.	S-Disc (sub: fact)
L:	Oh.	Admiration
S:	I think it is normal to eat with your family at home.	S-Disc (sub: pref (neutral))
L:	Thanks.	Thanks
	Do you have any brothers or sisters?	Question (sub: fact)
	Soon, my brother and his wife will visit my home.	S-Disc (sub: plan)
S:	I see.	Sympathy
L:	I want to use expensive meat in my "niku-jaga."	S-Disc (sub: desire)
	Oh.	Admiration
	Please give me your recipe.	Question (sub: information)
S:	My friends claim that my "niku-jaga" is as good as a restaurant's.	Information
L:	I'd love to try it	S-Disc (sub: desire)

Figure 6: Excerpt of a listening-oriented dialogue made from tag sequences of POMDP

evaluation scores, we conclude that randomness is necessary in non-task-oriented dialogues and that some randomness can be included with our approach. We do not discuss "Rule-based" here because its tag sequence was meant to have small perplexity.

6 Conclusion and Future work

This paper investigated the possibility of automatically building a dialogue control module from dialogue data to create automated listening agents.

With a POMDP as a learning framework, a dialogue control module was learned from the listening-oriented dialogues we collected and compared with five different systems. Our POMDP system showed higher performance in subjective evaluations than other statistically motivated systems, such as an HMM-based one, that work by selecting the most likely subsequent action in the dialogue data. When we investigated the output sequences of our POMDP system, the system frequently chose to self-disclose and question, which corresponds to human listener behavior, as revealed in the literature (Meguro et al., 2009a). This suggests that learning dialogue control by POMDPs is achievable for listening-oriented dialogues.

The main contribution of this paper is that we successfully showed that POMDPs can be used to train dialogue control policies for less task-oriented dialogue systems, such as listening agents, where the user goals are not as clear as task-oriented ones. We also revealed that the reward function can be learned effectively by our formulation that simultaneously maximizes user satisfaction and smoothness. Finding an appropriate reward function is a real challenge for less task-oriented dialogue systems; this work has presented the first workable solution.

Much work still remains. Even though we conducted an evaluation experiment by simulation (i.e, offline evaluation), human dialogues obviously do not necessarily proceed as in simulations. Therefore, we plan to evaluate our system using online evaluation, which also forces us to implement utterance understanding and generation modules. We also want to incorporate the idea of topic shift into our policy learning because we observed in our data that listeners frequently change topics to keep speakers motivated. We are also considering adapting the system behavior to users. Specifically, we want to investigate dialogue control that adapts to the personality traits of users because it has been found that the flow of listening-oriented dialogues differs depending on the personality traits of users (Meguro et al., 2009b). Finally, although we only dealt with text, we also want to extend our approach to speech and other modalities, such as gestures and facial expressions.

Abstract

Texts are commonly interpreted based on the entire discourse in which they are situated. Discourse processing has been shown useful for inference-based application; yet, most systems for textual entailment – a generic paradigm for applied inference – have only addressed discourse considerations via off-the-shelf coreference resolvers. In this paper we explore various discourse aspects in entailment inference, suggest initial solutions for them and investigate their impact on entailment performance. Our experiments suggest that discourse provides useful information, which significantly improves entailment inference, and should be better addressed by future entailment systems.

1 Introduction

This paper investigates the problem of recognising textual entailment within discourse. Textual Entailment (TE) is a generic framework for applied semantic inference (Dagan et al., 2009). Under TE, the relationship between a *text* (T) and a textual assertion (*hypothesis*, H) is defined such that *T entails H* if humans reading T would infer that H is most likely true (Dagan et al., 2006).

TE has been successfully applied to a variety of natural language processing applications, including information extraction (Romano et al., 2006) and question answering (Harabagiu and Hickl, 2006). Yet, most entailment systems have thus far paid little attention to discourse aspects of inference. In part, this is the result of the unavailability of adept tools for handling the kind of discourse processing required for inference. In addition in the main TE benchmarks, the Recognising Textual Entailment (RTE) challenges, discourse played little role. This state of affairs has started to change with the recent introduction of the RTE Pilot "Search" task (Bentivogli et al., 2009b), in which assessed texts are situated within complete documents. In this setting, texts need to be interpreted based on their entire discourse (Bentivogli et al., 2009a), hence attending to discourse issues becomes essential. Consider the following example from the task's dataset:

(T) *The seven men on board were said to have as little as 24 hours of air.*

For the interpretation of T, e.g. the identity and whereabouts of the seven men, one must consider T's discourse. The preceding sentence T', for instance, provides useful information to that aim:

(T') *The Russian navy worked desperately to save a small military submarine.*

This example demonstrates a common situation in texts, and is also applicable to the RTE Search task's setting. Still, little was done by the task's participants to consider discourse, and sentences were mostly processed independently.

Analyzing the Search task's development set, we identified several key discourse aspects that affect entailment in a discourse-dependent setting. First, we observed that the coverage of available coreference resolution tools is considerably limited. To partly address this problem, we extend the set of coreference relations to phrase pairs with a certain degree of lexical overlap, as long as no semantic incompatibility is found between them. Second, many bridging relations (Clark, 1975) are realized in the form of "global information" perceived as known for entire documents. As bridging falls completely out of the scope of available resolvers, we address this phenomenon by identifying and weighting prominent document terms and allowing their incorporation in inference even

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 770–778,
Beijing, August 2010

when they are not explicitly mentioned in a sentence. Finally, we observed a coherence-related discourse phenomenon, namely inter-relations between entailing sentences in the discourse, such as the tendency of entailing sentences to be adjacent to one another. To that end, we apply a two-phase classification scheme, where a second-phase meta-classifier is applied, extracting discourse and document-level features based on the classification of each sentence on its own.

Our results show that, even when simple solutions are employed, the reliance on discourse-based information is helpful and achieves a significant improvement of results. We analyze the contribution of each component and suggest some future work to better attend to discourse in entailment systems. To our knowledge, this is the most extensive effort thus far to empirically explore the effect of discourse on entailment systems.

2 Background

Discourse plays a key role in text understanding applications such as question answering or information extraction. Yet, such applications typically only handle a narrow aspect of discourse, addressing coreference by term substitution (Dali et al., 2009; Li et al., 2009). The limited coverage and scope of existing tools for coreference resolution and the unavailability of tools for addressing other discourse aspects also contribute to this situation. For instance, VP anaphora and bridging relations are usually not handled at all by such resolvers. A similar situation is seen in the TE research field.

The prominent benchmark for entailment systems evaluation is the series of RTE challenges. The main task in these challenges has traditionally been to determine, given a text-hypothesis pair (T,H), whether T entails H. Discourse played no role in the first two RTE challenges as T's were constructed of short simplified texts. In RTE-3 (Giampiccolo et al., 2007), where some paragraph-long texts were included, inter-sentential relations became relevant for correct inference. Yet the texts in the task were manually modified to ensure they are self-contained. Consequently, little effort was invested by the challenges' participants to address discourse issues beyond the standard substitution of coreferring nominal phrases, using publicly available tools such as JavaRap (Qiu et al., 2004) or OpenNLP[1], e.g. (Bar-Haim et al., 2008).

A major step in the RTE challenges towards a more practical setting of text processing applications occurred with the introduction of the Search task in the Fifth RTE challenge (RTE-5). In this task entailing sentences are situated within documents and depend on other sentences for their correct interpretation. Thus, discourse becomes a substantial factor impacting inference. Surprisingly, discourse hardly received any treatment in this task beyond the standard use of coreference resolution (Castillo, 2009; Litkowski, 2009), and an attempt to address globally-known information by removing from H words that appear in document headlines (Clark and Harrison, 2009).

3 The RTE Search Task

The RTE-5 Search task was derived from the TAC Summarization task[2]. The dataset consists of several corpora, each comprised of news articles concerning a specific *topic*, such as the impact of global warming on the Arctic or the London terrorist attacks in 2005. *Hypotheses* were manually generated based on Summary Content Units (Nenkova et al., 2007), clause-long statements taken from manual summaries of the corpora. *Texts* are unmodified sentences in the articles. Given a topic and a hypothesis, entailment systems are required to identify all sentences in the topic's corpus that entail the hypothesis.

Each sentence-hypothesis pair in both the development and test sets was annotated, judging whether the sentence entails the hypothesis. Out of 20,104 annotations in the development set, only 810 were judged as positive. This small ratio (4%) of positive examples, in comparison to 50% in traditional RTE tasks, better corresponds to the natural distribution of entailing texts in a corpus, thus better simulates practical settings.

The task may seem as a variant of information retrieval (IR), as it requires finding specific texts in a corpus. Yet, it is fundamentally different from IR for two reasons. First, the target output is a set

[1] http://opennlp.sourceforge.net

[2] http://www.nist.gov/tac/2009/Summarization/

of sentences, each evaluated independently, rather than a set of documents. Second, the decision criterion is *entailment* rather than *relevance*.

Despite the above, apparently, IR techniques provided hard-to-beat baselines for the RTE Search task (MacKinlay and Baldwin, 2009), outperforming every other system that relied on inference without IR-based pre-filtering. At the current state of performance of entailment systems, it seems that lexical coverage largely overshadows any other approach in this task. Still, most (6 out of 8) participants in the challenge applied their entailment systems to the entire dataset without a prior retrieval of candidate sentences. F_1 scores for such systems vary between 10% and 33%, in comparison to over 40% of the IR-based methods.

4 The Baseline RTE System

In this work we used BIUTEE, Bar-Ilan University Textual Entailment Engine (Bar-Haim et al., 2008; Bar-Haim et al., 2009), a state of the art RTE system, as a baseline and as a basis for our discourse-based enhancements. This section describes this system's architecture; the methods by which it was augmented to address discourse are presented in Section 5.

To determine entailment, BIUTEE performs the following main steps:

Preprocessing First, all documents are parsed and processed with standard tools for named entity recognition (Finkel et al., 2005) and coreference resolution. For the latter purpose, we use OpenNLP and enable the substitution of coreferring terms. This is the only way by which BIUTEE addresses discourse, representing the state of the art in entailment systems.

Entailment-based transformations Given a T-H pair (both represented as dependency parse trees), the system applies a sequence of knowledge-based entailment transformations over T, generating a set of texts which are entailed by it. The goal is to obtain consequent texts which are more similar to H. Based on preliminary results on the development set, in our experiments (Section 6) we use WordNet (Fellbaum, 1998) as the system's only knowledge resource, using its synonymy, hyponymy and derivation relations.

Classification A supervised classifier, trained on the development set, is applied to determine entailment of each pair based on a set of syntactic and lexical syntactic features assessing the degree by which T and its consequents cover H.

5 Addressing Discourse

In the following subsections we describe the prominent discourse phenomena that affect inference, which we have identified in an analysis of the development set and addressed in our implementation. As mentioned, these phenomena are poorly addressed by available reference resolvers or fall completely out of their scope.

5.1 Augmented coreference set

A large number of coreference relations are comprised of terms which share lexical elements, (e.g. *"airliners's first flight"* and *"Airbus A380's first flight"*). Although common in coreference relations, standard resolvers miss many of these cases. For the purpose of identifying additional coreferring terms, we consider two noun phrases in the same document as coreferring if: (i) their heads are identical and (ii) no semantic incompatibility is found between their modifiers. The types of incompatibility we handle are: (a) mismatching numbers, (b) antonymy and (c) co-hyponymy (coordinate terms), as specified by WordNet. For example, two nodes of the noun *distance* would be considered incompatible if one is modified by *short* and the second by its antonym *long*. Similarly, two modifier co-hyponyms of *distance*, such as *walking* and *running* would also result such an incompatibility. Adding more incompatibility types (e.g. *first* vs. *second flight*) may further improve the precision of this method.

5.2 Global information

Key terms or prominent pieces of information that appear in the document, typically at the title or the first few sentences, are many times perceived as "globally" known throughout the document. For example, the geographic location of the document theme, mentioned at the beginning of the document, is assumed to be known from that point on, and will often not be mentioned explicitly in further sentences. This is a bridging phenomenon that is typically not addressed by available discourse processing tools. To compensate for that, we identify key terms for each document based on *tf-idf* scores and consider them as global information for that document. For example, global terms for the topic discussing the ice melting in the Arctic, typically contain a location such as *Arctic* or *Antarctica* and terms referring to *ice*, like *permafrost* or *iceshelf*.

We use a variant of *tf-idf*, where term frequency is computed as follows: $tf(t_{i,j}) = n_{i,j} + \vec{\lambda}^{\top} \cdot \vec{f_{i,j}}$. Here, $n_{i,j}$ is the frequency of term i in document j ($t_{i,j}$), which is incremented by additional positive weights ($\vec{\lambda}$) for a set of features ($\vec{f_{i,j}}$) of the term. Based on our analysis, we defined the following features, which correlated mostly with global information: (i) does the term appear in the title? (ii) is it a proper name? (iii) is it a location? The weights for these features are set empirically.

The document's top-n global terms are added to each of its sentences. As a result, a global term that occurs in the hypothesis is matched in each sentence of the document, regardless of whether the term explicitly appears in the sentence.

Considering the previous sentence Another method for addressing missing coreference and bridging relations is based on the assumption that adjacent sentences often refer to the same entities and events. Thus, when extracting classification features for a given sentence, in addition to the features extracted from the parse tree of the sentence itself, we extract the same set of features from the current and previous sentences together. Recall the example presented in Section 1. T is annotated as entailing the hypothesis *"The AS-28 mini-submarine was trapped underwater"*, but the word *submarine*, e.g., appears only in its preceding sentence T'. Thus, considering both sentences together when classifying T increases its coverage of the hypothesis. Indeed, a bridging reference relates *on board* in T with *submarine* in T', justifying our assumption in this case.

5.3 Document-level classification

Beyond discourse references addressed above, further information concerning discourse and document structure is available in the Search setting and may contribute to entailment classification. We observed that entailing sentences tend to come in bulks. This reflects a common coherence aspect, where the discussion of a specific topic is typically continuous rather than scattered across the entire document. This *locality* phenomenon may be useful for entailment classification since knowing that a sentence entails the hypothesis increases the probability that adjacent sentences entail the hypothesis as well.

To capture this phenomenon, we use a two-phase meta-classification scheme, in which a *meta-classifier* utilizes entailment classifications of the first classification phase to extract *meta-features* and determine the final classification decision. This scheme also provides a convenient way to combine scores from multiple classifiers used in the first classification phase. We refer to these as *base-classifiers*. This scheme and the meta-features we used are detailed hereunder.

Let us write (s, h) for a sentence-hypothesis pair. We denote the set of pairs in the development (training) set as $\mathcal{D}$ and in the test set as $\mathcal{T}$. We split $\mathcal{D}$ into two halves, $\mathcal{D}_1$ and $\mathcal{D}_2$. We make use of n base-classifiers, $C_1, \ldots, C_n$, among which $C^\star$ is a designated classifier with additional roles in the process, as described below. Classifiers may differ, for example, in their classification algorithm. An additional meta-classifier is denoted C_M. The classification scheme is shown as Algorithm 1.

Algorithm 1 Meta-classification

```
Training
1: Extract features for every $(s, h)$ in $\mathcal{D}$
2: Train $C_1, \ldots, C_n$ on $\mathcal{D}_1$
3: Classify $\mathcal{D}_2$, using $C_1, \ldots, C_n$
4: Extract meta-features for $\mathcal{D}_2$ using the
   classification of $C_1, \ldots, C_n$
5: Train $C_M$ on $\mathcal{D}_2$

Classification
6: Extract features for every $(s, h)$ in $\mathcal{T}$
7: Classify $\mathcal{T}$ using $C_1, \ldots, C_n$
8: Extract meta-features for $\mathcal{T}$
9: Classify $\mathcal{T}$ using $C_M$
```

At Step 1, features are extracted for every (s, h) pair in the training set, as in the baseline system.

#	Ent?	Closest	*d*	2nd closest	*d*
1	NO	6	5	7	6
2	NO	6	4	7	5
3	NO	6	3	7	4
4	NO	6	2	7	3
5	NO	6	1	7	2
6	YES	7	1	7	1
7	YES	6 or 8	1	6 or 8	1
8	YES	7 or 9	1	7 or 9	1
9	YES	8	1	8	1
10	NO	8	1	8	2
11	NO	8	2	8	3

Figure 1: Comparison of the *closest* and *second-closest* schemes when applied to a bulk of entailing sentences (in white) situated within a non-entailing environment (in gray). Unlike the *closest* one, the *second-closest* scheme assigns larger distance values to non-entailing sentences located on the 'edge' of the bulk (5 and 10) than to entailing ones.

In Steps 2 and 3 we split the training set into two halves (taking half of each topic), train n different classifiers on the first half and then classify the second half using each of the n classifiers. Given the classification scores of the n base-classifiers to the (s, h) pairs in the second half of the training set, $\mathcal{D}_2$, we add in Step 4 the meta-features described in Section 5.3.1.

After adding the meta-features, we train (Step 5) a meta-classifier on this new set of features. Test sentences then go through the same process: features are extracted for them and they are classified by the already trained n classifiers (Steps 6 and 7), meta-features are extracted in Step 8, and a final classification decision is made by the meta-classifier in Step 9.

A retrieval step may precede the actual entailment classification, allowing the processing of fewer and potentially "better" candidates.

5.3.1 Meta-features

The following features are extracted in our meta-classification scheme:

Classification scores The classification score of each of the n base-classifiers.

Title entailment In many texts, and in news articles in particular, the title and the first few sentences often represent the entire document's content. Thus, knowing whether these sentences entail the hypothesis may be an indicator to the general potential of the document to include entailing sentences. Two binary features are added according to the classification of $C^\star$ indicating whether the title entails the hypothesis and whether the first sentence entails it.

Second-closest entailment Considering the locality phenomenon described above, we add a feature assigning higher scores to sentences in the vicinity of an entailment environment. This feature is computed as the distance to the second-closest entailing sentence in the document (counting the sentence itself as well), according to the classification of $C^\star$. Formally, let i be the index of the current sentence and $\mathcal{J}$ be the set of indices of entailing sentences in the document according to $C^\star$. For each $j \in \mathcal{J}$ we compute $d_{i,j} = |i-j|$, and choose the second smallest $d_{i,j}$ as d_i. The idea is that if entailing sentences indeed always come in bulks, then $d_i = 1$ for all entailing sentences, but $d_i > 1$ for all non-entailing ones. Figure 1 illustrates such a case, comparing the *second-closest* distance with the distance to the *closest* entailing sentence. In the *closest* scheme we do not count the sentence as closest to itself since it would disregard the environment of the sentence altogether, eliminating the desired effect. We scale the distance and add the feature score: $-\log(d_i)$.

Smoothed entailment This feature addressed the locality phenomenon by smoothing the classification score of sentence i with the scores of adjacent sentences, weighted by their distance from the current sentence i. Let $s(i)$ be the score assigned by $C^\star$ to sentence i. We add the Smoothed Entailment feature score:

$$\text{SE}(i) = \frac{\sum_w (b^{|w|} \cdot s(i+w))}{\sum_w (b^{|w|})}$$

where $0 < b < 1$ is the decay parameter and w is an integer bounded between $-N$ and N, denoting the distance from sentence *i*.

1$^{\text{st}}$ sentence entailing title Bensley and Hickl (2008) showed that the first sentence in a news article typically entails the article's title. We therefore assume that in each document, $s_1 \Rightarrow s_0$, where s_1 and s_0 are the document's first sentence and title respectively. Hence, under entailment transitivity, if $s_0 \Rightarrow h$ then $s_1 \Rightarrow h$. The corresponding binary feature states whether the sentence being classified is the document's first sentence *and* the title entails h according to $C^\star$.

	P (%)	R (%)	F_1 (%)
BIU-BL	14.53	55.25	23.00
BIU-DISC	20.82	57.25	30.53
BIU-BL^3	14.86	59.00	23.74
BIU-DISC$_{no-loc}$	22.35	57.12	32.13
All-yes baseline	4.6	100.0	8.9

Table 1: Micro-average results.

Note that the above locality-based features rely on high accuracy of the base classifier $C^{\star}$. Otherwise, it will provide misleading information to the features computation. We analyze the effect of this accuracy in Section 6.

6 Results and Analysis

Using the RTE-5 Search data, we compare BiuTee in its baseline configuration (cf. Section 4), denoted *BIU-BL*, with its discourse-aware enhancement (*BIU-DISC*) which uses all the components described in Section 5. To alleviate the strong IR effect described in Section 3, both systems are applied to the complete datasets (both training and test), without candidates pre-filtering.

BIU-DISC uses three base-classifiers ($n = 3$): *SVM*^{perf} (Joachims, 2006), and Naïve Bayes and Logistic Regression from the WEKA package (Witten and Frank, 2005). The first among these is set as our designated classifier $C^{\star}$, which is used for the computation of the document-level features. *SVM*^{perf} is also used for the meta-classifier. For the smoothed entailment score (cf. Section 5.3), we used $b = 0.9$ and $N = 3$. Global information is added by enriching each sentence with the highest-ranking term in the document, according to *tf-idf* scores (cf. Section 5.2), where document frequencies were computed based on about half a million documents from the TIPSTER corpus (Harman, 1992). The set of weights $\vec{\lambda}$ equals $\{2, 1, 4\}$ for title terms, proper names and locations, respectively. All parameters were tuned based on a 10-fold cross-validation on the development set, optimizing the micro-averaged F_1.

The results are presented in Table 1. As can be seen in the table, *BIU-DISC* outperforms *BIU-BL* in every measure, showing the impact of addressing discourse in this setting. To rule out the option that the improvement is simply due to the fact that we use three classifiers for *BIU-DISC* and a single one for *BIU-BL*, we show (*BIU-BL*^{3}) the results when the baseline system is applied in the same meta-classification configuration as *BIU-DISC*, with the same three classifiers. Apparently, without the discourse information this configuration's contribution is limited.

	P (%)	R (%)	F_1 (%)
	By Topic		
BIU-BL	16.54	55.62	25.50
BIU-DISC	22.69	57.96	32.62
All-yes baseline	4.85	100.00	9.25
	By Hypothesis		
BIU-BL	22.87	59.62	33.06
BIU-DISC	27.81	61.97	38.39
All-yes baseline	4.96	100.00	9.46

Table 2: Macro-average results.

As mentioned in Section 5.3, the benefit from the locality features rely directly on the performance of the base classifiers. Hence, considering the low precision scores obtained here, we applied *BIU-DISC* to the data in the meta-classification scheme, but with locality features removed. The results, shown as *BIU-DISC*$_{no-loc}$ in the Table, indicate that indeed performance increases without these features. The last line of the table shows the results obtained by a naïve baseline where all test-set pairs are considered entailing.

For completeness, Table 2 shows the macro-averaged results, when averaged over the topics or over the hypotheses. Although we tuned our system to maximize micro-averaged F_1, these figures comply with the ones shown in Table 1.

Analysis of locality As discussed in Section 5, determining whether a sentence entails a hypothesis should take into account whether adjacent sentences also entail the hypothesis. In the above experiment we were unable to show the contribution of our system's component that attempts to capture this information; on the contrary, the results show it had a negative impact on performance.

Still, we claim that this information can be useful when used within a more accurate system. We try to validate this conjecture by understanding how performance of the locality features varies as the systems becomes more accurate. We do so via the following simulation.

When classifying a certain sentence, the classi-

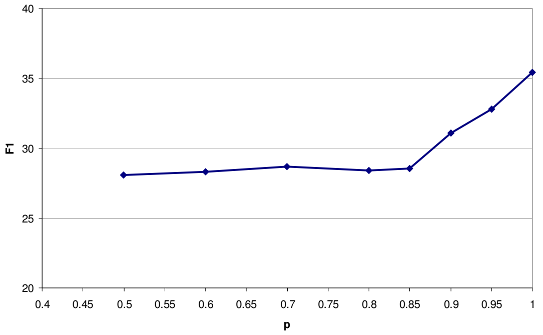

Figure 2: F_1 performance of *BIU-DISC* as a function of the accuracy in classifying adjacent sentences.

fications of its adjacent sentences are given by an *oracle classifier* that provides the correct answer with probability p. The system is applied using two locality features: the *1^{st} sentence entailing title* feature and a close variant of the *smoothed entailment* feature, which calculates the weighted average of adjacent sentences, but disregards the score of the currently evaluated sentence.[3] Thus we supply information about adjacent sentences and test whether overall performance increases with the accuracy of this information.

We performed this experiment for p in a range of [0.5-1.0]. Figure 2 shows the results of this simulation, based on the average F_1 of five runs for each p. Since performance, from a certain point, increases with the accuracy of the oracle classifier, we can conclude that indeed precise information about adjacent sentences improves performance on the current sentence, and that locality is a true phenomenon in the data. We note, however, that performance improves only when accuracy is very high, suggesting the currently limited practical potential of this information, at least in the way locality was represented in this work.

Ablation tests Table 3 presents the results of the ablation tests performed to evaluate the contribution of each component. Based on the result reported in Table 1 and the above discussion, the tests were performed relative to *BIU-DISC*$_{no-loc}$, the optimal configuration. As seen in the table, the removal of each component causes a drop in results. For global information we see a minor difference, which is not surprising considering the conservative approach we took, using a single global term for each sentence. Possibly, this information is also included in the other components, thus proving no marginal contribution relative to them. Under the conditions of an overwhelming majority of negative examples, this is a risky method to use, and should be considered when the ratio of positive examples is higher. For future work, we intend to use this information via classification features (e.g. the coverage obtained with and without global information), rather than the crude addition of the term to the sentence.

Component removed	F_1 (%)	ΔF_1 (%)
Previous sent. features	28.55	3.58
Augmented coref.	26.73	5.40
Global information	31.76	0.37

Table 3: Results of ablation tests relative to *BIU-DISC*$_{no-loc}$. The columns specify the component removed, the micro-averaged F_1 score achieved without it, and the marginal contribution of the component.

Analysis of augmented coreferences We analyzed the performance of the component for augmenting coreference relations relative to the OpenNLP resolver. Recall that our component works on top of the resolver's output and can add or remove coreference relations. As a complete annotation of coreference chains in the dataset is unavailable, we performed the following evaluation. Recall is computed based on the number of identified pairs from a sample of 100 intra-document coreference and bridging relations from the annotated dataset described in (Mirkin et al., 2010). Precision is computed based on 50 pairs sampled from the output of each method, equally distributed over topics. The results, shown in Table 4, indicate the much higher recall obtained by our component at some cost in precision. Although rather simple, the ablation test of this component shows its usefulness. Still, both methods achieve low absolute recall, suggesting the need for more robust tools for this task.

	P (%)	R (%)	F_1 (%)
OpenNLP	74	16	26.3
Augmented coref.	60	28	38.2

Table 4: Performance of coreference methods.

[3] The *second-closest entailment* feature was not used as it considers the oracle's decision for the current sentence, while we wish to use only information about adjacent sentences.

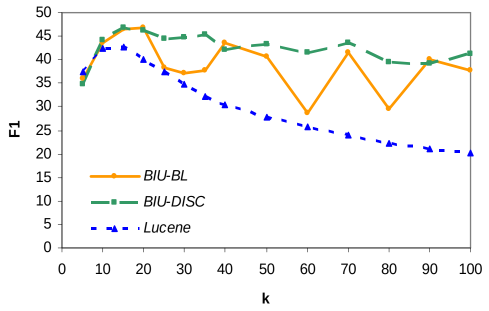

Figure 3: F_1 performance as a function of the number of retrieved candidates.

Candidate retrieval setting As mentioned in Section 3, best performance of RTE systems in the task was obtained when applying a first step of IR-based candidate filtering. We therefore compare the performance of *BIU-DISC* with that of *BIU-BL* under this setting as well.[4] For candidate retrieval we used Lucene, a state of the art search engine[5], in a range of top-k retrieved candidates. The results are shown in Figure 3. For reference, the figure also shows the performance along this range of Lucene as-is, when no further inference is applied to the retrieved candidates.

While *BIU-DISC* does not outperform *BIU-BL* at every point, the area under the curve is clearly larger for *BIU-DISC*. The figure also indicates that *BIU-DISC* is far more robust, maintaining a stable F_1 and enabling a stable tradeoff between recall and precision along the whole range (recall ranges between 42% and 55% for $k \in [15 - 100]$, with corresponding precision range of 51% to 33%).

Finally, Table 5 shows the results of the best systems as determined in our first experiment. We performed a single experiment to compare *BIU-DISC*$_{no-loc}$ and *BIU-BL*^{3} under a candidate retrieval setting, using $k = 20$, where both systems highly perform. We compare these results to the highest score obtained by Lucene, as well as to the two best submissions to the RTE-5 Search task[6]. *BIU-DISC*$_{no-loc}$ outperforms all other methods and its result is significantly better than *BIU-BL*^{3} with $p < 0.01$ according to McNemar's test.

	P (%)	R (%)	F_1 (%)
BIU-DISC$_{no-loc}$	50.77	45.12	47.78

7 Conclusions

While it is generally assumed that discourse interacts with semantic entailment inference, the concrete impacts of discourse on such inference have been hardly explored. This paper presented a first empirical investigation of discourse processing aspects related to entailment. We argue that available discourse processing tools should be substantially improved towards this end, both in terms of the phenomena they address today, namely nominal coreference, and with respect to the covering of additional phenomena, such as bridging anaphora. Our experiments show that even rather simple methods for addressing discourse can have a substantial positive impact on the performance of entailment inference. Concerning the locality phenomenon stemming from discourse coherence, we learned that it does carry potentially useful information, which might become beneficial in the future when better-performing entailment systems become available. Until then, integrating this information with entailment confidence may be useful. Overall, we suggest that entailment systems should extensively incorporate discourse information, while developing sound algorithms for addressing various discourse phenomena, including the ones described in this paper.

Acknowledgements

The authors are thankful to Asher Stern and Ilya Kogan for their help in implementing and evaluating the augmented coreference component, and to Roy Bar-Haim for useful advice concerning this paper. This work was partially supported by the Israel Science Foundation grant 1112/08 and the PASCAL-2 Network of Excellence of the European Community FP7-ICT-2007-1-216886. Jonathan Berant is grateful to the Azrieli Foundation for the award of an Azrieli Fellowship.

[4] This time, for global information, the document's three highest ranking terms were added to each sentence.

Abstract

The detailed analyses of sentence structure provided by parsers have been applied to address several information extraction tasks. In a recent bio-molecular event extraction task, state-of-the-art performance was achieved by systems building specifically on dependency representations of parser output. While intrinsic evaluations have shown significant advances in both general and domain-specific parsing, the question of how these translate into practical advantage is seldom considered. In this paper, we analyze how event extraction performance is affected by parser and dependency representation, further considering the relation between intrinsic evaluation and performance at the extraction task. We find that good intrinsic evaluation results do not always imply good extraction performance, and that the types and structures of different dependency representations have specific advantages and disadvantages for the event extraction task.

1 Introduction

Advanced syntactic parsing methods have been shown to effective for many information extraction tasks. The BioNLP 2009 Shared Task, a recent bio-molecular event extraction task, is one such task: analysis showed that the application of a parser correlated with high rank in the task (Kim et al., 2009). The automatic extraction of bio-molecular events from text is important for a number of advanced domain applications such as pathway construction, and event extraction thus a key task in Biomedical Natural Language Processing (BioNLP).

Methods building feature representations and extraction rules around dependency representations of sentence syntax have been successfully applied to a number of tasks in BioNLP. Several parsers and representations have been applied in high-performing methods both in domain studies in general and in the BioNLP'09 shared task in particular, but no direct comparison of parsers or representations has been performed. Likewise, a number of evaluation of parser outputs against gold standard corpora have been performed in the domain, but the broader implications of the results of such intrinsic evaluations are rarely considered. The BioNLP'09 shared task involved documents contained also in the GENIA treebank (Tateisi et al., 2005), creating an opportunity for direct study of intrinsic and task-oriented evaluation results. As the treebank can be converted into various dependency formats using existing format conversion methods, evaluation can further be extended to cover the effects of different representations.

In this this paper, we consider three types of dependency representation and six parsers, evaluating their performance from two different aspects: dependency-based intrinsic evaluation, and effectiveness for bio-molecular event extraction with a state-of-the-art event extraction system. Comparison of intrinsic and task-oriented evaluation re-

sults shows that performance against gold standard annotations is not always correlated with event extraction performance. We further find that the dependency types and overall structures employed by the different dependency representations have specific advantages and disadvantages for the event extraction task.

2 Bio-molecular Event Extraction

In this study, we adopt the event extraction task defined in the BioNLP 2009 Shared Task (Kim et al., 2009) as a model information extraction task. Figure 1 shows an example illustrating the task of event extraction from a sentence. The shared task provided common and consistent task definitions, data sets for training and evaluation, and evaluation criteria. The shared task defined five simple events (Gene expression, Transcription, Protein catabolism, Phosphorylation, and Localization) that take one core argument, a multi-participant binding event (Binding), and three regulation events (Regulation, Positive regulation, and Negative regulation) used to capture both biological regulation and general causation. The participants of simple and Binding events were specified to be of the general Protein type, while regulation-type events could also take other events as arguments, creating complex event structures.

We consider two subtasks, Task 1 and Task 2, out of the three defined in the shared task. Task 1 focuses on core event extraction, and Task 2 involves augmenting extracted events with secondary arguments (Kim et al., 2009). Events are represented with a textual trigger, type, and arguments, where the trigger is a span of text that states the event in text. In Task 1 the event arguments that need to be extracted are restricted to the core Theme and Cause roles, with secondary arguments corresponding to locations and sites considered in Task 2.

2.1 Event Extraction System

For evaluation, we apply the system of Miwa et al. (2010b). The system was originally developed for finding core events (Task 1) using the native output of the Enju and GDep parsers. The system consists of three supervised classification-based modules: a trigger detector, an event edge detector, and a complex event detector. The trigger detector classifies each word into the appropriate event types, the event edge detector classifies each edge between an event and a candidate participant into an argument type, and the complex event detector classifies event candidates constructed by all edge combinations, deciding between event and non-event. The system uses one-vs-all support vector machines (SVMs) for classification.

The system operates on one sentence at a time, building features for classification based on the syntactic analyses for the sentence provided by the two parsers as well as the sequence of the words in the sentence, including the target candidate. The features include the constituents/words around entities (triggers and proteins), the dependencies, and the shortest paths among the entities. The feature generation is format-independent regarding the shared properties of different formats, but makes use also of format-specific information when available for extracting features, including the dependency tags, word-related information (e.g. a lexical entry in Enju format), and the constituents and their head information.

We apply here a variant of the base system incorporating a number of modifications. The applied system performs feature selection removing two classes of features that were found not to be beneficial for extraction performance, and applies a refinement of the trigger expressions of events. The system is further extended to find also secondary arguments (Task 2). For a detailed description of these improvements, we refer to Miwa et al. (2010a).

3 Parsers and Representations

Six publicly available parsers and three dependency formats are considered in this paper. The

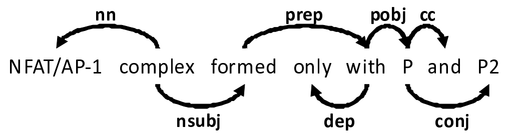

Figure 2: Stanford basic dependency tree

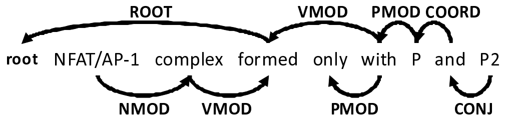

Figure 3: CoNLL-X dependency tree

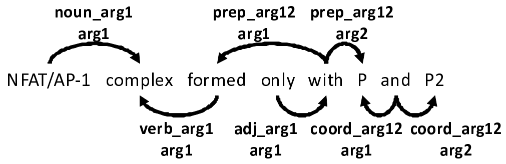

Figure 4: Predicate Argument Structure

parsers are GDep (Sagae and Tsujii, 2007), the Bikel parser (Bikel) (Bikel, 2004), the Stanford parser with two probabilistic context-free grammar (PCFG) models[1] (Wall Street Journal (WSJ) model (Stanford WSJ) and "augmented English" model (Stanford eng)) (Klein and Manning, 2003), the Charniak-Johnson reranking parser, using David McClosky's self-trained biomedical parsing model (MC) (McClosky, 2009), the C&C CCG parser, adapted to biomedical text (C&C) (Rimell and Clark, 2009), and the Enju parser with the GENIA model (Miyao et al., 2009). The formats are Stanford Dependencies (SD) (Figure 2), the CoNLL-X dependency format (CoNLL) (Figure 3) and the predicate-argument structure (PAS) format used by Enju (Figure 4). With the exception of Stanford and Enju, the analyses of these parsers were provided by the BioNLP 2009 Shared Task organizers.

The six parsers operate in a number of different frameworks, reflected in their analyses. GDep is a native dependency parser that produces CoNLL dependency trees, with dependency types similar to those of CoNLL 2007. Bikel, Stanford, and MC are phrase-structure parsers trained on Penn Treebank format (PTB) style treebanks, and they produce PTB trees. C&C is a deep parser based on Combinatory Categorial Grammar (CCG), and its native output is in a CCG-specific format. The output of C&C can be converted into SD by a rule-based conversion script (Rimell and Clark, 2009). Enju is deep parser based on Head-driven Phrase Structure Grammar (HPSG) and produces a format containing predicate argument structures along with a phrase structure tree in Enju format, which can be converted into PTB format (Miyao et al., 2009).

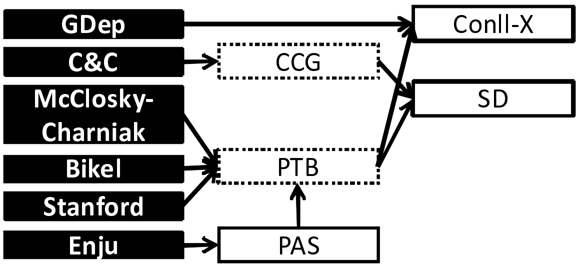

Figure 5: Format conversion dependencies in six parsers. Formats adopted for the evaluation are shown in solid boxes. SD: Stanford Dependency format, CCG: Combinatory Categorial Grammar output format, PTB: Penn Treebank format, and PAS: Predicate Argument Structure in Enju format.

For direct comparison and for the study of contribution of the formats in which the six parsers output their analyses to task performance, we apply a number of conversions between the outputs, shown in Figure 5. The Enju PAS output is converted into PTB using the method introduced by (Miyao et al., 2009). SD is generated from PTB by the Stanford tools (de Marneffe et al., 2006), and CoNLL generated from PTB by using Treebank Converter (Johansson and Nugues, 2007). With the exception of GDep, all CoNLL outputs are generated by the conversion and thus share dependency types. We note that all of these conversions can introduce some errors in the conversion process.

[1] Experiments showed no benefit from using the lexicalized models with the Stanford parser.

4 Evaluation Setting

4.1 Event Extraction Evaluation

Event extraction performance is evaluated using the evaluation script provided by the BioNLP'09 shared task organizers for the development data set, and the online evaluation system of the task for the test data set[2] . Results are reported under the official evaluation criterion of the task, i.e. the "Approximate Span Matching/Approximate Recursive Matching" criterion.

The event extraction system described in Section 2.1 is used with the default settings given in (Miwa et al., 2010b). The C-values of SVMs are set to 1.0, but the positive and negative examples are balanced by placing more weight on the positive examples. The examples predicted with confidence greater than 0.5, as well as the examples with the most confident labels, are extracted. Task 1 and Task 2 are solved at once for the evaluation.

Some of the parse results do not include word base forms or part-of-speech (POS) tags, which are required by the event extraction system. To apply these parsers, the GENIA Tagger (Tsuruoka et al., 2005) output is adopted to add this information to the results.

4.2 Dependency Representation Evaluation

The parsers are evaluated with precision, recall, and F-score for each dependency type. We note that the parsers may produce more fine-grained word segmentations than that of the gold standard: for example, two words "p70(S6)-kinase activation" in the gold standard tree (Figure 6 (a)) is segmented into five words by Enju (Figure 6 (b)). In the evaluation the word segmentations in the gold tree are used, and dependency transfer and word-based normalization are performed to match parser outputs to these. Dependencies related to the segmentations are transferred to the enclosing word as follows. If one word is segmented into several segments by a parser, all the dependencies between the segments are removed (Figure 6 (c)) and the dependency between another word and the segments is converted into the dependency between the two words (Figure 6 (d)).

The parser outputs in SD and CoNLL can be assumed to be trees, so each node in the tree have only one parent node. However, in the converted tree nodes can have more than one parent. We cannot simply apply accuracy, or (un)labeled attachment score[3]. Word-based normalization is performed to avoid negative impact by the word segmentations by parsers. When (a) and (d) in Figure 6 are compared, the counts of correct relations will be 1.0 (0.5 for upper NMOD and 0.5 for lower NMOD in Figure 6 (d)) for the parser (precision), and the counts of correct relations will be 1.0 (for NMOD in Figure 6 (a)) for the gold (recall). This F-score is a good approximation of accuracy.

4.3 GENIA treebank processing

For comparison and evaluation, the texts in the GENIA treebank (Tateisi et al., 2005) are converted to the various formats as follows. To create PAS, the treebank is converted with Enju, and for trees that fail conversion, parse results are used instead. The GENIA treebank is also converted into PTB[4], and then converted into SD and CoNLL as described in Section 3. While based on manually annotated gold data, the converted treebanks are not always correct due to conversion errors.

5 Evaluation

This section presents evaluation results. Intrinsic evaluation is first performed in Section 5.1. Section 5.2 considers the effect of different SD variants. Section 5.3 presents the results of experiments with different parsers. Section 5.4 shows the performance of different parsers. Finally, the performance of the event extraction system is discussed in context of other proposed methods for the task in Section 5.5.

5.1 Intrinsic Evaluation

We initially briefly consider the results of an intrinsic evaluation comparing parser outputs to reference data automatically derived from the gold standard treebank. Table 1 shows results for the parsers whose outputs could be converted into the

Table 1: Comparison of precision, recall, and F-score results with five parsers (two models for Stanford) in two different formats on the development data set (SP abbreviates for Stanford Parser). Results shown separately for evaluation including dependency types and one eliminating them. Parser/model combinations above the line do not use in-domain data, others do.

SD and CoNLL dependency representations using the Stanford tools and Treebank Converter, respectively. For Stanford, both the Penn Treebank WSJ section and "augmented English" (eng) models were tested; the latter includes biomedical domain data. The Enju results for PAS are 91.48 with types and 93.39 without in F-score. GDep not shown as its output is not compatible with that of Treebank Converter.

Despite numerical differences, the two representations and two criteria (typed/untyped) all produce largely the same ranking of the parsers.[5] The evaluations also largely agree on the magnitude of the reduction in error afforded through the use of in-domain training data for the Stanford parser, with all estimates falling in the 15-19% range. Similarly, all show substantial differences between the parsers, indicating e.g. that the error rate of Enju is 50% or less of that of Bikel.

These results serve as a reference point for extrinsic evaluation results. However, it should be noted that as the parsers make use of annotated domain training data to different extents, this evaluation does not provide a sound basis for direct comparison of the parsers themselves.

	BD	CD	CDP	CTD
Task 1	**55.60**	54.35	54.59	54.42
Task 2	**53.94**	52.65	52.88	52.76

Table 2: Comparison of the F-score results with different SD variants on the development data set with the MC parser. The best score in each task is shown in bold.

5.2 Stanford Dependency Setting

SD have four different variants: basic dependencies (BD), collapsed dependencies (CD), collapsed dependencies with propagation of conjunct dependencies (CDP), and collapsed tree dependencies (CTD) (de Marneffe and Manning, 2008). Except for BD, these variants do not necessarily connect all the words in the sentence, and CD and CDP do not necessarily form a tree structure. Table 2 shows the comparison results with the MC parser. Dependencies are generalized by removing expressions after "_" of the dependencies (e.g.

[5] One larger divergence is between typed and untyped SD results for MC. Analysis suggest one cause is frequent errors in tagging hyphenated noun-modifiers such as *NF-kappaB* as adjectives.

"_with" in prep_with) for better performance. We find that basic dependencies give the best performance to event extraction, with little difference between the other variants. This result is surprising, as variants other than basic have features such as the resolution of conjunctions that are specifically designed for practical applications. However, basic dependencies were found to consistently provide best performance also for the other parsers[6]. Thus, in the following evaluation, the basic dependencies are adopted for all SD results.

5.3 Parser Comparison on Event Extraction

Results with different parsers and different formats on the development data set are summarized in Table 3. Baseline results are produced by removing dependency information from the parse results. The baseline results differ between the representations as the word base forms and POS tags produced by the GENIA tagger for use with SD and CoNLL are different from PAS, and because head word information in the Enju format is used. The evaluation finds best results for both tasks with Enju, using its native output format. However, as discussed in Section 2.1, the treatment of PAS and the other two formats are slightly different, this result does not necessarily indicate that PAS is the best alternative for event extraction.

The Bikel and Stanford WSJ parsers, lacking models adapted to the biomedical domain, performs mostly worse than the other parsers. The other parsers, even though trained on the treebank, do not provide performance as high as that for using the GENIA treebank, but, with the exception of Stanford eng with CoNLL, results with the parsers are only slightly worse than results with the treebank. The results with the data derived from the GENIA treebank can be considered as upper bounds for the parsers and formats at the task, although conversion errors are expected to lower these bounds to some extent. The results suggest that there is relative little remaining benefit to be gained from improving parser performance.

5.4 Effects of Dependency Representation

Intrinsic evaluation results (Section 5.1) cannot be used directly for comparing the parsers, since some of the parsers contain models trained on the GENIA treebank. To investigate the effects of the evaluation results to the event extraction, we performed event extraction with eliminating the dependency types. Table 4 summarizes the results with the dependency structures (without the dependency types) on the development data set. Interestingly, we find the performance increases in Bikel and Stanford by eliminating the dependency types. This implies that the inaccurate dependency types shown in Table 1 confused the event extraction system. SD and PAS drops more than CoNLL, and Enju with CoNLL structures perform best in total when the dependency types are removed. This result shows that the formats have their own strengths in finding events, and CoNLL structure with SD or PAS types can be a good representation for the event extraction.

By comparing Table 3, Table 1, and Table 4, we found that the better dependency performance does not always produce better event extraction performance especially when the difference of the dependency performance is small. MC and Enju results show that performance in dependency is important for event extraction. SD can be better than CoNLL for the event extraction (shown with the gold treebank data in Table 3), but the types and relations of CoNLL were well predicted, and MC and Enju performed better for CoNLL than for SD in total.

5.5 Performance of Event Extraction System

Several systems are compared by the extraction performance on the shared task test data in Table 5. GDep and Enju with PAS are used for the evaluation, which is the same evaluation setting with the original system by Miwa et al. (2010b). The performance of the best systems in the original shared task is shown for reference ((Björne et al., 2009) in Task 1 and (Riedel et al., 2009) in Task 2). The event extraction system performs significantly better than the best systems in the shared task, further outperforming the original system. This shows that the comparison of the parsers is performed with a state-of-the-art sys-

[6] Collapsed tree dependencies are not evaluated on the C&C parser since the conversion is not provided.

6 Related Work

Many approaches for parser comparison have been proposed, and most comparisons have used gold treebanks with intermediate formats (Clegg and Shepherd, 2007; Pyysalo et al., 2007). Parser comparison has also been proposed on specific tasks such as unbounded dependencies (Rimell et al., 2009) and textual entailment (Önder Eker, 2009)[7]. Among them, application-oriented parser comparison across several formats was first introduced by Miyao et al. (2009), who compared eight parsers and five formats for the protein-protein interaction (PPI) extraction task. PPI extraction, the

[7] http://pete.yuret.com/

recognition of binary relations of between proteins, is one of the most basic information extraction tasks in the BioNLP field. Our findings do not conflict with those of Miyao et al. Event extraction can be viewed as an additional extrinsic evaluation task for syntactic parsers, providing more reliable and evaluation and a broader perspective into parser performance. An additional advantage of application-oriented evaluation on BioNLP shared task data is the availability of a manually annotated gold standard treebank, the GENIA treebank, that covers the same set of abstracts as the task data. This allows the gold treebank to be considered as an evaluation standard, in addition to comparison of performance in the primary task.

7 Conclusion

We compared six parsers and three formats on a bio-molecular event extraction task with a state-of-the-art event extraction system from two different aspects: dependency-based intrinsic evaluation and task-based extrinsic evaluation. The specific task considered was the BioNLP shared task, allowing the use of the GENIA treebank as a gold standard parse reference. Five of the six considered parsers were applied using biomedical models trained on the GENIA treebank, and they were found to produce similar performance. The comparison of the parsers from two aspects showed slightly different results, and and the dependency representations have advantages and disadvantages for the event extraction task.

The contributions of this paper are 1) the comparison of intrinsic and extrinsic evaluation on several commonly used parsers with a state-of-the-art system, and 2) demonstration of the limitation and possibility of the parser and system improvement on the task. One limitation of this study is that the comparison between the parsers is not perfect, as the parsers are used with the provided models, the format conversions miss some information from the original formats, and results with different formats depend on the ability of the event extraction system to take advantage of their strengths. To maximize comparability, the system was designed to extract features identically from similar parts of the dependency-based formats, further adding information provided by other formats, such as the lexical entries of the Enju format, from external resources. The results of this paper are expected to be useful as a guide not only for parser selection for biomedical information extraction but also for the development of event extraction systems.

The comparison in the present evaluation is limited to the dependency representation. As future work, it would be informative to extend the comparison to other syntactic representation, such as the PTB format. Finally, the evaluation showed that the system fails to recover approximately 40% of events even when provided with manually annotated treebank data, showing that other methods and resources need to be adopted to further improve bio-molecular event extraction systems. Such improvement is left as future work.

Abstract

Relations between entities in text have been widely researched in the natural language processing and information-extraction communities. The region connecting a pair of entities (in a parsed sentence) is often used to construct kernels or feature vectors that can recognize and extract interesting relations. Such regions are useful, but they can also incorporate unnecessary distracting information. In this paper, we propose a rule-based method to remove the information that is unnecessary for relation extraction. Protein–protein interaction (PPI) is used as an example relation extraction problem. A dozen simple rules are defined on output from a deep parser. Each rule specifically examines the entities in one target interaction pair. These simple rules were tested using several PPI corpora. The PPI extraction performance was improved on all the PPI corpora.

1 Introduction

Relation extraction (RE) is the task of finding a relevant semantic relation between two given target entities in a sentence (Sarawagi, 2008). Some example relation types are person–organization relations (Doddington et al., 2004), protein–protein interactions (PPI), and disease–gene associations (DGA) (Chun et al., 2006). Among the possible RE tasks, we chose the PPI extraction problem. PPI extraction is a major RE task; around 10 corpora have been published for training and evaluation of PPI extraction systems.

Recently, machine-learning methods, boosted by NLP techniques, have proved to be effective for RE. These methods are usually intended to highlight or select the relation-related regions in parsed sentences using feature vectors or kernels. The shortest paths between a pair of entities (Bunescu and Mooney, 2005) or pair-enclosed trees (Zhang et al., 2006) are widely used as focus regions. These regions are useful, but they can include unnecessary sub-paths such as appositions, which cause noisy features.

In this paper, we propose a method to remove information that is deemed unnecessary for RE. Instead of selecting the whole region between a target pair, the target sentence is simplified into simpler, pair-related, sentences using general, task-independent, rules. By addressing particularly the target entities, the rules do not affect important relation-related expressions between the target entities. We show how rules of two groups can be easily defined using the analytical capability of a deep parser with specific examination of the target entities. Rules of the first group can replace a sentence with a simpler sentence, still including the two target entities. The other group of rules can replace a large region (phrase) representing one target entity, with just a simple mention of that target entity. With only a dozen simple rules, we show that we can solve several simple well-known problems in RE, and that we can improve the performance of RE on all corpora in our PPI test-set.

2 Related Works

The general paths, such as the shortest path or pair-enclosed trees (Section 1), can only cover a part of the necessary information for relation extraction. Recent machine-learning methods specifically examine how to extract the missing information without adding too much noise. To find more representative regions, some information from outside the original regions must be included. Several tree kernels have been proposed to extract such regions from the parse structure (Zhang et al., 2006). Also the graph kernel method emphasizes internal paths without ignoring outside information (Airola et al., 2008). Composite kernels have been used to combine original information with outside information (Zhang et al., 2006; Miwa et al., 2009).

The approaches described above are useful, but they can include unnecessary information that distracts learning. Jonnalagadda and Gonzalez (2009) applied bioSimplify to relation extraction. BioSimplify is developed to improve their link grammar parser by simplifying the target sentence in a general manner, so their method might remove important information for a given target relation. For example, they might accidentally simplify a noun phrase that is needed to extract the relation. Still, they improved overall PPI extraction recall using such simplifications.

To remove unnecessary information from a sentence, some works have addressed sentence simplification by iteratively removing unnecessary phrases. Most of this work is not task-specific; it is intended to compress all information in a target sentence into a few words (Dorr et al., 2003; Vanderwende et al., 2007). Among them, Vickrey and Koller (2008) applied sentence simplification to semantic role labeling. With retaining all arguments of a verb, Vickrey simplified the sentence by removing some information outside of the verb and arguments.

3 Entity-Focused Sentence Simplification

We simplify a target sentence using simple rules applicable to the output of a deep parser called Mogura (Matsuzaki et al., 2007), to remove noisy information for relation extraction. Our method relies on the deep parser; the rules depend on the Head-driven Phrase Structure Grammar (HPSG) used by Mogura, and all the rules are written for the parser Enju XML output format. The deep parser can produce deep syntactic and semantic information, so we can define generally applicable comprehensive rules on HPSG with specific examination of the entities.

For sentence simplification in relation extraction, the meaning of the target sentence itself is less important than maintaining the truth-value of the relation (interact or not). For that purpose, we define rules of two groups: clause-selection rules and entity-phrase rules. A clause-selection rule constructs a simpler sentence (still including both target entities) by removing noisy information before and after the relevant clause. An entity-phrase rule simplifies an entity-containing region without changing the truth-value of the relation. By addressing the target entities particularly, we can define rules for many applications, and we can simplify target sentences with less danger of losing relation-related mentions. The rules are summarized in Table 1.

Our method is different from the sentence simplification in other systems (ref. Section 2). First, our method relies on the parser, while bioSimplify by Jonnalagadda and Gonzalez (2009) is developed for the improvement of their parser. Second, our method tries to keep only the relation-related regions, unlike other general systems including bioSimplify which tried to keep all information in a sentence. Third, our entity-phrase rules modify only the entity-containing phrases, while Vickrey and Koller (2008) tries to remove all information outside of the target verb and arguments.

3.1 Clause-selection Rules

In compound or complex sentences, it is natural to assume that one clause includes both the target entities and the relation-related information. It can also be assumed that the remaining sentence parts, outside the clause, contain less related (or noisy) information. The clause-selection rules simplify a sentence by retaining only the clause that includes the target entities (and by discarding the remainder of the sentence). We define three types of

Rule Group	Rule Type	#	Example (original → simplified)
Clause Selection	Sentence Clause	1	We show that A interacts with B. → A interacts with B.
	Relative Clause	2	... A that interacts with B. → A interacts with B.
	Copula	1	A is a protein that interacts with B. → A interacts with B.
Entity Phrase	Apposition	2	a protein, A → A
	Exemplification	4	proteins, such as A → A
	Parentheses	2	a protein (A) → A
	Coordination	3	protein and A → A

Table 1: Rules for Sentence Simplification. (# is the rule count. A and B are the target entities.)

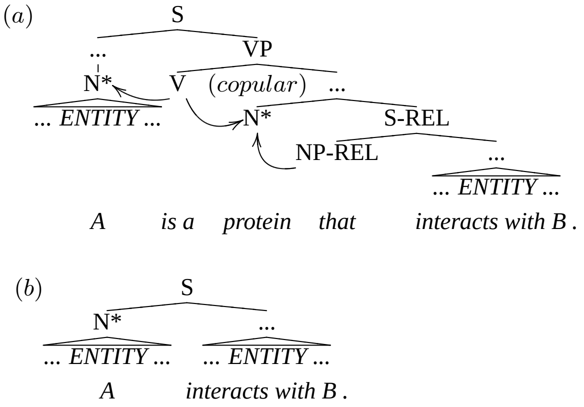

Figure 1: Copula Rule. (a) is simplified to (b). The arrows represent predicate–argument relations.

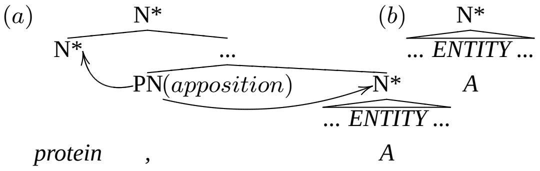

Figure 2: Apposition Rule.

clause-selection rules for sentence clauses, relative clauses, and copula. The *sentence clause rule* finds the (smallest) clause that includes both target entities. It then replaces the original sentence with the clause. The *relative clause rules* construct a simple sentence from a relative clause and the antecedent. If this simple sentence includes the target entities, it is used instead of the original sentence. We define two rules for the case where the antecedent is the subject of the relative clause. One rule is used when the relative clause includes both the target entities. The other rule is used when the antecedent includes one target entity and the relative clause includes the other target entity. The *copula rule* is for sentences that include copular verbs (e.g. be, is, become, etc). The rule constructs a simple sentence from a relative clause with the subject of the copular verb as the antecedent subject of the clause. The rule replaces the target sentence with the constructed sentence, if the relative clause includes one target entity and the subject of a copular verb includes the other target entity, as shown in Figure 1.

3.2 Entity-phrase Rules

Even the simple clauses (or paths between two target entities) include redundant or noisy expressions that can distract relation extraction. Some of these expressions are related to the target entities, but because they do not affect the truth-value of the relation, they can be deleted to make the path simple and clear. The target problem affects which expressions can be removed. We define four types of rules for appositions, exemplifications, parentheses, and coordinations. Two *apposition rules* are defined to select the correct element from an appositional expression. One element modifies or defines the other element in apposition, but the two elements represent the same information from the viewpoint of PPI. If the target entity is in one of these elements, removing the other element does not affect the truth-value of the interaction. Many of these apposition expressions are identified by the deep parser. The rule to select the last element is presented in Figure 2. Four *exemplification rules* are defined for the two major types of expressions using the phrases “including” or “such as”. Exemplification is represented by hyponymy or hypernymy. As for appositions, the truth-value of the interaction does not change whether we use the specific mention or the hyperclass that the mention represents. Two *parentheses rules* are defined. Parentheses are useful for synonyms, hyponyms, or hypernyms (ref. the two

14: **return** $S$
```

Figure 3: Pseudo-code for sentence simplification.

former rules). Three *coordination rules* are defined. Removing other phrases from coordinated expressions that include a target entity does not affect the truth-value of the target relation. Two rules are defined for simple coordination between two phrases (e.g. select left or right phrase), and one rule is defined to (recursively) remove one element from lists of more than two coordinated phrases (while maintaining the coordinating conjunction, e.g. “and”).

3.3 Sentence Simplification

To simplify a sentence, we apply rules repeatedly until no more applications are possible as presented in Figure 3. After one application of one rule, the simplified sentence is re-parsed before attempting to apply all the rules again. This is because we require a consistent parse tree as a starting point for additional applications of the rules, and because a parser can produce more reliable output for a partly simplified sentence than for the original sentence. Using this method, we can also backtrack and seek out conversion errors by examining the cascade of partly simplified sentences.

4 Evaluation

To elucidate the effect of the sentence simplification, we applied the rules to five PPI corpora and evaluated the PPI extraction performance. We then analyzed the errors. The evaluation settings will be explained in Section 4.1. The results of the PPI extraction will be explained in Section 4.2. Finally, the deeper analysis results will be presented in Section 4.3.

4.1 Experimental Settings

The state-of-the-art PPI extraction system AkaneRE by Miwa et al. (2009) was used to evaluate our approach. The system uses a combination of three feature vectors: bag-of-words (BOW), shortest path (SP), and graph features. Classification models are trained with a support vector machine (SVM), and AkaneRE (with Mogura) is used with default parameter settings. The following two systems are used for a state-of-the-art comparison: AkaneRE with multiple parsers and corpora (Miwa et al., 2009), and Airola et al. (2008) single-parser, single-corpus system.

The rules were evaluated on the BioInfer (Pyysalo et al., 2007), AIMed (Bunescu et al., 2005), IEPA (Ding et al., 2002), HPRD50 (Fundel et al., 2006), and LLL (Nédellec, 2005) corpora[1]. Table 2 shows the number of positive (interacting) vs. all pairs. One duplicated abstract in the AIMed corpus was removed.

These corpora have several differences in their definition of entities and relations (Pyysalo et al., 2008). In fact, BioInfer and AIMed target all occurring entities related to the corpora (proteins, genes, etc). On the other hand, IEPA, HPRD50, and LLL only use limited named entities, based either on a list of entity names or on a named entity recognizer. Only BioInfer is annotated for other event types in addition to PPI, including static relations such as protein family membership. The sentence lengths are also different. The duplicated pair-containing sentences contain the following numbers of words on average: 35.8 in BioInfer, 31.3 in AIMed, 31.8 in IEPA, 26.5 in HPRD50, and 33.4 in LLL.

For BioInfer, AIMed, and IEPA, each corpus is split into training, development, and test datasets[2]. The training dataset from AIMed was the only training dataset used for validating the rules. The development datasets are used for error analysis. The evaluation was done on the test dataset, with models trained using training and development

datasets). Ten-fold cross-validation (CV) was done to facilitate comparison with other existing systems. For HPRD50 and LLL, there are insufficient examples to split the data, so we use these corpora only for comparing the scores and statistics. We split the corpora for the CV, and measured the F-score (%) and area under the receiver operating characteristic (ROC) curve (AUC) as recommended in (Airola et al., 2008). We count each occurrence as one example because the correct interactions must be extracted for each occurrence if the same protein name occurs multiple times in a sentence.

In the experiments, the rules are applied in the following order: sentence–clause, exemplification, apposition, parentheses, coordination, copula, and relative-clause rules. Furthermore, if the same rule is applicable in different parts of the parse tree, then the rule is first applied closest to the leaf-nodes (deepest first). The order of the rules is arbitrary; changing it does not affect the results much. We conducted five experiments using the training and development dataset in IEPA, each time with a random shuffling of the order of the rules; the results were 77.8±0.26 in F-score and 85.9±0.55 in AUC.

4.2 Performance of PPI Extraction

The performance after rule application was better than the baseline (no application) on all the corpora, and most rules could be frequently applied. We show the PPI extraction performance on BioInfer, AIMed, and IEPA with rules of different groups in Table 3. The effect of using rules of different types for PPI extraction from HPRD50 and LLL is reported in Table 4 and Table 5. Table 6 shows the number of times each rule was applied in an "apply all-rules" experiment. The usability of the rules depends on the corpus, and different combinations of rules produce different

results. For the clause-selection rules, the performance was as good as or better than the baseline for all corpora, except for HPRD50, which indicates that the pair-containing clauses also include most of the important information for PPI extraction. Clause selection rules alone could improve the overall performance for the BioInfer and AIMed corpora. Entity-phrase rules greatly improved the performance on the IEPA, HPRD50, and LLL corpora, although these rules degraded the performance on the BioInfer and AIMed corpora. These phenomena hold even if we use small parts of the two corpora, so this is not because of the size of the corpora.

We compare our results with the results by Miwa et al. (2009) and Airola et al. (2008) in Table 7. On three of five corpora, our method provides better results than the state-of-the-art system by Airola et al. (2008), and also provides comparable results to those obtained using multiple parsers and corpora (Miwa et al., 2009) despite the fact that our method uses one parser and one corpus at a time. We cannot directly compare our result with Jonnalagadda and Gonzalez (2009) because the evaluation scheme, the baseline system, and test parts differ.

[FP→TN][Sentence, Parenthesis, Coordination] To characterize the AAV functions mediating this effect, cloned AAV type 2 wild-type or mutant genomes were transfected into simian virus 40 (SV40)-transformed hamster cells together with the six HSV replication genes (encoding UL5, UL8, major DNA-binding protein, **DNA polymerase**, UL42 , and **UL52**) which together are necessary and sufficient for the induction of SV40 DNA amplification (R. Heilbronn and H. zur Hausen, J. Virol. 63:3683-3692, 1989). (BioInfer.d760.s0)

[TP→FN][Coordination] Both the **GT155-calnexin** and the GT155-CAP-60 interactions were dependent on the presence of a correctly modified oligosaccharide group on GT155, a characteristic of many calnexin interactions. (AIMed.d167.s1408)

[TN→TN][Coordination, Parenthesis] **Leptin** may act as a negative feedback signal to the hypothalamic control of appetite through suppression of **neuropeptide Y** (NPY) secretion and stimulation of cocaine and amphetamine regulated transcript (CART) . (IEPA.d190.s454)

Figure 4: A rule-related error, a critical error, and a parser-related error. Regions removed by the rules are underlined, and target proteins are shown in bold. Predictions, applied rules, and sentence IDs are shown.

[FN→TP][Sentence, Coordination] **WASp** contains a binding motif for the Rho GTPase CDC42Hs as well as **verprolin** / cofilin-like actin-regulatory domains , but no specific actin structure regulated by CDC42Hs-WASp has been identified. (BioInfer.d795.s0)

[FN→TP][Parenthesis, Apposition] The protein **Raf-1** , a key mediator of mitogenesis and differentiation, associates with **p21ras** (refs 1-3) . (AIMed.d124.s1055)

[FN→TP][Sentence, Parenthesis] On the basis of far-Western blot and plasmon resonance (BIAcore) experiments, we show here that recombinant **bovine prion protein** (bPrP) (25-242) strongly interacts with the catalytic alpha/alpha' subunits of **protein kinase CK2** (also termed 'casein kinase 2') (IEPA.d197.s479)

Figure 5: Correctly simplified cases. The first sentence is a difficult (not PPI) relation, which is typed as "Similar" in the BioInfer corpus.

4.3 Analysis

We trained models using the training datasets and classified the examples in the development datasets. Two types of analysis were performed based on these results: *simplification-based* and *classification-based analysis*.

For the *simplification-based analysis*, we compared positive (interacting) and negative pair sentences that produce the exact same (inconsistent) sentence after protein names normalization and

	BioInfer				AIMed				IEPA				
Before simplification	FN	FP	TP	TN	FN	FP	TP	TN	FN	FP	TP	TN	Not Affected
After simplification	TP	TN	FN	FP	TP	TN	FN	FP	TP	TN	FN	FP	
No Error	18	2	3	35	14	21	21	8	3	2	0	4	32
No Application	3	2	0	3	0	7	8	0	0	1	0	1	7
Number of Errors	0	2	0	32	4	2	1	4	0	0	0	0	1
Number of Pairs	21	6	3	70	18	30	30	12	3	3	0	5	40
Coordination	0	0	0	20	4	2	1	0	0	0	0	0	1
Sentence	0	2	0	4	0	0	0	4	0	0	0	0	0
Parenthesis	0	0	0	5	0	0	0	0	0	0	0	0	0
Exemplification	0	0	0	2	0	0	0	0	0	0	0	0	0
Apposition	0	0	0	1	0	0	0	0	0	0	0	0	0

Table 8: Distribution of sentence simplification errors compared to unsimplified predictions with their types (on the three development datasets). TP, True Positive; TN, True Negative; FN, False Negative; FP, False Positive. “No Error” means that simplification was correct; “No Application” means that no rule could be applied; Other rule names mean that an error resulted from that rule application. “Not Affected” means that the prediction outcome did not change.

simplification in the training dataset. The numbers of such inconsistent sentences are 7 for BioInfer, 78 for AIMed, and 1 for IEPA. The few inconsistencies in BioInfer and IEPA are from errors by the rules, mainly triggered by parse errors. The frequent inconsistencies in AIMed are mostly from inconsistent annotations. For example, even if all coordinated proteins are either interacting or not, only the first protein mention is annotated as interacting.

For the *classification-based analysis*, we specifically examine simplified pairs that were predicted differently before and after the simplification. Pairs predicted differently before and after rule application were selected: 100 random pairs from BioInfer and all 90 pairs from AIMed. For IEPA, all 51 pairs are reported. Simplified results are classified as errors when the rules affect a region unrelated to the entities in the smallest sentence clause. The results of analysis are shown in Table 8. There were 34 errors in BioInfer, and 11 errors in AIMed. Among the errors, there were five *critical errors* (in two sentences, in AIMed). Critical errors mean that the pairs lost relation-related mentions, and the errors are the only errors which caused the changes in the truth-value of the relation. There was also a *rule-related error* (in BioInfer), which means that rules with correct parse results affect a region unrelated to the entities, and parse errors (*parser-related errors*). Figure 4 shows the rule-related error in BioInfer, one critical error in AIMed, and one parser-related error in IEPA.

5 Discussion

Our end goal is to provide consistent relation extraction for real tasks. Here we discuss the “safety” of applying our simplification rules, the difficulties in the BioInfer and AIMed corpora, the reduction of errors, and the requirements for such a general (PPI) extraction system.

Our rules are applicable to sentences, with little danger of changing the relation-related mentions. Figure 5 shows three successfully simplified cases (“No Error” cases from Table 8). The sentence simplification leaves sufficient information to determine the value of the relation in these examples. Relation-related mentions remained for most of the simplification error cases. There were only five critical errors, which changed the truth-value of the relation, out of 46 errors in 241 pairs shown in Table 8. Please note that some rules can be dangerous for other relation extraction tasks. For example, the *sentence clause rule* could remove modality information (negation, speculation, etc.) modifying the clause, but there are few such cases in the PPI corpora (see Table 8). Also, the task of hedge detection (Morante and Daelemans, 2009) can be solved separately, in the original sentences, after the interacting pairs have been found. For example, in the BioNLP shared task challenge and the BioInfer corpus, interaction detection and modality are treated as two different tasks. Once other NLP tasks, like static relation (Pyysalo et al., 2009) or coreference resolution, become good enough, they can supplement or even substitute some of the proposed rules.

There are different difficulties in the BioInfer and AIMed corpora. BioInfer includes more complicated sentences and problems than the other corpora do, because 1) the apposition, coordination, and exemplification rules are more frequently used in the BioInfer corpus than in the other corpora (shown in Table 6), 2) there were more errors in the BioInfer corpus than in other corpora among the simplified sentences (shown in Table 8), and 3) BioInfer has more words per sentence and more relation types than the other corpora. AIMed contains several annotation inconsistencies as explained in Section 4.3. These inconsistencies must be removed to properly evaluate the effect of our method.

Simplification errors are mostly caused by parse errors. Our rule specifically examines a part of parser output; a probability is attached to the part. The probability is useful for defining the order of rule applications, and the n-best results by the parser are useful to fix major errors such as coordination errors. By using these modifications of rule applications and by continuous improvement in parsing technology for the biomedical domain, the performance on the BioInfer and AIMed corpora will be improved also for the all rules case.

The PPI extraction system lost the ability to capture some of the relation-related expressions left by the simplification rules. This indicates that the system used to extract some relations (before simplification) by using back-off features like bag-of-words. The system can reduce bad effects caused by parse errors, but it also captures the annotation inconsistencies in AIMed. Our simplification (without errors) can capture more general expressions needed for relation extraction. To provide consistent PPI relation extraction in a general setting (e.g. for multiple corpora or for other public text collections), the parse errors must be dealt with, and a relation extraction system that can capture (only) general relation-related expressions is needed.

6 Conclusion

We proposed a method to simplify sentences, particularly addressing the target entities for relation extraction. Using a few simple rules applicable to the output of a deep parser called Mogura, we showed that sentence simplification is effective for relation extraction. Applying all the rules improved the performance on three of the five corpora, while applying only the clause-selection rules raised the performance for the remaining two corpora as well. We analyzed the simplification results, and showed that the simple rules are applicable with little danger of changing the truth-values of the interactions.

The main contributions of this paper are: 1) explanation of general sentence simplification rules using HPSG for relation extraction, 2) presenting evidence that application of the rules improve relation extraction performance, and 3) presentation of an error analysis from two viewpoints: simplification and classification results.

As future work, we are planning to refine and complete the current set of rules, and to cover the shortcomings of the deep parser. Using these rules, we can then make better use of the parser's capabilities. We will also attempt to apply our simplification rules to other relation extraction problems than those of PPI.

Abstract

In this paper we explore the possibility of using cross lingual projections that help to automatically induce role-semantic annotations in the PropBank paradigm for Urdu, a resource poor language. This technique provides annotation projections based on word alignments. It is relatively inexpensive and has the potential to reduce human effort involved in creating semantic role resources. The projection model exploits lexical as well as syntactic information on an English-Urdu parallel corpus. We show that our method generates reasonably good annotations with an accuracy of 92% on short structured sentences. Using the automatically generated annotated corpus, we conduct preliminary experiments to create a semantic role labeler for Urdu. The results of the labeler though modest, are promising and indicate the potential of our technique to generate large scale annotations for Urdu.

1 Introduction

Semantic Roles (also known as thematic roles) help to understand the semantic structure of a document (Fillmore, 1968). At a fundamental level, they help to capture the similarities and differences in the meaning of verbs via the arguments they define by generalizing over surface syntactic configurations. In turn, these roles aid in domain independent understanding as the semantic frames and semantic understanding systems do not depend on the syntactic configuration for each new application domain. Identifying semantic roles benefit several language processing tasks - information extraction (Surdeanu *et al.*, 2003), text categorization (Moschitti, 2008) and finding relations in textual entailment (Burchardt and Frank 2006).

Automatically identifying semantic roles is often referred to as shallow semantic parsing (Gildea and Jurafsky, 2002). For English, this process is facilitated by the existence of two main SRL annotated corpora – FrameNet (Baker *et al.*, 1998) and PropBank (Palmer *et al.*, 2005). Both datasets mark almost all surface realizations of semantic roles. FrameNet has 800 semantic frames that cover 120,000 example sentences[1]. PropBank has annotations that cover over 113,000 predicate-argument structures. Clearly English is well supported with resources for semantic roles. However, there are other widely spoken resource poor languages that are not as privileged. The PropBank based resources available for languages like Chinese (Xue and Palmer, 2009), Korean (Palmer *et al.*, 2006) and Spanish (Taule, 2008) are only about two-thirds the size of the English PropBank.

Several alternative techniques have been explored in the literature to generate semantic role labeled corpora for resource poor languages as providing manually annotated data is time consuming and involves intense human labor. Ambati and Chen (2007) have conducted an extensive survey and outlined the benefits of using parallel corpora to transfer annotations. A wide range of annotations from part of speech (Hi and Hwa, 2005) and chunks (Yarowsky *et al.*, 2001) to word senses (Diab and Resnik, 2002), dependencies (Hwa *et al.*, 2002) and semantic roles (Pado and Lapata, 2009) have been successfully transferred between languages. FrameNet style annotations in Chinese is obtained by mapping English FrameNet entries directly to concepts listed in HowNet[2] (online ontology for Chinese) with an accuracy of 68% (Fung and Chen, 2004).

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 797–805,
Beijing, August 2010

Fung *et al.* (2007) analyze an automatically annotated English-Chinese parallel corpus and show high cross-lingual agreement for PropBank roles (range of 75%-95% based on the roles).

In this paper we explore the possibility of using English-Urdu parallel corpora to generate SRL annotations for Urdu, a less commonly taught language (LCTL). Earlier attempts to generate SRL corpora using annotation projections have been for languages such as German, French (Pado and Lapata, 2009) and Italian (Moschitti, 2009) that have high vocabulary overlap with English. Also, German belongs to the same language family as English (Germanic family). Urdu on the other hand is an Indic language that is grammatically very different and shares almost no vocabulary with English.

The technique of cross lingual projections warrants good BLEU score that ensures correct word alignments. According to NIST 2008 Open Machine Translation challenge [3], a 0.2280 best BLEU score was achieved for Urdu to English translation. This is comparable to the BLEU scores achieved for German to English – 0.253 and French to English – 0.3 (Koehn, 2005). But, for SRL transfer, perfect word alignment is not mandatory as SRL requires semantic correspondence only. According to Fillmore (1982) semantic frames are based on conceptual structures. They are generalizations over surface structures and hence less prone to syntactic variations. Since English and Urdu have a reasonable semantic correspondence (Example 3), we believe that the projections when capped with a post processing step will considerably reduce the noise induced by inaccurate alignments and produce acceptable mappings.

Hindi is syntactically similar to Urdu. These languages are standardized forms of Hindustani. They are free word order languages and follow a general SOV (Subject-Object-Verb) structure. Projection approach has been used by (Mukerjee *et al.*, 2006) and (Sinha, 2009) to transfer verb predicates from English onto Hindi. Sinha (2009) achieves a 90% F-Measure in verb predicate transfer from English to Hindi. This shows that using cross lingual transfer approach to obtain semantic annotations for Urdu from English is an idea worth exploring.

1.1 Approach

Our approach leverages existing English PropBank annotations provided via the SemLink[4] corpus. SemLink provides annotations for VerbNet using the **pb** (**P**rop**B**ank) attribute. By using English-Urdu parallel corpus we acquire verb predicates and their arguments. When we transfer verb predicates (lemmas), we also transfer **pb** attributes. We obtain annotation projections from the parallel corpora as follows:

1. Take a pair of sentences *E* (in English) and *U* (in Urdu) that are translations of each other.
2. Annotate *E* with semantic roles.
3. Project the annotations from *E* onto *U* using word alignment information, lexical information and linguistic rules that involve syntactic information.

There are several challenges to the annotation projection technique. Dorr (1994) presents some major lexical-semantic divergence problems applicable in this scenario:

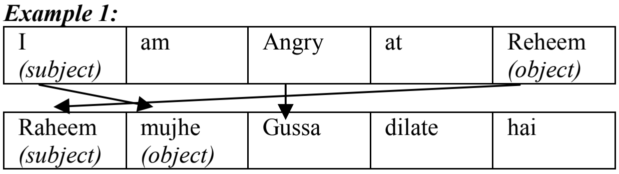
(a) Thematic Divergence - In some cases, although there exists semantic parallelism, the theme of the English sentence captured in the subject changes into an object in the Urdu sentence (Example 1).

(b) Conflatational Divergence - Sometimes target translations spans over a group of words (Example 1: *plays* is mapped to *kirdar ada).* Trying to ascertain this word span for semantic roles is difficult as the alignments can be incomplete and very noisy.

(c) Demotional divergence and Structural divergence - Despite semantic relatedness, in some sentence pairs, alignments obtained from simple projections generate random matchings as the usage is syntactically dissimilar (Example 2).

Handling all challenges adds complexity to our model. The heuristic rules that we implement are guided by linguistic knowledge of Urdu. This increases the effectiveness of the alignments.

Example 1:



I *(subject)*	am	Angry	at	Reheem *(object)*

Raheem *(subject)*	mujhe *(object)*	Gussa	dilate	hai

(Raheem brings anger in me)

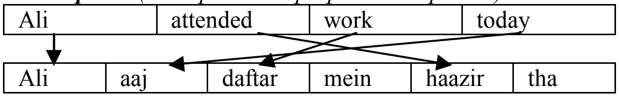
Example 2: *(noun phrase to prepositional pharse)*



(Ali was present at work today)

2 Generating Parallel Corpora

PropBank provides SRL annotated corpora for English. It uses predicate independent labels (ARG0, ARG1, etc.) which indicate how a verb relates to its arguments. The argument types are consistent across all uses of a single verb and do not consider the sense of the verb. We use the PropBank annotations provided for the Wall Street Journal (WSJ) part of the Penn Tree bank corpus (Marcus *et al.*, 2004). The arguments of a verb are labeled sequentially from ARG0 to ARG5 where ARG0 is the proto-typical Agent, ARG1 is the proto-typical patient, ARG2 is the recipient, and so on. There are other adjunct tags in the dataset that are indicated by ARGM that include tags for location (ARGM-LOC), temporal tags (ARGM-TMP) etc.

An Urdu corpus of 6000 sentences corresponding to 317 WSJ articles of Penn Tree Bank corpus is provided by CRULP[5] (used in the NIST 2008 machine translation task). We consider 2350 English sentences with PropBank annotations that have corresponding Urdu translations (CRULP corpus) for our experiments.

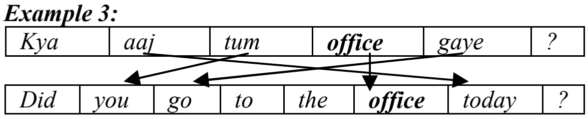
2.1 Sentence Alignment

Sentence alignment is a prerequisite for any parallel corpora processing. As the first step, we had to generate a perfect sentence aligned parallel corpus as the translated sentences, despite belonging to the same domain (WSJ – Penn tree bank), had several errors in demarcating the sentence boundaries.

Sentence alignment between English and Urdu is achieved over two iterations. In the first iteration, the length of each sentence is calculated based on the occurrence of words belonging to important part of speech categories such as proper nouns, adjectives and verbs. Considering main POS categories for length assessment helps overcome the conflatational divergence issue. For each English sentence, Urdu sentences with the same length are considered to be probable candidates for alignment. In the second iteration, an Urdu-English lexicon is used on the Urdu corpus and English translations are obtained. An English-Urdu sentence pair with maximum lexical match is considered to be sentence aligned.

Clearly this method is highly dependent on the existence of an exhaustive Urdu-English dictionary. The lexicons that we use to perform lookups are collected by mining Wikipedia and other online resources (Mukund *et al.,* 2010). However, lexicon lookups will fail for Out-Of-Vocabulary words. There could also be a collision if Urdu sentences have English transliterated words (Example 3, *"office"*). Such errors are manually verified for correctness.

Example 3:



2.2 Word Alignment

In the case of generating word alignments it is beneficial to calculate alignments in both translation directions (English – Urdu and Urdu - English). This nature of symmetry will help to reduce alignment errors. We use the Berkeley Aligner[6] word alignment package which implements a joint training model with posterior decoding (Liang *et al.*, 2006) to consider bidirectional alignments. Predictions are made based on the agreements obtained by two bidirectional models in the training phase. The intuitive objective function that incorporates data likelihood and a measure of agreement between the models is maximized using an EM-like algorithm. This alignment model is known to provide 29% reduction in AER over IBM model 4 predictions.

On our data set the word alignment accuracy is 71.3% (calculated over 200 sentence pairs). In order to augment the alignment accuracy, we added 3000 Urdu-English words and phrases obtained from the Urdu-English dictionary to our parallel corpus. The alignment accuracy improved by 3% as the lexicon affects the word cooccurrence count.

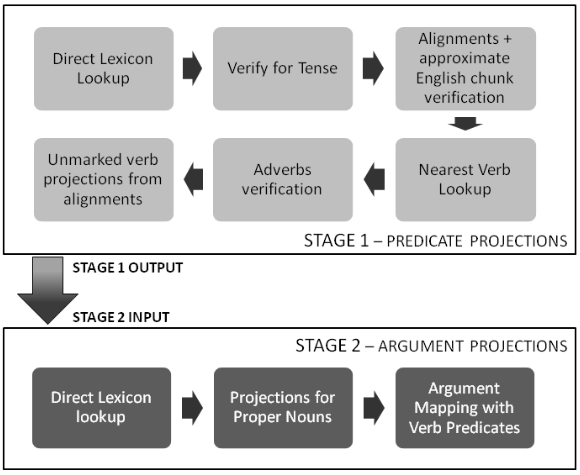
Word alignment in itself does not produce accurate semantic role projections from English to Urdu. This is because the verb predicates in Urdu can span more than one token. Semantic roles

[5] http://www.crulp.org/

[6] http://nlp.cs.berkeley.edu/Main.html

can cover sentential constituents of arbitrary length, and simply using word alignments for projection is likely to result in wrong role spans. Also, alignments are not obtained for all words. This could lead to missing projections.

One way to correct these alignment errors is to devise token based heuristic rules. This is not very beneficial as writing generic rules is difficult and different errors demand specific rules. We propose a method that considers POS, tense and chunk information along with word alignments to project annotations.



Direct Lexicon Lookup
Verify for Tense
Alignments + approximate English chunk verification
Nearest Verb Lookup
Adverbs verification
Unmarked verb projections from alignments
STAGE 1 – PREDICATE PROJECTIONS
STAGE 1 OUTPUT
STAGE 2 INPUT
STAGE 2 – ARGUMENT PROJECTIONS
Direct Lexicon lookup
Projections for Proper Nouns
Argument Mapping with Verb Predicates

Figure 1: Projection model

Our proposed approach can be explained in two stages as shown in figure 1. In Stage 1 only verb predicates are transferred from English to Urdu. Stage 2 involves transfer of arguments and depends on the output of Stage 1. Predicate transfer cannot rely entirely on word alignments (§3). Rules devised around the chunk boundaries boost the verb predicate recognition rate.

Any verb group sequence consisting of a main verb and its auxiliaries are marked as a verb chunk. Urdu data is tagged using the chunk tag set proposed exclusively for Indian languages by Bharati *et al.*, (2006). Table 1 shows the tags that are important for this task.

Verb Chunk	Description
VGF	Verb group is finite (decided by the auxiliaries)
VGNF	Verb group for non-finite adverbial and adjectival chunk
VGNN	Verb group has a gerund

Table 1: Verb chunk tags in Urdu

The sentence aligned parallel corpora that we feed as input to our model is POS tagged for both English and Urdu. Urdu data is also tagged for chunk boundaries and morphological features like tense, gender and number information. Named Entities are also marked on the Urdu data set as they help in tagging the ARGM arguments. All the NLP taggers (POS, NE, Chunker, and Morphological Analyzer) used in this work are detailed in Mukund *et al.,* (2010).

English data is not chunked using a conventional chunk tagger. Each English sentence is split into virtual phrases at boundaries determined by the following parts of speech – IN, TO, MD, POS, CC, DT, SYM,: (Penn Tree Bank tagset). These tags represent positions in a sentence that typically mark context transitions (they are mostly the closed class words). We show later how these approximate chunks assist in correcting predicate mappings.

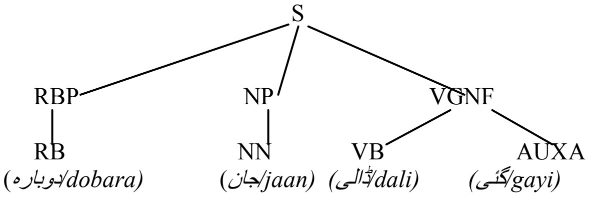
We use an Urdu-English dictionary (§2.1) that assigns English meanings to Urdu words in each sentence. Using translation information from a dictionary can help transfer verb predicates when the translation equivalent preserves the lexical meaning of the source language.

The first rule that gets applied for predicate transfer is based on lexicon lookup. If the English verb is found to be a synonym to an Urdu word that is part of a verb chunk, then the lemma associated with the English word is transferred to the entire verb chunk in Urdu. However not all translations' equivalents are lexically synonymous. Sometimes the word used in Urdu is different in meaning to that in English but relevant in the context (lexical divergence).

The word alignments considered in proximity to the approximate English chunks come to rescue in such scenarios. Here, for all the words occurring in each Urdu verb chunk, corresponding English aligned words are found from the word alignments. If the words that are found belong to the same approximate English chunk, then the verb predicate of that chunk (if present) is projected onto the verb chunk in Urdu. This heuristic technique increases the verb projection accuracy by about 15% as shown in §4.

The Penn tree bank tag set for English part of speech has different tags for verbs based on the tense information. VBD is used to indicate past tense, and VBP and VBZ for present tense. Urdu also has the tense information associated with the verbs in some cases. We exploit this similarity to project the verb predicates from English onto Urdu.

The adverbial chunk in Urdu includes pure adverbial phrases. These chunks also form part of the verb predicates.



[English meaning – Revitalized]

Figure 2: example for demotional divergence

E.g. consider the English word “revitalized” (figure 2). This is tagged VBD. However, the Urdu equivalent of this word is *“دوبارہ جان ڈالی گئی” (dobara jaan daali gayi ~ to put life in again)*. The POS tags are “RB, NN, VB, AUXA” *(adverb, noun, verb, aspectual auxiliary)*. The word *“dobara”* is a part of the adverbial chunk RBP and the infinite verb chunk VGNF spans across the last two words *“daali gayi”*. *“jaan”* is a noun chunk. This kind of demotional divergence is commonly observed in languages like Hindi and Urdu. In order to consider this entire phrase to be the Urdu equivalent representation of the English word *“revitalized”,* a rule for adverbial chunk is included as the last step to account for unaccommodated English verbs in the projections.

In the PropBank corpus, predicate argument relations are marked for almost all occurrences of non-copula verbs. We however do not have POS tags that help to identify non-copula words. Words that can be auxiliary verbs occur as non-copula verbs in Urdu. We maintain a list of such auxiliary verbs. When the verb chunk in Urdu contains only one word and belongs to the list, we simply ignore the verb chunk and proceed to the next chunk. This avoids several false positives in verb projections.

Stage 2 of the model includes the transfer of arguments. In order to see how well our method works, we project all argument annotations from English onto Urdu. We do not consider word alignments for arguments with proper nouns. The double metaphone algorithm (Philips 2000) is applied on both English NNP (proper noun) tagged words as well as English transliterated Urdu (NNP) tagged words. Arguments from English are mapped onto Urdu for word pairs with the same metaphone code.

For other arguments, we consider word alignments in proximity to verb predicates. The argument boundaries are determined based on chunk and POS information. We observe that our method projects the annotations associated with nouns fairly well. However, when the arguments contain adjectives, the boundaries are discontinuous. In such cases, we consider the entire chunk without the case marker as a probable candidate for the projected argument. We also have some issues with the ARGM-MOD arguments in that they overlap with the verb predicates. When the verb predicate that it overlaps with is a complex predicate, we consider the entire verb chunk to be the Urdu equivalent candidate argument. These rules along with word alignments yield fairly accurate projections.

The rules that we propose are dependent on the POS, chunk and tense information that are language specific. Hence our method is language independent only to the extent that the new language considered should have similar syntactic structure as Urdu. Indic languages fall in this category.

3 Verb Predicates

Detecting verb predicates can be a challenging task especially if very reliable and efficient tools such as POS tagger and chunkers are not available. We apply the POS tagger (CRULP tagset, 88% F-Score) and Chunker (Hindi tagset, 90% F-Score) provided by Mukund *et al.,* (2010) on the Urdu data set and show that syntactic information helps to compensate alignment errors. Stanford POS tagger[7] (Penn Tree bank tagset) is applied on the English data set.

Predicates can be simple predicates that lie within the chunk boundary or complex predicates when they span across chunk boundaries. When verbs in English are expressed in Urdu/Hindi, in several cases, more than one word is used to achieve perfect translation. In English the tense of the verb is mostly captured by the verb morpheme such as *“ask**ed**” “sa**id**” “say**ing**”*. In Urdu the tense is mostly captured by the auxiliary verbs. So a single word English verb such as *“talking”* would be translated into two words

[7] http://nlp.stanford.edu/software/tagger.shtml

"batein karna" where *"karna"~ do* is the auxiliary verb. However this cannot be generalized as there are instances when translations are word to word. E.g. *"said"* is mapped to a single word Urdu verb *"kaha"*.

Complex predicates in Urdu can occur in the following POS combinations. *Noun+Verb, Adjective+Verb, Verb+Verb, Adverb+Verb*. Table 2 lists the main verb tags present in the Urdu POS tagset. (refer Penn Tree bank POS tagset for English tags).

Urdu Tags	Description
VB	Verb
VBI	Infinitive Verb
VBL	Light Verb
VBLI	Infinitive Light Verb
VBT	Verb to be
AUXA	Aspectual Auxiliary
AUXT	Tense Auxiliary

Table 2: Verb tags

Auxiliary verbs in Urdu occur alongside VB, VBI, VBL or VBLI tags. Sinha (2009) defines complex predicates as a group of words consisting of a noun (NN/NNP), an adjective (JJ), a verb (VB) or an adverb (RB) followed by a light verb (VBL/VBLI). Light verbs are those which contribute to the tense and agreement of the verb (Butt and Geuder, 2001). However, despite the existence of a light verb tag, it is noticed that in several sentences, verbs followed by auxiliary verbs need to be grouped as a single predicate. Hence, we consider such combinations as belonging to the complex predicate category.

ENG- *According*_VBG *to*_TO *some*_DT *estimates*_NNS *the*_DT *rule*_NN *changes*_NNS *would*_MD ***cut_VB*** *insider*_NN *filings*_NNS *by*_IN *more*_JJR *than*_IN *a*_DT *third*_JJ
URD- [*Kuch*_QN *andaazon*_NN *ke*_CM *mutabiq*_NNCM]_NP [*kanoon*_NN *mein*_CM]_NP [*tabdeeliayan*_NN]_NP[*androni*_JJ *drjbndywn*_NN *ko*_CM]_NP [*ayk*_CD *thayiy*_FR *se*_CM]_NP [***zyada***_I ***kam***_JJ]_JJP [***karey***_VBL ***gi***_AUXT]_VGF

Example 4

Example 4 demonstrates the existence of a light verb in a complex predicate. The English verb *"cut"* is mapped to *"کم کریں گی" (kam karey gi)* belonging to the VBF chunk group.

ENG- *Rolls*_NNP *-*_*:* *Royce*_NNP *Motor*_NNP *Cars*_NNPS *Inc.*_NNP ***said***_VBD *it*_PRP ***expects***_VBZ *its*_PRP*$* *U.S.*_NNP *sales*_NNS *to*_TO ***remain***_VB *steady*_JJ *at*_IN *about*_IN *1 200*_CD *cars*_NNS *in*_IN *1990*_CD
URD - [*Rolls Royce motor car inc*_NNPC *ne*_CM]_NP [***kaha*_VB**]_VBNF [*wo*_PRP]_NP [*apney*_PRRFP$]_NP [*U.S.*_NNP *ki*_CM]_NP [*frwKt*_NN *ko*_CM]_NP [*1990*_CD *mein*_CM]_NP [*takreeban*_RB]_RBP [*1200_CD karon*_NN *par*_CM]_NP [*mtwazn*_JJ]_JJP [*rakhne*_VBI *ki*_CM]_VGNN [*tawaqqo*_NN]_NP [*karte*_VB *hai*_AUXT]_VGF

Example 5

In example 5, *"said"* corresponds to one Urdu word *"کہا"(kaha)* that also captures the tense information (past). However, consider the verb *"expects"*. This is a clear case of noun-verb complex predicate where *"expects"* is mapped to *"توقع کرتی ہے"(tawaqqo karte hai)*.

ENG- *Not*_RB *all*_PDT *those*_DT *who*_WP ***wrote***_VBD ***oppose***_VBP *the*_DT *changes*_NNS
URD -*wo tamaam jinhon ne* ***likha*** *tabdeeliyon ke* [***mukhalif***_JJ]_JJP [*nahi*_RB]_RBP [***hain***_VBT]_VGF

Example 6

In example 6, verb predicates are *"wrote"* and *"oppose"*. Consider the word *"oppose"*. There are two ways of representing this word in Urdu. As a verb chunk the translation would be ***"mukhalifat** nahi karte"* and as an adjectival chunk *"**mukhalif** nahi hai"*. The latter form of representation is used widely in the available translation corpus. The Urdu equivalent *of "oppose"* is *"مخالف ہیں"(mukhalif hai).*

Another interesting observation in example 6 is the existence of discontinuous predicates. Though *"oppose"* is one word in English, the Urdu representation has two words that do not occur together. The adverb *"nahi"* ~*"not"* occurs between the adjective and the verb. Statistically dealing with this issue is extremely challenging and affects the boundaries of other arguments. Generalizing the rules needed to identify discontinuous predicates requires more detailed analysis of the corpus – from the linguistic aspect – and has not been attempted in this paper. We however map *"مخالف نہیں ہیں"(mukhalif nahi hai)* to the predicate *"oppose"*. *"nahi"* is treated as an argument ARG_NEG in PropBank.

4 Projection Results

It is impossible for us to report our projection results on the entire data set as we do not have it manually annotated. For the purpose of evaluation, we manually annotated 100 long sentences (L) and 100 short sentences (S) from the full 2350 sentence set. All the results are reported on this 200 set of sentences. Set L has sentences that each has more than two verb predicates and several arguments. The number of words per sentence here is greater than 55. S; on the other hand has sentences with about 40 words each and no complex SOV structures.

The results shown in Table 3 are for all tags (verbs+args) that are projected from English onto Urdu. In order to understand why the performance over L dips, consider the results in Table 4 that are for verb projections only. Some long sentences in English have Urdu translations that do not maintain the same structure. For example an English phrase – *"... might **prompt** individuals to **get** out of stocks altogether"* is written in Urdu in a way that the English representation would be *"what makes individuals to **get** out of stocks is ..."*. The Urdu equivalent word for *"prompt"* is missing and the associated lemma gets assigned to the Urdu equivalent of *"get"* (the next lemma). This also affects the argument projections. Another reason is the effect of word alignments itself. Clearly longer sentences have greater alignment errors.

All tags[8]	100 long sentences	100 short sentences
Actual Tags	1267	372
Correct Tags	943	325
Found Tags	1212	353
L : Precision 77.8% Recall 74.4% F-Score 76%		
S: Precision 92% Recall 87.4% F-Score 89.7%		

Table 3: when all tags are considered

Comparing the results of Table 4 to Table 3, we see that argument projections affect the recall. This is because the projections of arguments depend not only on the word alignments but also on the verb predicates. Incorrect verb predicates affect the argument projections.

Only lemma	100 long sentences	100 short sentences
Actual Tags	670	240
Correct Tags	490	208
Overall Tags	720	257
L: Precision 68% Recall 73.1% F-Score 70.45%		
S : Precision 80.9% Recall 86.6% F-Score 83.65%		

Table 4: for verb projections only

Table 5 summarizes the results obtained when only the word alignments are considered to project all tags. But when virtual phrase boundaries in English are also considered, the F-score improves by 8% (Table 6). This is because virtual boundaries in a way mark context switch and when considered in proximity to the word alignments yield better predicate boundaries.

100 long sentences : only alignments	
Actual Tags	1267
Correct Tags	617
Overall Tags	782
Precision 78.9% Recall 48.7% F-Score 60.2%	

Table 5: with only word alignments

100 long sentences : alignments + virtual boundaries	
Actual Tags	1267
Correct Tags	792
Overall Tags	1044
Precision 75.8% Recall 62.5% F-Score 68.5%	

Table 6: with word alignments and virtual boundaries

100 Sentences	ARG 0	ARG 1	ARG 2	ARG 3	ARG M
Long	124	271	67	25	140
Found	111	203	36	12	114
P %	89.5	74.9	53.7	48	81.42
Short	34	47	4	2	19
Found	30	45	4	2	19
P %	88.2	95.7	100	100	100

Table 7: results of argument projections Precision (P) on arguments

Table 7 shows the results of argument projections over the first 4 arguments of PropBank – ARG0, ARG1, ARG2 and ARG3 (out of 24 arguments, majority are sparse in our test set) and the adjunct tag set ARGM.

5 Automatic Detection

The size of SRL annotated corpus generated for Urdu is limited with only 2350 sentences. To explore the possibilities of augmenting this data set, we train verb predicate and argument detection models. The results show great promise in generating large-scale automatic annotations.

5.1 Verb Predicate Detection

Verb predicate detection happens in two stages. In the first stage, the predicate boundaries are marked using a CRF (Lafferty *et al.*, 2001) based sequence labeling approach. The training data for the model is generated by annotating the automatically annotated Urdu SRL corpus using BI

[8] Tags - lemma (verb predicates) + arguments, Actual tags – number of tags in the English set, Found tags – number of tags transferred to Urdu, Correct Tags – number of tags correctly transferred

annotations. E.g. *kam* B-VG, k*arne par* I-VG. The non-verb predicates are labeled “-1”. The model uses POS, chunk and lexical information as features. We report the results on a set of 77 sentences containing a mix of short and long sentences.

Number of verb predicates correctly marked	377
Num of verb predicates found	484
Actual num of verb predicates	451
Precision 77.8% Recall 83.5% F-Score 80.54%	

Table 8: CRF results for verb boundaries

Every verb predicate is associated with a lemma mapped from the English VerbNet map file[9]. E.g. the Urdu verb *“کم کرنے پر” (kam karne par)* has the lemma *“lower”*. The second stage includes assigning these lemmas. Lemma assignment is based on lookups from a VerbNet like map file. We have compiled a large set of Urdu verb predicates by mapping translations found in the automatically annotated corpus to the VerbNet map file. This Urdu verb predicate list also accommodates complex predicates that occur along with verbs such as *“karna – to do”, “paana – to get”,* etc. (along with different variations of these verbs – *karte, kiya, paate etc.*). This verb predicate list (manually corrected) consists of 800 entries. Since our gold standard test set is very small, the lemma assignment for all verb predicates is 100% (no **pb** values and hence no senses). This list, however, has to be augmented further to meet the standards of the English VerbNet map file.

5.2 Argument Detection

Argument detection (SRL) is done in two steps: (1) argument boundary detection (2) argument label assignment. We perform tests for step 2 to show how well a standard SVM role detection model works on the automatically generated Urdu data set. For each pair of correct predicate *p* and an argument *i* we create a feature representation $F_{p,a}$ ~ set T of all arguments. To train a multi-class role-classifier, given the set T of all arguments, T can be rationalized as $T^{+}_{\arg i}$ (positive instances) and $T^{-}_{\arg i}$ (negative instances) for each argument *i*. In this way, individual ONE-vs-ALL (Gildea and Jurafsky, 2002) classifier for each argument *i* is trained. In the testing phrase, given an unseen sentence, for each argument $F_{p,q}$ is generated and classified by each individual classifier.

We created a set of *standard* SRL features as shown in table 9. The results (Tables 10 and 11), though not impressive, are promising. We believe that by increasing the number of samples (for each argument) in the training set and intelligently controlling the negative samples, the results can be improved significantly.

Training – 2270 sentences with 7315 argument instances. Test – 77 sentences with 496 argument instances. (22 different role types)

BaseLine Features (BL)	phrase-type (syntactic category; NP, PP etc.), predicate (in our case, verb group), path (syntactic path from the argument constituent to the predicate), head words (argument and the predicate respectively), position (whether the phrase is before or after the predicate)
Detailed Features	BL + POS (of the first word in the predicate), chunk tag of the predicate, POS (of the first word of the constituent argument), head word (of the verb group in a complex predicate), named entity (whether the argument contains any named entity, such as location, person, organization etc.)

Table 9: Features for SRL

Kernel/features	Precision	Recall	F-Score
LK – BL	71.88	48.25	57.74
LK – all	73.91	47.55	57.87
PK – BL	74.19	48.25	58.47
PK –all (best)	73.47	49.65	59.26

Table 10: Arg0 performance

Kernel/features	Precision	Recall	F-Score
LK – BL	69.35	22.87	34.40
LK – all	69.84	23.4	35.05
PK – BL	73.77	24.14	36.38
PK –all (best)	73.8	26.06	38.52

Table 11: Arg1 Performances
(PK - polynomial kernel LK – Linear kernel)

6 Conclusion

In this work, we develop an alignment system that is tailor made to fit the SRL problem scope for Urdu. Furthermore, we have shown that despite English being a totally different language, resources for Urdu can be generated if the subtle grammatical nuances of Urdu are accounted for while projecting the annotations. We plan to work on argument boundary detection and explore other features for argument detection. The lemma set generated for Urdu is being refined for finer granularity.

Abstract

The main task we address in our research is classification of text using fine-grained attitude labels. The developed @AM system relies on the compositionality principle and a novel approach based on the rules elaborated for semantically distinct verb classes. The evaluation of our method on 1000 sentences, that describe personal experiences, showed promising results: average accuracy on the fine-grained level (14 labels) was 62%, on the middle level (7 labels) – 71%, and on the top level (3 labels) – 88%.

1 Introduction and Related Work

With rapidly growing online sources aimed at encouraging and stimulating people's discussions concerning personal, public or social issues (news, blogs, discussion forums, etc.), there is a great need in development of a computational tool for the analysis of people's attitudes. According to the Appraisal Theory (Martin and White, 2005), attitude types define the specifics of appraisal being expressed: affect (personal emotional state), judgment (social or ethical appraisal of other's behaviour), and appreciation (evaluation of phenomena).

To analyse contextual sentiment of a phrase or a sentence, rule-based approaches (Nasukawa and Yi, 2003; Moilanen and Pulman, 2007; Subrahmanian and Reforgiato, 2008), a machine-learning method using not only lexical but also syntactic features (Wilson et al., 2005), and a model of integration of machine learning approach with compositional semantics (Choi and Cardie, 2008) were proposed. With the aim to recognize fine-grained emotions from text on the level of distinct sentences, researchers have employed a keyword spotting technique (Chuang and Wu, 2004; Strapparava et al., 2007), a technique calculating emotion scores using Pointwise Mutual Information (PMI) (Kozareva et al., 2007), an approach inspired by common-sense knowledge (Liu et al., 2003), rule-based linguistic approaches (Boucouvalas, 2003; Chaumartin, 2007), machine-learning methods (Alm, 2008; Aman and Szpakowicz, 2008; Strapparava and Mihalcea, 2008), and an ensemble based multi-label classification technique (Bhowmick et al., 2009).

Early attempts to focus on distinct attitude types in the task of attitude analysis were made by Taboada and Grieve (2004), who determined a potential value of adjectives for affect, judgement and appreciation by calculating the PMI with the pronoun-copular pairs '*I was (affect)*', '*He was (judgement)*', and '*It was (appreciation)*', and Whitelaw et al. (2005), who used a machine learning technique (SVM) with fine-grained semantic distinctions in features (attitude type, orientation) in combination with "bag of words" to classify movie reviews. However, the concentration only on adjectives expressing appraisal and their modifiers greatly narrows the potential of the Whitelaw et al. (2005) approach.

In this paper we introduce our system @AM (**AT**titude **A**nalysis **M**odel), which (1) classifies sentences according to the fine-grained attitude labels (nine affect categories (Izard, 1971): 'anger', 'disgust', 'fear', 'guilt', 'interest', 'joy', 'sadness', 'shame', 'surprise'; four polarity labels for judgment and appreciation: 'POS jud', 'NEG jud', 'POS app', 'NEG app'; and 'neutral'); (2) assigns the strength of the attitude; and (3) determines the level of confidence, with which the attitude is expressed. @AM relies on a compositionality principle and a novel approach

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 806–814,
Beijing, August 2010

based on the rules elaborated for semantically distinct verb classes.

2 Lexicon for Attitide Analysis

We built a lexicon for attitude analysis that includes: (1) attitude-conveying terms; (2) modifiers; (3) “functional” words; and (4) modal operators.

2.1 The Core of Lexicon

As a core of lexicon for attitude analysis, we employ an Affect database and extended version of the SentiFul database developed by Neviarouskaya et al. (2009). The affective features of each emotion-related word are encoded using nine emotion labels (‘anger’, ‘disgust’, ‘fear’, ‘guilt’, ‘interest’, ‘joy’, ‘sadness’, ‘shame’, and ‘surprise’) and corresponding emotion intensities that range from 0.0 to 1.0. The original version of SentiFul database, which contains sentiment-conveying adjectives, adverbs, nouns, and verbs annotated by sentiment polarity, polarity scores and weights, was manually extended using attitude labels. Some examples of annotated attitude-conveying words are listed in Table 1. It is important to note here that some words may express different attitude types (affect, judgment, appreciation) depending on context; such lexical entries were annotated by all possible categories.

POS	Word	Category	Intensity
adjective	*honorable*	POS jud	0.3
	unfriendly	NEG aff (sadness)	0.5
		NEG jud	0.5
		NEG app	0.5
adverb	*gleefully*	POS aff (joy)	0.9
noun	*abnormality*	NEG app	0.25
verb	*frighten*	NEG aff (fear)	0.8
	desire	POS aff (interest)	1.0
		POS aff (joy)	0.5

Table 1. Examples of attitude-conveying words and their annotations.

2.2 Modifiers and Functional Words

We collected 138 modifiers that have an impact on contextual attitude features of related words, phrases, or clauses. They include:

1. Adverbs of degree (e.g., ‘*significantly*’, ‘*slightly*’ etc.) and affirmation (e.g., ‘*absolutely*’, ‘*seemingly*’) that have an influence on the strength of the attitude of related words. Two annotators gave coefficients for intensity degree strengthening or weakening (from 0.0 to 2.0) to each adverb, and the result was averaged (e.g., coeff(‘*slightly*’) = 0.2).
2. Negation words (e.g., ‘*never*’, ‘*nothing*’ etc.) reversing the polarity of related statement.
3. Adverbs of doubt (e.g., ‘*scarcely*’, ‘*hardly*’ etc.) and falseness (e.g., ‘*wrongly*’ etc.) reversing the polarity of related statement.
4. Prepositions (e.g., ‘*without*’, ‘*despite*’ etc.) neutralizing the attitude of related words.
5. Condition operators (e.g., ‘*if*’, ‘*even though*’ etc.) that neutralize the attitude of related words.

We distinguish two types of “functional” words that influence contextual attitude and its strength:

1. *Intensifying* adjectives (e.g., ‘*rising*’, ‘*rapidly-growing*’), nouns (e.g., ‘*increase*’), and verbs (e.g., ‘*to grow*’, ‘*to rocket*’) that increase the strength of attitude of related words.
2. *Reversing* adjectives (e.g., ‘*reduced*’), nouns (e.g., ‘*termination*), and verbs (e.g., ‘*to decrease*’, ‘*to limit*’, ‘*to diminish*’), which reverse the prior polarity of related words.

2.3 Modal Operators

Consideration of the modal operators in the tasks of opinion mining and attitude analysis is very important, as they indicate a degree of person’s belief in the truth of the proposition, which is subjective in nature (Hoye, 1997). Modals are distinguished by their *confidence level*. We collected modal operators of two categories: modal verbs (13 verbs) and modal adverbs (61 adverbs). Three human annotators assigned the *confidence level* ranging from 0.0 to 1.0 to each modal verb and adverb; these ratings were averaged (e.g., conf(‘*vaguely*’) = 0.17, conf(‘*arguably*’) = 0.63, conf(‘*would*’) = 0.8, conf(‘*veritably*’) = 1.0).

3 Compositionality Principle

Our algorithm for attitude classification is designed based on the *compositionality principle*, according to which we determine the attitudinal meaning of a sentence by composing the pieces that correspond to lexical units or other linguistic constituent types governed by the rules of *polarity reversal, aggregation (fusion)*, *propagation*, *domination*, *neutralization*, and *intensification*, at various grammatical levels.

Polarity reversal means that a phrase or statement containing an attitude-conveying term/phrase with prior positive polarity becomes negative, and vice versa. The rule of *polarity reversal* is applied in three cases: (1) negation word-modifier in relation with an attitude-conveying statement (e.g., '*never*' & POS('*succeed*') => NEG('*never succeed*')); (2) adverb of doubt in relation with attitude-conveying statement (e.g., '*scarcely*' & POS('*relax*') => NEG('*scarcely relax*')); (3) functional word of *reversing* type in relation with attitude-conveying statement (e.g., adjective '*reduced*' & POS('*enthusiasm*') => NEG('*reduced enthusiasm*')). In the case of judgment and appreciation, the use of the *polarity reversal* rule is straightforward ('POS jud' <=> 'NEG jud', 'POS app' <=> 'NEG app'). However, it is not trivial to find pairs of opposite emotions in the case of a fine-grained classification, except for 'joy' and 'sadness'. Therefore, we assume that (1) the opposite emotion for three positive emotions, i.e. 'interest', 'joy', and 'surprise', is 'sadness' ('POS aff' => 'sadness'); and (2) the opposite emotion for six negative emotions, i.e. 'anger', 'disgust', 'fear', 'guilt', 'sadness', and 'shame', is 'joy' ('NEG aff' => 'joy').

The rules of *aggregation (fusion)* are as follows: (1) if polarities of attitude-conveying terms in adjective-noun, noun-noun, adverb-adjective, adverb-verb phrases have opposite directions, mixed polarity with dominant polarity of a pre-modifier is assigned to the phrase (e.g., POS('*beautiful*') & NEG('*fight*') => POS-neg('*beautiful fight*'); NEG('*shamelessly*') & POS('*celebrate*') => NEG-pos('*shamelessly celebrate*')); otherwise (2) the resulting polarity is based on the equal polarities of terms, and the strength of attitude is measured as a maximum between polarity scores (intensities) of terms (*max*(score1,score2)).

The rule of *propagation* is useful, as proposed in (Nasukawa and Yi, 2003), for the task of the detection of local sentiments for given subjects. "Propagation" verbs propagate the sentiment towards the arguments; "transfer" verbs transmit sentiments among the arguments. The rule of *propagation* is applied when a verb of "propagation" or "transfer" type is used in a phrase/clause and sentiment of an argument that has prior neutral polarity needs to be investigated (e.g., PROP-POS('*to admire*') & '*his behaviour*' => POS('*his behaviour*'); '*Mr. X*' & TRANS('*supports*') & NEG('*crime business*') => NEG('*Mr. X*')).

The rules of *domination* are as follows: (1) if polarities of a verb (this rule is applied only for certain classes of verbs) and an object in a clause have opposite directions, the polarity of verb is prevailing (e.g., NEG('*to deceive*') & POS('*hopes*') => NEG('*to deceive hopes*')); (2) if compound sentence joints clauses using coordinate connector '*but*', the attitude features of a clause following after the connector are dominant (e.g., 'NEG(*It was hard to climb a mountain all night long*), *but* POS(*a magnificent view rewarded the traveler at the morning*).' => POS(whole sentence)).

The rule of *neutralization* is applied when preposition-modifier or condition operator relate to the attitude-conveying statement (e.g., '*despite*' & NEG('*worries*') => NEUT('*despite worries*')).

The rule of *intensification* means strengthening or weakening of the polarity score (intensity), and is applied when:

1. adverb of degree or affirmation relates to attitude-conveying term (e.g., Pos_score('*happy*') < Pos_score('*extremely happy*'));
2. adjective or adverb is used in a comparative or superlative form (e.g., Neg_score('*sad*') < Neg_score('*sadder*') < Neg_score ('*saddest*')).

Our method is capable of processing sentences of different complexity, including simple, compound, complex (with complement and relative clauses), and complex-compound sentences. We employ Connexor Machinese Syntax parser (`http://www.connexor.eu/`) that returns lemmas, parts of speech, dependency functions, syntactic function tags, and morphological tags. When handling the parser output, we represent the sentence as a set of primitive clauses. Each clause might include Subject formation, Verb formation and Object formation, each of which may consist of a main element (subject, verb, or object) and its attributives and complements. For the processing of complex or compound sentences, we build a so-called "relation matrix", which contains information about dependences (e.g., coordination, subordination, condition, contingency, etc.) between different clauses in a sentence. While applying the compositionality principle, we consecutively assign attitude features to words, phrases, formations, clauses, and finally, to the whole sentence.

4 Consideration of the Semantics of Verbs

All sentences must include a verb, because the verb tells us what action the subject is performing and object is receiving. In order to elaborate rules for attitude analysis based on the semantics of verbs, we investigated VerbNet (Kipper et al., 2007), the largest on-line verb lexicon that is organized into verb classes characterized by syntactic and semantic coherence among members of a class. Based on the thorough analysis of 270 first-level classes of VerbNet and their members, 73 verb classes (1) were found useful for the task of attitude analysis, and (2) were further classified into 22 classes differentiated by the role that members play in attitude analysis and by rules applied to them. Our classification is shown in Table 2.

For each of our verb classes, we developed set of rules that are applied to attitude analysis on the phrase/clause-level. Some verb classes (e.g., "*Psychological state or emotional reaction*", "*Judgment*", "*Bodily state and damage to the body*", "*Preservation*" etc.) include verbs annotated by attitude type, prior polarity orientation, and the strength of attitude. The attitude features of phrases that involve positively or negatively charged verbs from such classes are context-sensitive and are defined by means of rules designed for each of the class.

As an example, we provide short description and rules elaborated for the subclass "*Object-centered (oriented) emotional state*".

Features: subject experiences emotions towards some stimulus; verb prior polarity: positive or negative; context-sensitive.

Verb-Object rules (subject is ignored):

1. "Interior perspective" (subject's inner emotion state or attitude):

S & V+('*admires*') & O+('*his brave heart*') => (fusion, *max*(V_score,O_score)) => 'POS aff'.

S & V+('*admires*') & O-('*mafia leader*') => (verb valence dominance, V_score) => 'POS aff'.

S & V-('*disdains*') & O+('*his honesty*') => (verb valence dominance, V_score) => 'NEG aff'.

S & V-('*disdains*') & O-('*criminal activities*') => (fusion, *max*(V_score,O_score)) => 'NEG aff'.

2. "Exterior perspective" (social/ethical judgment):

S & V+('*admires*') & O+('*his brave heart*') => (fusion, *max*(V_score,O_score)) => 'POS jud'.

S & V+('*admires*') & O-('*mafia leader*') => (verb valence reversal, *max*(V_score,O_score)) => 'NEG jud'.

S & V-('*disdains*') & O+('*his honesty*') => (verb valence dominance, *max*(V_score,O_score)) => 'NEG jud'.

S & V-('*disdains*') & O-('*criminal activities*') => (verb valence reversal, *max*(V_score,O_score)) => 'POS jud'.

Verb class (verb samples)
1 Psychological state or emotional reaction
1.1 Object-centered (oriented) emotional state (*adore*)
1.2 Subject-driven change in emotional state (trans.) (*charm*, *inspire*, *bother*)
1.3 Subject-driven change in emotional state (intrans.) (*appeal to*, *grate on*)
2 Judgment
2.1 Positive judgment (*bless*, *honor*)
2.2 Negative judgment (*blame*, *punish*)
3 Favorable attitude (*accept*, *allow*, *tolerate*)
4 Adverse (unfavorable) attitude (*discourage*, *forbid*)
5 Favorable or adverse calibratable changes of state (*grow*, *decline*)
6 Verbs of removing
6.1 Verbs of removing with neutral charge (*delete*)
6.2 Verbs of removing with negative charge (*expel*)
6.3 Verbs of removing with positive charge (*evacuate*)
7 Negatively charged change of state (*break*, *crush*)
8 Bodily state and damage to the body (*sicken*, *injure*)
9 Aspectual verbs
9.1 Initiation, continuation of activity, and sustaining (*begin*, *continue*, *maintain*)
9.2 Termination of activity (*quit*, *finish*)
10 Preservation (*defend*, *insure*)
11 Verbs of destruction and killing (*damage*, *poison*)
12 Disappearance (*disappear*, *die*)
13 Limitation and subjugation (*confine*, *restrict*)
14 Assistance (*succor*, *help*)
15 Obtaining (*win*, *earn*)
16 Communication indicator/reinforcement of attitude (*guess*, *complain*, *deny*)
17 Verbs of leaving (*abandon*, *desert*)
18 Changes in social status or condition (*canonize*)
19 Success and failure
19.1 Success (*succeed*, *manage*)
19.2 Failure (*fail*, *flub*)
20 Emotional nonverbal expression (*smile*, *weep*)
21 Social interaction (*marry*, *divorce*)
22 Transmitting verbs (*supply*, *provide*)

Table 2. Verb classes for attitude analysis.

3. In case of neutral object => attitude type and prior polarity of verb, verb score (V_score).

Verb-PP (prepositional phrase) rules:

1. In case of negatively charged verb and PP starting with '*from*' => verb dominance:

S & V-('*suffers*') & PP-('*from illness*') => interior: 'NEG aff'; exterior: 'NEG jud'.

S & V-('*suffers*') & PP+ ('*from love*') => interior: 'NEG aff'; exterior: 'NEG jud'.

2. In case of positively charged verb and PP starting with '*in*'/'*for*' => treat PP the same way as object (see above):

S & V+('*believes*') & PP-('*in evil*') => interior: 'POS aff'; exterior: 'NEG jud'.

S & V+('*believes*') & PP+('*in kindness*') => interior: 'POS aff'; exterior: 'POS jud'.

In the majority of rules the strength of attitude is measured as a maximum between attitude scores (for example, the attitude conveyed by '*to suffer from grave illness*' is stronger than that of '*to suffer from slight illness*').

In contrast to the rules of "*Object-centered (oriented) emotional state*" subclass, which ignore attitude features of a subject in a sentence, the rules elaborated for the "*Subject-driven change in emotional state (trans.)*" disregard the attitude features of object, as in sentences involving members of this subclass object experiences emotion, and subject causes the emotional state. For example (due to limitation of space, here and below we provide only some cases):

S('*Classical music*') & V+('*calmed*') & O-('*disobedient child*') => interior: 'POS aff'; exterior: 'POS app'.

S-('*Fatal consequences of GM food intake*') & V-('*frighten*') & O('*me*') => interior: 'NEG aff'; exterior: 'NEG app'.

The Verb-Object rules for the "*Judgment*" subclasses, namely "*Positive judgment*" and "*Negative judgment*", are very close to those defined for the subclass "*Object-centered (oriented) emotional state*". However, Verb-PP rules have some specifics: for both positive and negative judgment verbs, we treat PP starting with '*for*'/'*of*'/'*as*' the same way as object in Verb-Object rules. For example:

S('*He*') & V-('*blamed*') & O+('*innocent person*') => interior: 'NEG jud'; exterior: 'NEG jud'.

S('*They*') & V-('*punished*') & O('*him*') & PP-('*for his misdeed*') => interior: 'NEG jud'; exterior: 'POS jud'.

Verbs from classes "*Favorable attitude*" and "*Adverse (unfavorable) attitude*" have prior neutral polarity and positive or negative reinforcement, correspondingly, that means that they only impact on the polarity and strength of non-neutral phrase (object in a sentence written in active voice, or subject in a sentence written in passive voice, or PP in case of some verbs). The rules are:

1. If verb belongs to the "*Favorable attitude*" class and the polarity of phrase is not neutral, then the attitude score of the phrase is intensified (symbol '^' means intensification):

S('*They*') & [V pos. reinforcement]('*elected*') & O+('*fair judge*') => 'POS app'; O_score^.

S('*They*') & [V pos. reinforcement]('*elected*') & O-('*corrupt candidate*') => 'NEG app'; O_score^.

2. If verb belongs to the "*Adverse (unfavorable) attitude*" class and the polarity of phrase is not neutral, then the polarity of phrase is reversed and score is intensified:

S('*They*') & [V neg. reinforcement]('*prevented*') & O-('*the spread of disease*') => 'POS app'; O_score^.

S+('*His achievements*') & [V neg. reinforcement]('*were overstated*') => 'NEG app'; S_score^.

Below are examples of processing the sentences with verbs from "*Verbs of removing*" class.

"*Verbs of removing with neutral charge*":

S('*The tape-recorder*') & [V neutral rem.]('*automatically ejects*') & O-neutral('*the tape*') => neutral.

S('*The safety invention*') & [V neutral rem.]('*ejected*') & O('*the pilot*') & PP-('*from burning plane*') => 'POS app'; PP_score^.

"*Verbs of removing with negative charge*":

S('*Manager*') & [V neg. rem.]('*fired*') & O-('*careless employee*') & PP('*from the company*') => 'POS app'; *max*(V_score,O_score).

"*Verbs of removing with positive charge*":

S('*They*') & [V pos. rem.]('*evacuated*') & O('*children*') & PP-('*from dangerous place*') => 'POS app'; *max*(V_score,PP_score).

Along with modal verbs and modal adverbs, members of the "*Communication indicator/reinforcement of attitude*" verb class also indicate the confidence level or degree of certainty concerning given opinion. Features are: subject (communicator) expresses statement with/without attitude; statement is PP starting with '*of*', '*on*', '*against*', '*about*', '*concerning*', '*regarding*', '*that*', '*how*' etc.; ground: positive or negative; reinforcement: positive or negative. The rules are:

1. If the polarity of expressed statement is neutral, then the attitude is neutral:

S('*Professor*') & [V pos. ground, pos. reinforcement, confidence:0.83]('*dwelled*') & PP-neutral('*on a question*') => neutral.

2. If the polarity of expressed statement is not neutral and the reinforcement is positive, then the score of the statement (PP) is intensified:

S('*Jane*') & [V neg. ground, pos. reinforcement, confidence:0.8]('*is complaining*') & PP-('*of a headache again*') => 'NEG app'; PP_score^; confidence:0.8.

3. If the polarity of expressed statement is not neutral and reinforcement is negative, then the polarity of the statement (PP) is reversed and score is intensified:

S('*Max*') & [V neg. ground, neg. reinforcement, confidence:0.2]('*doubt*') & PP-{'*that*' S+('*his good fortune*') & [V termination]('*will ever end*')} => 'POS app'; PP_score^; confidence:0.2.

In the last example, to measure the sentiment of PP, we apply rule for the verb '*end*' from the "*Termination of activity*" class, which reverses the non-neutral polarity of subject (in intransitive use of verb) or object (in transitive use of verb). For example, the polarity of both sentences '*My whole enthusiasm and excitement disappear like a bubble touching a hot needle*' and '*They discontinued helping children*' is negative.

5 Decision on Attitude Label

The decision on the most appropriate final label for the clause, in case @AM annotates it using different attitude types according to the words with multiple annotations (e.g., see word '*unfriendly*' in Table 1) or based on the availability of the words conveying different attitude types, is made based on the analysis of:

1) morphological tags of nominal heads and their premodifiers in the clause (e.g., first person pronoun, third person pronoun, demonstrative pronoun, nominative or genitive noun, etc.);

2) the sequence of hypernymic semantic relations of a particular noun in WordNet (Miller, 1990), which allows to determine its conceptual domain (e.g., "person, human being", "artifact", "event", etc.);

3) the annotations from the Stanford Named Entity Recognizer (Finkel et al. 2005) that labels PERSON, ORGANIZATION, and LOCATION entities.

For ex., '*I feel highly unfriendly attitude towards me*' conveys emotion ('NEG aff': 'sadness'), while '*The shop assistant's behavior was really unfriendly*' and '*Plastic bags are environment unfriendly*' express judgment ('NEG jud') and appreciation ('NEG app'), correspondingly.

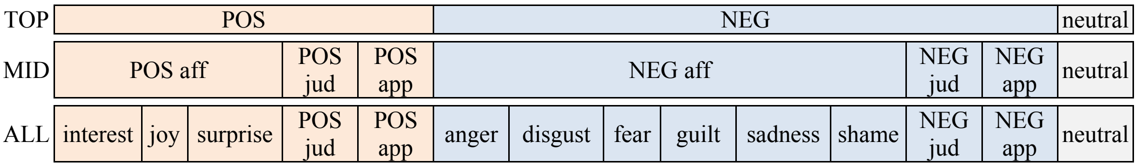
6 Evaluation

For the experiments, we used our own data set, as, to the best of our knowledge, there is no publicly available data set of sentences annotated by the fine-grained labels proposed in our work. In order to evaluate the performance of our algorithm, we created the data set of sentences extracted from personal stories about life experiences that were anonymously published on the *Experience Project* website (`www.experienceproject.com`), where people share personal experiences, thoughts, opinions, feelings, passions, and confessions through the network of personal stories. With over 4 million experiences accumulated (as of February 2010), *Experience Project* is a perfect source for researchers interested in studying different types of attitude expressed through text.

6.1 Data Set Description

For our experiment we extracted 1000 sentences[1] from various stories grouped by topics within 13 different categories, such as "Arts and entertainment", "Current events", "Education", "Family and friends", "Health and wellness", "Relationships and romance" and others, on the *Experience Project* website. Sentences were collected from 358 distinct topic groups, such as "I still remember September 11", "I am intelligent but airheaded", "I think bullfighting is cruel", "I quit smoking", "I am a fashion victim", "I was adopted" and others.

[1] This annotated data set is freely available upon request.



<table>
<tr><td>TOP</td><td colspan="5">POS</td><td colspan="8">NEG</td><td>neutral</td></tr>
<tr><td>MID</td><td colspan="3">POS aff</td><td>POS jud</td><td>POS app</td><td colspan="6">NEG aff</td><td>NEG jud</td><td>NEG app</td><td>neutral</td></tr>
<tr><td>ALL</td><td>interest</td><td>joy</td><td>surprise</td><td>POS jud</td><td>POS app</td><td>anger</td><td>disgust</td><td>fear</td><td>guilt</td><td>sadness</td><td>shame</td><td>NEG jud</td><td>NEG app</td><td>neutral</td></tr>
</table>

Figure 1. Hierarchy of attitude labels.

We considered three hierarchical levels of attitude labels in our experiment (see Figure 1). Three independent annotators labeled the sentences with one of 14 categories from the ALL level and a corresponding score (the strength or intensity value). These annotations were further interpreted using labels from the MID and the TOP levels. Fleiss' Kappa coefficient was used as a measure of reliability of human raters' annotations. The agreement coefficient on 1000 sentences was 0.53 on ALL level, 0.57 on MID level, and 0.73 on TOP level.

Only those sentences, on which at least two out of three human raters completely agreed, were included in the gold standards for our experiment. Three gold standards were created according to the hierarchy of attitude labels. Fleiss' Kappa coefficients are 0.62, 0.63, and 0.74 on ALL, MID, and TOP levels, correspondingly. Table 3 shows the distributions of labels in the gold standards.

ALL level		**MID level**	
Label	**Number**	**Label**	**Number**
anger	45	POS aff	233
disgust	21	NEG aff	332
fear	54	POS jud	66
guilt	22	NEG jud	78
interest	84	POS app	100
joy	95	NEG app	29
sadness	133	neutral	87
shame	18	**total**	925
surprise	36		
POS jud	66	**TOP level**	
NEG jud	78	**Label**	**Number**
POS app	100	POS	437
NEG app	29	NEG	473
neutral	87	neutral	87
total	868	**total**	997

Table 3. Label distributions in gold standards.

6.2 Results

The results of a simple method selecting the attitude label with the maximum intensity from the annotations of sentence tokens found in the database were considered as the baseline. After processing each sentence from the data set by the baseline method and our @AM system, we measured averaged accuracy, precision, recall, and F-score for each label in ALL, MID, and TOP levels. The results are shown in Table 4.

As seen from the obtained results, our algorithm performed with high accuracy significantly surpassing the baselines in all levels of attitude hierarchy, thus demonstrating the contribution of the sentence parsing and our hand-crafted rules to the reliable recognition of attitude from text. Two-tailed t-tests with significance level of 0.05 showed that the differences in accuracy between the baseline method and our @AM system are statistically significant ($p<0.001$) in fine-grained as well as coarse-grained classifications.

In the case of fine-grained attitude recognition (ALL level), the highest precision was obtained for 'shame' (0.923) and 'NEG jud' (0.889), while the highest recall was received for 'sadness' (0.917) and 'joy' (0.905) emotions at the cost of low precision (0.528 and 0.439, correspondingly). The algorithm performed with the worst results in recognition of 'NEG app' and 'neutral'.

The analysis of a confusion matrix for the ALL level revealed the following top confusions of our system: (1) 'anger', 'fear', 'guilt', 'shame', 'NEG jud', 'NEG app' and 'neutral' were predominantly incorrectly predicted as 'sadness' (for ex., @AM resulted in 'sadness' for the sentence '*I know we have several months left before the election, but I am already sick and tired of seeing the ads on TV*', while human annotations were 'anger'/'anger'/'disgust'); (2) 'interest', 'POS jud' and 'POS app' were mostly confused with 'joy' by our algorithm (e.g., @AM classified the sentence '*It's one of those life changing artifacts that we must have in order to have happier, healthier lives*' as 'joy'(-ful), while human annotations were 'POS app'/'POS app'/'interest').

Our system achieved high precision for all categories on the MID level (Table 4), with the exception of 'NEG app' and 'neutral', although

Level	Label	Baseline method				@AM			
		Accuracy	Precision	Recall	F-score	Accuracy	Precision	Recall	F-score
ALL	anger	0.437	0.742	0.511	0.605	**0.621**	0.818	0.600	0.692
	disgust		0.600	0.857	0.706		0.818	0.857	0.837
	fear		0.727	0.741	0.734		0.768	0.796	0.782
	guilt		0.667	0.364	0.471		0.833	0.455	0.588
	interest		0.380	0.357	0.368		0.772	0.524	0.624
	joy		0.266	0.579	0.364		0.439	0.905	0.591
	sadness		0.454	0.632	0.528		0.528	0.917	0.670
	shame		0.818	0.500	0.621		0.923	0.667	0.774
	surprise		0.625	0.694	0.658		0.750	0.833	0.789
	POS jud		0.429	0.227	0.297		0.824	0.424	0.560
	NEG jud		0.524	0.141	0.222		0.889	0.410	0.561
	POS app		0.349	0.150	0.210		0.755	0.400	0.523
	NEG app		0.250	0.138	0.178		0.529	0.310	0.391
	neutral		0.408	0.483	0.442		0.559	0.437	0.490
MID	POS aff	0.524	0.464	0.695	0.557	**0.709**	0.668	0.888	0.762
	NEG aff		0.692	0.711	0.701		0.765	0.910	0.831
	POS jud		0.405	0.227	0.291		0.800	0.424	0.554
	NEG jud		0.458	0.141	0.216		0.842	0.410	0.552
	POS app		0.333	0.150	0.207		0.741	0.400	0.519
	NEG app		0.222	0.138	0.170		0.474	0.310	0.375
	neutral		0.378	0.483	0.424		0.514	0.437	0.472
TOP	POS	0.732	0.745	0.796	0.770	**0.879**	0.918	0.920	0.919
	NEG		0.831	0.719	0.771		0.912	0.922	0.917
	neutral		0.347	0.483	0.404		0.469	0.437	0.452

Table 4. Results of the evaluation of performance of the baseline method and @AM system.

high recall was obtained only in the case of categories related to affect ('POS aff', 'NEG aff'). These results indicate that affect sensing is easier than recognition of judgment or appreciation from text. TOP level results (Table 4) show that our algorithm classifies sentences that convey positive or negative sentiment with high accuracy (92% and 91%, correspondingly). On the other hand, 'neutral' sentences still pose a challenge.

The analysis of errors revealed that system requires common sense or additional context to deal with sentences like '*All through my life I've felt like I'm second fiddle*' (gold standard: 'sadness'; @AM: 'neutral') or '*For me every minute on my horse is alike an hour in heaven!*' (gold standard: 'joy'; @AM: 'neutral').

We also evaluated the system performance with regard to attitude intensity estimation. The percentage of attitude-conveying sentences (not considering neutral ones), on which the result of our system conformed to the fine-grained gold standard (ALL level), according to the measured distance between intensities given by human raters (averaged values) and those obtained by our system is shown in Table 5. As seen from the table, our system achieved satisfactory results in estimation of the strength of attitude expressed through text.

Range of intensity difference	Percent of sentences, %
[0.0 – 0.2]	55.5
(0.2 – 0.4]	29.5
(0.4 – 0.6]	12.2
(0.6 – 0.8]	2.6
(0.8 – 1.0]	0.2

Table 5. Results on intensity.

7 Conclusions

In this paper we introduced @AM, which is so far, to the best of our knowledge, the only system classifying sentences using fine-grained attitude types, and extensively dealing with the semantics of verbs in attitude analysis. Our composition approach broadens the coverage of sentences with complex contextual attitude. The evaluation results indicate that @AM achieved reliable results in the task of textual attitude analysis. The limitations include dependency on lexicon and on accuracy of the parser. The primary objective for the future research is to develop a method for the extraction of reasons behind the expressed attitude.

Abstract

We present an unsupervised word segmentation model for machine translation. The model uses existing monolingual segmentation techniques and models the joint distribution over source sentence segmentations and alignments to the target sentence. During inference, the monolingual segmentation model and the bilingual word alignment model are coupled so that the alignments to the target sentence guide the segmentation of the source sentence. The experiments show improvements on Arabic-English and Chinese-English translation tasks.

1 Introduction

In statistical machine translation, the smallest unit is usually the *word*, defined as a token delimited by spaces. Given a parallel corpus of source and target text, the training procedure first builds a word alignment, then extracts phrase pairs from this word alignment. However, in some languages (e.g., Chinese) there are no spaces between words.

The same problem arises when translating between two very different languages, such as from a language with rich morphology like Hungarian or Arabic to a language with poor morphology like English or Chinese. A single word in a morphologically rich language is often the composition of several morphemes, which correspond to separate words in English.[1]

Often some preprocessing is applied involving word segmentation or morphological analysis of the source and/or target text. Such preprocessing tokenizes the text into morphemes or words, which linguists consider the smallest meaning-bearing units of the language. Take as an example the Arabic word "fktbwha" and its English translation "so they wrote it". The preferred segmentation of "fktbwha" would be "f-ktb-w-ha (*so-wrote-they-it*)," which would allow for a one-to-one mapping between tokens in the two languages. However, the translation of the phrase in Hebrew is "wktbw ath". Now the best segmentation of the Arabic words would be "fktbw-ha," corresponding to the two Hebrew words. This example shows that there may not be one correct segmentation that can be established in a preprocessing step. Rather, tokenization depends on the language we want to translate into and needs to be tied in with the alignment process. In short, we want to find the tokenization yielding the best alignment, and thereby the best translation system.

We propose an unsupervised tokenization method for machine translation by formulating a generative Bayesian model to "explain" the bilingual training data. Generation of a sentence pair is described as follows: first a monolingual tokenization model generates the source sentence, then the alignment model generates the target sentence through the alignments with the source sentence. Breaking this generation process into two steps provides flexibility to incorporate existing monolingual morphological segmentation models such as those of Mochihashi et al. (2009) or Creutz and Lagus (2007). Using nonparametric

[1] We will use the terms *word segmentation*, *morphological analysis*, and *tokenization* more or less interchangeably.

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 815–823,
Beijing, August 2010

models and the Bayesian framework makes it possible to incorporate linguistic knowledge as prior distributions and obtain the posterior distribution through inference techniques such as MCMC or variational inference.

As new test source sentences do not have translations which can help to infer the best segmentation, we *decode* the source string according to the posterior distribution from the inference step.

In summary, our segmentation technique consists of the following steps:

- A joint model of segmented source text and its target translation.
- Inference of the posterior distribution of the model given the training data.
- A decoding algorithm for segmenting source text.
- Experiments in translation using the preprocessed source text.

Our experiments show that the proposed segmentation method leads to improvements on Arabic-English and Chinese-English translation tasks.

In the next section we will discuss related work. Section 3 will describe our model in detail. The inference will be covered in Section 4, and decoding in Section 5. Experiments and results will be presented in Section 6.

2 Related Work

The problem of segmentation for machine translation has been studied extensively in recent literature. Most of the work used some linguistic knowledge about the source and the target languages (Nießen and Ney, 2004; Goldwater and McClosky, 2005). Sadat and Habash (2006) experimented with a wide range of tokenization schemes for Arabic-English translation. These experiments further show that even for a single language pair, different tokenizations are needed depending on the training corpus size. The experiments are very expensive to conduct and do not generalize to other language pairs. Recently, Dyer (2009) created manually crafted lattices for a subset of source words as references for segmentation when translating into English, and then learned the segmentation of the source words to optimize the translation with respect to these references. He showed that the parameters of the model can be applied to similar languages when translating into English. However, manually creating these lattices is time-consuming and requires a bilingual person with some knowledge of the underlying statistical machine translation system.

There have been some attempts to apply unsupervised methods for tokenization in machine translation (Chung and Gildea, 2009; Xu et al., 2008). The alignment model of Chung and Gildea (2009) forces every source word to align with a target word. Xu et al. (2008) modeled the source-to-null alignment as in the source word to target word model. Their models are special cases of our proposed model when the source model[2] is a unigram model. Like Xu et al. (2008), we use Gibbs sampling for inference. Chung and Gildea (2009) applied efficient dynamic programming-based variational inference algorithms.

We benefit from existing unsupervised monolingual segmentation. The source model uses the nested Pitman-Yor model as described by Mochihashi et al. (2009). When sampling each potential word boundary, our inference technique is a bilingual extension of what is described by Goldwater et al. (2006) for monolingual segmentation.

Nonparametric models have received attention in machine translation recently. For example, DeNero et al. (2008) proposed a hierarchical Dirichlet process model to learn the weights of phrase pairs to address the degeneration in phrase extraction. Teh (2006) used a hierarchical Pitman-Yor process as a smoothing method for language models.

Recent work on multilingual language learning successfully used nonparametric models for language induction tasks such as grammar induction (Snyder et al., 2009; Cohen et al., 2010), morphological segmentation (Goldwater et al., 2006; Snyder and Barzilay, 2008), and part-of-speech tagging (Goldwater and Griffiths, 2007; Snyder et al.,

[2] Note that "source model" here means a model of source text, not a source model in the noisy channel paradigm.

2008).

3 Models

We start with the generative process for a source sentence and its alignment with a target sentence. Then we describe individual models employed by this generation scheme.

3.1 Generative Story

A source sentence is a sequence of word tokens, and each word is either aligned or not aligned. We focus only on the segmentation problem and not reordering source words; therefore, the model will not generate the order of the target word tokens. A sentence pair and its alignment are captured by four components:

- a sequence of words in the source sentence,
- a set of null-aligned source tokens,
- a set of null-aligned target tokens, and
- a set of (source word to target word) alignment pairs.

We will start with a high-level story of how the segmentation of the source sentence and the alignment are generated.

1. A source language monolingual segmentation model generates the source sentence.
2. Generate alignments:
   (a) Given the sequence of words of the source sentence already generated in step 1, the alignment model marks each source word as either aligned or unaligned. If a source word is aligned, the model also generates the target word.
   (b) Unaligned target words are generated.

The model defines the joint probability of a segmented source language sentence and its alignment. During inference, the two parts are coupled, so that the alignment will influence which segmentation is selected. However, there are several advantages in breaking the generation process into two steps.

First of all, in principle the model can incorporate any existing probabilistic monolingual segmentation to generate the source sentence. For example, the source model can be the nested Pitman-Yor process as described by Mochihashi et al. (2009), the minimum description length model presented by Creutz and Lagus (2007), or something else. Also the source model can incorporate linguistic knowledge from a rule-based or statistical morphological disambiguator.

The model generates the alignment after the source sentence with word boundaries already generated. Therefore, the alignment model can be any existing word alignment model (Brown et al., 1993; Vogel et al., 1996). Even though the choices of source model or alignment model can lead to different inference methods, the model we propose here is highly extensible. Note that we assume that the alignment consists of at most one-to-one mappings between source and target words, with null alignments possible on both sides.

Another advantage of a separate source model lies in the segmentation of an unseen test set. In section 5 we will show how to apply the source model distribution learned from training data to find the best segmentation of an unseen test set.

Notation and Parameters

We will use bold font for a sequence or bags of words and regular font for an individual word. A source sentence $\mathbf{s}$ is a sequence of $|\mathbf{s}|$ words s_i: $\left(s_1, \ldots, s_{|\mathbf{s}|}\right)$; the translation of sentence $\mathbf{s}$ is the target sentence $\mathbf{t}$ of $|\mathbf{t}|$ words $\left(t_1, \ldots, t_{|\mathbf{t}|}\right)$. In sentence $\mathbf{s}$ the list of unaligned words is $\mathbf{s}_{\text{nal}}$ and the list of aligned source words is $\mathbf{s}_{\text{al}}$. In the target sentence $\mathbf{t}$ the list of unaligned words is $\mathbf{t}_{\text{nal}}$ and the list of target words having one-to-one alignment with source words $\mathbf{s}_{\text{al}}$ is $\mathbf{t}_{\text{al}}$. The alignment $\mathbf{a}$ of $\mathbf{s}$ and $\mathbf{t}$ is represented by $\{\langle s_i, \mathsf{null}\rangle \mid s_i \in \mathbf{s}_{\text{nal}}\} \cup \{\langle s_i, t_{a_i}\rangle \mid s_i \in \mathbf{s}_{\text{al}}; t_{a_i} \in \mathbf{t}_{\text{al}}\} \cup \{\langle \mathsf{null}, t_j\rangle \mid t_j \in \mathbf{t}_{\text{nal}}\}$ where a_i denotes the index in $\mathbf{t}$ of the word aligned to s_i.

The probability of a sequence or a set is denoted by $\mathbb{P}(.)$, probability at the word level is $\mathsf{p}(.)$. For example, the probability of sentence $\mathbf{s}$ is $\mathbb{P}(\mathbf{s})$, the probability of a word s is $\mathsf{p}(s)$, the probability that the target word t aligns to an aligned source word s is $\mathsf{p}\left(t \mid s\right)$.

A sentence pair and its alignment are generated from the following models:

- The *source* model generates sentence s with probability $\mathbb{P}\left(\mathbf{s}\right)$.

- The *source-to-null* alignment model decides independently for each word s whether it is unaligned with probability $\mathsf{p}\left(\mathsf{null} \mid s_i\right)$ or aligned with probability: $1 - \mathsf{p}\left(\mathsf{null} \mid s_i\right)$. The probability of this step, for all source words, is: $\mathbb{P}\left(\mathsf{s}_{\text{nal}}, \mathsf{s}_{\text{al}} \mid \mathsf{s}\right) = \prod_{s_i \in \mathbf{s}_{\text{nal}}} \mathsf{p}\left(\mathsf{null} \mid s_i\right) \times \prod_{s_i \in \mathbf{s}_{\text{al}}} \left(1 - \mathsf{p}\left(\mathsf{null} \mid s_i\right)\right)$.

  We will also refer to the source-to-null model as the *deletion model*, since words in s_{nal} are effectively deleted for the purposes of alignment.

- The *source-to-target* alignment model generates a bag of target words $\mathbf{t}_{\text{al}}$ aligned to the source words s_{al} with probability: $\mathbb{P}\left(\mathbf{t}_{\text{al}} \mid \mathsf{s}_{\text{al}}\right) = \prod_{s_i \in \mathbf{s}_{\text{al}}; t_{a_i} \in \mathbf{t}_{\text{al}}} \mathsf{p}\left(t_{a_i} \mid s_i\right)$. Note that we do not need to be concerned with generating $\mathbf{a}$ explicitly, since we do not model word order on the target side.

- The *null-to-target* alignment model generates the list of unaligned target words $\mathbf{t}_{\text{nal}}$ given aligned target words $\mathbf{t}_{\text{al}}$ with $\mathbb{P}\left(\mathbf{t}_{\text{nal}} \mid \mathbf{t}_{\text{al}}\right)$ as follows:

  - Generate the number of unaligned target words $|\mathbf{t}_{\text{nal}}|$ given the number of aligned target words $|\mathbf{t}_{\text{al}}|$ with probability $\mathbb{P}\left(|\mathbf{t}_{\text{nal}}| \mid |\mathbf{t}_{\text{al}}|\right)$.
  - Generate $|\mathbf{t}_{\text{nal}}|$ unaligned words $t \in \mathbf{t}_{\text{nal}}$ independently, each with probability $\mathsf{p}\left(t \mid \mathsf{null}\right)$.

  The resulting null-to-target probability is therefore: $\mathbb{P}\left(\mathbf{t}_{\text{nal}} \mid \mathbf{t}_{\text{al}}\right) = \mathbb{P}\left(|\mathbf{t}_{\text{nal}}| \mid |\mathbf{t}_{\text{al}}|\right) \prod_{t \in \mathbf{t}_{\text{nal}}} \mathsf{p}\left(t \mid \mathsf{null}\right)$.

  We also call the null-to-target model the *insertion* model.

The above generation process defines the joint probability of source sentence s and its alignment $\mathbf{a}$ as follows:

$$\mathbb{P}\left(\mathbf{s}, \mathbf{a}\right) = \underbrace{\mathbb{P}\left(\mathbf{s}\right)}_{\text{source model}} \times \underbrace{\mathbb{P}\left(\mathbf{a} \mid \mathbf{s}\right)}_{\text{alignment model}} \quad (1)$$

$$\mathbb{P}\left(\mathbf{a} \mid \mathbf{s}\right) = \mathbb{P}\left(\mathbf{t}_{\text{al}} \mid \mathbf{s}_{\text{al}}\right) \times \mathbb{P}\left(\mathbf{t}_{\text{nal}} \mid \mathbf{t}_{\text{al}}\right) \quad (2)$$
$$\times \prod_{s_i \in \mathbf{s}_{\text{nal}}} \mathsf{p}\left(\mathsf{null} \mid s_i\right) \times \prod_{s_i \in \mathbf{s}_{\text{al}}} \left(1 - \mathsf{p}\left(\mathsf{null} \mid s_i\right)\right)$$

3.2 Source Model

Our generative process provides the flexibility of incorporating different monolingual models into the probability distribution of a sentence pair. In particular we use the existing state-of-the-art nested Pitman-Yor n-gram language model as described by Mochihashi et al. (2009). The probability of s is given by

$$\mathbb{P}\left(\mathsf{s}\right) = \mathbb{P}\left(|\mathsf{s}|\right) \prod_{i=1}^{|\mathsf{s}|} \mathsf{p}\left(s_i \mid s_{i-n}, \ldots, s_{i-1}\right) \quad (3)$$

where the n-gram probability is a hierarchical Pitman-Yor language model using $(n-1)$-gram as the base distribution.

At the unigram level, the model uses the base distribution $\mathsf{p}\left(s\right)$ as the infinite-gram character-level Pitman-Yor language model.

3.3 Modeling Null-Aligned Source Words

The probability that a source word aligns to null $\mathsf{p}\left(\mathsf{null} \mid s\right)$ is defined by a binomial distribution with Beta prior $\mathrm{Beta}\left(\alpha p, \alpha\left(1-p\right)\right)$, where α and p are model parameters. When $p \to 0$ and $\alpha \to \infty$ the probability $\mathsf{p}\left(\mathsf{null} \mid s\right)$ converges to 0 forcing each source words align to a target word. We fixed $p = 0.1$ and $\alpha = 20$ in our experiment.

Xu et al. (2008) view the null word as another target word, hence in their model the probability that a source word aligns to null can only depend on itself.

By modeling the source-to-null alignment separately, our model lets the distribution depend on the word's n-gram context as in the source model. $\mathsf{p}\left(\mathsf{null} \mid s_{i-n}, \ldots, s_i\right)$ stands for the probability that the word s_i is not aligned given its context $\left(s_{i-n}, \ldots, s_{i-1}\right)$.

The n-gram source-to-null distribution $\mathsf{p}\left(\mathsf{null} \mid s_{i-n}, \ldots, s_i\right)$ is defined similarly to

$\mathsf{p}(\mathsf{null} \mid s_i)$ definition above in which the base distribution p now becomes the $(n-1)$-gram: $\mathsf{p}(\mathsf{null} \mid s_{i-n+1}, \ldots, s_i)$.[3]

3.4 Source-Target Alignment Model

The probability $\mathsf{p}(t \mid s)$ that a target word t aligns to a source word s is a Pitman-Yor process:

$$t \mid s \sim \mathrm{PY}(d, \alpha, \mathsf{p}_0(t \mid s))$$

here d and α are the input parameters, and $\mathsf{p}_0(t \mid s)$ is the base distribution.

Let $|s, \cdot|$ denote the number of times s is aligned to any t in the corpus and let $|s, t|$ denote the number of times s is aligned to t anywhere in the corpus. And let $\mathsf{ty}(s)$ denote the number of different target words t the word s is aligned to anywhere in the corpus. In the Chinese Restaurant Process metaphor, there is one restaurant for each source word s, the s restaurant has $\mathsf{ty}(s)$ tables and total $|s, \cdot|$ customers; table t has $|s, t|$ customers.

Then, at a given time in the generative process for the corpus, we can write the probability that t is generated by the word s as:

- if $|s, t| > 0$:

$$\mathsf{p}(t \mid s) = \frac{|s, t| - d + [\alpha + d\mathsf{ty}(s)]\mathsf{p}_0(t \mid s)}{|s, \cdot| + \alpha}$$

- if $|s, t| = 0$:

$$\mathsf{p}(t \mid s) = \frac{[\alpha + d\mathsf{ty}(s)]\mathsf{p}_0(t \mid s)}{|s, \cdot| + \alpha}$$

For language pairs with similar character sets such as English and French, words with similar surface form are often translations of each other. The base distribution can be defined based on the edit distance between two words (Snyder and Barzilay, 2008).

We are working with diverse language pairs (Arabic-English and Chinese-English), so we use the base distribution as the flat distribution $\mathsf{p}_0(t \mid s) = \frac{1}{T}$; T is the number of distinct target words in the training set. In our experiment, the model parameters are $\alpha = 20$ and $d = .5$.

3.5 Modeling Null-Aligned Target Words

The null-aligned target words are modeled conditioned on previously generated target words as:

$$\mathbb{P}(\mathbf{t}_{\mathrm{nal}} \mid \mathbf{t}_{\mathrm{al}}) = \mathbb{P}(|\mathbf{t}_{\mathrm{nal}}| \mid |\mathbf{t}_{\mathrm{al}}|) \prod_{t \in \mathbf{t}_{\mathrm{nal}}} \mathsf{p}(t \mid \mathsf{null})$$

This model uses two probability distributions:

- the number of unaligned target words: $\mathbb{P}(|\mathbf{t}_{\mathrm{nal}}| \mid |\mathbf{t}_{\mathrm{al}}|)$, and
- the probability that each word in $\mathbf{t}_{\mathrm{nal}}$ is generated by null: $\mathsf{p}(t \mid \mathsf{null})$.

We model the number of unaligned target words similarly to the distribution in the IBM3 word alignment model (Brown et al., 1993). IBM3 assumes that each aligned target words generates a null-aligned target word with probability p_0 and fails to generate a target word with probability $1 - p_0$. So the parameter p_0 can be used to control the number of unaligned target words. In our experiments, we fix $p_0 = .05$. Following this assumption, the probability of $|\mathbf{t}_{\mathrm{nal}}|$ unaligned target words generated from $|\mathbf{t}_{\mathrm{al}}|$ words is: $\mathbb{P}(|\mathbf{t}_{\mathrm{nal}}| \mid |\mathbf{t}_{\mathrm{al}}|) = \binom{|\mathbf{t}_{\mathrm{al}}|}{|\mathbf{t}_{\mathrm{nal}}|} p_0^{|\mathbf{t}_{\mathrm{nal}}|}(1 - p_0)^{|\mathbf{t}_{\mathrm{al}}| - |\mathbf{t}_{\mathrm{nal}}|}$.

The probability that a target word t aligns to null, $\mathsf{p}(t \mid \mathsf{null})$, also has a Pitman-Yor process prior. The base distribution of the model is similar to the source-to-target model's base distribution which is the flat distribution over target words.

4 Inference

We have defined a probabilistic generative model to describe how a corpus of alignments and segmentations can be generated jointly. In this section we discuss how to obtain the posterior distributions of the missing alignments and segmentations given the training corpus, using Gibbs sampling.

Suppose we are provided a morphological disambiguator for the source language such as MADA morphology tokenization toolkit (Sadat and Habash, 2006) for Arabic.[4] The morphological disambiguator segments a source word to

[3] We also might have conditioned this decision on words *following* s_i, since those have all been generated already at this stage.

[4] MADA provides several segmentation schemes; among them the MADA-D3 scheme seeks to separate all morphemes of each word.

morphemes of smallest meaning-bearing units of the source language. Therefore, a target word is equivalent to one or several morphemes. Given a morphological disambiguation toolkit, we use its output to bias our inference by not considering word boundaries after every character but only considering potential word boundaries as a subset of the morpheme boundaries set. In this way, the inference uses the morphological disambiguation toolkit to limit its search space.

The inference starts with an initial segmentation of the source corpus and also its alignment to the target corpus. The Gibbs sampler considers one potential word boundary at a time. There are two hypotheses at any given boundary position of a sentence pair $(\mathbf{s}, \mathbf{t})$: the *merge* hypothesis stands for no word boundary and the resulting source sentence $\mathbf{s}_{\text{merge}}$ has a word s spanning over the sample point; the *split* hypothesis indicates the resulting source sentence $\mathbf{s}_{\text{split}}$ has a word boundary at the sample point separating two words $s_1 s_2$. Similar to Goldwater et al. (2006) for monolingual segmentation, the sampler randomly chooses the boundary according to the relative probabilities of the merge hypothesis and the split hypothesis.

The model consists of source and alignment model variables; given the training corpora size of a machine translation system, the number of variables is large. So if the Gibbs sampler samples both source variables and alignment variables, the inference requires many iterations until the sampler mixes. Xu et al. (2008) fixed this by repeatedly applying GIZA++ word alignment after each sampling iteration through the training corpora.

Our inference technique is not precisely Gibbs sampling. Rather than sampling the alignment or attempting to collapse it out (by summing over all possible alignments when calculating the relative probabilities of the merge and split hypotheses), we seek the *best* alignment for each hypothesis. In other words, for each hypothesis, we perform a local search for a high-probability alignment of the merged word or split words, given the rest of alignment for the sentence. Up to one word may be displaced and realigned. This “local-best” alignment is used to score the hypothesis, and after sampling merge or split, we keep that best alignment.

This inference technique is motivated by runtime demands, but we do not yet know of a theoretical justification for combining random steps with maximization over some variables. A more complete analysis is left to future work.

5 Decoding for Unseen Test Sentences

Section 4 described how to get the model’s posterior distribution and the segmentation and alignment of the training data under the model. We are left with the problem of *decoding* or finding the segmentation of test sentences where the translations are not available. This is needed when we want to translate new sentences. Here, tokenization is performed as a preprocessing step, decoupled from the subsequent translation steps.

The decoding step uses the model’s posterior distribution for the training data to segment unseen source sentences. Because of the clear separation of the source model and the alignment model, the source model distribution learned from the Gibbs sampling directly represents the distribution over the source language and can therefore also handle the segmentation of unknown words in new test sentences. Only the source model is used in preprocessing.

The best segmentation $\mathbf{s}^*$ of a string of characters $\mathbf{c} = \left(c_1, \ldots, c_{|\mathbf{c}|}\right)$ according to the n-gram source model is:

$$\mathbf{s}^* = \underset{\mathbf{s}\text{ from }\mathbf{c}}{\operatorname{argmax}}\, \mathsf{p}\left(|\mathbf{s}|\right) \prod_{i=1}^{i=|\mathbf{s}|} \mathsf{p}\left(s_i \,|\, s_{i-n}, \ldots, s_{i-1}\right)$$

We use a stochastic finite-state machine for decoding. This is possible by composition of the following two finite state machines:

- Acceptor $\mathcal{A}_{\mathbf{c}}$. The string of characters $\mathbf{c}$ is represented as an finite state acceptor machine where any path through the machine represents an unweighted segmentation of $\mathbf{c}$.

- Source model weighted finite state transducer $\mathcal{L}_{\mathbf{c}}$. Knight and Al-Onaizan (1998) show how to build an n-gram language model by a weighted finite state machine. The states of the transducer are $(n-1)$-gram history, the edges are words from the language. The arc s_i coming from state

$(s_{i-n}, \ldots, s_{i-1})$ to state $(s_{i-n+1}, \ldots, s_i)$ has weight $\mathsf{p}\,(s_i \,|\, s_{i-n}, \ldots, s_{i-1})$.

The best segmentation s^* is given as $\mathrm{s}^* = \mathrm{BestPath}(\mathcal{A}_\mathbf{c} \circ \mathcal{L}_\mathbf{c})$.

6 Experiments

This section presents experimental results on Arabic-English and Chinese-English translation tasks using the proposed segmentation technique.

6.1 Arabic-English

As a training set we use the BTEC corpus distributed by the International Workshop on Spoken Language Translation (IWSLT) (Matthias and Chiori, 2005). The corpus is a collection of conversation transcripts from the travel domain. The "Supplied Data" track consists of nearly 20K Arabic-English sentence pairs. The development set consists of 506 sentences from the IWSLT04 evaluation test set and the unseen set consists of 500 sentences from the IWSLT05 evaluation test set. Both development set and test set have 16 references per Arabic sentence.

6.2 Chinese-English

The training set for Chinese-English translation task is also distributed by the IWSLT evaluation campaign. It consists of 67K Chinese-English sentence pairs. The development set and the test set each have 489 Chinese sentences and each sentence has 7 English references.

6.3 Results

We will report the translation results where the preprocessing of the source text are our unigram, bigram, and trigram source models and source-to-null model.

The MCMC inference algorithm starts with an initial segmentation of the source text into full word forms. For Chinese, we use the original word segmentation as distributed by IWSLT. To get an initial alignment, we generate the IBM4 Viterbi alignments in both directions using the GIZA++ toolkit (Och and Ney, 2003) and combine them using the "grow-diag-final-and" heuristic. The output of combining GIZA++ alignment for a sentence pair is a sequence of s_i-t_j entries where i is an index of the source sentence and j is an index of the target sentence. As our model allows only one-to-one mappings between the words in the source and target sentences, we remove s_i-t_j from the sequence if either the source word s_i or target word t_j is already in a previous entry of the combined alignment sequence. The resulting alignment is our initial alignment for the inference.

We also apply the MADA morphology segmentation toolkit (Habash and Rambow, 2005) to preprocess the Arabic corpus. We use the D3 scheme (each Arabic word is segmented into morphemes in sequence [CONJ+ [PART+ [Al+ BASE +PRON]]]), mark the morpheme boundaries, and then combine the morphemes again to have words in their original full word form. During inference, we only sample over these morpheme boundaries as potential word boundaries. In this way, we limit the search space, allowing only segmentations consistent with MADA-D3.

The inference samples 150 iterations through the whole training set and uses the posterior probability distribution from the last iteration for decoding. The decoding process is then applied to the entire training set as well as to the development and test sets to generate a consistent tokenization across all three data sets. We used the OpenFST toolkit (Allauzen et al., 2007) for finite-state machine implementation and operations. The output of the decoding is the preprocessed data for translation. We use the open source Moses phrase-based MT system (Koehn et al., 2007) to test the impact of the preprocessing technique on translation quality.[5]

6.3.1 Arabic-English Translation Results

We consider the Arabic-English setting. We use two baselines: original full word form and MADA-D3 tokenization scheme for Arabic-English translation. Table 1 compares the translation results of our segmentation methods with these baselines. Our segmentation method shows improvement over the two baselines on both the development and test sets. According to Sadat and Habash (2006), the MADA-D3 scheme per-

[5] The Moses translation alignment is the output of GIZA++, not from our MCMC inference.

	Dev.	Test
Original	59.21	54.00
MADA-D3	58.28	54.92
Unigram	**59.44**	56.18
Bigram	58.88	56.18
Trigram	58.76	**56.82**

Table 1: Arabic-English translation results (BLEU).

forms best for their Arabic-English translation especially for small and moderate data sizes. In our experiments, we see an improvement when using the MADA-D3 preprocessing over using the original Arabic corpus on the unseen test set, but not on the development set.

The Gibbs sampler only samples on the morphology boundary points of MADA-D3, so the improvement resulting from our segmentation technique does not come from removing unknown words. It is due to a better matching between the source and target sentences by integrating segmentation and alignment. We therefore expect the same impact on a larger training data set in future experiments.

6.3.2 Chinese-English Translation Results

	Dev.	Test
Whole word	23.75	**29.02**
Character	23.39	27.74
Unigram	**24.90**	**28.97**
Trigram	23.98	28.20

Table 2: Chinese-English translation result in BLEU score metric.

We next consider the Chinese-English setting. The translation performance using our word segmentation technique is shown in Table 2. There are two baselines for Chinese-English translation: (a) the source text in the full word form distributed by the IWSLT evaluation and (b) no segmentation of the source text, which is equivalent to interpreting each Chinese character as a single word.

Taking development and test sets into account, the best Chinese-English translation system results from our unigram model. It is significantly better than other systems on the development set and performs almost equally well with the IWSLT segmentation on the test set. Note that the segmentation distributed by IWSLT is a manual segmentation for the translation task.

Chung and Gildea (2009) and Xu et al. (2008) also showed improvement over a simple monolingual segmentation for Chinese-English translation. Our character-based translation result is comparable to their monolingual segmentations. Both trigram and unigram translation results outperform the character-based translation.

We also observe that there are no additional gains for Chinese-English translation when using a higher n-gram model. Our Gibbs sampler has the advantage that the samples are guaranteed to converge eventually to the model's posterior distributions, but in each step the modification to the current hypothesis is small and local. In iterations 100–150, the average number of boundary changes for the unigram model is 14K boundaries versus only 1.5K boundary changes for the trigram model. With 150 iterations, the inference output of trigram model might not yet represent its posterior distribution. We leave a more detailed investigation of convergence behavior to future work.

Conclusion and Future Work

We presented an unsupervised segmentation method for machine translation and presented experiments for Arabic-English and Chinese-English translation tasks. The model can incorporate existing monolingual segmentation models and seeks to learn a segmenter appropriate for a particular translation task (target language and dataset).

Automatic Discovery of Feature Sets for Dependency Parsing

Peter Nilsson **Pierre Nugues**

Abstract

This paper describes a search procedure to discover optimal feature sets for dependency parsers. The search applies to the shift–reduce algorithm and the feature sets are extracted from the parser configuration. The initial feature is limited to the first word in the input queue. Then, the procedure uses a set of rules founded on the assumption that topological neighbors of significant features in the dependency graph may also have a significant contribution. The search can be fully automated and the level of greediness adjusted with the number of features examined at each iteration of the discovery procedure.

Using our automated feature discovery on two corpora, the Swedish corpus in CoNLL-X and the English corpus in CoNLL 2008, and a single parser system, we could reach results comparable or better than the best scores reported in these evaluations. The CoNLL 2008 test set contains, in addition to a *Wall Street Journal* (WSJ) section, an out-of-domain sample from the Brown corpus. With sets of 15 features, we obtained a labeled attachment score of 84.21 for Swedish, 88.11 on the WSJ test set, and 81.33 on the Brown test set.

1 Introduction

The selection of relevant feature sets is crucial to the performance of dependency parsers and this process is still in large part manual. Moreover, feature sets are specific to the languages being analyzed and a set optimal for, say, English can yield poor results in Chinese. With dependency parsers being applied today to dozens of languages, this makes the parametrization of a parser both a tedious and time-consuming operation. Incidentally, the advent of machine-learning methods seems to have shifted the tuning steps in parsing from polishing up grammar rules to the optimization of feature sets. And as with the writing of a grammar, the selection of features is a challenging task that often requires a good deal of effort and inspiration.

Most automatic procedures to build feature sets resort to greedy algorithms. Forward selection constructs a set by adding incrementally features from a predetermined superset while backward elimination removes them from the superset (Attardi et al., 2007). Both methods are sometimes combined (Nivre et al., 2006b). The selection procedures evaluate the relevance of a candidate feature in a set by its impact on the overall parsing score: Does this candidate improve or decrease the performance of the set?

Greedy search, although it simplifies the design of feature sets, shows a major drawback as it starts from a closed superset of what are believed to be the relevant features. There is a broad consensus on a common feature set including the words close to the top of the stack or the beginning of the queue, for the shift–reduce algorithm, but no clear idea on the limits of this set.

In this paper, we describe an automatic discovery procedure that is not bounded by any prior knowledge of a set of potentially relevant features. It applies to the shift–reduce algorithm and the ini-

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 824–832,
Beijing, August 2010

tial feature consists solely of the first word of the queue. The search explores nodes along axes of the parser's data structures and the partially built graph using proximity rules to uncover sequences of relevant, efficient features. Using this procedure on the Swedish corpus in CoNLL-X and the English corpus in CoNLL 2008, we built feature sets that enabled us to reach a labeled attachment score of 84.21 for Swedish, 88.11 on the *Wall Street Journal* section of CoNLL 2008, and 81.33 on the Brown part of it with a set cardinality of 15.

2 Transition-based Parsing

Transition-based methods (Covington, 2001; Nivre, 2003; Yamada and Matsumoto, 2003; Zhang and Clark, 2009) have become a popular approach in multilingual dependency parsing because of their speed and performance. Transition-based methods share common properties and build a dependency graph from a sequence of actions, where each action is determined using a feature function. In a data-driven context, the function is typically implemented as a classifier and the features are extracted from the partially built graph and the parser's data structures, most often a queue and a stack.

2.1 Parser Implementation

In this study, we built a parser using Nivre's algorithm (Nivre, 2003). The parser complexity is linear and parsing completes in at most $2n+1$ operations, where n is the length of the sentence. Table 1 shows the transitions and actions to construct a dependency graph.

Given a sentence to parse, we used a classifier-based guide to predict the transition sequence to apply. At each step, the guide extracts features from the parser configuration and uses them as input to a classifier to predict the next transition. Before training the classification models, we projectivized the corpus sentences (Kunze, 1967; Nivre and Nilsson, 2005). We did not attempt to recover nonprojective sentences after parsing.

2.2 Training and Parsing Procedure

We extracted the features using a gold-standard parsing of the training set. We organized the classification, and hence the feature extraction, as a two-step process. The first step determines the action among *LeftArc*, *RightArc*, *Reduce*, and *Shift*; the second one, the grammatical function, if the action is either a left arc or a right arc.

Action	Parser configuration
Init.	$\langle nil, W, \emptyset \rangle$
LeftArc	$\langle n \mid S, n' \mid Q, G \rangle \rightarrow \langle S, n' \mid Q, G \cup \{\langle n', n \rangle\} \rangle$
RightArc	$\langle n \mid S, n' \mid Q, G \rangle \rightarrow \langle n' \mid n \mid S, Q, G \cup \{\langle n, n' \rangle\} \rangle$
Reduce	$\langle n \mid S, Q, G \rangle \rightarrow \langle S, Q, G \rangle$
Shift	$\langle S, n \mid Q, G \rangle \rightarrow \langle n \mid S, Q, G \rangle$

Table 1: Parser transitions (Nivre, 2003). W is the input, G, the graph, S, the stack, and Q, the queue. The triple $\langle S, Q, G \rangle$ represents the parser configuration and n, n', and n'' are lexical tokens. $\langle n', n \rangle$ represents an arc from n' to n.

Once the features are extracted, we train the corresponding models that we apply to the test corpus to predict the actions and the arc labels.

3 Feature Discovery

We designed an automatic procedure to discover and select features that is guided by the structure of the graph being constructed. The search algorithm is based on the assumption that if a feature makes a significant contribution to the parsing performance, then one or more of its topological neighbors in the dependency graph may also be significant. The initial state, from which we derive the initial feature, consists of the first word in the queue. There is no other prior knowledge on the features.

3.1 Node Attributes

In the discovery procedure, we considered the nodes of four data structures: the queue, the stack, the sentence, and the graph being constructed. We extracted three attributes (or fields) from each node: two static ones, the lexical value of the node and its part of speech, and a dynamic one evaluated at parse time: the dependency label of the arc linking the node to its head, if it exists. We denoted the attributes of node w, respectively,

$LEX(w)$, $POS(w)$, and $DEP(w)$. These attributes are used as input by most dependency parsers, whatever the language being parsed.

3.2 Search Axes

The feature search covers three different axes: the parser's data structures – the queue and the stack –, the graph being constructed, and the sentence. Given a feature set at step n of the discovery procedure, we defined a successor function that generates the set of topological neighbors of all the members in the feature set along these three axes. For a particular feature:

The data structure axis consists of the nodes in the stack and the queue. The immediate neighbors of a node in the stack are the adjacent nodes above and below. In the queue, these are the adjacent nodes before and after it. The top node on the stack and the next node in the queue have a special connection, since they are the ones used by the parser when creating an arc. Therefore, we considered them as immediate neighbors to each other. For a node that is neither in the stack, nor in the queue, there is no connection along this axis.

The graph axes traverse the partially constructed graph horizontally and vertically. The horizontal axis corresponds to the sibling nodes connected by a common head (Figure 1). The immediate neighbors of a node are its nearest siblings to the left and to the right. The vertical axis corresponds to the head and child nodes. The immediate neighbors are the head node as well as the leftmost and rightmost child nodes. There is no connection for nodes not yet part of the graph.

The sentence axis traverses the nodes in the order they occur in the original sentence. The immediate neighbors of a node are the previous and next words in the sentence.

4 Representing Features and Their Neighbors

We represented features with a parameter format partly inspired by MaltParser (Nivre et al., 2006a).

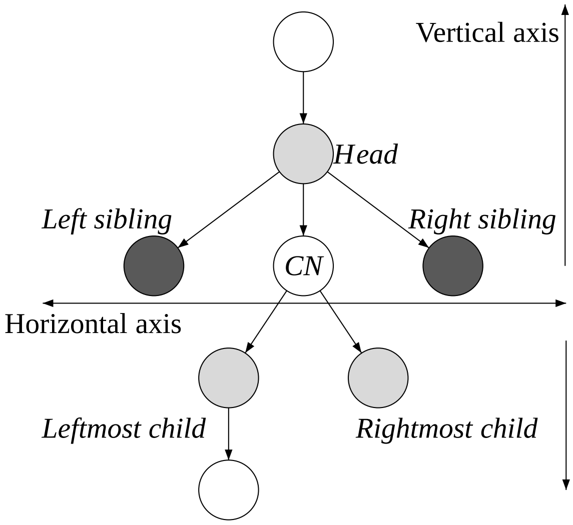

Figure 1: The vertical and horizontal axes, respectively in light and dark gray, relative to *CN*.

Each parameter consists of two parts. The first one represents a node in a data structure (*STACK* or *QUEUE*) and an attribute:

The nodes are identified using a zero-based index. Thus $STACK_1$ designates the second node on the stack.

The attribute of a node is one of part of speech (*POS*), lexical value (*LEX*), or dependency label (*DEP*), as for instance $LEX(QUEUE_0)$ that corresponds to the lexical value of the first token in the queue.

The second part of the parameter is an optional navigation path that allows to find other destination nodes in the graph. It consists of a sequence of instructions to move from the start node to the destination node. The list of possible instructions are:

- h: head of the current node;
- lc/rc: leftmost/rightmost child of the node;
- pw/fw: previous/following word of the node in the original sentence.

An example of a feature obtained using the navigation part is $POS(STACK_1\ lc\ pw)$, which is interpreted as: start from $STACK_1$. Then, using the instructions lc and pw, move to the left child of the start node and to the previous word of this child in the sentence. The requested feature is the part of speech of the destination node.

5 Initial State and Successor Function

The feature discovery is an iterative procedure that grows the feature set with one new feature at each iteration. We called *generation* such an iteration, where generation 1 consists of a single node. We denoted $FeatSet_i = \{f_1, f_2, ..., f_i\}$ the feature set obtained at generation i.

Although the features of a classifier can be viewed as a set, we also considered them as a tuple, where $Feat_i = \langle f_1, f_2, ..., f_i \rangle$ is the i-tuple at generation i and f_k, the individual feature discovered at generation k with $1 \leqslant k \leqslant i$. This enables us to keep the order in which the individual features are obtained during the search.

5.1 Initial State

We start the feature search with the empty set, $\emptyset$, that, by convention, has one neighbor: the first node in the queue $QUEUE_0$. We chose this node because this is the only one which is certain to exist all along the parsing process. Intuitively, this is also obvious that $QUEUE_0$ plays a significant role when deciding a parsing action. We defined the successor function of the empty set as: $SUCC(\emptyset) = \{POS(QUEUE_0), LEX(QUEUE_0)\}$.

5.2 Successors of a Node

The successors of a node consist of itself and all its topological neighbors along the three axes with their three possible attributes: part of speech, lexical value, and dependency label. For a particular feature in *FeatSet*, the generation of its successors is carried out through the following steps:

1. Interpret the feature with its possible navigation path and identify the destination node n.
2. Find all existing immediate neighboring nodes of n along the three search axes.
3. Assign the set of attributes – *POS*, *LEX*, and *DEP* – to n and its neighboring nodes.

If at any step the requested node does not exist, the feature evaluates to *NOTHING*.

5.3 Rules to Generate Neighbors

The generation of all the neighbors of the features in *FeatSet* may create duplicates as a same node can sometimes be reached from multiple paths. For instance, if we move to the leftmost child of a node and then to the head of this child, we return to the original node.

To compute the successor function, we built a set of rules shown in Table 2. It corresponds to a subset of the rules described in the axis search (Sect. 3.2) so that it omits the neighbors of a node that would unavoidably create redundancies. The third column in Table 2 shows the rules to generate the neighbors of $POS(QUEUE_0)$. They correspond to the rows:

PL. This stands for the *POS* and *LEX* attributes of the node. We only add $LEX(QUEUE_0)$ as we already have $POS(QUEUE_0)$.

PLD lc *and* PLD rc. *POS*, *LEX*, and *DEP* of the node's leftmost and rightmost children.

PLD pw. *POS*, *LEX*, and *DEP* of the previous word in the original string. The following word is the same as the next node in the queue, which is added in the next step. For that reason, *following word* is not added.

PL $QUEUE_1$. *POS* and *LEX* of $QUEUE_1$.

PLD $STACK_0$. *POS*, *LEX*, and *DEP* of $STACK_0$. This rule connects the queue to the top node of the stack.

Table 3 summarizes the results of the rule application and shows the complete list of successors of $POS(QUEUE_0)$. In this way, the search for a node's neighbors along the axes is reduced to one direction, either left or right, or up or down, that will depend on the topological relation that introduced the node in the feature set.

6 Feature Selection Algorithm

At each generation, we compute the Cartesian product of the current feature tuple $Feat_i$ and the set defined by its neighbors. We define the set of candidate tuples $CandFeat_{i+1}$ at generation $i+1$ as:

$$CandFeat_{i+1} = \{Feat_i\} \times SUCC(Feat_i),$$

where we have $Card(CandFeat_{i+1}) = Card(SUCC(Feat_i))$.

The members of $CandFeat_{i+1}$ are ranked according to their parsing score on the development

Data structures				Navigation paths					
$STACK_0$	$STACK_n, n > 0$	$QUEUE_0$	$QUEUE_n, n > 0$	*h*	*lc, rc*	*ls*	*rs*	*pw*	*fw*
PLD	PLD	PL	PL	h				h	h
PLD h	PLD h				lc	lc	lc	lc	lc
PLD lc	PLD lc	PLD lc			rc	rc	rc	rc	rc
PLD rc	PLD rc	PLD rc		ls	ls	ls		ls	ls
PLD ls	PLD ls			rs	rs		rs	rs	rs
PLD rs	PLD rs			pw	pw	pw	pw	pw	
PLD pw	PLD pw	PLD pw		fw	fw	fw	fw		fw
PLD fw	PLD fw								
PLD $STACK_1$	PLD $STACK_{n+1}$	PL $QUEUE_1$	PL $QUEUE_{n+1}$						
PL $QUEUE_0$		PLD $STACK_0$							

Table 2: Rules to compute the successors of a node. For each node category given in row 2, the procedure adds the features in the column headed by the category. PLD stands for the *POS*, *LEX*, and *DEP* attributes. In the right-hand side of the table, the category corresponds to the last instruction of the navigation path, if it exists, for instance *pw* in the feature $POS(STACK_1\ lc\ pw)$. We read the six successors of this node in the fifth column headed by *pw*: $STACK_1\ lc\ pw\ h$, $STACK_1\ lc\ pw\ lc$, $STACK_1\ lc\ pw\ rc$, $STACK_1\ lc\ pw\ ls$, $STACK_1\ lc\ pw\ rs$, and $STACK_1\ lc\ pw\ pw$. We then apply all the attributes to these destination nodes to generate the features.

Initial feature	POS	QUEUE	0	
Successors	LEX	QUEUE	0	
	PLD	QUEUE	0	lc
	PLD	QUEUE	0	rc
	PLD	QUEUE	0	pw
	PL	QUEUE	1	
	PLD	STACK	0	

Table 3: Features generated by the successor function $SUCC(\{POS(QUEUE_0)\})$. PLD stands for the three attributes *POS*, *LEX*, and *DEP* of the node; PL for *POS* and *LEX*.

set and when applying a greedy best-first search, $Feat_{i+1}$ is assigned with the tuple yielding the highest score:

$$Feat_{i+1} \leftarrow eval\_best(CandFeat_{i+1}).$$

The procedure is repeated with the immediate neighbors of $Feat_{i+1}$ until the improvement of the score is below a certain threshold.

We extended this greedy version of the discovery with a beam search that retains the *N*-best successors from the candidate set. In our experiments, we used beam widths of 4 and 8.

7 Experimental Setup

In a first experiment, we used the Swedish corpus of the CoNLL-X shared task (Buchholz and Marsi, 2006). In a second experiment, we applied the feature discovery procedure to the English corpus from CoNLL 2008 (Surdeanu et al., 2008), a dependency corpus converted from the Penn Treebank and the Brown corpus. In both experiments, we used the LIBSVM package (Chang and Lin, 2001) with a quadratic kernel, $\gamma = 0.2$, $C = 0.4$, and $\varepsilon = 0.1$. These parameters are identical to Nivre et al. (2006b) to enable a comparison of the scores.

We evaluated the feature candidates on a development set using the labeled and unlabeled attachment scores (LAS and UAS) that we computed with the `eval.pl` script from CoNLL-X. As there was no development set for the Swedish corpus, we created one by picking out every 10th sentence from the training set. The training was then carried out on the remaining part of the set.

8 Feature Discovery on a Swedish Corpus

In a first run, the search was optimized for the UAS. In a second one, we optimized the LAS. We also report the results we obtained subsequently on the CoNLL-X test set as an indicator of how well the training generalized.

8.1 The First and Second Generations

Table 4 shows the feature performance at the first generation sorted by UAS. The first row shows the two initial feature candidates, $\langle POS(QUEUE_0)\rangle$ and $\langle LEX(QUEUE_0)\rangle$. The third row shows the score produced by the initial features alone. The next rows show the unlabeled and labeled attachment scores with feature pairs combining one of the initial features and the one listed in the row. The combination of $POS(QUEUE_0)$ and $POS(STACK_0)$ yielded the best UAS: 74.02. The second feature improves the performance of $POS(QUEUE_0)$ by more than 30 points from 43.49.

For each generation, we applied a beam search. We kept the eight best pairs as starting states for the second generation and we added their neighboring nodes. Table 5 shows the eight best results out of 38 for the pair $\langle POS(QUEUE_0), POS(STACK_0)\rangle$.

Parent state: $\langle POS(QUEUE_0), POS(STACK_0)\rangle$				
Dev set		Test set		
UAS	LAS	UAS	LAS	Successors
79.50	65.34	79.07	65.86	P QUEUE 1
78.73	66.98	76.04	64.51	L STACK 0 fw
77.42	63.08	74.63	61.86	L QUEUE 1
77.06	64.54	75.28	62.90	L QUEUE 0 pw
76.83	66.01	73.61	63.77	L QUEUE 0
76.63	63.62	74.75	63.17	P STACK 0 fw
76.44	64.24	74.09	62.02	L STACK 0
76.39	63.12	73.99	61.16	L QUEUE 0 lc

Table 5: Ranking the successors of $\langle POS(QUEUE_0), POS(STACK_0)\rangle$ on the Swedish corpus. Out of the 38 successors, we show the eight that yielded the best results. P stands for *POS*, L for *LEX*, and D for *DEP*.

8.2 Optimizing the Unlabeled Attachement Score

We iterated the process over a total of 16 generations. Table 6, left-hand side, shows the list of the best scores for each generation. The scores on the development set increased steadily until generation 13, then reached a plateau, and declined around generation 15. The test set closely followed the development set with values about 1% lower. On this set, we reached a peak performance at generation 12, after which the results decreased.

Table 6, right-hand side, shows the features producing the final score in their order of inclusion in the feature set. As we applied a beam search, a feature listed at generation *i* does not necessary correspond to the highest score for this generation, but belongs to the feature tuple producing the best result at generation 16.

8.3 Optimizing the Labeled Attachement Score

We also applied the feature discovery with a search optimized for the labeled attachment score. This time, we reduced the beam width used in the search from 8 to 4 as we noticed that the candidates between ranks 5 and 8 never contributed to the best scoring feature set for any generation.

We observed a score curve similar to that of the UAS-optimized search. The train set followed the development set with increasing values for each generation but 1-2% lower. The optimal value was obtained at generation 15 with 84.21% for the test set. Then, the score for the test set decreased.

9 Feature Discovery on a Corpus of English

The training and development sets of the CoNLL 2008 corpus contain text from the *Wall Street Journal* exclusively. The test set contains text from the Brown corpus as well as from the *Wall Street Journal*. Table 7 shows the results after 16 generations. We used a beam width of 4 and the tests were optimized for the unlabeled attachment score. As for Swedish, we reached the best scores around generation 14-15. The results on the in-domain test set peaked at 90.89 and exceeded the results on the development set. As expected, the results for the out-of-domain corpus were lower, 87.50, however the drop was limited to 3.4.

10 Discussion and Conclusion

The results we attained with feature set sizes as small as 15 are competitive or better than figures

Parent state		$\langle POS(QUEUE_0)\rangle$	$\langle LEX(QUEUE_0)\rangle$

Table 7: Best results for each generation. English corpus. Selection optimized for UAS.

reported by state-of-the-art transition-based systems. We reached a UAS of 89.66 on the CoNLL-X Swedish corpus. On the same corpus, the top scores reported in the shared task were slightly lower: 89.54 and 89.50. Our best LAS was 84.21, and the two best scores in CoNLL-X were 84.58 and 82.55. Our results for the English corpus from CoNLL 2008 were optimized for an unlabeled attachment score and we obtained 90.89 for the in-domain test set and 87.50 for the out-of-domain one. Our best LAS were 88.11 and 81.33. Official results in CoNLL 2008 only reported the labeled attachment scores, respectively 90.13 and 82.81[1].

We believe these results remarkable. We used a single-parser system as opposed to ensemble systems and the results on the Brown corpus show an excellent resilience and robustness on out-of-domain data. The automatic discovery produced results matching or exceeding comparable systems, although no prior knowledge of the language being analyzed was used and no feature set was provided to the parser.

Although, a systematic search requires no intuitive guessing, it still consumes a considerable machine time. Due to the learning algorithm we use, SVM, training a model takes between 1 and 130 hours depending on the size of the corpus. The number of models to train at each generation corresponds to the number of feature candidates times the beam width. The first generation contains about 15 feature candidates per feature set and since features are only added, the number of candidates can grow to 100 at generation 10.

We believe there is a margin for improvement both in the parsing scores and in the time needed to determine the feature sets. Our scores in Swedish were obtained with models trained on 90% of the training set. They could probably be slightly improved if they had been trained on a complete set. In our experiments, we used three attributes: the part of speech, lexical value, and dependency label of the node. These attributes could be extended to lemmas and grammatical features. SVMs yield a high performance, but they are slow to train. Logistic regression with, for instance, the LIBLINEAR package (Fan et al., 2008) would certainly reduce the exploration time.

[1] Results are not exactly comparable as we used the CoNLL-X evaluation script that gives slightly higher figures.

Abstract

We evaluate two dependency parsers, MSTParser and MaltParser, with respect to their capacity to recover unbounded dependencies in English, a type of evaluation that has been applied to grammar-based parsers and statistical phrase structure parsers but not to dependency parsers. The evaluation shows that when combined with simple post-processing heuristics, the parsers correctly recall unbounded dependencies roughly 50% of the time, which is only slightly worse than two grammar-based parsers specifically designed to cope with such dependencies.

1 Introduction

Though syntactic parsers for English are reported to have accuracies over 90% on the Wall Street Journal (WSJ) section of the Penn Treebank (PTB) (McDonald et al., 2005; Sagae and Lavie, 2006; Huang, 2008; Carreras et al., 2008), broad-coverage parsing is still far from being a solved problem. In particular, metrics like attachment score for dependency parsers (Buchholz and Marsi, 2006) and Parseval for constituency parsers (Black et al., 1991) suffer from being an average over a highly skewed distribution of different grammatical constructions. As a result, infrequent yet semantically important construction types could be parsed with accuracies far below what one might expect.

This shortcoming of aggregate parsing metrics was highlighted in a recent study by Rimell et al. (2009), introducing a new parser evaluation corpus containing around 700 sentences annotated with unbounded dependencies in seven different grammatical constructions. This corpus was used to evaluate five state-of-the-art parsers for English, focusing on grammar-based and statistical phrase structure parsers. For example, in the sentence *By Monday, they hope to have a sheaf of* **documents** *both sides can* **trust**., parsers should recognize that there is a dependency between **trust** and **documents**, an instance of object extraction out of a (reduced) relative clause. In the evaluation, the recall of state-of-the-art parsers on this kind of dependency varies from a high of 65% to a low of 1%. When averaging over the seven constructions in the corpus, none of the parsers had an accuracy higher than 61%.

In this paper, we extend the evaluation of Rimell et al. (2009) to two dependency parsers, MSTParser (McDonald, 2006) and MaltParser (Nivre et al., 2006a), trained on data from the PTB, converted to Stanford typed dependencies (de Marneffe et al., 2006), and combined with a simple post-processor to extract unbounded dependencies from the basic dependency tree. Extending the evaluation to dependency parsers is of interest because it sheds light on whether highly tuned grammars or computationally expensive parsing formalisms are necessary for extracting complex linguistic phenomena in practice. Unlike the best performing grammar-based parsers studied in Rimell et al. (2009), neither MSTParser nor MaltParser was developed specifically as a parser for English, and neither has any special mechanism for dealing with unbounded dependencies. Dependency parsers are also often asymptotically faster than grammar-based or constituent parsers, e.g., MaltParser parses sentences in linear time.

Our evaluation ultimately shows that the recall of MSTParser and MaltParser on unbounded dependencies is much lower than the average (un)labeled attachment score for each system. Nevertheless, the two dependency parsers are found to perform only slightly worse than the best grammar-based parsers evaluated in Rimell et al.

Figure 1: Examples of seven unbounded dependency constructions (**a**–**g**). Arcs drawn *below* each sentence represent the dependencies scored in the evaluation, while the tree *above* each sentence is the Stanford basic dependency representation, with solid arcs indicating crucial dependencies (cf. Section 4). All examples are from the development sets.

(2009) and considerably better than the other statistical parsers in that evaluation. Interestingly, though the two systems have similar accuracies overall, there is a clear distinction between the kinds of errors each system makes, which we argue is consistent with observations by McDonald and Nivre (2007).

2 Unbounded Dependency Evaluation

An unbounded dependency involves a word or phrase interpreted at a distance from its surface position, where an unlimited number of clause boundaries may in principle intervene. The unbounded dependency corpus of Rimell et al. (2009) includes seven grammatical constructions: object extraction from a relative clause (ObRC), object extraction from a reduced relative clause (ObRed), subject extraction from a relative clause (SbRC), free relatives (Free), object questions (ObQ), right node raising (RNR), and subject extraction from an embedded clause (SbEm), all chosen for being relatively frequent and easy to identify in PTB trees. Examples of the constructions can be seen in Figure 1. The evaluation set contains 80 sentences per construction (which may translate into more than 80 dependencies, since sentences containing coordinations may have more than one gold-standard dependency), while the development set contains between 13 and 37 sentences per construction. The data for ObQ sentences was obtained from various years of TREC, and for the rest of the constructions from the WSJ (0-1 and 22-24) and Brown sections of the PTB.

Each sentence is annotated with one or more gold-standard dependency relations representing the relevant unbounded dependency. The gold-standard dependencies are shown as arcs below the sentences in Figure 1. The format of the dependencies in the corpus is loosely based on the Stanford typed dependency scheme, although the evaluation procedure permits alternative representations and does not require that the parser output match the gold-standard exactly, as long as the "spirit" of the construction is correct.

The ability to recover unbounded dependencies is important because they frequently form part of the basic predicate-argument structure of a sentence. Subject and object dependencies in particular are crucial for a number of tasks, including information extraction and question answering. Moreover, Rimell et al. (2009) show that, although individual types of unbounded dependencies may be rare, the unbounded dependency types in the corpus, considered as a class, occur in as many as 10% of sentences in the PTB.

In Rimell et al. (2009), five state-of-the-art parsers were evaluated for their recall on the gold-standard dependencies. Three of the parsers were based on grammars automatically extracted from the PTB: the C&C CCG parser (Clark and Curran, 2007), the Enju HPSG parser (Miyao and Tsujii, 2005), and the Stanford parser (Klein and Manning, 2003). The two remaining systems were the

RASP parser (Briscoe et al., 2006), using a manually constructed grammar and a statistical parse selection component, and the DCU post-processor of PTB parsers (Cahill et al., 2004) using the output of the Charniak and Johnson reranking parser (Charniak and Johnson, 2005). Because of the wide variation in parser output representations, a mostly manual evaluation was performed to ensure that each parser got credit for the constructions it recovered correctly. The parsers were run essentially "out of the box", meaning that the development set was used to confirm input and output formats, but no real tuning was performed. In addition, since a separate question model is available for C&C, this was also evaluated on ObQ sentences. The best overall performers were C&C and Enju, which is unsurprising since they are deep parsers based on grammar formalisms designed to recover just such dependencies. The DCU post-processor performed somewhat worse than expected, often identifying the existence of an unbounded dependency but failing to identify the grammatical class (subject, object, etc.). RASP and Stanford, although not designed to recover such dependencies, nevertheless recovered a subset of them. Performance of the parsers also varied widely across the different constructions.

3 Dependency Parsers

In this paper we repeat the study of Rimell et al. (2009) for two dependency parsers, with the goal of evaluating how parsers based on dependency grammars perform on unbounded dependencies.

MSTParser[1] is a freely available implementation of the parsing models described in McDonald (2006). According to the categorization of parsers in Kübler et al. (2008) it is a *graph-based* parsing system in that core parsing algorithms can be equated to finding directed maximum spanning trees (either projective or non-projective) from a dense graph representation of the sentence. Graph-based parsers typically rely on global training and inference algorithms, where the goal is to learn models in which the weight/probability of correct trees is higher than that of incorrect trees. At inference time a global search is run to find the highest weighted dependency tree. Unfortunately, global inference and learning for graph-based dependency parsing is typically NP-hard (McDonald and Satta, 2007). As a result, graph-based parsers (including MSTParser) often limit the scope of their features to a small number of adjacent arcs (usually two) and/or resort to approximate inference (McDonald and Pereira, 2006).

MaltParser[2] is a freely available implementation of the parsing models described in Nivre et al. (2006a) and Nivre et al. (2006b). MaltParser is categorized as a *transition-based* parsing system, characterized by parsing algorithms that produce dependency trees by transitioning through abstract state machines (Kübler et al., 2008). Transition-based parsers learn models that predict the next state given the current state of the system as well as features over the history of parsing decisions and the input sentence. At inference time, the parser starts in an initial state, then greedily moves to subsequent states – based on the predictions of the model – until a termination state is reached. Transition-based parsing is highly efficient, with run-times often linear in sentence length. Furthermore, transition-based parsers can easily incorporate arbitrary non-local features, since the current parse structure is fixed by the state. However, the greedy nature of these systems can lead to error propagation if early predictions place the parser in incorrect states.

McDonald and Nivre (2007) compared the accuracy of MSTParser and MaltParser along a number of structural and linguistic dimensions. They observed that, though the two parsers exhibit indistinguishable accuracies overall, MSTParser tends to outperform MaltParser on longer dependencies as well as those dependencies closer to the root of the tree (e.g., verb, conjunction and preposition dependencies), whereas MaltParser performs better on short dependencies and those further from the root (e.g., pronouns and noun dependencies). Since long dependencies and those near to the root are typically the last constructed in transition-based parsing systems, it was concluded that MaltParser does suffer from some form of error propagation. On the other hand, the

[1] http://mstparser.sourceforge.net

[2] http://www.maltparser.org

richer feature representations of MaltParser led to improved performance in cases where error propagation has not occurred. However, that study did not investigate unbounded dependencies.

4 Methodology

In this section, we describe the methodological setup for the evaluation, including parser training, post-processing, and evaluation.[3]

4.1 Parser Training

One important difference between MSTParser and MaltParser, on the one hand, and the best performing parsers evaluated in Rimell et al. (2009), on the other, is that the former were never developed specifically as parsers for English. Instead, they are best understood as data-driven parser generators, that is, tools for generating a parser given a training set of sentences annotated with dependency structures. Over the years, both systems have been applied to a wide range of languages (see, e.g., McDonald et al. (2006), McDonald (2006), Nivre et al. (2006b), Hall et al. (2007), Nivre et al. (2007)), but they come with no language-specific enhancements and are not equipped specifically to deal with unbounded dependencies.

Since the dependency representation used in the evaluation corpus is based on the Stanford typed dependency scheme (de Marneffe et al., 2006), we opted for using the WSJ section of the PTB, converted to Stanford dependencies, as our primary source of training data. Thus, both parsers were trained on section 2–21 of the WSJ data, which we converted to Stanford dependencies using the Stanford parser (Klein and Manning, 2003). The Stanford scheme comes in several varieties, but because both parsers require the dependency structure for each sentence to be a tree, we had to use the so-called *basic* variety (de Marneffe et al., 2006).

It is well known that questions are very rare in the WSJ data, and Rimell et al. (2009) found that parsers trained only on WSJ data generally performed badly on the questions included in the evaluation corpus, while the C&C parser equipped with a model trained on a combination of WSJ and question data had much better performance. To investigate whether the performance of MSTParser and MaltParser on questions could also be improved by adding more questions to the training data, we trained one variant of each parser using data that was extended with 3924 questions taken from QuestionBank (QB) (Judge et al., 2006).[4] Since the QB sentences are annotated in PTB style, it was possible to use the same conversion procedure as for the WSJ data. However, it is clear that the conversion did not always produce adequate dependency structures for the questions, an observation that we will return to in the error analysis below.

In comparison to the five parsers evaluated in Rimell et al. (2009), it is worth noting that MSTParser and MaltParser were trained on the same basic data as four of the five, but with a different kind of syntactic representation – dependency trees instead of phrase structure trees or theory-specific representations from CCG and HPSG. It is especially interesting to compare MSTParser and MaltParser to the Stanford parser, which essentially produces the same kind of dependency structures as output but uses the original phrase structure trees from the PTB as input to training.

For our experiments we used MSTParser with the same parsing algorithms and features as reported in McDonald et al. (2006). However, unlike that work we used an atomic maximum entropy model as the second stage arc predictor as opposed to the more time consuming sequence labeler. McDonald et al. (2006) showed that there is negligible accuracy loss when using atomic rather than structured labeling. For MaltParser we used the projective Stack algorithm (Nivre, 2009) with default settings and a slightly enriched feature model. All parsing was projective because the Stanford dependency trees are strictly projective.

[3] To ensure replicability, we provide all experimental settings, post-processing scripts and additional information about the evaluation at http://stp.ling.uu.se/∼nivre/exp/.

[4] QB contains 4000 questions, but we removed all questions that also occurred in the test or development set of Rimell et al. (2009), who sampled their questions from the same TREC QA test sets.

4.2 Post-Processing

All the development and test sets in the corpus of Rimell et al. (2009) were parsed using MSTParser and MaltParser after part-of-speech tagging the input using SVMTool (Giménez and Màrquez, 2004) trained on section 2–21 of the WSJ data in Stanford basic dependency format. The Stanford parser has an internal module that converts the *basic* dependency representation to the *collapsed* representation, which explicitly represents additional dependencies, including unbounded dependencies, that can be inferred from the basic representation (de Marneffe et al., 2006). We performed a similar conversion using our own tool.

Broadly speaking, there are three ways in which unbounded dependencies can be inferred from the Stanford basic dependency trees, which we will refer to as *simple*, *complex*, and *indirect*. In the simple case, the dependency coincides with a single, direct dependency relation in the tree. This is the case, for example, in Figure 1**d**–**e**, where all that is required is that the parser identifies the dependency relation from a governor to an argument (`dobj(see, What)`, `dobj(have, effect)`), which we call the Arg relation; no post-processing is needed.

In the complex case, the dependency is represented by a *path* of direct dependencies in the tree, as exemplified in Figure 1**a**. In this case, it is not enough that the parser correctly identifies the Arg relation `dobj(carries, that)`; it must also find the dependency `rcmod(fragment, carries)`. We call this the Link relation, because it links the argument role inside the relative clause to an element outside the clause. Other examples of the complex case are found in Figure 1**c** and in Figure 1**f**.

In the indirect case, finally, the dependency cannot be defined by a path of labeled dependencies, whether simple or complex, but must be inferred from a larger context of the tree using heuristics. Consider Figure 1**b**, where there is a Link relation (`rcmod(things, do)`), but no corresponding Arg relation inside the relative clause (because there is no overt relative pronoun). However, given the other dependencies, we can infer with high probability that the implicit relation is `dobj`. Another example of the indirect case is in Figure 1**g**. Our post-processing tool performs more heuristic inference for the indirect case than the Stanford parser does (cf. Section 4.3).

In order to handle the complex and indirect cases, our post-processor is triggered by the occurrence of a Link relation (`rcmod` or `conj`) and first tries to add dependencies that are directly implied by a single Arg relation (relations involving relative pronouns for `rcmod`, shared heads and dependents for `conj`). If there is no overt relative pronoun, or the function of the relative pronoun is underspecified, the post-processor relies on the obliqueness hierarchy `subj` < `dobj` < `pobj` and simply picks the first "missing function", unless it finds a clausal complement (indicated by the labels `ccomp` and `xcomp`), in which case it descends to the lower clause and restarts the search there.

4.3 Parser Evaluation

The evaluation was performed using the same criteria as in Rimell et al. (2009). A dependency was considered correctly recovered if the gold-standard head and dependent were correct and the label was an "acceptable match" to the gold-standard label, indicating the grammatical function of the extracted element at least to the level of subject, passive subject, object, or adjunct.

The evaluation in Rimell et al. (2009) took into account a wide variety of parser output formats, some of which differed significantly from the gold-standard. Since MSTParser and MaltParser produced Stanford dependencies for this experiment, evaluation required less manual examination than for some of the other parsers, as was also the case for the output of the Stanford parser in the original evaluation. However, a manual evaluation was still performed in order to resolve questionable cases.

5 Results

The results are shown in Table 1, where the accuracy for each construction is the percentage of gold-standard dependencies recovered correctly. The *Avg* column represents a macroaverage, i.e. the average of the individual scores on the seven constructions, while the *WAvg* column represents

Parser	ObRC	ObRed	SbRC	Free	ObQ	RNR	SbEm	Avg	WAvg
MST	34.1	47.3	78.9	65.5	13.8	**45.4**	**37.6**	46.1	63.4
Malt	**40.7**	**50.5**	**84.2**	**70.2**	16.2	39.7	23.5	46.4	**66.9**
MST-Q					**41.2**			**50.0**	
Malt-Q					31.2			48.5	

Table 1: Parser accuracy on the unbounded dependency corpus.

Parser	ObRC	ObRed	SbRC	Free	ObQ	RNR	SbEm	Avg	WAvg
C&C	**59.3**	62.6	80.0	72.6	**81.2**	**49.4**	22.4	**61.1**	69.9
Enju	47.3	**65.9**	82.1	**76.2**	32.5	47.1	32.9	54.9	**70.9**
MST	34.1	47.3	78.9	65.5	41.2	45.4	**37.6**	50.0	63.4
Malt	40.7	50.5	**84.2**	70.2	31.2	39.7	23.5	48.5	66.9
DCU	23.1	41.8	56.8	46.4	27.5	40.8	5.9	34.6	47.0
RASP	16.5	1.1	53.7	17.9	27.5	34.5	15.3	23.8	34.1
Stanford	22.0	1.1	74.7	64.3	41.2	45.4	10.6	37.0	50.3

Table 2: Parser accuracy on the unbounded dependency corpus. The ObQ score for C&C, MSTParser, and MaltParser is for a model trained with additional questions (without this C&C scored 27.5; MSTParser and MaltParser as in Table 1).

a weighted macroaverage, where the constructions are weighted proportionally to their relative frequency in the PTB. WAvg excludes ObQ sentences, since frequency statistics were not available for this construction in Rimell et al. (2009).

Our first observation is that the accuracies for both systems are considerably below the ∼90% unlabeled and ∼88% labeled attachment scores for English that have been reported previously (McDonald and Pereira, 2006; Hall et al., 2006). Comparing the two parsers, we see that MaltParser is more accurate on dependencies in relative clause constructions (ObRC, ObRed, SbRC, and Free), where argument relations tend to be relatively local, while MSTParser is more accurate on dependencies in RNR and SbEm, which involve more distant relations. Without the additional QB training data, the average scores for the two parsers are indistinguishable, but MSTParser appears to have been better able to take advantage of the question training, since MST-Q performs better than Malt-Q on ObQ sentences. On the weighted average MaltParser scores 3.5 points higher, because the constructions on which it outperforms MSTParser are more frequent in the PTB, and because WAvg excludes ObQ, where MSTParser is more accurate.

Table 2 shows the results for MSTParser and MaltParser in the context of the other parsers evaluated in Rimell et al. (2009).[5] For the parsers which have a model trained on questions, namely C&C, MSTParser, and MaltParser, the figure shown for ObQ sentences is that of the question model. It can be seen that MSTParser and MaltParser perform below C&C and Enju, but above the other parsers, and that MSTParser achieves the highest score on SbEm sentences and MaltParser on SbRC sentences. It should be noted, however, that Table 2 does not represent a direct comparison across all parsers, since most of the other parsers would have benefited from heuristic post-processing of the kind implemented here for MSTParser and MaltParser. This is especially true for RASP, where the grammar explicitly leaves some types of attachment decisions for post-processing. For DCU, improved labeling heuristics would significantly improve performance. It is instructive to compare the dependency parsers to the Stanford parser, which uses the same output representation and has been used to prepare the training data for our experiments. Stanford has very low recall on ObRed and SbEm, the categories where heuristic inference plays the largest role, but mirrors MSTParser for most other categories.

6 Error Analysis

We now proceed to a more detailed error analysis, based on the development sets, and classify

[5] The average scores reported differ slightly from those in Rimell et al. (2009), where a microaverage (i.e., average over all dependencies in the corpus, regardless of construction) was reported.

the errors made by the parsers into three categories: A *global* error is one where the parser completely fails to build the relevant clausal structure – the relative clause in ObRC, ObRed, SbRC, Free, SbEmb; the interrogative clause in ObQ; and the clause headed by the higher conjunct in RNR – often as a result of surrounding parsing errors. When a global error occurs, it is usually meaningless to further classify the error, which means that this category excludes the other two. An Arg error is one where the parser has constructed the relevant clausal structure but fails to find the Arg relation – in the simple and complex cases – or the set of surrounding Arg relations needed to infer an implicit Arg relation – in the indirect case (cf. Section 4.2). A Link error is one where the parser fails to find the crucial Link relation – `rcmod` in ObRC, ObRed, SbRC, SbEmb; `conj` in RNR (cf. Section 4.2). Link errors are not relevant for Free and ObQ, where all the crucial relations are clause-internal.

Table 3 shows the frequency of different error types for MSTParser (first) and MaltParser (second) in the seven development sets. First of all, we can see that the overall error distribution is very similar for the two parsers, which is probably due to the fact that they have been trained on exactly the same data with exactly the same annotation (unlike the five parsers previously evaluated). However, there is a tendency for MSTParser to make fewer Link errors, especially in the relative clause categories ObRC, ObRed and SbRC, which is compatible with the observation from the test results that MSTParser does better on more global dependencies, while MaltParser has an advantage on more local dependencies, although this is not evident from the statistics from the relatively small development set.

Comparing the different grammatical constructions, we see that Link errors dominate for the relative clause categories ObRC, ObRed and SbRC, where the parsers make very few errors with respect to the internal structure of the relative clauses (in fact, no errors at all for MaltParser on SbRC). This is different for SbEm, where the analysis of the argument structure is more complex, both because there are (at least) two clauses involved and because the unbounded dependency can only be inferred indirectly from the basic dependency representation (cf. Section 4.2). Another category where Arg errors are frequent is RNR, where all such errors consist in attaching the relevant dependent to the second conjunct instead of to the first.[6] Thus, in the example in Figure 1**f**, both parsers found the `conj` relation between **puzzled** and **angered** but attached **by** to the second verb.

Type	Global	Arg	Link	A+L	Errors	# Deps
ObRC	0/1	1/1	7/11	5/3	13/16	20
ObRed	0/1	0/1	6/7	3/4	9/13	23
SbRC	2/1	1/0	7/13	0/0	10/14	43
Free	2/1	3/5	–	–	5/6	22
ObQ	4/7	13/13	–	–	17/20	25
RNR	6/4	4/6	0/0	4/5	14/15	28
SbEm	3/4	3/2	0/0	3/3	9/9	13

Table 3: Distribution of error types in the development sets; frequencies for MSTParser listed first and MaltParser second. The columns Arg and Link give frequencies for Arg/Link errors occurring without the other error type, while A+L give frequencies for joint Arg and Link errors.

Global errors are most frequent for RNR, probably indicating that coordinate structures are difficult to parse in general, and for ObQ (especially for MaltParser), probably indicating that questions are not well represented in the training set even after the addition of QB data.[7] As noted in Section 4.1, this may be partly due to the fact that conversion to Stanford dependencies did not seem to work as well for QB as for the WSJ data. Another problem is that the part-of-speech tagger used was trained on WSJ data only and did not perform as well on the ObQ data. Uses of *What* as a determiner were consistently mistagged as pronouns, which led to errors in parsing. Thus, for the example in Figure 1**e**, both parsers produced the correct analysis except that, because of the tagging error, they treated **What** rather than **effect** as the head of the *wh*-phrase, which counts as an error in the evaluation.

In order to get a closer look specifically at the Arg errors, Table 4 gives the confusion matrix

[6] In the Stanford scheme, an argument or adjunct must be attached to the first conjunct in a coordination to indicate that it belongs to both conjuncts.

[7] Parsers trained without QB had twice as many global errors.

	Sb	Ob	POb	EmSb	EmOb	Other	Total
Sb	–	0/0	0/0	0/0	0/0	2/1	2/1
Ob	2/3	–	0/0	0/1	0/0	4/2	6/6
POb	2/0	7/5	–	0/0	0/0	5/8	14/13
EmSb	1/1	4/2	0/0	–	0/0	1/2	6/5
EmOb	0/0	3/1	0/0	0/0	–	1/6	4/7
Total	5/4	14/8	0/0	0/1	0/0	13/19	32/32

Table 4: Confusion matrix for Arg errors (excluding RNR and using parsers trained on QB for ObQ); frequencies for MSTParser listed first and MaltParser second. The column Other covers errors where the function is left unspecified or the argument is attached to the wrong head.

for such errors, showing which grammatical functions are mistaken for each other, with an extra category Other for cases where the function is left unspecified by the parser or the error is an attachment error rather than a labeling error (and excluding the RNR category because of the special nature of the Arg errors in this category). The results again confirm that the two parsers make very few errors on subjects and objects clause-internally. The few cases where an object is mistaken as a subject occur in ObQ, where both parsers perform rather poorly in general. By contrast, there are many more errors on prepositional objects and on embedded subjects and objects. We believe an important part of the explanation for this pattern is to be found in the Stanford dependency representation, where subjects and objects are marked as such but all other functions realized by *wh* elements are left unspecified (using the generic *rel* dependency), which means that the recovery of these functions currently has to rely on heuristic rules as described in Section 4.2. Finally, we think it is possible to observe the tendency for MaltParser to be more accurate at local labeling decisions – reflected in fewer cross-label confusions – and for MSTParser to perform better on more distant attachment decisions – reflected in fewer errors in the Other category (and in fewer Link errors).

7 Conclusion

In conclusion, the capacity of MSTParser and MaltParser to recover unbounded dependencies is very similar on the macro and weighted macro level, but there is a clear distinction in their strengths – constructions involving more distant dependencies such as ObQ, RNR and SbEm for MSTParser and constructions with more locally defined configurations such as ObRC, ObRed, SbRC and Free for MaltParser. This is a pattern that has been observed in previous evaluations of the parsers and can be explained by the global learning and inference strategy of MSTParser and the richer feature space of MaltParser (McDonald and Nivre, 2007).

Perhaps more interestingly, the accuracies of MSTParser and MaltParser are only slightly below the best performing systems in Rimell et al. (2009) – C&C and Enju. This is true even though MSTParser and MaltParser have not been engineered specifically for English and lack special mechanisms for handling unbounded dependencies, beyond the simple post-processing heuristic used to extract them from the output trees. Thus, it is reasonable to speculate that the addition of such mechanisms could lead to computationally lightweight parsers with the ability to extract unbounded dependencies with high accuracy.

Acknowledgments

We thank Marie-Catherine de Marneffe for great help with the Stanford parser and dependency scheme, Lluís Màrquez and Jesús Giménez for great support with SVMTool, Josef van Genabith for sharing the QuestionBank data, and Stephen Clark and Mark Steedman for helpful comments on the evaluation process and the paper. Co-STAR: A Co-training Style Algorithm for Hyponymy Relation Acquisition from Structured and Unstructured Text

Jong-Hoon Oh, Ichiro Yamada, Kentaro Torisawa, and Stijn De Saeger
Language Infrastructure Group, MASTAR Project,
National Institute of Information and Communications Technology (NICT)
{rovellia,iyamada,torisawa,stijn}@nict.go.jp

Abstract

This paper proposes a co-training style algorithm called Co-STAR that acquires hyponymy relations simultaneously from structured and unstructured text. In Co-STAR, two independent processes for hyponymy relation acquisition – one handling structured text and the other handling unstructured text – collaborate by repeatedly exchanging the knowledge they acquired about hyponymy relations. Unlike conventional co-training, the two processes in Co-STAR are applied to different source texts and training data. We show the effectiveness of this algorithm through experiments on large-scale hyponymy-relation acquisition from Japanese Wikipedia and Web texts. We also show that Co-STAR is robust against noisy training data.

1 Introduction

Acquiring semantic knowledge, especially semantic relations between lexical terms, is regarded as a crucial step in developing high-level natural language applications. This paper proposes Co-STAR (a **Co**-training **ST**yle **A**lgorithm for hyponymy **R**elation acquisition from structured and unstructured text). Similar to co-training (Blum and Mitchell, 1998), two hyponymy relation extractors in Co-STAR, one for structured and the other for unstructured text, iteratively collaborate to boost each other's performance.

Many algorithms have been developed to automatically acquire semantic relations from structured and unstructured text. Because term pairs are encoded in structured and unstructured text in different styles, different kinds of evidence have been used for semantic relation acquisition:

Evidence from unstructured text: lexico-syntactic patterns and distributional similarity (Ando et al., 2004; Hearst, 1992; Pantel et al., 2009; Snow et al., 2006; De Saeger et al., 2009; Van Durme and Pasca, 2008);

Evidence from structured text: topic hierarchy, layout structure of documents, and HTML tags (Oh et al., 2009; Ravi and Pasca, 2008; Sumida and Torisawa, 2008; Shinzato and Torisawa, 2004).

Recently, researchers have used both structured and unstructured text for semantic-relation acquisition, with the aim of exploiting such different kinds of evidence at the same time. They either tried to improve semantic relation acquisition by putting the different evidence together into a single classifier (Pennacchiotti and Pantel, 2009) or to improve the coverage of semantic relations by combining and ranking the semantic relations obtained from two source texts (Talukdar et al., 2008).

In this paper we propose an algorithm called Co-STAR. The main contributions of this work can be summarized as follows.

- Co-STAR is a semi-supervised learning method composed of two parallel and iterative processes over structured and unstructured text. It was inspired by bilingual co-training, which is a framework for hyponymy relation acquisition from source texts in two languages (Oh et al., 2009). Like bilingual co-training, two processes in Co-STAR operate independently on structured text and unstructured text. These two processes are trained in a supervised manner with their initial training data and then each of them tries to enlarge the existing training data of the other by iteratively exchanging what they have learned (more precisely, by transferring reliable classification results on common instances to one another) (see Section 4 for comparison Co-STAR and bilingual co-training). Unlike the ensemble semantic framework (Pennacchiotti and Pantel, 2009), Co-STAR does not have a single "*master*" classifier or ranker to integrate the different evidence found in structured and unstructured text. We experimentally show that, at least in our setting, Co-STAR works better than a single "*master*" classifier.

- Common relation instances found in both structured and unstructured text act as a *communication channel* between the two acquisition processes. Each process in Co-STAR classifies common relation instances and then transfers its high-confidence classification results to training data of the other process (as shown in Fig. 1), in order to improve classification results of the other process. Moreover, the efficiency of this exchange can be boosted by increasing the "bandwidth" of this channel. For this purpose each separate acquisition process automatically generates a set of relation instances that are likely to be *negative*. In our experiments, we show that the above idea proved highly effective.

- Finally, the acquisition algorithm we propose is robust against noisy training data. We show this by training one classifier in Co-STAR with manually labeled data and training the other with automatically generated but noisy training data. We found that Co-STAR performs well in this setting. This issue is discussed in Section 6.

This paper is organized as follows. Sections 2 and 3 precisely describe our algorithm. Section 4 describes related work. Sections 5 and 6 describe our experiments and present their results. Conclusions are drawn in Section 7.

2 Co-STAR

Co-STAR consists of two processes that simultaneously but independently extract and classify hyponymy relation instances from structured and unstructured text. The core of Co-STAR is the collaboration between the two processes, which continually exchange and compare their acquired knowledge on hyponymy relations. This collaboration is made possible through common instances shared by both processes. These common instances are classified separately by each process, but high-confidence classification results by one process can be transferred as new training data to the other.

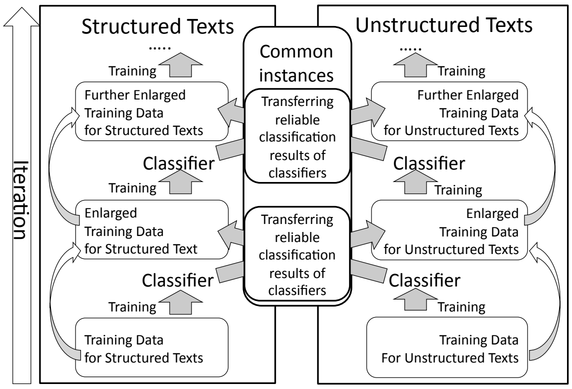

Figure 1: Concept of *Co-STAR*.

2.1 Common Instances

Let S and U represent a source (i.e. corpus) of structured and unstructured text, respectively. In this paper, we use the hierarchical layout of Wikipedia articles and the Wikipedia category system as structured text S (see Section 3.1), and a corpus of ordinary Web pages as unstructured text U. Let X_S and X_U denote a set of hyponymy relation candidates extracted from S and U, respectively. X_S is extracted from the hierarchical layout of Wikipedia articles (Oh et al., 2009) and X_U is extracted by lexico-syntactic patterns for hyponymy relations (i.e., *hyponym* such as *hyponymy*) (Ando et al., 2004) (see Section 3 for a detailed explanation)

We define two types of common instances, called "*genuine*" common instances (G) and "*virtual*" common instances (V). The set of common instances is denoted by $Y = G \cup V$. Genuine common instances are hyponymy relation candidates found in both S and U ($G = X_S \cap X_U$). On the other hand, term pairs are obtained as virtual common instances when:

- 1) they are extracted as hyponymy relation candidates in either S or U and;
- 2) they do not seem to be a hyponymy relation in the other text

The first condition corresponds to $X_S \oplus X_U$. Term pairs satisfying the second condition are defined as R_S and R_U, where $R_S \cap X_S = \phi$ and $R_U \cap X_U = \phi$.

R_S contains term pairs that are found in the Wikipedia category system but neither term appears as ancestor of the other[1]. For example, (*nutrition,protein*) and (*viruses,viral disease*), respectively, hold a category-article relation, where *nutrition* is not ancestor of *viruses* and vice versa in the Wikipedia category system. Here, term pairs, such as (*nutrition, viruses*) and (*viral disease, nutrition*), can be ones in R_S.

R_U is a set of term pairs extracted from U when:

- they are not hyponymy relation candidates in X_U and;
- they regularly co-occur in the same sentence as arguments of the same verb (e.g., A *cause* B or A *is made by* B);

As a result, term pairs in R_U are thought as holding some other semantic relations (e.g., A and B in "A *cause* B" may hold a cause/effect relation) than hyponymy relation. Finally, virtual common instances are defined as:

- $V = (X_S \oplus X_U) \cap (R_S \cup R_U)$

The virtual common instances, from the viewpoint of either S or U, are unlikely to hold a hyponymy relation even if they are extracted as hyponymy relation candidates in the other text. Thus many virtual common instances would be a negative example for hyponymy relation acquisition. On the other hand, genuine common instances (hyponymy relation candidates found in both S and U) are more likely to hold a hyponymy relation than virtual common instances.

In summary, genuine and virtual common instances can be used as different ground for collaboration as well as broader collaboration channel between the two processes than genuine common instances used alone.

2.2 Algorithm

We assume that classifier c assigns class label $cl \in \{yes, no\}$ ("yes" (hyponymy relation) or "no" (not a hyponymy relation)) to instances in $x \in X$ with confidence value $r \in \mathbb{R}^+$, a non-negative real number. We denote the classification result by classifier c as $c(x) = (x, cl, r)$. We used support vector machines (SVMs) in our experiments and the absolute value of the distance between a sample and the hyperplane determined by the SVMs as confidence value r.

```
**Input**: Common instances ($Y = G \cup V$) and the initial training data ($L_S^0$ and $L_U^0$)
**Output**: Two classifiers ($c_S^n$ and $c_U^n$)
$i = 0$
**repeat**
    $c_S^i := LEARN(L_S^i)$
    $c_U^i := LEARN(L_U^i)$
    $CR_S^i := \{c_S^i(y) | y \in Y, y \notin L_S^i \cup L_U^i\}$
    $CR_U^i := \{c_U^i(y) | y \in Y, y \notin L_S^i \cup L_U^i\}$
    **for** each $(y, cl_S, r_S) \in TopN(CR_S^i)$ and $(y, cl_U, r_U) \in CR_U^i$ **do**
        **if** ($r_S > \alpha$ and $r_U < \beta$)
        or ($r_S > \alpha$ and $cl_S = cl_U$) **then**
            $L_U^{(i+1)} := L_U^{(i+1)} \cup \{(y, cl_S)\}$
        **end if**
    **end for**
    **for** each $(y, cl_U, r_U) \in TopN(CR_U^i)$ and $(y, cl_S, r_S) \in CR_S^i$ **do**
        **if** ($r_U > \alpha$ and $r_S < \beta$)
        or ($r_U > \alpha$ and $cl_S = cl_U$) **then**
            $L_S^{(i+1)} := L_S^{(i+1)} \cup \{(y, cl_U)\}$
        **end if**
    **end for**
    $i = i + 1$
**until** stop condition is met
```

Figure 2: Co-STAR algorithm

[1] A term pair often holds a hyponymy relation if one term in the term pair is a parent of the other in the Wikipedia category system (Suchanek et al., 2007).

The Co-STAR algorithm is given in Fig. 2. The algorithm is interpreted as an iterative procedure 1) to train classifiers (c_U^i, c_S^i) with the existing training data (L_S^i and L_U^i) and 2) to select new training instances from the common instances to be added to existing training data. These are repeated until stop condition is met.

In the initial stage, two classifiers c_S^0 and c_U^0 are trained with manually prepared labeled instances (or training data) L_S^0 and L_U^0, respectively. The learning procedure is denoted by $c = LEARN(L)$ in lines 5–6, where c is a resulting classifier. Then c_S^i and c_U^i are applied to classify common instances in Y (lines 7–8). We denote CR_S^i as a set of the classification results of c_S^i for common instances, which are not included in the current training data $L_S^i \cup L_U^i$. Lines 9–13 describe a way of selecting instances in CR_S^i to be added to the existing training data in U. During the selection, c_S^i acts as a teacher and c_U^i as a student. $TopN(CR_S^i)$ is a set of $c_S^i(y) = (y, cl_S, r_S)$, whose r_S is the top-N highest in CR_S^i. (In our experiments, $N = 900$.) The teacher instructs his student the class label of y if the teacher can decide the class label of y with a certain level of confidence ($r_S > \alpha$) and the student satisfies one of the following two conditions:

- the student agrees with the teacher on class label of y ($cl_S = cl_U$) or

- the student's confidence in classifying y is low ($r_U < \beta$)

$r_U < \beta$ enables the teacher to instruct his student in spite of their disagreement over a class label. If one of the two conditions is satisfied, (y, cl_S) is added to existing labeled instances $L_U^{(i+1)}$. The roles are reversed in lines 14–18, so that c_U^i becomes the teacher and c_S^i the student.

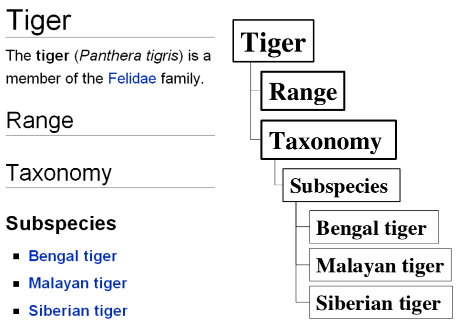
The iteration stops if the change in the difference between the two classifiers is stable enough. The stability is estimated by $d(c_S^i, c_U^i)$ in Eq. (1), where σ^i represents the change in the average difference between the confidence values of the two classifiers in classifying common instances. We terminate the iteration if $d(c_S^i, c_U^i)$ is smaller than 0.001 in three consecutive rounds (Wang and Zhou, 2007).

$$d(c_S^i, c_U^i) = |\sigma^i - \sigma^{(i-1)}|/|\sigma^{(i-1)}| \qquad (1)$$

3 Hyponymy Relation Acquisition

In this section we explain how each process extracts hyponymy relations from its respective text source either Wikipedia or Web pages. Each process extracts hyponymy relation candidates (denoted by (*hyper,hypo*) in this section). Because there are many non-hyponymy relations in these candidates[2], we classify hyponymy relation candidates into correct hyponymy relation or not. We used SVMs (Vapnik, 1995) for the classification in this paper.

3.1 Acquisition from Wikipedia



(a) Layout structure (b) Tree structure

Figure 3: Example borrowed from Oh et al. (2009): Layout and tree structures of Wikipedia article TIGER

We follow the method in Oh et al. (2009) for acquiring hyponymy relations from the Japanese Wikipedia. Every article is transformed into a tree structure as shown in Fig. 3, based on the items in its hierarchical layout including *title*, *(sub)section headings*, and *list items*. Candidate relations are extracted from this tree structure by regarding a node as a hypernym candidate and all of its subordinate nodes as potential hyponyms of the hypernym candidate (e.g., (TIGER, TAXONOMY) and (TIGER, SIBERIAN TIGER) from Fig. 3). We obtained 1.9×10^7 Japanese hyponymy relation candidates from Wikipedia.

[2] Only 25–30% of candidates was true hyponymy relation in our experiments.

	Type	Description
Feature from Wikipedia ("WikiFeature")	Lexical	Morphemes and POS of *hyper* and *hypo*; *hyper* and *hypo* themselves
	Structure	Distance between *hyper* and *hypo* in a tree structure; Lexical patterns for article or section names, where listed items often appear; Frequently used section headings in Wikipedia (e.g., "Reference"); Layout item type (e.g., section or list); Tree node type (e.g., root or leaf); Parent and children nodes of *hyper* and *hypo*
	Infobox	Attribute type and its value obtained from Wikipedia infoboxes
Feature from Web texts ("WebFeature")	Lexical	Morphemes and POS of *hyper* and *hypo*; *hyper* and *hypo* themselves
	Pattern	Lexico-syntactic patterns applied to *hyper* and *hypo*; PMI score between pattern and hyponymy relation candidate *(hyper,hypo)*
	Collocation	PMI score between *hyper* and *hypo*
	Noun Class	Noun classes relevant to *hyper* and *hypo*

Table 1: Feature sets (WikiFeature and WebFeature): *hyper* and *hypo* represent hypernym and hyponym parts of hyponymy relation candidates, respectively.

As features for classification we used lexical, structure, and infobox information from Wikipedia (WikiFeature), as shown in Table 1. Because they are the same feature sets as those used in Oh et al. (2009), here we just give a brief overview of the feature sets. Lexical features[3] are used to recognize the lexical evidence for hyponymy relations encoded in *hyper* and *hypo*. For example, the common head morpheme *tiger* in (TIGER, BENGAL TIGER) can be used as the lexical evidence. Such information is provided along with the words/morphemes and the parts of speech of *hyper* and *hypo*, which can be multi-word/morpheme nouns.

Structure features provide evidence found in layout or tree structures for hyponymy relations. For example, hyponymy relations (TIGER, BENGAL TIGER) and (TIGER,MALAYAN TIGER) can be obtained from tree structure "(root node, children nodes of *Subspecies*)" in Fig 3.

3.2 Acquisition from Web Texts

As the target for hyponymy relation acquisition from the Web, we used 5×10^7 pages from the TSUBAKI corpus (Shinzato et al., 2008), a 10^8 page Japanese Web corpus that was dependency parsed with KNP (Kurohashi-Nagao Parser) (Kurohashi and Kawahara, 2005). Hyponymy relation candidates are extracted from the corpus based on the lexico-syntactic patterns such as "*hypo* nado *hyper* (*hyper* such as *hypo*)" and "*hypo* to iu *hyper* (*hyper* called *hypo*)" (Ando et al., 2004). We extracted 6×10^6 Japanese hyponymy relation candidates from the Japanese Web texts. Features (WebFeature) used for classification are summarized in Table 1. Similar to the hyponymy relation acquisition from Wikipedia, lexical features are used to recognize the lexical evidence for hyponymy relations.

Lexico-syntactic patterns for hyponymy relation show different coverage and accuracy in hyponymy relation acquisition (Ando et al., 2004). Further if multiple lexico-syntactic patterns support acquisition of hyponymy relation candidates, these candidates are more likely to be actual hyponymy relations. The pattern feature of hyponymy relation candidates is used for these evidence.

We use PMI (point-wise mutual information) of hyponymy relation candidate (*hyper*, *hypo*) as a collocation feature (Pantel and Ravichandran, 2004), where we assume that *hyper* and *hypo* in candidates would frequently co-occur in the same sentence if they hold a hyponymy relation.

Semantic noun classes have been regarded as useful information in semantic relation acquisition (De Saeger et al., 2009). EM-based clustering (Kazama and Torisawa, 2008) is used for obtaining 500 semantic noun classes[4] from 5×10^5 nouns (including single-word and multi-word ones) and their 4×10^8 dependency relations with 5×10^5 verbs and other nouns in our target Web

[3] MeCab (`http://mecab.sourceforge.net/`) was used to provide the lexical features.

[4] Because EM clustering provides a probability distribution over noun class nc, we obtain discrete classes of each noun n with a probability threshold $p(nc|n) \geq 0.2$ (De Saeger et al., 2009).

	Co-training (Blum and Mitchell, 1998)	Bilingual co-training (Oh et al., 2009)	Co-STAR (Proposed method)
Instance space	Same	Different	Almost different
Feature space	Split by human decision	Split by languages	Split by source texts
Common instances	Genuine-common (or All unlabeled) instances	Genuine-common instances (Translatable)	Genuine-common and virtual-common instances

Table 2: Differences among co-training, bilingual co-training, and Co-STAR

corpus. For example, noun class C_{311} includes biological or chemical substances such as *tatou* (*polysaccharide*) and *yuukikagoubutsu* (*organic compounds*). Noun classes (i.e., C_{311}) relevant to *hyper* and *hypo*, respectively, are used as a noun class feature.

4 Related Work

There are two frameworks, which are most relevant to our work – bilingual co-training and ensemble semantics.

The main difference between bilingual co-training and Co-STAR lies in an instance space. In bilingual co-training, instances are in different spaces divided by languages while, in Co-STAR, many instances are in different spaces divided by their source texts. Table 2 shows differences between co-training, bilingual co-training and Co-STAR.

Ensemble semantics is a relation acquisition framework, where semantic relation candidates are extracted from multiple sources and a single ranker ranks or classifies the candidates in the final step (Pennacchiotti and Pantel, 2009). In ensemble semantics, one ranker is in charge of ranking all candidates extracted from multiple sources; while one classifier classifies candidates extracted from one source in Co-STAR.

5 Experiments

We used the July version of Japanese Wikipedia (jawiki-20090701) as structured text. We randomly selected 24,000 hyponymy relation candidates from those identified in Wikipedia and manually checked them. 20,000 of these samples were used as training data for our initial classifier, the rest was equally divided into development and test data for Wikipedia. They are called "WikiSet." As unstructured text, we used 5×10^7 Japanese Web pages in the TSUBAKI corpus (Shinzato et al., 2008). Here, we manually checked 9,500 hyponymy relation candidates selected randomly from Web texts. 7,500 of these were used as training data. The rest was split into development and test data. We named this data "WebSet".

In both classifiers, the development data was used to select the optimal parameters, and the test data was used to evaluate our system. We used TinySVM (TinySVM, 2002) with a polynomial kernel of degree 2 as a classifier. α (the threshold value indicating high confidence), β (the threshold value indicating low confidence), and $TopN$ (the maximum number of training instances to be added to the existing training data in each iteration) were selected through experiments on the development set. The combination of $\alpha = 1$, $\beta = 0.3$, and $TopN$=900 showed the best performance and was used in the following experiments. Evaluation was done by precision (P), recall (R), and F-measure (F).

5.1 Results

We compare six systems. Three of these, B1–B3, show the effect of different feature sets ("WikiFeature" and "WebFeature" in Table 1) and different training data. We trained two separate classifiers in B1 and B2, while we integrated feature sets and training data for training a single classifier in B3. The classifiers in these three systems are trained with manually prepared training data ("WikiSet" and "WebSet"). For the purpose of our experiment, we consider **B3** as the closest possible approximation of the ensemble semantics framework (Pennacchiotti and Pantel, 2009).

- **B1** consists of two completely independent classifiers. Both S and U classifiers are trained and tested on their own feature and data sets (respectively "WikiSet + WikiFeature" and "WebSet + WebFeature").

- **B2** is the same as B1, except that both classifiers are trained with all available training data — WikiSet and WebSet are combined (27,500 training instances in total). However, each classifier only uses its own feature set (WikiFeature or WebFeature)[5].

- **B3** adds a *master* classifier to **B1**. This third classifier is trained on the complete 27,500 training instances (same as **B2**) using all available features from Table 1, including each instance's SVM scores obtained from the two **B1** classifiers[6]. The verdict of the master classifier is considered to be the final classification result.

The other three systems, BICO, Co-B, and Co-STAR (our proposed method), are for comparison between bilingual co-training (Oh et al., 2009) (BICO) and variants of Co-STAR (Co-B and Co-STAR). Especially, we prepared Co-B and Co-STAR to show the effect of different configurations of common instances on the Co-STAR algorithm. We use both B1 and B2 as the initial classifiers of Co-B and Co-STAR. We notate Co-B and Co-STAR without '∗' when B1 is used as their initial classifier and those with '∗' when B2 is used.

- **BICO** implements the bilingual co-training algorithm of (Oh et al., 2009), in which two processes collaboratively acquire hyponymy relations in two *different languages*. For BICO, we prepared 20,000 English and 20,000 Japanese training samples (Japanese ones are the same as training data in the WikiSet) by hand.

- **Co-B** is a variant of Co-STAR that uses only the genuine-common instances as common instances (67,000 instances)[7], to demonstrate the effectiveness of the virtual common instances.

- **Co-STAR** is our proposed method, which uses both genuine-common and virtual-common instances (643,000 instances in total).

	WebSet			WikiSet		
	P	R	F	P	R	F
B1	84.3	65.2	73.5	87.8	74.7	80.7
B2	83.4	69.6	75.9	87.4	79.5	83.2
B3	82.2	72.0	76.8	86.1	77.7	81.7
BICO	N/A	N/A	N/A	84.5	**81.8**	83.1
Co-B	**86.2**	63.5	73.2	**89.7**	74.1	81.2
Co-B∗	85.5	69.9	77.0	89.6	76.5	82.5
Co-STAR	85.9	76.0	80.6	88.0	**81.8**	**84.8**
Co-STAR∗	83.3	**80.7**	**82.0**	87.6	**81.8**	84.6

Table 3: Comparison of different systems

Table 3 summarizes the result. Features for common instances in Co-B and Co-STAR are prepared in the same way as training data in B2, so that both classifiers can classify the common instances with their trained feature sets.

Comparison between B1–B3 shows that B2 and B3 outperform B1 in F-measure. More training data used in B2–B3 (27,500 instances for both WebSet and WikiSet) results in higher performance than that of B1 (7,500 and 20,000 instances used separately). We think that the lexical features, assigned regardless of source text to instances in B2–B3, are mainly responsible for the performance gain over B1, as they are the least domain-dependent type of features. B2–B3 are composed of different number of classifiers, each of which is trained with different feature sets and training instances. Despite this difference, B2 and B3 showed similar performance in F-measure.

Co-STAR outperformed the algorithm similar to the ensemble semantics framework (B3), although we admit that a more extensive comparison is desirable. Further Co-STAR outperformed BICO. While the manual cost for building the initial training data used in Co-STAR and BICO is hard to quantify, Co-STAR achieves better performance with fewer training data in total (27,500 instances) than BICO (40,000 instances). The difference in performance between Co-B and Co-STAR shows the effectiveness of

[5] Note that training instances from WebSet (or WikiSet) can have WikiFeature (or WebFeature) if they also appear in Wikipedia (or Web corpus). But they can always have lexical feature, the common feature set between WikiFeature and WebFeature.

[6] SVM scores are assigned to the instances in training data in a 10-fold cross validation manner.

[7] Co-B can be considered as conventional co-training (Blum and Mitchell, 1998) in the sense that two classifiers collaborate through actual common instances.

the automatically generated virtual-common instances. From these comparison, we can see that virtual-common instances coupled with genuine-common instances can be leveraged to enable more effective collaboration between the two classifiers in Co-STAR.

As a result, our proposed method outperforms the others in F-measure by 1.4–8.5%. We obtained 4.3×10^5 hyponymy relations from Web texts and 4.6×10^6 ones from Wikipedia[8].

6 Co-STAR with Automatically Generated Training Data

For Co-STAR, we need two sets of manually prepared training data, one for structured text and the other for unstructured text. As in any other supervised system, the cost of preparing the training data is an important issue. We therefore investigated whether Co-STAR can be trained for a lower cost by generating more of its training data automatically.

We automatically built training data for Web texts by using definition sentences[9] and category names in the Wikipedia articles, while we stuck to manually prepared training data for Wikipedia. To obtain hypernyms from Wikipedia article names, we used definition-specific lexico-syntactic patterns such as "*hyponym* is *hypernym*" and "*hyponym* is a type of *hypernym*" (Kazama and Torisawa, 2007; Sumida and Torisawa, 2008). Then, we extracted hyponymy relations consisting of pairs of Wikipedia category names and their member articles when the Wikipedia category name and the hypernym obtained from the definition of the Wikipedia article shared the same head word. Next, we selected a subset of the extracted hyponymy relations that are also hyponymy relation candidates in Web texts, as positive instances for hyponymy relation acquisition from Web text. We obtained around 15,000 positive instances in this way. Negative instances were chosen from virtual-common instances, which also originated from the Wikipedia category system and hyponymy relation candidates in Web texts (around 293,000 instances).

The automatically built training data was noisy and its size was much bigger than manually prepared training data in WebSet. Thus 7,500 instances as training data (the same number of manually built training data in WebSet) were randomly chosen from the positive and negative instances with a positive:negative ratio of 1:4[10].

	WebSet			WikiSet		
	P	R	F	P	R	F
B1	81.0	47.6	60.0	**87.8**	74.7	80.7
B2	80.0	55.4	65.5	87.1	79.5	83.1
B3	82.0	33.7	47.8	87.1	75.6	81.0
Co-STAR	**82.2**	60.8	69.9	87.3	80.7	83.8
Co-STAR$*$	79.2	**69.6**	**74.1**	87.0	**81.8**	**84.4**

Table 4: Results with automatically generated training data

With the automatically built training data for Web texts and manually prepared training data for Wikipedia, we evaluated B1–B3 and Co-STAR, which are the same systems in Table 3. The results in Table 4 are encouraging. Co-STAR was robust even when faced with noisy training data. Further Co-STAR showed better performance than B1–B3, although its performance in Table 4 dropped a bit compared to Table 3. This result shows that we can reduce the cost of manually preparing training data for Co-STAR with only small loss of the performance.

7 Conclusion

This paper proposed Co-STAR, an algorithm for hyponymy relation acquisition from structured and unstructured text. In Co-STAR, two independent processes of hyponymy relation acquisition from structured texts and unstructured texts, collaborate in an iterative manner through common instances. To improve this collaboration, we introduced virtual-common instances.

Through a series of experiments, we showed that Co-STAR outperforms baseline systems and virtual-common instances can be leveraged to achieve better performance. We also showed that Co-STAR is robust against noisy training data, which requires less human effort to prepare it.

[8] We obtained them with 90% precision by setting the SVM score threshold to 0.23 for Web texts and 0.1 for Wikipedia.

[9] The first sentences of Wikipedia articles.

[10] We select the ratio by testing different ratio from 1:2 to 1:5 with our development data in WebSet and B1.

Abstract

This paper presents a simple and efficient algorithm for approximate dictionary matching designed for similarity measures such as cosine, Dice, Jaccard, and overlap coefficients. We propose this algorithm, called *CPMerge*, for the τ-overlap join of inverted lists. First we show that this task is solvable exactly by a τ-overlap join. Given inverted lists retrieved for a query, the algorithm collects fewer candidate strings and prunes unlikely candidates to efficiently find strings that satisfy the constraint of the τ-overlap join. We conducted experiments of approximate dictionary matching on three large-scale datasets that include person names, biomedical names, and general English words. The algorithm exhibited scalable performance on the datasets. For example, it retrieved strings in 1.1 ms from the string collection of Google Web1T unigrams (with cosine similarity and threshold 0.7).

1 Introduction

Languages are sufficiently flexible to be able to express the same meaning through different diction. At the same time, inconsistency of surface expressions has persisted as a serious problem in natural language processing. For example, in the biomedical domain, *cardiovascular disorder* can be described using various expressions: *cardiovascular diseases*, *cardiovascular system disorder*, and *disorder of the cardiovascular system*. It is a nontrivial task to find the entry from these surface expressions appearing in text.

This paper addresses *approximate dictionary matching*, which consists of finding all strings in a string collection V such that they have similarity that is no smaller than a threshold α with a query string x. This task has a broad range of applications, including spelling correction, flexible dictionary look-up, record linkage, and duplicate detection (Henzinger, 2006; Manku et al., 2007).

Formally, the task obtains a subset $\mathcal{Y}_{x,\alpha} \subseteq V$,

$$\mathcal{Y}_{x,\alpha} = \{y \in V \mid \mathrm{sim}(x, y) \geq \alpha\}, \qquad (1)$$

where $\mathrm{sim}(x, y)$ presents the similarity between x and y. A naïve solution to this task is to compute similarity values $|V|$ times, i.e., between x and every string $y \in V$. However, this solution is impractical when the number of strings $|V|$ is huge (e.g., more than one million).

In this paper, we present a simple and efficient algorithm for approximate dictionary matching designed for similarity measures such as cosine, Dice, Jaccard, and overlap coefficients. Our main contributions are twofold.

1. We show that the problem of approximate dictionary matching is solved exactly by a *τ-overlap join* (Sarawagi and Kirpal, 2004) of inverted lists. Then we present *CPMerge*, which is a simple and efficient algorithm for the τ-overlap join. In addition, the algorithm is easily implemented.

2. We demonstrate the efficiency of the algorithm on three large-scale datasets with person names, biomedical concept names,

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 851–859,
Beijing, August 2010

and general English words. We compare the algorithm with state-of-the-art algorithms, including Locality Sensitive Hashing (Ravichandran et al., 2005; Andoni and Indyk, 2008) and DivideSkip (Li et al., 2008). The proposed algorithm retrieves strings the most rapidly, e.g., in 1.1 ms from Google Web1T unigrams (with cosine similarity and threshold 0.7).

2 Proposed Method

2.1 Necessary and sufficient conditions

In this paper, we assume that the *features* of a string are represented arbitrarily by a set. Although it is important to design a string representation for an accurate similarity measure, we do not address this problem: our emphasis is *not on designing a better representation for string similarity* but *on establishing an efficient algorithm*.

The most popular representation is given by *n-grams*: all substrings of size n in a string. We use trigrams throughout this paper as an example of string representation. For example, the string “methyl sulphone” is expressed by 17 elements of letter trigrams[1], {'$$m', '$me', 'met', 'eth', 'thy', 'hyl', 'yl_', 'l_s', '_su', 'sul', 'ulp', 'lph', 'pho', 'hon', 'one', 'ne$', 'e$$'}. We insert two $s before and after the string to denote the start or end of the string. In general, a string x consisting of $|X|$ letters yields $(|x| + n - 1)$ elements of n-grams. We call $|x|$ and $|X|$ the *length* and *size*, respectively, of the string x.

Let X and Y denote the feature sets of the strings x and y, respectively. The cosine similarity between the two strings x and y is,

$$\text{cosine}(X, Y) = \frac{|X \cap Y|}{\sqrt{|X||Y|}}. \tag{2}$$

Table 1: Conditions for each similarity measure

Measure	$\min |Y|$	$\max |Y|$	$\tau (= \min |X \cap Y|)$
Dice	$\frac{\alpha}{2-\alpha}|X|$	$\frac{2-\alpha}{\alpha}|X|$	$\frac{1}{2}\alpha(|X| + |Y|)$
Jaccard	$\alpha|X|$	$|X|/\alpha$	$\frac{\alpha(|X|+|Y|)}{1+\alpha}$
Cosine	$\alpha^2|X|$	$|X|/\alpha^2$	$\alpha\sqrt{|X||Y|}$
Overlap	—	—	$\alpha \min\{|X|, |Y|\}$

By integrating this definition with Equation 1, we obtain the necessary and sufficient condition for approximate dictionary matching,

$$\left\lceil \alpha\sqrt{|X||Y|} \right\rceil \leq |X \cap Y| \leq \min\{|X|, |Y|\}. \tag{3}$$

This inequality states that two strings x and y must have at least $\tau = \left\lceil \alpha\sqrt{|X||Y|} \right\rceil$ features in common. When ignoring $|X \cap Y|$ in the inequality, we have an inequality about $|X|$ and $|Y|$,

$$\left\lceil \alpha^2|X| \right\rceil \leq |Y| \leq \left\lfloor \frac{|X|}{\alpha^2} \right\rfloor \tag{4}$$

This inequality presents the search range for retrieving similar strings; that is, we can ignore strings whose feature size is out of this range. Other derivations are also applicable to similarity measures, including Dice, Jaccard, and overlap coefficients. Table 1 summarizes the conditions for these similarity measures.

We explain one usage of these conditions. Let query string x = “methyl sulphone” and threshold for approximate dictionary matching $\alpha = 0.7$ with cosine similarity. Representing the strings with letter trigrams, we have the size of x, $|X| = 17$. The inequality 4 gives the search range of $|Y|$ of the retrieved strings, $9 \leq |Y| \leq 34$. Presuming that we are searching for strings of $|Y| = 16$, we obtain the necessary and sufficient condition for the approximate dictionary matching from the inequality 3, $\tau = 12 \leq |X \cap Y|$. Thus, we need to search for strings that have at least 12 letter trigrams that overlap with X. When considering a string y = “methyl sulfone”, which is a spelling variant of y (*ph* → *f*), we confirm that the string is a solution for approximate dictionary matching because $|X \cap Y| = 13$ $(\geq \tau)$. Here, the actual similarity is $\text{cosine}(X, Y) = 13/\sqrt{17 \times 16} = 0.788$ $(\geq \alpha)$.

2.2 Data structure and algorithm

Algorithm 1 presents the pseudocode of the approximate dictionary matching based on Table 1.

[1] In practice, we attach ordinal numbers to n-grams to represent multiple occurrences of n-grams in a string (Chaudhuri et al., 2006). For example, the string “prepress”, which contains two occurrences of the trigram 'pre', yields the set {'$$p'#1, '$pr'#1, 'pre'#1, 'rep'#1, 'epr'#1, 'pre'#2, 'res'#1, 'ess'#1, 'ss$'#1, 's$$'#1}.

```
Input: $V$: collection of strings
Input: $x$: query string
Input: $\alpha$: threshold for the similarity
Output: $\mathcal{Y}$: list of strings similar to the query
1 $X \leftarrow$ string_to_feature($x$);
2 $\mathcal{Y} \leftarrow$[];
3 for $l \leftarrow$ min_y($|X|$, $\alpha$) to max_y($|X|$, $\alpha$) do
4     $\tau \leftarrow$ min_overlap($|X|$, $l$, $\alpha$);
5     $R \leftarrow$ overlapjoin($X$, $\tau$, $V$, $l$);
6     foreach $r \in R$ do append $r$ to $\mathcal{Y}$;
7 end
8 return $\mathcal{Y}$;
```

Algorithm 1: Approximate dictionary matching.

Given a query string x, a collection of strings V, and a similarity threshold α, the algorithm computes the size range (line 3) given by Table 1. For each size l in the range, the algorithm computes the minimum number of overlaps τ (line 4). The function `overlapjoin` (line 5) finds similar strings by solving the following problem (τ-*overlap join*): given a list of features of the query string X and the minimum number of overlaps τ, enumerate strings of size l in the collection V such that they have at least τ feature overlaps with X.

To solve this problem efficiently, we build an inverted index that stores a mapping from the features to their originating strings. Then, we can perform the τ-overlap join by finding strings that appear at least τ times in the inverted lists retrieved for the query features X.

Algorithm 2 portrays a naïve solution for the τ-overlap join (AllScan algorithm). In this algorithm, function `get`(V, l, q) returns the inverted list of strings (of size l) for the feature q. In short, this algorithm scans strings in the inverted lists retrieved for the query features X, counts the frequency of occurrences of every string in the inverted lists, and returns the strings whose frequency of occurrences is no smaller than τ.

```
Input: $X$: array of features of the query string
Input: $\tau$: minimum number of overlaps
Input: $V$: collection of strings
Input: $l$: size of target strings
Output: $R$: list of strings similar to the query
$M \leftarrow \{\}$;
$R \leftarrow []$;
foreach $q \in X$ do
    foreach $i \in$ get($V$, $l$, $q$) do
        $M[i] \leftarrow M[i] + 1$;
        if $\tau \leq M[i]$ then
            append $i$ to $R$;
        end
    end
end
return $R$;
```

Algorithm 2: AllScan algorithm.

This algorithm is inefficient in that it scans all strings in the inverted lists. The number of scanned strings is large, especially when some query features appear frequently in the strings, e.g., `'s$$'` (words ending with 's') and `'pre'` (words with substring 'pre'). To make matters worse, such features are too common for characterizing string similarity. The AllScan algorithm is able to maintain numerous candidate strings in M, but most candidates are not likely to qualified because they have few overlaps with X.

To reduce the number of the candidate strings, we refer to *signature-based algorithms* (Arasu et al., 2006; Chaudhuri et al., 2006):

Property 1 *Let there be a set (of size h) X and a set (of any size) Y. Consider any subset $Z \subseteq X$ of size $(h - \tau + 1)$. If $|X \cap Y| \geq \tau$, then $Z \cap Y \neq \phi$.*

We explain one usage of this property. Let query string x = "methyl sulphone" and its trigram set X be features (therefore, $|X| = h = 17$). Presuming that we seek strings whose trigrams are size 16 and have 12 overlaps with X, then string y must have at least one overlap with any subset of size 6 (= 17 − 12 + 1) of X. We call the subset *signatures*. The property leads to an algorithmic design by which we obtain a small set of candidate strings from the inverted lists for signatures, $(|X| - \tau + 1)$ features in X, and verify whether each candidate string satisfies the τ overlap with the remaining $(\tau - 1)$ n-grams.

Algorithm 3 presents the pseudocode employing this idea. In line 1, we arrange the features in X in ascending order of the number of strings in their inverted lists. We denote the k-th element in the ordered features as X_k ($k \in \{0, ..., |X| - 1\}$), where the index number begins with 0. Based on this notation, X_0 and $X_{|X|-1}$ are the most uncommon and the most common features in X, respectively.

In lines 2–7, we use $(|X| - \tau + 1)$ features

```
    Input: $X$: array of features of the query string
    Input: $\tau$: minimum number of overlaps
    Input: $V$: collection of strings
    Input: $l$: size of target strings
    Output: $R$: list of strings similar to the query
1   sort elements in $X$ by order of $|$get $(V, l, X_k)|$;
2   $M \leftarrow \{\}$;
3   for $k \leftarrow 0$ to $(|X| - \tau)$ do
4       foreach $s \in$ get $(V, l, X_k)$ do
5           $M[s] \leftarrow M[s] + 1$;
6       end
7   end
8   $R \leftarrow []$;
9   for $k \leftarrow (|X| - \tau + 1)$ to $(|X| - 1)$ do
10      foreach $s \in M$ do
11          if bsearch(get $(V, l, X_k)$, $s$) then
12              $M[s] \leftarrow M[s] + 1$;
13          end
14          if $\tau \leq M[s]$ then
15              append $s$ to $R$;
16              remove $s$ from $M$;
17          else if $M[s] + (|X| - k - 1) < \tau$ then
18              remove $s$ from $M$;
19          end
20      end
21  end
22  return $R$;
```

Algorithm 3: CPMerge algorithm.

$X_0, ..., X_{|X|-\tau}$ to generate a compact set of candidate strings. The algorithm stores the occurrence count of each string s in $M[s]$. In lines 9–21, we increment the occurrence counts if each of $X_{|X|-\tau+1}, ..., X_{|X|-1}$ inverted lists contain the candidate strings. For each string s in the candidates (line 10), we perform a binary search on the inverted list (line 11), and increment the overlap count if the string s exists (line 12). If the overlap counter of the string reaches τ (line 14), then we append the string s to the result list R and remove s from the candidate list (lines 15–16). We prune a candidate string (lines 17–18) if the candidate is found to be unreachable for τ overlaps even if it appears in all of the unexamined inverted lists.

3 Experiments

We report the experimental results of approximate dictionary matching on large-scale datasets with person names, biomedical names, and general English words. We implemented various systems of approximate dictionary matching.

- **Proposed**: CPMerge algorithm.
- **Naive**: Naïve algorithm that computes the cosine similarity $|V|$ times for every query.
- **AllScan**: AllScan algorithm.
- **Signature**: CPMerge algorithm without pruning; this is equivalent to Algorithm 3 without lines 17–18.
- **DivideSkip**: our implementation of the algorithm (Li et al., 2008)[2].
- **Locality Sensitive Hashing (LSH)** (Andoni and Indyk, 2008): This baseline system follows the design of previous work (Ravichandran et al., 2005). This system *approximately* solves Equation 1 by finding dictionary entries whose LSH values are within the (bit-wise) hamming distance of θ from the LSH value of a query string. To adapt the method to approximate dictionary matching, we used a 64-bit LSH function computed with letter trigrams. By design, this method does not find an exact solution to Equation 1; in other words, the method can miss dictionary entries that are actually similar to the query strings. This system has three parameters, θ, q (number of bit permutations), and B (search width), to control the tradeoff between retrieval speed and recall[3]. Generally speaking, increasing these parameters improves the recall, but slows down the speed. We determined $\theta = 24$ and $q = 24$ experimentally[4], and measured the performance when $B \in \{16, 32, 64\}$.

The systems, excluding LSH, share the same implementation of Algorithm 1 so that we can specifically examine the differences of the algorithms for τ-overlap join. The C++ source code of the system used for this experiment is available[5]. We ran all experiments on an application server running Debian GNU/Linux 4.0 with Intel Xeon 5140 CPU (2.33 GHz) and 8 GB main memory.

[2] We tuned parameter values $\mu \in \{0.01, 0.02, 0.04, 0.1, 0.2, 0.4, 1, 2, 4, 10, 20, 40, 100\}$ for each dataset. We selected the parameter with the fastest response.

[3] We followed the notation of the original paper (Ravichandran et al., 2005) here. Refer to the original paper for definitions of the parameters θ, q, and B.

[4] q was set to 24 so that the arrays of shuffled hash values are stored in memory. We chose $\theta = 24$ from $\{8, 16, 24\}$ because it showed a good balance between accuracy and speed.

[5] http://www.chokkan.org/software/simstring/

3.1 Datasets

We used three large datasets with person names (IMDB actors), general English words (Google Web1T), and biomedical names (UMLS).

- **IMDB actors**: This dataset comprises actor names extracted from the IMDB database[6]. We used all actor names (1,098,022 strings; 18 MB) from the file `actors.list.gz`. The average number of letter trigrams in the strings is 17.2. The total number of trigrams is 42,180. The system generated index files of 83 MB in 56.6 s.
- **Google Web1T unigrams**: This dataset consists of English word unigrams included in the Google Web1T corpus (LDC2006T13). We used all word unigrams (13,588,391 strings; 121 MB) in the corpus after removing the frequency information. The average number of letter trigrams in the strings is 10.3. The total number of trigrams is 301,459. The system generated index files of 601 MB in 551.7 s.
- **UMLS**: This dataset consists of English names and descriptions of biomedical concepts included in the Unified Medical Language System (UMLS). We extracted all English concept names (5,216,323 strings; 212 MB) from `MRCONSO.RRF.aa.gz` and `MRCONSO.RRF.ab.gz` in UMLS Release 2009AA. The average number of letter trigrams in the strings is 43.6. The total number of trigrams is 171,596. The system generated index files of 1.1 GB in 1216.8 s.

For each dataset, we prepared 1,000 query strings by sampling strings randomly from the dataset. To simulate the situation where query strings are not only identical but also similar to dictionary entries, we introduced random noise to the strings. In this experiment, one-third of the query strings are unchanged from the original (sampled) strings, one-third of the query strings have one letter changed, and one-third of the query strings have two letters changed. When changing a letter, we randomly chose a letter position from a uniform distribution, and replaced the letter at the position with an ASCII letter randomly chosen from a uniform distribution.

3.2 Results

To examine the scalability of each system, we controlled the number of strings to be indexed from 10%–100%, and issued 1,000 queries. Figure 1 portrays the average response time for retrieving strings whose cosine similarity values are no smaller than 0.7. Although LSH (B=16) seems to be the fastest in the graph, this system missed many true positives[7]; the recall scores of approximate dictionary matching were 15.4% (IMDB), 13.7% (Web1T), and 1.5% (UMLS). Increasing the parameter B improves the recall at the expense of the response time. LSH (B=64)[8]. It not only ran slower than the proposed method, but also suffered from low recall scores, 25.8% (IMDB), 18.7% (Web1T), and 7.1% (UMLS). LSH was useful only when we required a quick response much more than recall.

The other systems were guaranteed to find the exact solution (100% recall). The proposed algorithm was the fastest of all exact systems on all datasets: the response times per query (100% index size) were 1.07 ms (IMDB), 1.10 ms (Web1T), and 20.37 ms (UMLS). The response times of the Naïve algorithm were too slow, 32.8 s (IMDB), 236.5 s (Web1T), and 416.3 s (UMLS).

The proposed algorithm achieved substantial improvements over the AllScan algorithm: the proposed method was 65.3 times (IMDB), 227.5 times (Web1T), and 13.7 times (UMLS) faster than the Naïve algorithm. We observed that the Signature algorithm, which is Algorithm 3 without lines 17–18, did not perform well: The Signature algorithm was 1.8 times slower (IMDB), 2.1 times faster (Web1T), and 135.0 times slower (UMLS) than the AllScan algorithm. These results indicate that it is imperative to minimize the number of candidates to reduce the number of binary-search operations. The proposed algorithm was 11.1–13.4 times faster than DivideSkip.

Figure 2 presents the average response time

[6] `ftp://ftp.fu-berlin.de/misc/movies/database/`

[7] Solving Equation 1, all systems are expected to retrieve the exact set of strings retrieved by the Naïve algorithm.

[8] The response time of LSH (B=64) on the IMDB dataset was 29.72 ms (100% index size).

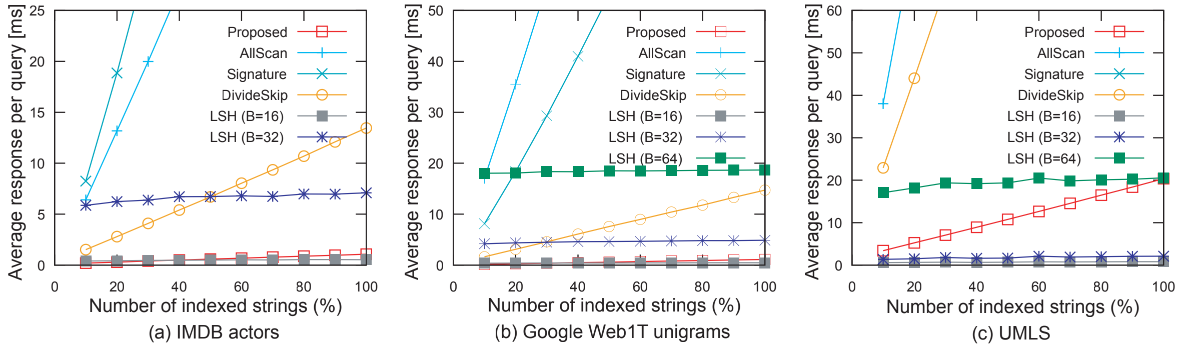

Figure 1: Average response time for processing a query (cosine similarity; $\alpha = 0.7$).

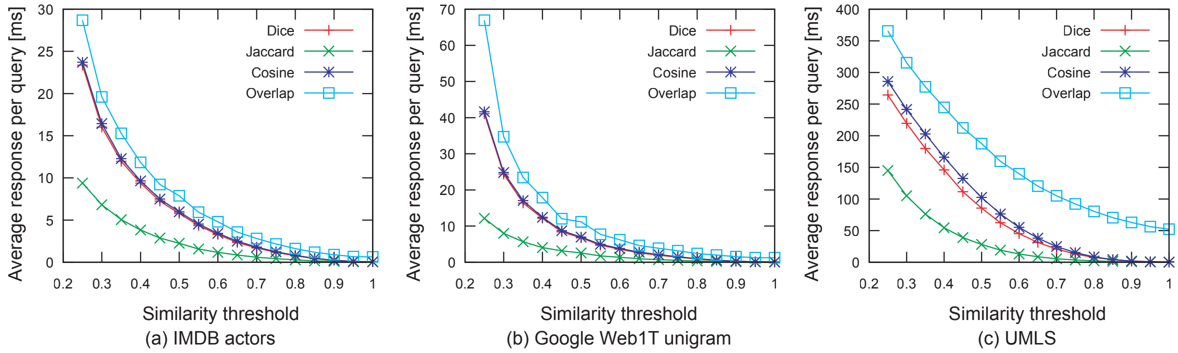

Figure 2: Average response time for processing a query.

of the proposed algorithm for different similarity measures and threshold values. When the similarity threshold is lowered, the algorithm runs slower because the number of retrieved strings $|\mathcal{Y}|$ increases exponentially. The Dice coefficient and cosine similarity produced similar curves.

Table 2 summarizes the run-time statistics of the proposed method for each dataset (with cosine similarity and threshold 0.7). Using the IMDB dataset, the proposed method searched for strings whose size was between 8.74 and 34.06; it retrieved 4.63 strings per query string. The proposed algorithm scanned 279.7 strings in 4.6 inverted lists to obtain 232.5 candidate strings. The algorithm performed a binary search on 4.3 inverted lists containing 7,561.8 strings in all. In contrast, the AllScan algorithm had to scan 16,155.1 strings in 17.7 inverted lists and considered 9,788.7 candidate strings, and found only 4.63 similar strings.

This table clearly demonstrates three key contributions of the proposed algorithm for efficient approximate dictionary matching. First, the proposed algorithm scanned far fewer strings than did the AllScan algorithm. For example, to obtain candidate strings in the IMDB dataset, the proposed algorithm scanned 279.7 strings, whereas the AllScan algorithm scanned 16,155.1 strings. Therefore, the algorithm examined only 1.1%–3.5% of the strings in the entire inverted lists in the three datasets. Second, the proposed algorithm considered far fewer candidates than did the AllScan algorithm: the number of candidate strings considered by the algorithm was 1.2%–6.6% of those considered by the AllScan algorithm. Finally, the proposed algorithm read fewer inverted lists than did the AllScan algorithm. The proposed algorithm actually read 8.9 (IMDB), 6.0 (Web1T), and 31.7 (UMLS) inverted lists during the experiments[9]. These values indicate that the proposed algorithm can solve τ-overlap join problems by checking only 50.3% (IMDB), 53.6% (Web1T), and 51.9% of the total inverted lists re-

[9] These values are 4.6 + 4.3, 3.1 + 2.9, and 14.3 + 17.4.

Table 2: Run-time statistics of the proposed algorithm for each dataset

Averaged item	IMDB	Web1T	UMLS	Description
$\min \lvert y \rvert$	8.74	5.35	21.87	minimum size of trigrams of target strings
$\max \lvert y \rvert$	34.06	20.46	88.48	maximum size of trigrams of target strings
τ	14.13	9.09	47.77	minimum number of overlaps required/sufficient per query
$\lvert \mathcal{Y} \rvert$	4.63	3.22	111.79	number of retrieved strings per query
Total				— averaged for each query and target size:
# inverted lists	17.7	11.2	61.1	number of inverted lists retrieved for a query
# strings	16 155.1	52 557.6	49 561.4	number of strings in the inverted list
# unique strings	9 788.7	44 834.6	17 457.5	number of unique strings in the inverted list
Candidate stage				— averaged for each query and target size:
# inverted lists	4.6	3.1	14.3	number of inverted lists scanned for generating candidates
# strings	279.7	552.7	1 756.3	number of strings scanned for generating candidates
# candidates	232.5	523.7	1 149.7	number of candidates generated for a query
Validation stage				— averaged for each query and target size:
# inverted lists	4.3	2.9	17.4	number of inverted lists examined by binary search for a query
# strings	7 561.8	19 843.6	20 443.7	number of strings targeted by binary search

trieved for queries.

4 Related Work

Numerous studies have addressed approximate dictionary matching. The most popular configuration uses n-grams as a string representation and the edit distance as a similarity measure. Gravano et al. (1998; 2001) presented various filtering strategies, e.g., count filtering, position filtering, and length filtering, to reduce the number of candidates. Kim et al. (2005) proposed two-level n-gram inverted indices (n-Gram/2L) to eliminate the redundancy of position information in n-gram indices. Li et al. (2007) explored the use of variable-length grams (VGRAMs) for improving the query performance. Lee et al. (2007) extended n-grams to include wild cards and developed algorithms based on a replacement semi-lattice. Xiao et al. (2008) proposed the Ed-Join algorithm, which utilizes mismatching n-grams.

Several studies addressed different paradigms for approximate dictionary matching. Bocek et al. (2007) presented the Fast Similarity Search (FastSS), an enhancement of the neighborhood generation algorithms, in which multiple variants of each string record are stored in a database. Wang et al. (2009) further improved the technique of neighborhood generation by introducing partitioning and prefix pruning. Huynh et al. (2006) developed a solution to the k-mismatch problem in compressed suffix arrays. Liu et al. (2008) stored string records in a trie, and proposed a framework called TITAN. These studies are specialized for the edit distance measure.

A few studies addressed approximate dictionary matching for similarity measures such as cosine and Jaccard similarities. Chaudhuri et al. (2006) proposed the SSJoin operator for similarity joins with several measures including the edit distance and Jaccard similarity. This algorithm first generates *signatures* for strings, finds all pairs of strings whose signatures overlap, and finally outputs the subset of these candidate pairs that satisfy the similarity predicate. Arasu et al. (2006) addressed *signature schemes*, i.e., methodologies for obtaining signatures from strings. They also presented an implementation of the SSJoin operator in SQL. Although we did not implement this algorithm in SQL, it is equivalent to the Signature algorithm in Section 3.

Sarawagi and Kirpal (2004) proposed the MergeOpt algorithm for the τ-overlap join to approximate string matching with overlap, Jaccard, and cosine measures. This algorithm splits inverted lists for a given query A into two groups, S and L, maintains a heap to collect candidate strings on S, and performs a binary search on L to verify the condition of the τ-overlap join for each candidate string. Their subsequent work includes an efficient algorithm for the top-k search of the overlap join (Chandel et al., 2006).

Li et al. (2008) extended this algorithm to the SkipMerge and DivideSkip algorithms. The SkipMerge algorithm uses a heap to compute the τ-overlap join on entire inverted lists A, but has an additional mechanism to increment the frontier pointers of inverted lists efficiently based on the strings popped most recently from the heap. Consequently, SkipMerge can reduce the number of strings that are pushed to the heap. Similarly to the MergeOpt algorithm, DivideSkip splits inverted lists A into two groups S and L, but it applies SkipMerge to S. In Section 3, we reported the performance of DivideSkip.

Charikar (2002) presented the Locality Sensitive Hash (LSH) function (Andoni and Indyk, 2008), which preserves the property of cosine similarity. The essence of this function is to map strings into N-bit hash values where the bitwise hamming distance between the hash values of two strings approximately corresponds to the angle of the two strings. Ravichandran et al. (2005) applied LSH to the task of noun clustering. Adapting this algorithm to approximate dictionary matching, we discussed its performance in Section 3.

Several researchers have presented refined similarity measures for strings (Winkler, 1999; Cohen et al., 2003; Bergsma and Kondrak, 2007; Davis et al., 2007). Although these studies are sometimes regarded as a research topic of approximate dictionary matching, they assume that two strings for the target of similarity computation are given; in other words, it is out of their scope to find strings in a large collection that are similar to a given string. Thus, it is a reasonable approach for an approximate dictionary matching to quickly collect candidate strings with a loose similarity threshold, and for a refined similarity measure to scrutinize each candidate string for the target application.

5 Conclusions

We present a simple and efficient algorithm for approximate dictionary matching with the cosine, Dice, Jaccard, and overlap measures. We conducted experiments of approximate dictionary matching on large-scale datasets with person names, biomedical names, and general English words. Even though the algorithm is very simple, our experimental results showed that the proposed algorithm executed very quickly. We also confirmed that the proposed method drastically reduced the number of candidate strings considered during approximate dictionary matching. We believe that this study will advance practical NLP applications for which the execution time of approximate dictionary matching is critical.

An advantage of the proposed algorithm over existing algorithms (e.g., MergeSkip) is that it does not need to read all the inverted lists retrieved by query n-grams. We observed that the proposed algorithm solved τ-overlap joins by checking approximately half of the inverted lists (with cosine similarity and threshold $\alpha = 0.7$). This characteristic is well suited to processing compressed inverted lists because the algorithm needs to decompress only half of the inverted lists. It is natural to extend this study to compressing and decompressing inverted lists for reducing disk space and for improving query performance (Behm et al., 2009).

Latent Mixture of Discriminative Experts for Multimodal Prediction Modeling

Derya Ozkan, Kenji Sagae and Louis-Philippe Morency
USC Institute for Creative Technologies
{ozkan,sagae,morency}@ict.usc.edu

Abstract

During face-to-face conversation, people naturally integrate speech, gestures and higher level language interpretations to predict the right time to start talking or to give backchannel feedback. In this paper we introduce a new model called Latent Mixture of Discriminative Experts which addresses some of the key issues with multimodal language processing: (1) temporal synchrony/asynchrony between modalities, (2) micro dynamics and (3) integration of different levels of interpretation. We present an empirical evaluation on listener nonverbal feedback prediction (e.g., head nod), based on observable behaviors of the speaker. We confirm the importance of combining four types of multimodal features: lexical, syntactic structure, eye gaze, and prosody. We show that our Latent Mixture of Discriminative Experts model outperforms previous approaches based on Conditional Random Fields (CRFs) and Latent-Dynamic CRFs.

1 Introduction

Face-to-face communication is highly interactive. Even when only one person speaks at a time, other participants exchange information continuously amongst themselves and with the speaker through gestures, gaze and prosody. These different channels contain complementary information essential to interpretation and understanding of human behaviors (Oviatt, 1999). Psycholinguistic studies also suggest that gesture and speech come from a single underlying mental process, and they are related both temporally and semantically (McNeill, 1992; Cassell and Stone, 1999; Kendon, 2004).

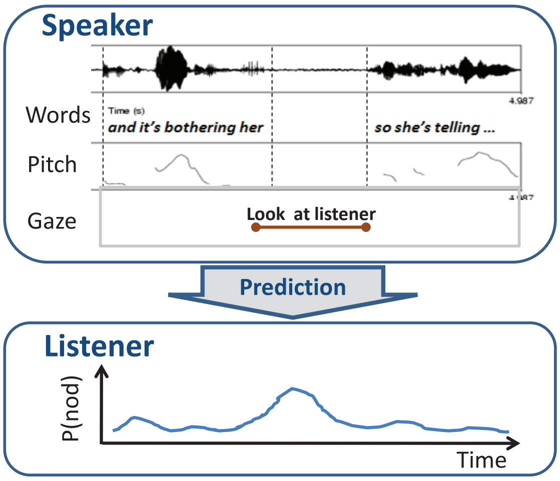

Figure 1: Example of multimodal prediction model: listener nonverbal backchannel prediction based on speaker's speech and eye gaze. As the speaker says the word *her*, which is the end of the clause (*her* is also the object of the verb *bothering*), and lowers the pitch while looking back at the listener and eventually pausing, the listener is then very likely to head nod (i.e., nonverbal backchannel).

A good example of such complementarity is how people naturally integrate speech, gestures and higher level language to predict when to give backchannel feedback. Building computational models of such a predictive process is challenging since it involves micro dynamics and temporal relationship between cues from different modalities (Quek, 2003). Figure 1 shows an example of backchannel prediction where a listener head nod is more likely. For example, a temporal sequence from the speaker where he/she reaches the end of segment (syntactic feature) with a low pitch and looks at the listener before pausing is a good opportunity for the listener to give nonverbal feedback (e.g., head nod). These prediction models have broad applicability, including the improvement of nonverbal behavior recognition, the synthesis of natural animations for robots and virtual humans, the training of cultural-specific nonverbal behaviors, and the diagnoses of social disorders (e.g., autism spectrum disorder).

In this paper we introduce a new model called Latent Mixture of Discriminative Experts (LMDE) which addresses some of the key issues with multimodal language processing: (1) temporal synchrony/asynchrony between modalities, (2) micro dynamics and (3) integration of different levels of interpretation. We present an empirical evaluation on nonverbal feedback prediction (e.g., head nod) confirming the importance of combining different types of multimodal features. We show that our LMDE model outperforms previous approaches based Conditional Random Fields (CRFs) and Latent-Dynamic CRFs.

2 Related Work

Earlier work in multimodal language processing focused on multimodal dialogue systems where the gestures and speech may be constrained (Johnston, 1998; Jurafsky et al., 1998). Most of the research in multimodal language processing over the past decade fits within two main trends that have emerged: (1) recognition of individual multimodal actions such as speech and gestures (e.g, (Eisenstein et al., 2008; Frampton et al., 2009; Gravano et al., 2007)), and (2) recognition/summarization of the social interaction between more than one participants (e.g., meeting analysis (Heylen and op den Akker, 2007; Moore, 2007; Murray and Carenini, 2009; Jovanovic et al., 2006)).

The work described in this paper can be seen from a third intermediate category where multimodal cues from one person is used to predict the social behavior of another participant. This type of predictive models has been mostly studied in the context of embodied conversational agents (Nakano et al., 2003; Nakano et al., 2007). In particular, backchannel feedback (the nods and paraverbals such as “uh-hu” and “mm-hmm” that listeners produce as someone is speaking) has received considerable interest due to its pervasiveness across languages and conversational contexts and this paper addresses the problem of how to predict and generate this important class of dyadic nonverbal behavior.

Several researchers have developed models to predict when backchannel should happen. In general, these results are difficult to compare as they utilize different corpora and present varying evaluation metrics. Ward and Tsukahara (2000) propose a unimodal approach where backchannels are associated with a region of low pitch lasting 110ms during speech. Models were produced manually through an analysis of English and Japanese conversational data. Nishimura et al. (2007) present a unimodal decision-tree approach for producing backchannels based on prosodic features. Cathcart et al. (2003) propose a unimodal model based on pause duration and trigram part-of-speech frequency. The model was constructed by identifying, from the HCRC Map Task Corpus (Anderson et al., 1991), trigrams ending with a backchannel. Fujie et al. (2004) used Hidden Markov Models to perform head nod recognition. In their paper, they combined head gesture detection with prosodic low-level features from the same person to determine strongly positive, weak positive and negative responses to yes/no type utterances.

In recent years, great research has shown the strength of latent variable models for natural language processing (Blunsom et al., 2008). One of the most relevant works is that of Eisenstein and Davis (2007), which presents a latent conditional model for fusion of multiple modalities (speech and gestures). One of the key difference of our work is that we are explicitly modeling the micro dynamics and temporal relationship between modalities.

3 Multimodal Prediction Models

Human face-to-face communication is a little like a dance, in that participants continuously adjust their behaviors based on verbal and nonverbal displays and signals. A topic of central interest in modeling such behaviors is the patterning of interlocutor actions and interactions, moment-by-moment, and one of the key challenges is identifying the patterns that best predict specific actions. Thus we are interested in developing predictive models of communication dynamics that integrate previous and current actions from all interlocutors to anticipate the most likely next actions of one or all interlocutors. Humans are good at this: they have an amazing ability to predict, at a micro-level, the actions of an interlocutor (Bavelas et al., 2000); and we know that better predictions can correlate with more empathy and better outcomes (Goldberg, 2005; Fuchs, 1987).

With turn-taking being perhaps the best-known example, we now know a fair amount about some aspects of communication dynamics, but much less about others. However, recent advances in machine learning and experimental methods, and recent findings from a variety of perspectives, including conversation analysis, social signal processing, adaptation, corpus analysis and modeling, perceptual experiments, and dialog systems-building and experimentation, mean that the time is ripe to start working towards more comprehensive predictive models.

The study of multimodal prediction models bring a new series of research challenges:

Multimodal asynchrony While speech and gestures seem to come from a single underlying mental process (McNeill, 1992), they not always happen at the same time, making it hard for earlier multimodal fusion approaches based on synchrony. A multimodal prediction model needs to be able to learn automatically the temporal relationship (and relative importance) between modalities.

Micro dynamics The dynamic between multimodal signals should be taken at a micro level since many of the interactions between speech and gesture happen at the sub-gesture level or sub-word level (Quek, 2003). Typical word-based sampling may not be sufficient and instead a higher sampling rate should be used.

Limited annotated data Given the time requirement to correctly annotate multimodal data, most multimodal datasets contain only a limited number of labeled examples. Since many machine learning algorithms rely on a large training corpus, effective training of a predictive model on multimodal datasets is challenging.

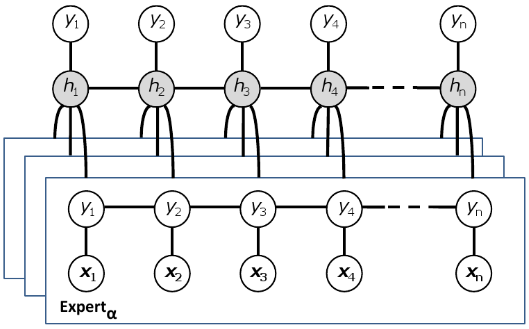

Figure 2: Latent Mixture of Discriminative Experts: a new dynamic model for multimodal fusion. In this graphical model, x_j represents the j^{th} multimodal observation, h_j is a hidden state assigned to x_j , and y_j the class label of x_j. Gray circles are latent variables. The micro dynamics and multimodal temporal relationships are automatically learned by the hidden states h_j during the learning phase.

4 Latent Mixture of Discriminative Experts

In this paper we present a multimodal fusion algorithm, called Latent Mixture of Discriminative Experts (shown in Figure 2), that addresses the three challenges discussed in the previous section. The hidden states of LMDE automatically learn the temporal asynchrony between modalities. By using a constant sample rate of 30Hz in our experiments, we can model the micro dynamics of speech and prosody (e.g., change of intonation in the middle of a word). And finally, by training separate experts for each modalities, we improve the prediction performance even with limited datasets.

The task of our LMDE model is to learn a mapping between a sequence of multimodal observations $\mathbf{x} = \{x_1, x_2, ..., x_m\}$ and a sequence of labels $\mathbf{y} = \{y_1, y_2, ..., y_m\}$. Each y_j is a class label for the j^{th} frame of a video sequence and is a member of a set $\mathcal{Y}$ of possible class labels, for example, $\mathcal{Y} = \{\texttt{head-nod}, \texttt{other-gesture}\}$.

Each frame observation x_j is represented by a feature vector $\phi(x_j) \in \mathbf{R}^d$, for example, the prosodic features at each sample. For each sequence, we also assume a vector of "sub-structure" variables $\mathbf{h} = \{h_1, h_2, ..., h_m\}$. These variables are not observed in the training examples and will therefore form a set of hidden variables in the model.

Following Morency et al. (2007), we define our LMDE model as follows:

$$P(\mathbf{y} \mid \mathbf{x}, \theta) = \sum_{\mathbf{h}} P(\mathbf{y} \mid \mathbf{h}, \mathbf{x}, \theta) P(\mathbf{h} \mid \mathbf{x}, \theta) \quad (1)$$

where θ is the model parameters that is to be estimated from training data.

To keep training and inference tractable, Morency et al. (2007) restrict the model to have disjoint sets of hidden states associated with each class label. Each h_j is a member of a set $\mathcal{H}_{y_j}$ of possible hidden states for the class label y_j. $\mathcal{H}$, the set of all possible hidden states, is defined to be the union of all $\mathcal{H}_y$ sets. Since sequences which have any $h_j \notin \mathcal{H}_{y_j}$ will by definition have $P(\mathbf{y} \mid \mathbf{h}, \mathbf{x}, \theta) = 0$, latent conditional model becomes:

$$P(\mathbf{y} \mid \mathbf{x}, \theta) = \sum_{\mathbf{h}:\forall h_j \in \mathcal{H}_{y_j}} P(\mathbf{h} \mid \mathbf{x}, \theta). \quad (2)$$

What differentiates our LMDE model from the original work of Morency et al. is the definition of $P(\mathbf{h}|\mathbf{x}, \theta)$:

$$P(\mathbf{h}| \mathbf{x}, \theta) = \frac{\exp\begin{pmatrix} \sum_l \theta_l \cdot \mathbf{T}_l(\mathbf{h}, \mathbf{x}) + \\ \sum_\alpha \theta_\alpha \cdot P_\alpha(\mathbf{y}|\mathbf{x}, \lambda_\alpha) \end{pmatrix}}{\mathcal{Z}(\mathbf{x}, \theta)}, \quad (3)$$

where $\mathcal{Z}$ is the partition function and $P_\alpha(\mathbf{y}|\mathbf{x})$ is the conditional distribution of the expert indexed by α. The expert conditional distributions are defined $P_\alpha(\mathbf{y}|\mathbf{x}, \lambda_\alpha)$ using the usual conditional random field formulation:

$$P_\alpha(\mathbf{y}| \mathbf{x}, \lambda_\alpha) = \frac{\exp\left(\sum_k \lambda_{\alpha,k} \cdot \mathbf{F}_{\alpha,k}(\mathbf{y}, \mathbf{x})\right)}{\mathcal{Z}_\alpha(\mathbf{x}, \lambda_\alpha)}, \quad (4)$$

$F_{\alpha,k}$ is defined as

$$\mathbf{F}_{\alpha,k}(\mathbf{y}, \mathbf{x}) = \sum_{j=1}^{m} f_{\alpha,k}(y_{j-1}, y_j, \mathbf{x}, j),$$

and each feature function $f_{\alpha,k}(y_{j-1}, y_j, \mathbf{x}, j)$ is either a state function $s_k(y_j, \mathbf{x}, j)$ or a transition function $t_k(y_{j-1}, y_j, \mathbf{x}, j)$. State functions s_k depend on a single hidden variable in the model while transition functions t_k can depend on pairs of hidden variables. $\mathbf{T}_l(\mathbf{h}, \mathbf{x})$, defined in Equation 3, is a special case, summing only over the transition feature functions $t_l(h_{l-1}, h_l, \mathbf{x}, l)$. Each expert α contains a different subset of $f_{\alpha,k}(y_{j-1}, y_j, \mathbf{x}, j)$. These feature functions are defined in Section 5.2.

4.1 Learning Model Parameters

Given a training set consisting of n labeled sequences $(\mathbf{x_i}, \mathbf{y_i})$ for $i = 1...n$, training is done in a two step process. First each expert α is trained following (Kumar and Herbert., 2003; Lafferty et al., 2001) objective function to learn the parameter λ^*_α:

$$L(\lambda_\alpha) = \sum_{i=1}^{n} \log P_\alpha(\mathbf{y}_i \mid \mathbf{x}_i, \lambda_\alpha) - \frac{1}{2\sigma^2}||\lambda_\alpha||^2 \quad (5)$$

The first term in Eq. 5 is the conditional log-likelihood of the training data. The second term is the log of a Gaussian prior with variance σ^2, i.e., $P(\lambda_\alpha) \sim \exp\left(\frac{1}{2\sigma^2}||\lambda_\alpha||^2\right)$.

Then the marginal probabilities $P_\alpha(y_j = a \mid \mathbf{y}, \mathbf{x}, \lambda^*_\alpha)$, are computed using belief propagation and used as input for Equation 3. The optimal parameter θ^* was learned using the log-likelyhood of the conditional probability defined in Equation 2 (i.e., no regularization).

4.2 Inference

For testing, given a new test sequence $\mathbf{x}$, we want to estimate the most probable sequence of labels $\mathbf{y}^*$ that maximizes our LMDE model:

$$\mathbf{y}^* = \arg\max_{\mathbf{y}} \sum_{\mathbf{h}:\forall h_i \in \mathcal{H}_{y_i}} P(\mathbf{h} \mid \mathbf{x}, \theta^*) \quad (6)$$

5 Experimental Setup

We evaluate our Latent Mixture of Discriminative Experts on the multimodal task of predicting listener nonverbal backchannel (i.e., head nods). Backchannel feedback (the nods and paraverbals such as "uh-hu" and "mm-hmm" that listeners produce as some is speaking) has received considerable interest due to its pervasiveness across languages and conversational contexts.

5.1 Dataset

We are using the RAPPORT dataset from (Maatman et al., 2005), which contains 47 dyadic interactions between a speaker and a listener. Data is drawn from a study of face-to-face narrative discourse ("quasi-monologic" storytelling). In this dataset, participants in groups of two were told they were participating in a study to evaluate a communicative technology. Subjects were randomly assigned the role of speaker and listener. The speaker viewed a short segment of a video clip taken from the Edge Training Systems, Inc. Sexual Harassment Awareness video. After the speaker finished viewing the video, the listener was led back into the computer room, where the speaker was instructed to retell the stories portrayed in the clips to the listener. The listener was asked to not talk during the story retelling. Elicited stories were approximately two minutes in length on average. Participants sat approximately 8 feet apart. Video sequences were manually annotated to determine the ground truth head nod labels. A total of 587 head nods occured over all video sequences.

5.2 Multimodal Features

This section describes the different multimodal features used to create our five experts.

PROSODY Prosody refers to the rhythm, pitch and intonation of speech. Several studies have demonstrated that listener feedback is correlated with a speaker's prosody (Nishimura et al., 2007; Ward and Tsukahara, 2000; Cathcart et al., 2003). For example, Ward and Tsukahara (2000) show that short listener backchannels (listener utterances like "ok" or "uh-huh" given during a speaker's utterance) are associated with a lowering of pitch over some interval. Listener feedback often follows speaker pauses or filled pauses such as "um" (see (Cathcart et al., 2003)). Using openSMILE (Eyben et al., 2009) toolbox, we extract the following prosodic features, including standard linguistic annotations and the prosodic features suggested by Ward and Tsukhara: downslopes in pitch continuing for at least 40ms, regions of pitch lower than the 26th percentile continuing for at least 110ms (i.e., lowness), drop or rise in energy of speech (i.e., energy edge), Fast drop or rise in energy of speech (i.e., energy fast edge), vowel volume (i.e., vowels are usually spoken softer) and Pause in speech (i.e., no speech).

VISUAL GESTURES Gestures performed by the speaker are often correlated with listener feedback (Burgoon et al., 1995). Eye gaze, in particular, has often been implicated as eliciting listener feedback. Thus, we manually annotate the following contextual feature: speaker looking at the listener.

LEXICAL Some studies have suggested an association between lexical features and listener feedback (Cathcart et al., 2003). Using the transcriptions, we included all individual words (i.e., unigrams) spoken by the speaker during the interactions.

SYNTACTIC STRUCTURE Finally, we attempt to capture syntactic information that may provide relevant cues by extracting four types of features from a syntactic dependency structure corresponding to the utterance. The syntactic structure is produced automatically using a CRF part-of-speech (POS) tagger and a data-driven left-to-right shift-reduce dependency parser (Sagae and Tsujii, 2007), both trained on POS tags and dependency trees extracted from the Switchboard section of the Penn Treebank (Marcus et al., 1994), converted to dependency trees using the Penn2Malt tool[1]. The four syntactic features are:

- Part-of-speech tags for each word (e.g. noun, verb, etc.), taken from the output of the POS tagger
- Grammatical function for each word (e.g. subject, object, etc.), taken directly from the dependency labels produced by the parser
- Part-of-speech of the syntactic head of each word, taken from the dependency links produced by the parser
- Distance and direction from each word to its syntactic head, computed from the dependency links produced by the parser

(b)
CRF Mixture of Experts
(c)

Figure 3: Baseline Models: **a)** Conditional Random Fields (CRF), **b)** Latent Dynamic Conditional Random Fields(LDCRF), **c)** CRF Mixture of Experts (no latent variable)

Although our current method for extracting these features requires that the entire utterance be available for processing, this provides us with a first step towards integrating information about syntactic structure in multimodal prediction models. Many of these features could in principle be computed incrementally with only a slight degradation in accuracy, with the exception of features that require dependency links where a word's syntactic head is to the right of the word itself. We leave an investigation that examines only syntactic features that can be produced incrementally in real time as future work.

5.3 Baseline Models

INDIVIDUAL EXPERTS Our first baseline model consists of a set of CRF chain models, each trained with different set of multimodel features (as described in the previous section). In other words, only visual, prosodic, lexical or syntactic features are used to train a single CRF expert. In one CRF chain model, each gesture class corresponds to a state label. (See Figure 3a).

MULTIMODAL CLASSIFIERS (EARLY FUSION) Our second baseline consists of two models: CRF and LDCRF (Morency et al., 2007). To train these models, we concatenate all multimodal features (lexical, syntactic, prosodic and visual) in one input vector. Graphical representation of these baseline models are given in Figure 3.

CRF MIXTURE OF EXPERTS To show the importance of latent variable in our LMDE model, we trained a CRF-based mixture of discriminative experts. This model is similar to the Logarithmic Opinion Pool (LOP) CRF suggested by Smith et al. (2005). The training is performed in two steps. A graphical representation of a CRF Mixture of experts is given in the last graph of Figure 3.

5.4 Methodology

We performed held-out testing by randomly selecting a subset of 11 interactions (out of 47) for the test set. The training set contains the remaining 36 dyadic interactions. All models in this paper were evaluated with the same training and test sets. Validation of all model parameters (regularization term and number of hidden states) was performed using a 3-fold cross-validation strategy on the training set. The regularization term was validated with values $10^k, k = -1..3$. Three different number of hidden states were tested for the LMDE models: 2, 3 and 4.

The performance is measured by using the F-measure. This is the weighted harmonic mean of precision and recall. Precision is the probability that predicted backchannels correspond to actual listener behavior. Recall is the probability that a backchannel produced by a listener in our test set was predicted by the model. We use the same weight for both precision and recall, so-called F_1. During validation we find all the peaks (i.e., local maxima) from the marginal probabilities. These backchannel hypotheses are filtered using the optimal threshold from the validation set. A backchannel (i.e., head nod) is predicted correctly if a peak happens during an actual listener backchannel with high enough probability. The same evaluation measurement is applied to all models.

The training of all CRFs and LDCRFs were done using the hCRF library[2]. The LMDE model was implemented in Matlab[3] based on the hCRF

library.

6 Results and Discussion

In this section we present the results of our empirical evaluation designed to test the three main characteristics of the LMDE model: (1) integration of multiple sources of information, (2) late fusion approach and (3) latent variable which models the hidden dynamic between experts. We also present an analysis of the output probabilities from the LMDE model and individual experts.

Individual Experts We trained one individual expert for each feature types: visual, prosodic, lexical and syntactic features (both part-of speech and syntactic structure). Precision, recall and F_1 values for each individual expert and our LMDE model are shown in Table 1 and Figure 4.

Pairwise two-tailed t-test comparison between our LMDE model and individual experts shows a significant difference for Lexical, Prosody, Syntactic and Eye gaze, with respective p-values of 0.0037, 0.0379, 0.0400 and 0.0233. Even though some experts may not perform well individually (e.g., eye gaze), they can bring important information once merged with others. Table 1 shows that our LMDE model was able to take advantage of the complementary information from each expert.

Table 2: Comparison of our Latent Mixture of Discriminative Experts (LMDE) with two early fusion technique (CRF vs LDCRF) and the CRF Mixture of Experts (Smith et al., 2005).

model	Precision	Recall	f1
LMDE	0.2295	0.5677	**0.3268**
Early CRF	0.13958	0.9245	0.2425
Early LDCRF	0.1826	0.2484	0.2105
Mixture CRF	0.1502	0.2712	0.1934

Late Fusion We compare our approach with two early fusion models: CRF and Latent-dynamic CRF (see Figure 3). Table 2 summarizes the results. The CRF model learns direct weights between input features and the gesture labels. The LDCRF is able to model more complex dynamics between input features with the latent variable. We can see that our LMDE model outperforms both early fusion approaches because of its late fusion approach. Pairwise two-tailed t-test analysis gives p-values of 0.0481 and 0.0748, for CRF and LDCRF respectively.

Latent Variable The CRF Mixture of Experts (2005) directly merges the expert outputs while our model uses a latent variable to model the hidden dynamic between experts (see Figure 3). Table 2 summarizes the results. Pairwise two-tailed t-test comparison between these two models shows a significant difference with a p-value of 0.0062. This result is important since it shows that our LMDE model does learn the hidden interaction between experts.

Model analysis To understand the multimodal integration which happens at the latent variable level in our LMDE model, Figure 5 shows the output probabilities for all five individual experts as well as our model. The strength of the latent variable is to enable different weigting

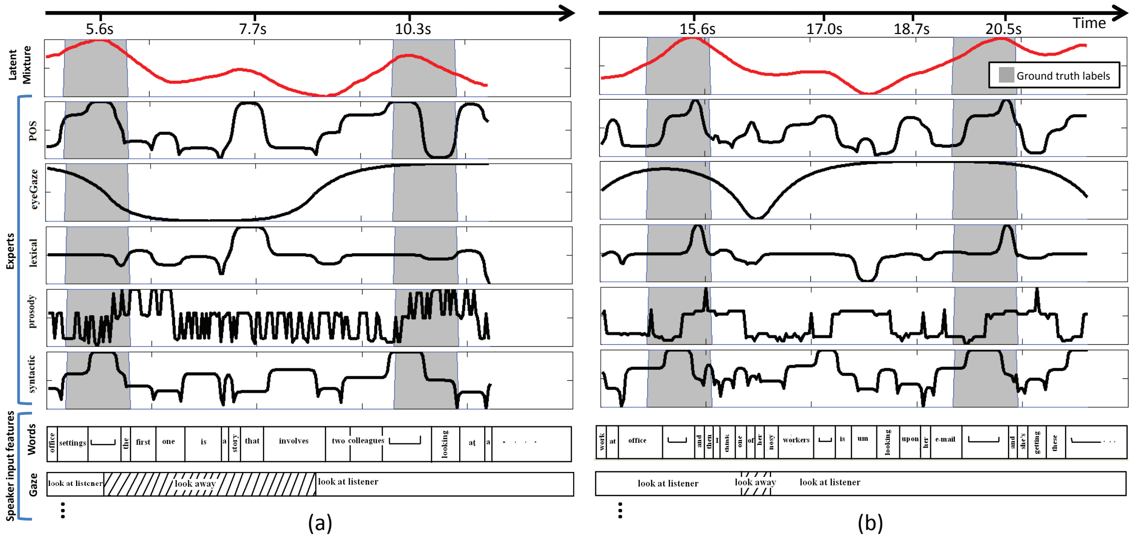

Figure 5: Output probabilities from LMDE and individual experts for two different sub-sequences. The gray areas in the graph corresponds to ground truth backchannel feedbacks of the listener.

of the experts at different point in time.

By analyzing the sequence (a), we observe that both the POS and Syntactic experts learned that when no words are present (i.e., pause) there is a high likelihood of backchennel feedback from the listener (shown at 5.6s and 10.3s). These two experts are highly weighted (by one of the hidden state) during this part of the sequence. Also, both the Lexical and POS experts learned that the word "'that"' (and its part-of-speech) are important but since the speaker is not looking at the listener when saying it, the output from LMDE model is low (see Figure 5, Sequence (a), 7.7s).

By analyzing sequence (b), we see that the Lexical and POS experts learned the importance of the "'and"' at 15.6s and 20.5s. More importantly, we can see at 17.0s and 18.7s that the influence of the POS and Syntactic experts have been reduced in the LMDE output probability. This difference of weighting shows that a different hidden state is active during Sequence (b).

7 Conclusion

In this paper we introduced a new model called Latent Mixture of Discriminative Experts (LMDE) for learning predictive models of human communication behaviors. Many of the interactions between speech and gesture happen at the sub-gesture or sub-word level. LMDE learns automatically the temporal relationship between different modalities. Since, we train separate experts for each modality, LMDE is capable of improving the prediction performance even with limited datasets.

We evaluated our model on the task of nonverbal feedback prediction (e.g., head nod). Our experiments confirm the importance of combining the four types of multimodal features: lexical, syntactic structure, eye gaze, and prosody. LMDE is a generic model that can be applied to a wide range of problems. As future work, we are planning to test our model on dialog act classification and multimodal behavior recognition tasks.

Abstract

Text summarization solves the problem of extracting important information from huge amount of text data. There are various methods in the literature that aim to find out well-formed summaries. One of the most commonly used methods is the Latent Semantic Analysis (LSA). In this paper, different LSA based summarization algorithms are explained and two new LSA based summarization algorithms are proposed. The algorithms are evaluated on Turkish documents, and their performances are compared using their ROUGE-L scores. One of our algorithms produces the best scores.

1 Introduction

The exponential growth in text documents brings the problem of finding out whether a text document meets the needs of a user or not. In order to solve this problem, text summarization systems which extract brief information from a given text are created. By just looking at the summary of a document, a user can decide whether the document is of interest to him/her without looking at the whole document.

The aim of a text summarization system is to generate a summary for a given document such that the generated summary contains all necessary information in the text, and it does not include redundant information. Summaries can have different forms (Hahn and Mani, 2000). Extractive summarization systems collect important sentences from the input text in order to generate summaries. Abstractive summarization systems do not collect sentences from the input text, but they try to capture the main concepts in the text, and generate new sentences to represent these main concepts. Abstractive summarization approach is similar to the way that human summarizers follow. Since creating abstractive summaries is a more complex task, most of automatic text summarization systems are extractive summarization systems.

Summarization methods can be categorized according to what they generate and how they generate it (Hovy and Lin, 1999). A summary can be extracted from a single document or from multiple documents. If a summary is generated from a single document, it is known as single-document summarization. On the other hand, if a single summary is generated from multiple documents on the same subject, this is known as multi-document summarization. Summaries are also categorized as generic summaries and query-based summaries. Generic summarization systems generate summaries containing main topics of documents. In query-based summarization, the generated summaries contain the sentences that are related to the given queries.

Extractive summarization systems determine the important sentences of the text in order to put them into the summary. The important sentences of the text are the sentences that represent the main topics of the text. Summarization systems use different approaches to determine the important sentences (Hahn and Mani, 2000; Hovy and Lin, 1999). Some of them look surface clues such as the position of the sentence and the words that are contained in the sentence. Some summarization systems use more semantic oriented analysis such as lexical chains in order to determine the important sentences. Lately, an algebraic method known as Latent Semantic Analysis (LSA) is used in the determination of

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 869–876,
Beijing, August 2010

the important sentences, and successful results are obtained (Gong and Liu, 2001).

In this paper, we present a generic extractive Turkish text summarization system based on LSA. We applied the known text summarization approaches based on LSA in order to extract the summaries of Turkish texts. One of the main contributions of this paper is the introduction of two new summarization methods based on LSA. One of our methods produced much better results than the results of the other known methods.

The rest of the paper is organized as follows. Section 2 presents the related work in summarization. Section 3 explains the LSA approach in detail. Then, the existing algorithms that use different LSA approaches are presented (Gong and Liu, 2001; Steinberger and Jezek 2004; Murray et al., 2005), and two new algorithms are proposed in Section 4. Section 5 presents the evaluation results of these algorithms, and Section 6 presents the concluding remarks.

2 Related Work

Text summarization is an active research area of natural language processing. Its aim is to extract short representative information from input documents. Since the 1950s, various methods are proposed and evaluated. The first studies conducted on text summaries use simple features like terms from keywords/key phrases, terms from user queries, frequency of words, and position of words/sentences (Luhn, 1958).

The use of statistical methods is another approach used for summary extraction. The most well known project that uses statistical approach is the SUMMARIST (Hovy and Lin, 1999). In this project, natural language processing methods are used together with the concept relevance information. The concept relevance information is extracted from dictionaries and WordNet.

Text connectivity is another approach used for summarization. The most well-known algorithm that uses text connectivity is the lexical chains method (Barzilay and Elhadad, 1997; Ercan and Cicekli, 2008). In lexical chains method, WordNet and dictionaries are used to determine semantic relations between words where semantically related words construct lexical chains. Lexical chains are used in the determination of the important sentences of the text.

TextRank (Mihalcea and Tarau, 2004) is a summarization algorithm which is based on graphs, where nodes are sentences and edges represent similarity between sentences. The similarity value is decided by using the overlapping terms. Cluster Lexrank (Qazvinian and Radev, 2008) is another graph-based summarization algorithm, and it tries to find important sentences in a graph in which nodes are sentences and edges are similarities.

In recent years, algebraic methods are used for text summarization. Most well-known algebraic algorithm is Latent Semantic Analysis (LSA) (Landauer et al., 1998). This algorithm finds similarity of sentences and similarity of words using an algebraic method, namely Singular Value Decomposition (SVD). Besides text summarization, the LSA algorithm is also used for document clustering and information filtering.

3 Latent Semantic Analysis

Latent Semantic Analysis (LSA) is an algebraic-statistical method that extracts meaning of words and similarity of sentences using the information about the usage of the words in the context. It keeps information about which words are used in a sentence, while preserving information of common words among sentences. The more common words between sentences mean that those sentences are more semantically related.

LSA method can represent the meaning of words and the meaning of sentences simultaneously. It averages the meaning of words that a sentence contains to find out the meaning of that sentence. It represents the meaning of words by averaging the meaning of sentences that contain this word.

LSA method uses Singular Value Decomposition (SVD) for finding out semantically similar words and sentences. SVD is a method that models relationships among words and sentences. It has the capability of noise reduction, which leads to an improvement in accuracy.

LSA has three main limitations. The first limitation is that it uses only the information in the input text, and it does not use the information of world knowledge. The second limitation is that it does not use the information of word order, syntactic relations, or morphologies. Such information is used for finding out the meaning of words and texts. The third limitation is that the performance of the algorithm decreases with large and inhomogeneous data. The decrease in performance is observed since SVD which is a very complex algorithm is used for finding out the similarities.

All summarization methods based on LSA use three main steps. These steps are as follows:

1. *Input Matrix Creation:* A matrix which represents the input text is created. The columns of the matrix represent the sentences of the input text and the rows represent the words. The cells are filled out to represent the importance of words in sentences using different approaches, whose details are described in the rest of this section. The created matrix is sparse.
2. *Singular Value Decomposition (SVD):* Singular value decomposition is a mathematical method which models the relationships among terms and sentences. It decomposes the input matrix into three other matrices as follows:

   $$A = U \sum V^T$$

   where A is the input matrix with dimensions *m x n*, U is an *m x n* matrix which represents the description of the original rows of the input matrix as a vector of extracted concepts, $\sum$ is an *n x n* diagonal matrix containing scaling values sorted in descending order, and V is an *m x n* matrix which represents the description of the original columns of input matrix as a vector of the extracted concepts.
3. *Sentence Selection*: Different algorithms are proposed to select sentences from the input text for summarization using the results of SVD. The details of these algorithms are described in Section 4.

The creation of the input matrix is important for summarization, since it affects the resulting matrices of SVD. There are some ways to reduce the row size of the input matrix, such as eliminating words seen in stop words list, or using the root words only. There are also different approaches to fill out the input matrix cell values, and each of them affects the performance of the summarization system differently. These approaches are as follows:

1. *Number of Occurrence:* The cell is filled with the frequency of the word in the sentence.
2. *Binary Representation of Number of Occurrence:* If the word is seen in the sentence, the cell is filled with 1; otherwise it is filled with 0.
3. *TF-IDF (Term Frequency–Inverse Document Frequency):* The cell is filled with TF-IDF value of the word. This method evaluates the importance of words in a sentence. The importance of a word is high if it is frequent in the sentence, but less frequent in the document. TF-IDF is equal to TF*IDF, and TF and IDF are computed as follows:

   $$tf\,(i,j) = n(i,j) \;/\; \sum_k n(k,j)$$

   where $n(i,j)$ is the number of occurrences of the considered word *i* in sentence *j*, and $\sum_k n(k,j)$ is the sum of number of occurrences of all words in sentence *j*.

   $$idf\,(i) = log(\,|D| \,/\, d_i)$$

   where $|D|$ is the total number of sentences in the input text, and d_i is the number of sentences where the word *i* appears
4. *Log Entropy*: The cell is filled with log-entropy value of the word, and it is computed as follows.

   $$sum = \sum_j p(i,j)\ log_2(p(i,j))$$
   $$global(i) = 1 + (sum \,/\, log_2(n))$$
   $$local(i,j)= log_2(1 + f(i,j))$$
   $$log\text{-}entropy = global*local$$

   where $p(i,j)$ is the probability of word *i* that is appeared in sentence *j*, $f(i,j)$ is the number of times word *i* appeared in sentence *j*, and *n* is the number of sentences in the document.
5. *Root Type:* If the root type of the word is noun, the related cell is filled with the frequency of the word in the sentence; otherwise the cell is filled with 0.
6. *Modified TF-IDF:* First the matrix is filled with TF-IDF values. Then, the average TF-IDF values in each row are calculated. If the value in the cell is less than or equal to the average value, the cell value is set to 0. This is our new approach which is proposed to eliminate the noise from the input matrix.

4 Text Summarization

The algorithms in the literature that use LSA for text summarization perform the first two steps of LSA algorithm in the same way. They differ in the way they fill out the input matrix cells.

4.1 Sentence Selection Algorithms in Literature

4.1.1. Gong & Liu (Gong and Liu, 2001)

After performing the first two steps of the LSA algorithm, Gong & Liu summarization algorithm uses V^T matrix for sentence selection. The columns of V^T matrix represent the sentences of the input matrix and the rows of it represent the concepts that are obtained from SVD method. The most important concept in the text is placed in the first row, and the row order indicates the importance of concepts. Cells of this matrix give information about how much the sentence is related to the given concept. A higher cell value means the sentence is more related to the concept.

In Gong & Liu summarization algorithm, the first concept is chosen, and then the sentence most related to this concept is chosen as a part of the resulting summary. Then the second concept is chosen, and the same step is executed. This repetition of choosing a concept and the sentence most related to that concept is continued until a predefined number of sentences are extracted as a part of the summary. In Figure 1, an example V^T matrix is given. First, the concept *con0* is chosen, and then the sentence *sent1* is chosen, since it has the highest cell value in that row.

There are some disadvantages of this algorithm, which are defined by Steinberger and Jezek (2004). First, the reduced dimension size has to be the same as the summary length. This approach may lead to the extraction of sentences from less significant concepts. Second, there exist some sentences that are related to the chosen concept somehow, but do not have the highest cell value in the row of that concept. These kinds of sentences cannot be included in the resulting summary by this algorithm. Third, all chosen concepts are thought to be in the same importance level, but some of those concepts may not be so important in the input text.

	sent0	sent1	sent2	sent3	sent4
con0	0,557	0,691	0,241	0,110	0,432
con1	0,345	0,674	0,742	0,212	0,567
con2	0,732	0,232	0,435	0,157	0,246
con3	0,628	0,836	0,783	0,265	0,343

Figure 1. Gong & Liu approach: From each row of V^T matrix which represents a concept, the sentence with the highest score is selected. This is repeated until a predefined number of sentences are collected.

4.1.2. Steinberger & Jezek (Steinberger and Jezek 2004)

As in the Gong & Liu summarization algorithm, the first two steps of LSA algorithm are executed before selecting sentences to be a part of the resulting summary. For sentence selection, both V and Σ matrixes are used.

The sentence selection step of this algorithm starts with the calculation of the length of each sentence vector which is represented by a row in V matrix. In order to find the length of a sentence vector, only concepts whose indexes are less than or equal to the number of dimension in the new space is used. The dimension of a new space is given as a parameter to the algorithm. The concepts which are highly related to the text are given more importance by using the values in Σ matrix as a multiplication parameter. If the dimension of the new space is *n*, the length of the sentence *i* is calculated as follows:

$$length_i = \sqrt{\sum_{j=1}^{n} V_{ij} * \Sigma_{jj}}$$

After the calculation of sentence lengths, the longest sentences are chosen as a part of the resulting summary. In Figure 2, an example V matrix is given, and the dimension of the new space is assumed to be 3. The lengths of the sentences are calculated using the first three concepts. Since the sentence *sent2* has the highest length, it is extracted first as a part of the summary.

The aim of this algorithm is to get rid of the disadvantages of Gong & Liu summarization algorithm, by choosing sentences which are related to all important concepts and at the same time choosing more than one sentence from an important topic.

	con0	con1	con2	con3	length
sent0	0,846	0,334	0,231	0,210	0,432
sent1	0,455	0,235	0,432	0,342	0,543
sent2	0,562	0,632	0,735	0,857	0,723
sent3	0,378	0,186	0,248	0,545	0,235

Figure 2. Steinberger & Jezek approach: For each row of V matrix, the lengths of sentences using n concepts are calculated. The value n is given as an input parameter. ∑ matrix values are also used as importance parameters in the length calculations.

	sent0	sent1	sent2	sent3	sent4
con0	0,557	0,691	0,241	0,110	0,432
con1	0,345	0,674	0,742	0,212	0,567
con2	0,732	0,232	0,435	0,157	0,246
con3	0,628	0,836	0,783	0,265	0,343

Figure 3. Murray & Renals & Carletta approach: From each row of V^T matrix, concepts, one or more sentences with the higher scores are selected. The number of sentences to be selected is decided by using ∑ matrix.

4.1.3. Murray & Renals & Carletta (Murray et al., 2005)

The first two steps of the LSA algorithm are executed, as in the previous algorithms before the construction of the summary. V^T and ∑ matrices are used for sentence selection.

In this approach, one or more sentences are collected from the topmost concepts in V^T matrix. The number of sentences to be selected depends on the values in the ∑ matrix. The number of sentences to be collected for each topic is determined by getting the percentage of the related singular value over the sum of all singular values, which are represented in the ∑ matrix. In Figure 3, an example V^T matrix is given. Let's choose two sentences from *con0,* and one sentence from *con1*. Thus, the sentences *sent1* and *sent0* are selected from *con0,* and *sent2* is selected from *con1* as a part of the summary.

This approach tries to solve the problems of Gong & Liu's approach. The reduced dimension has not to be same as the number of sentences in the resulting summary. Also, more than one sentence can be chosen even they do not have the highest cell value in the row of the related concept.

4.2 Proposed Sentence Selection Algorithms

The analysis of input documents indicates that some sentences, especially the ones in the introduction and conclusion parts of the documents, belong to more than one main topic. In order to observe whether these sentences are important or they cause noise in matrices of LSA, we propose a new method, named as *Cross*.

Another concern about matrices in LSA is that the concepts that are found after the SVD step may represent main topics or subtopics. So, it is important to determine whether the found concepts are main topics or subtopics. This causes the ambiguity that whether these concepts are subtopics of another main topic, or all the concepts are main topics of the input document. We propose another new method, named as *Topic*, in order to distinguish main topics from subtopics and make sentence selections from main topics.

4.2.1. Cross Method

In this approach, the first two steps of LSA are executed in the same way as the other approaches. As in the Steinberger and Jezek approach, the V^T matrix is used for sentence selection. The proposed approach, however, preprocesses the V^T matrix before selecting the sentences. First, an average sentence score is calculated for each concept which is represented by a row of V^T matrix. If the value of a cell in that row is less than the calculated average score of that row, the score in the cell is set to zero. The main idea is that there can be sentences such that they are not the core sentences representing the topic, but they are related to the topic in some way. The preprocessing step removes the overall effect of such sentences.

After preprocessing, the steps of Steinberger and Jezek approach are followed with a modification. In our Cross approach, first the cell values are multiplied with the values in the ∑ matrix, and the total lengths of sentence vectors, which are represented by the columns of the V^T matrix, are calculated. Then, the longest sentence vectors are collected as a part of the resulting summary.

In Figure 4, an example V^T matrix is given. First, the average scores of all concepts are calculated, and the cells whose values are less than the average value of their row are set to zero.

The boldface numbers are below row averages in Figure 4, and they are set to zero before the calculation of the length scores of sentences. Then, the length score of each sentence is calculated by adding up the concept scores of sentences in the updated matrix. In the end, the sentence *sent1* is chosen for the summary as the first sentence, since it has the highest length score.

	sent0	sent1	sent2	sent3	average
con0	0,557	0,691	**0,241**	**0,110**	0,399
con1	**0,345**	0,674	0,742	**0,212**	0,493
con2	0,732	**0,232**	0,435	**0,157**	0,389
con3	**0,628**	**0,436**	0,783	0,865	0,678
con4	0,557	0,691	**0,241**	0,710	0,549
length	1,846	2,056	1,960	1,575	

Figure 4. Cross approach: For each row of V^T matrix, the cell values are set to zero if they are less than the row average. Then, the cell values are multiplied with the values in the $\sum$ matrix, and the lengths of sentence vectors are found, by summing up all concept values in columns of V^T matrix, which represent the sentences.

4.2.2. Topic Method

The first two steps of LSA algorithm are executed as in the other approaches. For sentence selection, the V^T matrix is used. In the proposed approach, the main idea is to decide whether the concepts that are extracted from the matrix V^T are really main topics of the input text, or they are subtopics. After deciding the main topics which may be a group of subtopics, the sentences are collected as a part of the summary from the main topics.

In the proposed algorithm, a preprocessing step is executed, as in the Cross approach. First, for each concept which is represented by a row of V^T matrix, the average sentence score is calculated and the values less than this score are set to zero. So, a sentence that is not highly related to a concept is removed from the concept in the V^T matrix. Then, the main topics are found. In order to find out the main topics, a *concept x concept* matrix is created by summing up the cell values that are common between the concepts. After this step, the strength values of the concepts are calculated. For this calculation, each concept is thought as a node, and the similarity values in *concept x concept* matrix are considered as edge scores. The strength value of each concept is calculated by summing up the values in each row in *concept x concept* matrix. The topics with the highest strength values are chosen as the main topic of the input text.

	sent0	sent1	sent2	sent3	average
con0	0,557	0,691	**0,241**	**0,110**	0,399
con1	**0,345**	0,674	0,742	**0,212**	0,493
con2	0,732	**0,232**	0,435	**0,157**	0,389
con3	**0,628**	**0,436**	0,783	0,865	0,678
con4	0,557	0,691	**0,241**	0,710	0,549

⇩

	con0	con1	con2	con3	con4	strength
con0	1,248	1,365	1,289	0	2,496	6,398
con1	1,365	1,416	1,177	1,525	1,365	6,848
con2	1,289	1,177	0,732	1,218	1,289	5,705
con3	0	1,525	1,218	1,648	1,575	5,966
con4	2,496	1,365	1,289	1,575	1,958	8,683

⇩

	sent0	sent1	sent2	sent3
con0	0,557	0.691	0	0
con1	0	0,674	0,742	0
con2	0,732	0	0,435	0
con3	0	0	0,783	0,865
con4	0,557	0,691	0	0,710

Figure 5. Topic approach: From each row of V^T matrix, concepts, the values are set to zero if they are less than the row average. Then *concept x concept* similarity matrix is created, and the strength values of concepts are calculated, which show how strong the concepts are related to the other concepts. Then the concept whose strength value is highest is chosen, and the sentence with the highest score from that concept is collected. The sentence selection s repeated until a predefined number of sentences is collected.

After the above steps, sentence selection is performed in a similar manner to Gong and Liu approach. For each main topic selected, the sentence with the highest score is chosen. This selection is done until predefined numbers of sentences are collected.

In Figure 5, an example V^T matrix is given. First, the average scores of each concept is calculated and shown in the last column of the matrix. The cell values that are less than the row average value (boldface numbers in Figure 5) are set to zero. Then, a *concept x concept* matrix is created by filling a cell with the summation of the cell values that are common between those two concepts. The strength values of the concepts are calculated by summing up the concept values, and the strength values are shown in the last column of the related matrix. A higher strength value indicates that the concept is much more related to the other concepts, and it is one of the main topics of the input text. After finding out the main topic which is the concept *con4* in this example, the sentence with the highest cell value which is sentence *sent3* is chosen as a part of the summary.

5 Evaluation

Two different sets of scientific articles in Turkish are used for the evaluation our summarization approach. The articles are chosen from different areas, such as medicine, sociology, psychology, having fifty articles in each set. The second data set has longer articles than the first data set. The abstracts of these articles, which are human-generated summaries, are used for comparison. The sentences in the abstracts may not match with the sentences in the input text. The statistics about these data sets are given in Table 1.

	DS1	DS2
Number of documents	50	50
Sentences per document	89,7	147,3
Words per document	2302,2	3435
Words per sentence	25,6	23,3

Table 1. Statistics of datasets

Evaluation of summaries is an active research area. Judgment of human evaluators is a common approach for the evaluation, but it is very time consuming and may not be objective. Another approach that is used for summarization evaluation is to use the ROUGE evaluation approach (Lin and Hovy, 2003), which is based on n-gram co-occurrence, longest common subsequence and weighted longest common subsequence between the ideal summary and the extracted summary. Although we obtained all ROUGE results (ROUGE-1, ROUGE-2, ROUGE-3, ROUGE-W and ROUGE-L) in our evaluations, we only report ROUGE-L results in this paper. The discussions that are made depending on our ROUGE-L results are also applicable to other ROUGE results. Different LSA approaches are executed using different matrix creation methods.

	G&L	S&J	MRC	Cross	Topic
frequency	0,236	0,250	0,244	0,302	0,244
binary	0,272	0,275	0,274	0,313	0,274
tf-idf	0,200	0,218	0,213	0,304	0,213
logentropy	0,230	0,250	0,235	0,302	0,235
root type	0,283	0,282	0,289	0,320	0,289
mod. tf-idf	0,195	0,221	0,223	0,290	0,223

Table 2. ROUGE-L scores for the data set DS1

In Table 2, it can be observed that the Cross method has the highest ROUGE scores for all matrix creation techniques. The Topic method has the same results with Murray & Renals & Carletta approach, and it is better than the Gong & Liu approach.

Table 2 indicates that all algorithms give their best results when the input matrix is created using the root type of words. Binary and log-entropy approaches also produced good results. Modified tf-idf approach, which is proposed in this paper, did not work well for this data set. The modified tf-idf approach lacks performance because it removes some of the sentences/words from the input matrix, assuming that they cause noise. The documents in the data set DS1 are shorter documents, and most of words/sentences in shorter documents are important and should be kept.

Table 3 indicates that the best F-score is achieved for all when the log-entropy method is used for matrix creation. Modified tf-idf approach is in the third rank for all algorithms. We can also observe that, creating matrix according to the root types of words did not work well for this data set.

Given the evaluation results it can be said that *Cross* method, which is proposed in this paper, is a promising approach. Also *Cross* approach is not affected from the method of matrix creation. It produces good results when it is compared against an abstractive summary which is created by a human summarizer.

6 Conclusion

The growth of text based resources brings the problem of getting the information matching needs of user. In order to solve this problem, text summarization methods are proposed and evaluated. The research on summarization started with the extraction of simple features and improved to use different methods, such as lexical chains, statistical approaches, graph based approaches, and algebraic solutions. One of the algebraic-statistical approaches is Latent Semantic Analysis method.

In this study, text summarization methods which use Latent Semantic Analysis are explained. Besides well-known Latent Semantic Analysis approaches of Gong & Liu, Steinberger & Jezek and Murray & Renals & Carletta, two new approaches, namely Cross and Topic, are proposed.

Two approaches explained in this paper are evaluated using two different datasets that are in Turkish. The comparison of these approaches is done using the ROUGE-L F-measure score. The results show that the Cross method is better than all other approaches. Another important result of this approach is that it is not affected by different input matrix creation methods.

In future work, the proposed approaches will be improved and evaluated in English texts as well. Also, ideas that are used in other methods, such as graph based approaches, will be used together with the proposed approaches to improve the performance of summarization.

Knowing What to Believe
(when you already know something)

Jeff Pasternack **Dan Roth**

Abstract

Although much work in NLP has focused on simply determining what a document *means*, we also must know whether or not to *believe* it. Fact-finding algorithms attempt to identify the "truth" among competing claims in a corpus, but fail to take advantage of the user's prior knowledge and presume that truth itself is universal and objective rather than subjective. We introduce a framework for incorporating prior knowledge into *any* fact-finding algorithm, expressing both general "common-sense" reasoning and specific facts already known to the user as first-order logic and translating this into a tractable linear program. As our results show, this approach scales well to even large problems, both reducing error and allowing the system to determine truth respective to the user rather than the majority. Additionally, we introduce three new fact-finding algorithms capable of outperforming existing fact-finders in many of our experiments.

1 Introduction

Although establishing the trustworthiness of the information presented to us has always been a challenge, the advent of the Information Age and the Internet has made it more critical. Blogs, wikis, message boards and other collaborative media have eliminated the high entry barrier–and, with it, the enforced journalistic standards–of older, established media such as newspapers and television, and even these sometimes loosen their fact-checking in the face of increased competitive pressure. Consequently, we find that corpora derived from these sources now offer far more numerous views of far more questionable veracity. If one author claims Mumbai is the largest city in the world, and another claims it is Seoul, who do we believe? One or both authors could be intentionally lying, honestly mistaken or, alternatively, of different viewpoints of what constitutes a "city" (the city proper? The metropolitan area?) Truth is not objective: there may be many valid definitions of "city", but we should believe the claim that accords with our *user's* viewpoint. Note that the user may be another computational system rather than a human (e.g. building a knowledge base of city sizes for question answering), and often neither the user's nor the information source's perspective will be explicit (e.g. an author will not fully elaborate "the largest city by metropolitan area bounded by...") but will instead be implied (e.g. a user's statement that "I already know the population of city A is X, city B is Y..." implies that his definition of a city accords with these figures).

The most basic approach is to take a vote: if multiple claims are mutually exclusive of each other, select the one asserted by the most sources. In our experiments, sources will be the authors of the document containing the claim, but other sources could be publishers/websites (when no authorship is given), an algorithm that outputs claims, etc. Although sometimes competitive, we found voting to be generally lackluster. A class of algorithms called fact-finders are often a dramatic improvement, but are incapable of taking advantage of the user's prior knowledge. Our framework translates prior knowledge (expressed as first-order logic) into a linear program that constrains the claim beliefs produced by a fact-finder, ensuring that our belief state is consistent with both common sense ("cities usually grow") and known facts ("Los Angeles is more populous than Wichita"). While in the past first-order logic has been translated to NP-hard integer linear programs, we use polynomial-time-solvable linear programs, al-

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 877–885,
Beijing, August 2010

lowing us to readily scale to large problems with extensive prior knowledge, as demonstrated by our experiments.

We next discuss related work, followed by a more in-depth description of the fact-finding algorithms used in our experiments, including three novel, high-performing algorithms: Average·Log, Investment, and PooledInvestment. We then present the framework's mechanics and the translation of first-order logic into a linear program. Finally, we present our experimental setup and results over three domains chosen to illustrate different aspects of the framework, demonstrating that both our new fact-finders and our framework offer performance improvements over the current state of the art.

2 Related Work

The broader field of trust can be split into three areas of interest[1]: theoretical, reputation-based, and information-based.

2.1 Theoretical

Marsh (1994) observes that trust can be global (e.g. eBay's feedback scores), personal (each person has their own trust values), or situational (personal and specific to a context). Fact-finding algorithms are based on global trust, while our framework establishes personal trust by exploiting the user's individual prior knowledge.

Probabilistic logics have been explored as an alternate method of reasoning about trust. Manchala (1998) utilizes fuzzy logic (Novak et al., 1999), an extension of propositional logic permitting [0,1] belief over propositions. Yu and Singh (2003) employs Dempster-Shafer theory (Shafer, 1976), with belief triples (mass, belief, and plausibility) over *sets* of possibilities to permit the modeling of ignorance, while Josang et al. (2006) uses the related subjective logic (Josang, 1997). While our belief in a claim is decidedly Bayesian (the probability that the claim is true), "unknowns" (discussed later) allow us to reason about ignorance as subjective logic and Dempster-Shafer do, but with less complexity.

2.2 Reputation-based

Reputation-based systems determine an entity's trust or standing among peers via transitive recommendations, as PageRank (Brin and Page, 1998) does among web pages, Advogato (Levien, 2008) does among people, and Eigentrust (Kamvar et al., 2003) does among peers in a network. Some, such as Hubs and Authorities (Kleinberg, 1999), are readily adapted to fact-finding, as demonstrated later.

2.3 Information-Based

Information-based approaches utilize content (rather than peer recommendations) to compute trust, and are often specialized for a particular domain. For example, (Zeng et al., 2006) and Wikitrust (Adler and de Alfaro, 2007) determine trust in a wiki's text passages from sequences of revisions but lack the claim-level granularity and general applicability of fact-finders.

Given a large set of sources making conflicting claims, fact-finders determine "the truth" by iteratively updating their parameters, calculating belief in facts based on the trust in their sources, and the trust in sources based on belief in their facts. TruthFinder (Yin et al., 2008) is a straightforward implementation of this idea. AccuVote (Dong et al., 2009a; Dong et al., 2009b) improves on this by using calculated source dependence (where one source derives its information from another) to give higher credibility to independent sources. (Galland et al., 2010)'s 3-Estimates algorithm incorporates the estimated "hardness" of a fact, such that knowing the answer to an easy question earns less trust than to a hard one. Except for AccuVote (whose model of repeated source-to-source copying is inapplicable to our experimental domains) we experimented over all of these algorithms.

3 Fact-Finding

We have a set of sources S each asserting a set of claims C_s, with $C = \bigcup_{s \in S} C_s$. Each claim $c \in C$ belongs to a *mutual exclusion set* $M_c \subseteq C$, a set of claims (including c) that are mutually exclusive with one another; for example, "John was born in 1960" and "John was born in 1965" are mutually exclusive because a person cannot be born in more than one year. If c is not mutually exclusive

[1] Following the division proposed by Artz and Gil (2007); see also (Sabater and Sierra, 2005) for a survey from a different perspective.

to any other claims, then $M_c = \{c\}$. Assuming there exists exactly one true claim $\overline{c}$ in each mutual exclusion set M, our goal is to predict $\overline{c}$ for each M, with accuracy measured by the number of successful predictions divided by the number of mutual exclusion sets, ignoring trivially correct claims that are the sole members of their mutual exclusion set. To this end, fact-finding algorithms iterate to find the trustworthiness of each source $T^i(s)$ at iteration i in terms of the belief in its claims in the previous iteration $B^{i-1}(C_s)$, and belief in each claim $B^i(c)$ in terms of $T^i(S_c)$, where $S_c = \{s : s \in S, c \in C_s\}$ is the set of all sources asserting c. Note that "trustworthiness" and "belief" as used within a fact-finding algorithm typically do not have meaningful semantics (i.e. they are not $[0, 1]$ Bayesian probabilities). Iteration continues until convergence or some predefined stop criteria.

3.1 Priors

Except for 3-Estimates (where the priors are dictated by the algorithm itself), every fact-finder requires priors for $B^0(C)$. For each fact-finder we chose from $B^0_{voted}(c) = |S_c|/\sum_{d\in M_c}|S_d|$, $B^0_{uniform}(c) = 1/|M_c|$, and $B^0_{fixed}(c) = 0.5$.

3.2 Algorithms

3.2.1 Sums (Hubs and Authorities)

Hubs and Authorities (Kleinberg, 1999) gives each page a hub score and an authority score, where its hub score is the sum of the authority of linked pages and its authority is the sum of the hub scores of pages linking to it. This is adapted to fact-finding by viewing sources as hubs (with 0 authority) and claims as authorities (with 0 hub score):

$$T^i(s) = \sum_{c\in C_s} B^{i-1}(c) \quad B^i(c) = \sum_{s\in S_c} T^i(s)$$

We normalize to prevent $T^i(s)$ and $B^i(c)$ from growing unbounded (dividing by $\max_s T^i(s)$ and $\max_c B^i(c)$, respectively), a technique also used with the Investment and Average·Log algorithms (discussed next); this avoids numerical overflow. B^0_{fixed} priors are used.

3.2.2 Average·Log

Computing $T(s)$ as an average of belief in its claims overestimates the trustworthiness of a source with relatively few claims; certainly a source with 90% accuracy over a hundred examples is more trustworthy than a source with 90% accuracy over ten. However, summing the belief in claims allows a source with 10% accuracy to obtain a high trustworthiness score by simply making many claims. Average·Log attempts a compromise, while still using Sums' B^i update rule and B^0_{fixed} priors.

$$T^i(s) = \log|C_s| \cdot \frac{\sum_{c\in C_s} B^{i-1}(c)}{|C_s|}$$

3.2.3 Investment

In the Investment algorithm, sources "invest" their trustworthiness uniformly among their claims. The belief in each claim then grows according to a non-linear function $\mathcal{G}$, and a source's trustworthiness is calculated as the sum of the beliefs in their claims, weighted by the proportion of trust previously contributed to each (relative to the other investors). Since claims with higher-trust sources get higher belief, these claims become relatively more believed and their sources become more trusted. We used $\mathcal{G}(x) = x^g$ with $g = 1.2$ in our experiments, together with B^0_{voted} priors.

$$T^i(s) = \sum_{c\in C_s} B^{i-1}(c) \cdot \frac{T^{i-1}(s)}{|C_s| \cdot \sum_{r\in S_c} \frac{T^{i-1}(r)}{|C_r|}}$$

$$B^i(c) = \mathcal{G}\left(\sum_{s\in S_c} \frac{T^i(s)}{|C_s|}\right)$$

3.2.4 PooledInvestment

Like Investment, sources uniformly invest their trustworthiness in claims and obtain corresponding returns, so $T^i(s)$ remains the same, but now after the belief in the claims of mutual exclusion set M have grown according to $\mathcal{G}$, they are linearly scaled such that the total belief of the claims in M remains the same as it was before applying $\mathcal{G}(x) = x^g$, with $g = 1.4$ and $B^0_{uniform}$ priors used in our experiments. Given $H^i(c) = \sum_{s\in S_c} \frac{T^i(s)}{|C_s|}$, we have:

$$B^i(c) = H^i(c) \cdot \frac{\mathcal{G}(H^i(c))}{\sum_{d\in M_c} \mathcal{G}(H^i(d))}$$

3.3 TruthFinder

TruthFinder (Yin et al., 2008) is pseudoprobabilistic: the basic version of the algorithm below calculates the “probability” of a claim by assuming that each source’s trustworthiness is the probability of it being correct and then averages claim beliefs to obtain trustworthiness scores. We also used the “full”, more complex TruthFinder, omitted here for brevity. $B^0_{uniform}$ priors are used for both.

$$T^i(s) = \frac{\sum_{c \in C_s} B^{i-1}(c)}{|C_s|}$$
$$B^i(c) = 1 - \prod_{s \in S_c} \left(1 - T^i(s)\right)$$

3.3.1 3-Estimates

3-Estimates (Galland et al., 2010), also omitted for brevity, differs from the other fact-finders by adding a third set of parameters to capture the “difficulty” of a claim, such that correctly asserting a difficult claim confers more trustworthiness than asserting an easy one; knowing the exact population of a city is harder than knowing the population of Mars (presumably 0) and we should not trust a source merely because they provide what is already common knowledge.

4 The Framework

To apply prior knowledge to a fact-finding algorithm, we translate the user’s prior knowledge into a linear program. We then iterate the following until convergence or other stopping criteria:

1. Compute $T^i(s)$ for all $s \in S$
2. Compute $B^i(c)$ for all $c \in C$
3. “Correct” beliefs $B^i(C)$ with the LP

4.1 Propositional Linear Programming

To translate prior knowledge into a linear program, we first propositionalize our first-order formulae into propositional logic (Russell and Norvig, 2003). For example, assume we know that Tom is older than John and a person has exactly one age ($\exists_{x,y} Age(Tom, x) \wedge Age(John, y) \wedge x > y) \wedge (\forall_{x,y,z} Age(x, y) \wedge y \neq z \Rightarrow \neg Age(x, z)$), and our system is considering the following claims: $Age(Tom, 30)$, $Age(Tom, 40)$, $Age(John, 25)$, $Age(John, 35)$. Our propositional clauses (after removing redundancies) are then $Age(Tom, 30) \Rightarrow Age(John, 25) \wedge (Age(Tom, 30) \oplus Age(Tom, 40)) \wedge (Age(John, 25) \oplus Age(John, 35))$.

Each claim c will be represented by a proposition, and ultimately a $[0, 1]$ variable in the linear program corresponding, informally, to $P(c)$.[2] Propositionalized constraints have previously been used with *integer* linear programming (ILP) using binary $\{0, 1\}$ values corresponding to $\{false, true\}$, to find an (exact) consistent truth assignment minimizing some cost and solve a global inference problem, e.g. (Roth and Yih, 2004; Roth and Yih, 2007). However, propositional linear programming has two significant advantages:

1. ILP is “winner take all”, shifting all belief to one claim in each mutual exclusion set (even when other claims are nearly as plausible) and finding the single most believable consistent *binary assignment*; we instead wish to find a *distribution* of belief over the claims that is consistent with our prior knowledge and as close as possible to the distribution produced by the fact-finder.
2. Linear programs can be solved in polynomial time (e.g. by interior point methods (Karmarkar, 1984)), but ILP is NP-hard.

To create our constraints, we first convert our propositional formula into conjunctive normal form. Then, for each disjunctive clause consisting of a set P of positive literals (claims) and a set N of negations of literals, we add the constraint $\sum_{c \in P} c_v + \sum_{c \in N} (1 - c_v) \geq 1$, where c_v denotes the $[0, 1]$ variable corresponding to each c. The left-hand side is the union bound of at least one of the claims being true (or false, in the case of negated literals); if this bound is at least 1, the constraint is satisfied. This optimism can dilute the strength of our constraints by ignoring potential dependence among claims: $x \Rightarrow y$, $x \vee y$ implies y is true, but since we demand only $y_v \geq x_v$ and $x_v + y_v \geq 1$ we accept any $y_v \geq 0.5$ where

[2] This is a slight mischaracterization, since our linear constraints only *approximate* intersections and unions of events (where each event is “claim c is true”), and we will be satisfying them subject to a linear cost function.

$y_v \geq x_v \geq 1 - y_v$. However, when the claims are mutually exclusive, the union bound is exact; a common constraint is of the form $q \Rightarrow r^1 \vee r^2 \vee \ldots$, where the r literals are mutually exclusive, which translates exactly to $r_v^1 + r_v^2 + \ldots \geq q_v$. Finally, observe that mutual exclusion amongst n claims c^1, c^2, …, c^n can be compactly written as $c_v^1 + c_v^2 + \ldots + c_v^n = 1$.

4.2 The Cost Function

Having seen how first-order logic can be converted to linear constraints, we now consider the cost function, a distance between the new distribution of belief satisfying our constraints and the original distribution produced by the fact-finder.

First we determine the number of "votes" received by each claim c, computed as $\omega_c = \omega(B(c))$, which should scale linearly with the certainty of the fact-finder's belief in c. Recall that the semantics of the belief score are particular to the fact-finder, so different fact-finders require different vote functions. TruthFinder has pseudo-probabilistic [0,1] beliefs, so we use $\omega_{inv}(x) = \min((1-x)^{\text{-1}}, m_{inv})$ with $m_{inv} = 10^{10}$ limiting the maximum number of votes possible; we assume $1/0 = \infty$. ω_{inv} intuitively scales with "error": a belief of 0.99 receives ten times the votes of 0.9 and has a tenth the error (0.01 vs. 0.1). For the remainder of the fact-finders whose beliefs are already "linear", we use the identity function $\omega_{idn}(x) = x$.

The most obvious choice for the cost function might be to minimize "frustrated votes": $\sum_{c \in C} \omega_c (1 - c_v)$. Unfortunately, this results in the linear solver generally assigning 1 to the variable in each mutual exclusion set with the most votes and 0 to all others (except when constraints prevent this), shifting all belief to the highest-vote claim and yielding poor performance. Instead, we wish to satisfy the constraints while keeping each c_v close to ω_c / ω_{M_c}, where $\omega_{M_c} = \sum_{d \in M_c} \omega_d$, and so shift belief among claims as little as possible. We use a weighted Manhattan distance called **VoteDistance**, where the cost for increasing the belief in a claim is proportional to the number of votes against it, and the cost for decreasing belief is proportional to the number of votes for it:

$$\sum_{c \in C} \max \left(\begin{matrix} (\omega_{M_c} - \omega_c) \cdot (c_v - \omega_c / \omega_{M_c}), \\ \omega_c \cdot (\omega_c / \omega_{M_c} - c_v) \end{matrix} \right)$$

Thus, the belief distribution found by our LP will be the one that satisfies the constraints while simultaneously minimizing the number of votes frustrated by the change from the original distribution. Note that for any linear expressions e and f we can implement $\max(e, f)$ in the objective function by replacing it with a new $[-\infty, \infty]$ helper variable x and adding the linear constraints $x \geq e$ and $x \geq f$.

4.3 From Values to Votes to Belief

Solving the LP gives us $[0, 1]$ values for each variable c_v, but we need to calculate an updated belief $B(c)$. We propose two methods for this:

Vote Conservation: $B(c) = \omega^{-1}(c_v \cdot \omega_{M_c})$
Vote Loss: $B(c) = \omega^{-1}(\min(\omega_c,\ c_v \cdot \omega_{M_c}))$

ω^{-1} is an inverse of the vote function: $\omega_{idn}^{-1}(x) = x$ and $\omega_{inv}^{-1}(x) = 1 - (1 + y)^{-1}$. Vote Conservation reallocates votes such that the total number of votes in each mutual exclusion set, ω_M, remains the same after the redistribution. However, if the constraints force c to lose votes, should we believe the other claims in M_c more? Under Vote Loss, a claim can *only* lose votes, ensuring that if other claims in M_c become less believable, c does not itself become more believable relative to claims in other mutual exclusion sets. We found Vote Loss just slightly better on average and used it for all reported results.

4.4 "Unknown" Augmentation

Augmenting our data with "Unknown" claims ensures that every LP is feasible and can be used to model our ignorance given a lack of sufficient information or conflicting constraints. An Unknown claim U_M is added to every mutual exclusion set M (but invisible to the fact-finder) and represents our belief that *none* of the claims in M are sufficiently supported. Now we can write the mutual exclusion constraint for M as $U_M + \sum_{c \in M} c_v = 1$. When propositionalizing FOL, if a disjunctive clause contains a non-negated literal for a claim c, then we add $\vee U_{M_c}$ to the clause.

For example, $Age(John, 35) \Rightarrow Age(Tom, 40)$ becomes $Age(John, 35) \Rightarrow Age(Tom, 40) \vee Age(Tom, Unknown)$. The only exception is when the clause contains claims from only one mutual exclusion set (e.g. "I know Sam is 50 or 60"), and so the LP can only be infeasible if the user directly asserts a contradiction (e.g. "Sam is 50 *and* Sam is 60"). The Unknown itself has a fixed number of votes that cannot be lost; this effectively "smooths" our belief in the claims and imposes a floor for believability. If $Age(Kim, 30)$ has 5 votes, $Age(Kim, 35)$ has 3 votes, and $Age(Kim, Unknown)$ is fixed at 6 votes, we hold that Kim's age is unknown due to lack of evidence. The number of votes that should be given to each Unknown for this purpose depends, of course, on the particular fact-finder and ω function used; in our experiments, we are not concerned with establishing ignorance and thus assign 0 votes.

5 Experiments

Experiments were conducted over three domains (city population, basic biographies, and American vs. British spelling) with four datasets, all using the VoteDistance cost function and Vote Loss vote redistribution. We fixed the number of iterations of the framework (calculating $T^i(S)$, $B^i(S)$ and then solving the LP) at 20, which was found sufficient for all fact-finders. To evaluate accuracy, after the final iteration we look at each mutual exclusion set M and predict the highest-belief claim $c \in M$ (or, if u_M had the highest belief, the second-highest claim), breaking ties randomly, and check that it is the true claim t_M. We omit any M that does not contain a true claim (all known claims are false) and any M that is trivially correct (containing only one claim other than u_M). All results are shown in Table 1. **Vote** is the baseline, choosing either the claim occurring in the most Wikipedia revisions (in the Pop dataset) or claimed by the most sources (for all other datasets). **Sum** is Sums (Hubs and Authorities), **3Est** is 3-Estimates, **TF$^{\text{s}}$** is simplified TruthFinder, **TF$^{\text{c}}$** is "full" TruthFinder, **A·L** is Average·Log, **Inv**$^{1.2}$ is Investment with $g = 1.2$, and **Pool**$^{1.4}$ is PooledInvestment with $g = 1.4$.

5.1 IBT vs. L+I

We can enforce our prior knowledge against the beliefs produced by the fact-finder in each iteration, or we can apply these constraints just once, after running the fact-finder for 20 iterations without interference. By analogy to (Punyakanok et al., 2005), we refer to these approaches as inference based training (IBT) and learning + inference (L+I), respectively. Our results show that while L+I does better when prior knowledge is not entirely correct (e.g. "Growth" in the city population domain), generally performance is comparable when the effect of the constraints is mild, but IBT can outperform when prior knowledge is vital (as in the spelling domain) by allowing the fact-finder to learn from the provided corrections.

5.2 Wikipedia Infoboxes

To focus on the performance of the framework, we (like previous fact-finding work) naively assume that our data are accurately extracted, but we also require large corpora. Wikipedia Infoboxes (Wu and Weld, 2007) are a semi-structured source covering many domains with readily available authorship, and we produced our city population and basic biographic datasets from the most recent full-history dump of the English Wikipedia (taken January 2008). However, attribution is difficult: if an author edits the page but not the claim within the infobox, is the author implicitly agreeing with (and asserting) the claim? The best performance was achieved by being strict for City Population data, counting only the direct editing of a claim, and lax for Biography data, counting any edit. We hypothesize this is because editors may lack specific knowledge about a city's population (and thus fail to correct an erroneous value) but incorrect birth or death dates are more noticeable.

5.3 Results

5.3.1 City Population

We collected infoboxes for settlements (Geobox, Infobox Settlement, Infobox City, etc.) to obtain 44,761 populations claims qualified by year (e.g. $pop(Denver, 598707, 2008)$), with 4,107 authors total. We took as our "truth" U.S. census data, which gave us 308 non-trivial true facts to test against. Our "common sense" knowledge is that population grows

Table 1: Experimental Results ($\emptyset$ indicates no prior knowledge; all values are percent accuracy) Some results are omitted here (see text). A·L, Inv$^{1.2}$, Pool$^{1.4}$ are our novel algorithms

Dataset	Prior Knowledge	Vote	Sum	3Est	TF^s	TF^c	A·L	Inv$^{1.2}$	Pool$^{1.4}$
Pop	$\emptyset$	81.49	81.82	81.49	82.79	84.42	80.84	**87.99**	80.19
Pop	Growth$_{IBT}$	82.79	79.87	77.92	82.79	**86.36**	80.52	85.39	79.87
Pop	Growth$_{L+I}$	82.79	79.55	77.92	83.44	85.39	80.52	**89.29**	80.84
Pop	Larger$^{2500}_{IBT}$	85.39	85.06	80.52	86.04	87.34	84.74	**89.29**	84.09

Bio	CS$_{L+I}$	89.20	89.61	89.20	57.10	90.09	89.35	88.49	**90.24**
Bio	CS+Decades$_{IBT}$	90.58	90.88	90.58	80.30	91.25	90.91	90.02	**91.32**
Bio	CS+Decades$_{L+I}$	90.58	90.91	90.58	69.27	90.95	90.91	90.09	**91.17**
Spell	$\emptyset$	13.54	9.37	11.96	**41.93**	7.93	10.23	9.36	9.65
Spell	Words$^{100}_{IBT}$	13.69	9.02	12.72	**44.28**	8.05	9.98	11.11	8.86
Spell	Words$^{100}_{L+I}$	13.69	8.86	12.08	**46.54**	8.05	9.98	9.34	7.89
Spell	CS+Words$^{100}_{IBT}$	35.10	31.88	35.10	56.52	29.79	32.85	73.59	**80.68**
Spell	CS+Words$^{100}_{L+I}$	35.10	31.72	34.62	**55.39**	22.06	32.21	30.92	29.95

over time ("Growth" in table 1); therefore, $\forall_{v,w,x,y,z} pop(v,w,y) \wedge pop(v,x,z) \wedge y < z \Rightarrow x > w$. Of course, this often does not hold true: cities can shrink, but performance was nevertheless superior to no prior knowledge whatsoever. The L+I approach does appreciably better because it avoids forcing these sometimes-incorrect constraints onto the claim beliefs while the fact-finder iterates (which would propagate the resulting mistakes), instead applying them only at the end where they can correct more errors than they create. The sparsity of the data plays a role–only a fraction of cities have population claims for multiple years, and those that do are typically larger cities where the correct claim is asserted by an overwhelming majority, greatly limiting the potential benefit of our Growth constraints. We also considered prior knowledge of the relative sizes of some cities, randomly selecting 2500 pairs of them (a, b), where a was more populous than b in year t, asserting $\forall_{x,y} pop(a,x,t) \wedge pop(b,y,t) \Rightarrow x > y$. This "Larger" prior knowledge proved more effective than our oft-mistaken Growth constraint, with modest improvement to the highest-performing Investment fact-finder, and Investment$_{L+I}$ reaches **90.91%** with 10,000 such pairs.

5.3.2 Synthetic City Population

What if attribution were certain and the data more dense? To this end we created a synthetic dataset. We chose 100 random (real) cities and created 100 authors whose individual accuracy a was drawn uniformly from $[0,1]$. Between 1 and 10 claims (also determined uniformly) were made about each city in each year from 2000 to 2008 by randomly-selected authors. For each city with true population p and year, four incorrect claims were created with populations selected uniformly from $[0.5p, 1.5p]$, each author claiming p with probability a and otherwise asserting one of the four incorrect claims. Our common-sense knowledge was that population did not change by more than 8% per year (also tried on the Wikipedia dataset but with virtually no effect). Like "Growth", "Pop±8%" does not always hold, but a change of more than 8% is much rarer than a shrinking city. These constraints greatly improved results, although we note this would diminish if inaccurate claims had less variance around the true population.

5.3.3 Basic Biographies

We scanned infoboxes to find 129,847 claimed birth dates, 34,201 death dates, 10,418 parent-child pairs, and 9,792 spouses. To get "true" birth and death dates, we extracted data from several online repositories (after satisfying ourselves that they were independent and not derived from Wikipedia!), eliminating any date these sources disagreed upon, and ultimately obtained a total of 2,685 dates to test against. Our common sense ("CS") knowledge was: nobody dies before they are born, people are infertile before the age of 7, nobody lives past 125, all spouses have overlapping lifetimes, no child is born more than a year after a parent's (father's) death, nobody has more than two parents, and nobody is born or dies after 2008 (the "present day", the year of the Wikipedia dump). Applying this knowledge roughly halved convergence times, but had little effect on the results due to data sparsity similar to that seen in the population data–while we know many birthdays and some death dates, relatively few biographies had parent-child and spouse claims. To this we also added knowledge of the decade (but not the exact date) in which 15,145 people were born ("CS+Decades"). Although common sense alone does not notably improve results, it does very well in conjunction with specific knowledge.

5.3.4 American vs. British Spelling

Prior knowledge allows us to find a truth that conforms with the user's viewpoint, even if that viewpoint differs from the norm. After obtaining a list of words with spellings that differed between American and British English (e.g. "color" vs. "colour"), we examined the British National Corpus as well as Washington Post and Reuters news articles, taking the source's (the article author's) use of a disputed word as a claim that his spelling was correct. Our goal was to find the "true" British spellings that conformed to a British viewpoint, but American spellings predominate by far. Consequently, without prior knowledge the fact-finders do very poorly against our test set of 694 British words, predicting American spelling instead in accordance with the great majority of authors (note that accuracy from an American perspective is 1−"British" accuracy). Next we assumed that the user already knew the correct spelling of 100 random words (removing these from the test set, of course), but with little effect. Finally, we added our common sense ("CS") knowledge: if a spelling a is correct and of length ≥ 4, then if a is a substring of b, $a \Leftrightarrow b$ (e.g. colour $\Leftrightarrow$ colourful). Furthermore, while we do not know a priori whether a spelling is American or British, we do know if e and f are different spellings of the same word, and, if two such spellings have a chain of implication between them, we can break all links in this chain (while some American spellings will still be linked to British spellings, this removes most such errors). Interestingly, common sense alone actually *hurts* results (e.g. PooledInvestment (IBT) gets 6.2%), as it essentially makes the fact-finders more adept at finding the predominant American spellings! However, when some correct spellings are known, results improve greatly and demonstrate IBT's ability to spread strong prior knowledge, easily surpassing L+I. Results improve further with more known spellings (PooledInvestment gets **84.86%** with CS+Words$^{200}_{IBT}$).

6 Conclusion

We have introduced a new framework for incorporating prior knowledge into a fact-finding system, along with several new high-performing fact-finding algorithms (Investment, PooledInvestment, and Average·Log). While the benefits of prior knowledge were most dramatic in the Spelling domain, we saw gains from both "common sense" and specific knowledge in all experiments–even the difficult Biography domain saw faster convergence with common sense alone and notably higher results when specific knowledge was added. We find that while prior knowledge is helpful in reducing error, when the user's viewpoint disagrees with the norm it becomes absolutely essential and, formulated as a linear program, it need not be the computational burden that might otherwise be expected.

Abstract

We use web-scale N-grams in a base NP parser that correctly analyzes 95.4% of the base NPs in natural text. Web-scale data improves performance. That is, there is no data like more data. Performance scales log-linearly with the number of parameters in the model (the number of unique N-grams). The web-scale N-grams are particularly helpful in harder cases, such as NPs that contain conjunctions.

1 Introduction

Noun phrases (NPs) provide an index to the world's information. About 70% of web queries are NPs (Barr et al., 2008). A robust NP parser could help search engines improve retrieval performance on multi-word NP queries (Zhai, 1997). For example, by knowing the correct parse of "washed (baby carrots)," a search engine could ensure that returned pages (and advertisements) concern clean carrots rather than clean babies. NP structure is also helpful for query expansion and substitution (Jones et al., 2006).

This paper is concerned with base NP parsing. We are given a base NP string as input, and the task is to produce a parse tree as output. Base NPs are NPs that do not contain embedded noun phrases. These are sometimes called NP chunks, or core/non-recursive NPs (Church, 1988; Ramshaw and Marcus, 1995). Correctly parsing (or, equivalently, bracketing) base NPs is challenging because the same part-of-speech (POS) sequence can be parsed differently depending on the specific words involved. For example, "*retired (science teacher)*" and "*(social science) teacher*" have different structures even though they have identical POS sequences.

Lexical statistics are therefore needed in order to parse the above examples, and they must be computed over a lot of text to avoid sparsity. All of our lexical statistics are derived from a new and improved web-scale N-gram corpus (Lin et al., 2010), which we call Google V2.

Despite the importance of base NPs, most sentence parsers do not parse base NPs, since the main training corpus for parsers, the Penn Treebank (PTB) (Marcus et al., 1994), leaves a flat structure for base NPs. Recent annotations by Vadas and Curran (2007a) added NP structure to the PTB. We use these annotations (described in Section 3) for our experiments.

NP parsers usually focus on bracketing three-word noun compounds. Parsing three-word noun compounds is a fairly artificial task; we show that sequences of three nouns make up less than 1% of the three-word-or-longer base NPs in natural text. As the NP length increases, the number of possible binary trees (parses) increases with the Catalan numbers (Church and Patil, 1982). NPs of length three have just two possible parses (chance is 50%), while NPs of length six already have forty-two possible parses (chance is 2%). Long NPs therefore provide much more opportunity to improve performance over the baseline. In Table 1 (Section 7), we show the distribution of base NP length in the PTB. While most NPs are of length three, NP length has a long tail.

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 886–894,
Beijing, August 2010

The three-word noun compound assumption also restricts research to the case in which all words are nouns, while base NPs also contain determiners, possessives, adjectives, and conjunctions. Conjunctions and their scopes are particularly challenging. For example, in the NP, "*French television and movie producers*," a parser should conjoin "(*television*) *and* (*movie*)," as opposed to "(*French television*) *and* (*movie*)," "(*French television*) *and* (*movie producers*)" or "(*television*) *and* (*movie producers*)."

To resolve these issues, we train a classifier which uses contextual information from the entire NP and lexical statistics derived from the web-scale N-gram corpus to predict if a given span is a constituent. Our parser then uses this classifier to produce a score for every possible NP-internal bracketing and creates a chart of bracketing scores. This chart can be used as features in a full sentence parser or parsed directly with a chart parser. Our parses are highly accurate, creating a strong new standard for this task.

Finally, we present experiments that investigate the effects of N-gram frequency cutoffs and various sources of N-gram data. We show an interesting relationship between accuracy and the number of unique N-gram types in the data.

2 Related Work

2.1 Three-Word Noun Compounds

The most commonly used data for NP parsing is from Lauer (1995), who extracted 244 three-word noun compounds from the Grolier encyclopedia. When there are only three words, this task reduces to a binary decision:

- Left Branching: * [*retired science*] *teacher*
- Right Branching: *retired* [*science teacher*]

In Lauer (1995)'s set of noun compounds, two-thirds are left branching.

The main approach to these three-word noun compounds has been to compute association statistics between pairs of words and then choose the bracketing that corresponds to the more highly associated pair. The two main models are the *adjacency model* (Marcus, 1980; Liberman and Sproat, 1992; Pustejovsky et al., 1993; Resnik, 1993) and the *dependency model* (Lauer, 1995). Under the adjacency model, the bracketing decision is made by comparing the associations between words one and two versus words two and three (i.e. comparing *retired science* versus *science teacher*). In contrast, the dependency model compares the associations between one and two versus one and three (*retired science* versus *retired teacher*). Lauer (1995) compares the two models and finds the dependency model to be more accurate.

Nakov and Hearst (2005) compute the association scores using frequencies, conditional probabilities, χ^2, and mutual information, for both pairs of words and for linguistically-motivated paraphrases. Lapata and Keller (2005) found that using web-scale data for associations is better than using the (smaller) 100M-word British National Corpus.

2.2 Longer NPs

Focusing on only the three word case misses a large opportunity for base NP parsing. NPs longer than three words commonly occur, making up 29% of our test set. In addition, a chance baseline does exponentially worse as the length of the NP increases. These longer NPs are therefore a major opportunity to improve overall base NP parsing.

Since in the general case, NP parsing can no longer be thought of as a single binary classification problem, different strategies are required.

Barker (1998) reduces the task of parsing longer NPs to making sequential three-word decisions, moving a sliding window along the NP. The window is first moved from right-to-left, inserting right bracketings, and then again from left-to-right, finalizing left bracketings. While Barker (1998) assumes that these three-word decisions can be made in isolation, this is not always valid.[1] Vadas and Curran (2007b) employ Barker's algorithm, but use a supervised classifier to make the sequential bracketing decisions. Because these approaches rely on a sequence of binary decisions,

[1] E.g., although the right-most three words are identical in 1) "*soap opera stars and television producers*," and 2) "*movie and television producers*," the initial right-bracketing decision for "*and television producers*" should be different in each.

early mistakes can cascade and lead to a chain of incorrect bracketings.

Our approach differs from previous work in NP parsing; rather than greedily inserting brackets as in Barker's algorithm, we use dynamic programming to find the global maximum-scoring parse. In addition, unlike previous approaches that have used local features to make local decisions, we use the full NP to score each potential bracketing.

A related line of research aims to *segment* longer phrases that are queried on Internet search engines (Bergsma and Wang, 2007; Guo et al., 2008; Tan and Peng, 2008). Bergsma and Wang (2007) focus on NP queries of length four or greater. They use supervised learning to make segmentation decisions, with features derived from the noun compound bracketing literature. Evaluating the benefits of *parsing* NP queries, rather than simply segmenting them, is a natural application of our system.

3 Annotated Data

Our training and testing data are derived from recent annotations by Vadas and Curran (2007a). The original PTB left a flat structure for base noun phrases. For example, "*retired science teacher,*" would be represented as:

(NP (JJ retired) (NN science) (NN teacher))

Vadas and Curran (2007a) annotated NP-internal structure by adding annotations whenever there is a left-bracketing. If no annotations were added, right-branching is assumed. The inter-annotator agreement for exactly matching the brackets on an NP was 98.5%.

This data provides a valuable new resource for parsing research, but little work has so far made use of it. Vadas and Curran (2007b) perform some preliminary experiments on NP bracketing, but use gold standard part-of-speech and named-entity annotations as features in their classifier. Our work establishes a strong and realistic standard on this data; our results will serve as a basis for further research on this topic.

4 Unlabeled N-gram Data

All of our N-gram features described in Section 6.1 rely on probabilities derived from unlabeled data. To use the largest amount of data possible, we exploit web-scale N-gram corpora. N-gram counts are an efficient way to compress large amounts of data (such as all the text on the web) into a manageable size. An N-gram corpus records how often each unique sequence of words occurs. Co-occurrence probabilities can be calculated directly from the N-gram counts. To keep the size manageable, N-grams that occur with a frequency below a particular threshold can be filtered.

The corpus we use is **Google V2** (Lin et al., 2010): a new N-gram corpus with N-grams of length 1-5 that we created from the same 1 trillion word snapshot of the web as Google N-grams Version 1 (Brants and Franz, 2006), but with several enhancements. Duplicate sentences are removed, as well as "sentences" which are probably noise (indicated by having a large proportion of non-alphanumeric characters, being very long, or being very short). Removing duplicate sentences is especially important because automatically-generated websites, boilerplate text, and legal disclaimers skew the source web data, with sentences that may have only been authored once occurring millions of times. We use the suffix array tools described in Lin et al. (2010) to quickly extract N-gram counts.

5 Base NP Parsing Approach

Our goal is to take a base NP string as input and produce a parse tree as output. In practice, it would be most useful if the NP parse could be integrated into a sentence parser. Previous NP parsers are difficult to apply in practice.[2] Work in prepositional phrase attachment that assumes gold-standard knowledge of the competing attachment sites has been criticized as unrealistic (Atterer and Schütze, 2007).

Our system can easily be integrated into full parsers. Its input can be identified quickly and reliably and its output is compatible with downstream parsers.

[2] For example, Vadas and Curran (2007b) report results on NP parsing, but these results include NPs containing prepositional or adverbial phrases (confirmed by personal communication). Practical application of their system would therefore require resolving prepositional phrase attachment as a preprocessing step.

Our parser's input is base NPs, which can be identified with very high accuracy. Kudo and Matsumoto (2001) report 95.8% NP chunking accuracy on PTB data.

Once provided with an NP, our system uses a supervised classifier to predict the probability of a particular contiguous subsequence (span) of the NP being a constituent, given the entire NP as context. This probability can be inserted into the chart that a standard chart parser would use.

For example, the base NP "*French television and movie producers*" would be decomposed into nine different classification problems, scoring the following potential bracketings:

(French television) and movie producers
French (television and) movie producers
(French television and) movie producers ...
French television and (movie producers)

In Section 6, we detail the set of statistical and structural features used by the classifier.

The output of our classifier can be easily used as a feature in a full-sentence structured prediction parser, as in Taskar et al. (2004). Alternatively, our work could be integrated into a full-sentence parser by using our feature representations directly in a discriminative CFG parser (Finkel et al., 2008), or in a parse re-ranker (Ratnaparkhi et al., 1994; Collins and Koo, 2005; Charniak and Johnson, 2005).

While our main objective is to use web-scale lexical statistics to create an accurate classifier for base NP-internal constituents, we do produce a parse tree for evaluation purposes. The probability of a parse tree is defined as the product of the probabilities of all the spans (constituents) in the tree. The most probable tree is computed with the CYK algorithm.

6 Features

Over the course of development experiments, we discovered that the more position-specific our features were, the more effectively we could parse NPs. We define a word's position as its distance from the right of the full NP, as the semantic head of NPs is most often the right-most word. Ultimately, we decided to conjoin each feature with the position of the proposed bracketing. Since the features for differing proposed bracketings are now disjoint, this is equivalent to scoring bracketings with different classifiers, with each classifier chosen according to the bracketing position. We now outline the feature types that are common, but weighted differently, in each proposed bracketing's feature set.

6.1 N-gram Features

All of the features described in this section require estimates of the probability of specific words or sequences of words. All probabilities are computed using **Google V2** (Section 4).

6.1.1 PMI

Recall that the adjacency model for the three-word task uses the associations of the two pairs of adjacent words, while the dependency model uses the associations of the two pairs of attachment sites for the initial noun. We generalize the adjacency and dependency models by including the pointwise mutual information (Church and Hanks, 1990) between *all* pairs of words in the NP:

$$\mathrm{PMI}(x, y) = \log \frac{p(\text{“x y”})}{p(\text{“x”})p(\text{“y”})} \qquad (1)$$

For NPs of length n, for each proposed bracketing, we include separate features for the PMI between all $\binom{n}{2}$ pairs of words in the NP. For NPs including conjunctions, we include additional PMI features (Section 6.1.2).

Since these features are also tied to the proposed bracketing positions (as explained above), this allows us to learn relationships between various associations within the NP and each potential bracketing. For example, consider a proposed bracketing from word 4 to word 5. We learn that a high association of words inside a bracketing (here, a high association between word 4 and word 5) indicates a bracketing is likely, while a high association between words that cross a proposed bracketing (e.g., a high association between word 3 and word 4) indicates the bracketing is unlikely.

The value of these features is the PMI, if it is defined. If the PMI is undefined, we include one of two binary features:
$p(\text{“x y”}) = 0$ or $p(\text{“x”}) \vee p(\text{“y”}) = 0$.

We illustrate the PMI features with an example. In deciding whether (*movie producers*) is a reasonable bracketing within "*French television and movie producers*," the classifier weighs features for all of:

PMI(*French, television*)
PMI(*French, and*)
...
PMI(*television, producers*)
PMI(*and, producers*)
PMI(*movie, producers*)

6.1.2 Conjunctions

Properly handling NPs containing conjunctions (NP+conj) requires special statistical features. For example, *television* and *movie* are commonly conjoined, but the relevant statistics that suggest placing brackets around the phrase "*television and movie*" are not provided by the above PMI features (i.e., this is not clear from PMI(*television, and*), PMI(*television, movie*), nor PMI(*and, movie*)). Rather, we want to know if the full phrase "television and movie" is common.

We thus have additional NP+conj features that consider the PMI association across the word *and*:

$$\text{PMI}_{and}(x, y) = \log \frac{p(\text{“}x\ and\ y\text{”})}{p(\text{“}x\ and\text{”})p(\text{“}and\ y\text{”})} \quad (2)$$

When PMI$_{and}$ between a pair of words is high, they are likely to be the constituents of a conjunction.

Let $NP{=}(w_1 \ldots w_{i-1}, \text{‘}and\text{’}, w_{i+1} \ldots w_n)$ be an NP+conj. We include the PMI$_{and}$ features between w_{i-1} and all $w \in w_{i+1} \ldots w_n$. In the example "*French television and movie producers*," we would include features PMI$_{and}$(*television, movie*) and PMI$_{and}$(*television, producers*).

In essence, we are assuming w_{i-1} is the head of one of the items being conjoined, and we score the likelihood of each of the words to the right of the *and* being the head for the other item. In our running example, the conjunction has narrow scope, and PMI$_{and}$(*television, movie*) is greater than PMI$_{and}$(*television, producers*), indicating to our classifier that (*television and movie*) is a good bracketing. In other examples the conjunction will join heads that are further apart, as in *((French TV) and (British radio)) stars*, where both of the following hold:

PMI$_{and}$(TV, radio) $>$ PMI$_{and}$(TV, British)
PMI$_{and}$(TV, radio) $>$ PMI$_{and}$(TV, stars)

6.2 Lexical

We include a binary feature to indicate the presence of a particular word at each position in the NP. We learn that, for instance, the word *Inc.* in names tends to occur outside of brackets.

6.3 Shape

Previous work on NP bracketing has used gold-standard named entity tags (Vadas and Curran, 2007b) as features. We did not want to use any gold-standard features in our experiments, however NER information is helpful in separating premodifiers from names, i.e. *(news reporter) (Walter Cronkite).*

As an expedient way to get both NER information and useful information from hyphenated adjectives, abbreviations, and other punctuation, we normalize each string using the following regular expressions:

[A-Z]+ → A   [a-z]+ → a

We use this normalized string as an indicator feature. E.g. the word "Saudi-born" will fire the binary feature "Aa-a."

6.4 Position

We also include the position of the proposed bracketing as a feature. This represents the prior of a particular bracketing, regardless of the actual words.

7 Experiments

7.1 Experimental Details

We use Vadas and Curran (2007a)'s annotations (Section 3) to create training, development and testing data for base NPs, using standard splits of the Penn Treebank (Table 1). We consider all non-trivial base NPs, i.e., those longer than two words.

For training, we expand each NP in our training set into independent examples corresponding to all the possible internal NP-bracketings, and represent these examples as feature vectors (Section 5). Each example is positively labeled if it is

Data Set	Train	Dev	Test	Chance
PTB Section	2-22	24	23	
Length=3	41353	1428	2498	50%
Length=4	12067	445	673	20%
Length=5	3930	148	236	7%
Length=6	1272	34	81	2%
Length>6	616	29	34	< 1%
Total NPs	59238	2084	3522	

Table 1: Breakdown of the PTB base NPs used in our experiments. Chance = 1/Catalan(length).

Features	All NPs	NP+conj	NP-conj
All features	**95.4**	**89.7**	**95.7**
-N-grams	94.0	84.0	94.5
-lexical	92.2	87.4	92.5
-shape	94.9	**89.7**	95.2
-position	95.3	**89.7**	95.6
Right bracketing	72.6	58.3	73.5

Table 2: Accuracy (%) of base NPs parsing; ablation of different feature classes.

consistent with the gold-standard bracketing, otherwise it is a negative example.

We train using LIBLINEAR, an efficient linear Support Vector Machine (SVM).[3] We use an L2-loss function, and optimize the regularization parameter on the development set (reaching an optimum at C=1). We converted the SVM output to probabilities.[4] Perhaps surprisingly, since SVMs are not probabilistic, performance on the development set with these SVM-derived probabilities was higher than using probabilities from the LIBLINEAR logistic regression solver.

At test time, we again expand the NPs and calculate the probability of each constituent, inserting the score into a chart. We run the CYK algorithm to find the most probable parse of the entire NP according to the chart. Our evaluation metric is **Accuracy**: the proportion of times our proposed parse of the NP exactly matches the gold standard.

8 Results

8.1 Base NPs

Our method improves substantially over the baseline of assuming a completely right-branching structure, 95.4% versus 72.6% (Table 2). The accuracy of the constituency classifier itself (before the CYK parser is used) is 96.1%.

The lexical features are most important, but all feature classes are somewhat helpful. In particular, including N-gram PMI features significantly improves the accuracy, from 94.0% to 95.4%.[5] Correctly parsing more than 19 base NPs out of 20 is an exceptional level of accuracy, and provides a strong new standard on this task. The most comparable result is by Vadas and Curran (2007b), who achieved 93.0% accuracy on a different set of PTB noun phrases (see footnote 2), but their classifier used features based on gold-standard part-of-speech and named-entity information.

Exact match is a tough metric for parsing, and the difficulty increases as the length of the NP increases (because there are more decisions to make correctly). At three word NPs, our accuracy is 98.5%; by six word NPs, our accuracy drops to 79.0% (Figure 1). Our method's accuracy decreases as the length of the NP increases, but much less rapidly than a right-bracketing or chance baseline.

8.2 Base NPs with Conjunctions

N-gram PMI features help more on NP+conj than on those that do not contain conjunctions (NP-conj) (Table 2). N-gram PMI features are the most important features for NP+conj, increasing accuracy from 84.0% to 89.7%, a 36% relative reduction in error.

8.3 Effect of Thresholding N-gram data

We now address two important related questions: 1) how does our parser perform as the amount of unlabeled auxiliary data varies, and 2) what is the effect of thresholding an N-gram corpus? The second question is of widespread relevance as

[3] www.csie.ntu.edu.tw/~cjlin/liblinear/

[4] Following instructions in http://www.csie.ntu.edu.tw/~cjlin/liblinear/FAQ.html

[5] McNemar's test, $p < 0.05$

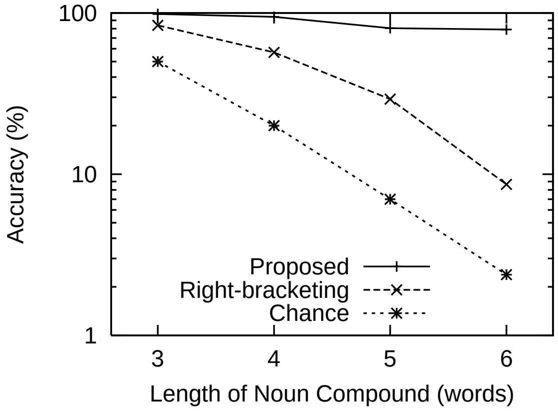

Figure 1: Accuracy (log scale) over different NP lengths, of our method, the right-bracketing baseline, and chance (1/Catalan(length)).

thresholded N-gram corpora are now widely used in NLP. Without thresholds, web-scale N-gram data can be unmanageable.

While we cannot lower the threshold after creating the N-gram corpus, we can raise it, filtering more N-grams, and then measure the relationship between threshold and performance.

Threshold	Unique N-grams	Accuracy
10	4,145,972,000	95.4%
100	391,344,991	95.3%
1,000	39,368,488	95.2%
10,000	3,924,478	94.8%
100,000	386,639	94.8%
1,000,000	37,567	94.4%
10,000,000	3,317	94.0%

Table 3: There is no data like more data. Accuracy improves with the number of parameters (unique N-grams).

We repeat the parsing experiments while including in our PMI features only N-grams with a count $\geq$10 (the whole data set), $\geq$100, $\geq$1000, . . ., $\geq 10^7$. All other features (lexical, shape, position) remain unchanged. The N-gram data almost perfectly exhibits Zipf's power law: raising the threshold by a factor of ten decreases the number of unique N-grams by a factor of ten (Table 3). The improvement in accuracy scales log-linearly with the number of unique N-grams. From a practical standpoint, we see a trade-off between storage and accuracy. There are consistent improvements in accuracy from lowering the threshold and increasing the amount of auxiliary data. If for some application it is necessary to reduce storage by several orders of magnitude, then one can easily estimate the resulting impact on performance.

Corpus	# of tokens	τ	# of types
NEWS	3.2 B	1	3.7 B
Google V1	1,024.9 B	40	3.4 B
Google V2	207.4 B	10	4.1 B

Table 4: N-gram data, with total number of words (*tokens*) in the original corpus (in billions, B), frequency threshold used to filter the data, τ, and total number of unique N-grams (*types*) remaining in the data after thresholding.

We repeat the thresholding experiments using two other N-gram sources:

NEWS: N-gram data created from a large set of news articles including the Reuters and Gigaword (Graff, 2003) corpora, not thresholded.

Google V1: The original web-scale N-gram corpus (Section 4).

Details of these sources are given in Table 4.

For a given number of unique N-grams, using any of the three sources does about the same (Figure 2). It does not matter that the source corpus for Google V1 is about five times larger than the source corpus for Google V2, which in turn is sixty-five times larger than NEWS (Table 4). Accuracies increase linearly with the log of the number of *types* in the auxiliary data set.

Google V1 is the one data source for which the relationship between accuracy and number of N-grams is not monotonic. After about 100 million unique N-grams, performance starts decreasing. This drop shows the need for Google V2. Since Google V1 contains duplicated web pages and sentences, mistakes that should be rare can appear to be quite frequent. Google V2, which comes from the same snapshot of the web as Google V1, but has only unique sentences, does not show this drop.

We regard the results in Figure 2 as a companion to Banko and Brill (2001)'s work on exponentially increasing the amount of labeled training data. Here we see that varying the amount of

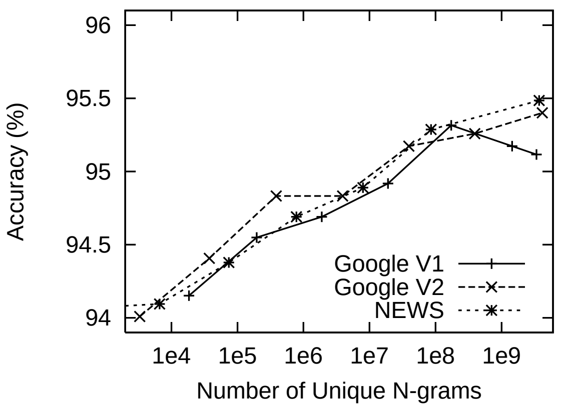

Figure 2: There is no data like more data. Accuracy improves with the number of parameters (unique N-grams). This trend holds across three different sources of N-grams.

unlabeled data can cause an equally predictable improvement in classification performance, without the cost of labeling data.

Suzuki and Isozaki (2008) also found a log-linear relationship between unlabeled data (up to a billion words) and performance on three NLP tasks. We have shown that this trend continues well beyond Gigaword-sized corpora. Brants et al. (2007) also found that more unlabeled data (in the form of input to a language model) leads to improvements in BLEU scores for machine translation.

Adding noun phrase parsing to the list of problems for which there is a “bigger is better” relationship between performance and unlabeled data shows the wide applicability of this principle. As both the amount of text on the web and the power of computer architecture continue to grow exponentially, collecting and exploiting web-scale auxiliary data in the form of N-gram corpora should allow us to achieve gains in performance linear in time, without any human annotation, research, or engineering effort.

9 Conclusion

We used web-scale N-grams to produce a new standard in performance of base NP parsing: 95.4%. The web-scale N-grams substantially improve performance, particularly in long NPs that include conjunctions. There is no data like more data. Performance improves log-linearly with the number of parameters (unique N-grams). One can increase performance with larger models, e.g., increasing the size of the unlabeled corpora, or by decreasing the frequency threshold. Alternatively, one can decrease storage costs with smaller models, e.g., decreasing the size of the unlabeled corpora, or by increasing the frequency threshold. Either way, the log-linear relationship between accuracy and model size makes it easy to estimate the trade-off between performance and storage costs.

Abstract

This paper presents an approach to summarize single scientific papers, by extracting its contributions from the set of citation sentences written in other papers. Our methodology is based on extracting significant keyphrases from the set of citation sentences and using these keyphrases to build the summary. Comparisons show how this methodology excels at the task of single paper summarization, and how it out-performs other multi-document summarization methods.

1 Introduction

In recent years statistical physicists and computer scientists have shown great interest in analyzing complex adaptive systems. The study of such systems can provide valuable insight on the behavioral aspects of the involved agents with potential applications in economics and science. One such aspect is to understand what motivates people to provide the $n + 1^{st}$ review of an artifact given that they are unlikely to add something significant that has not already been said or emphasized. Citations are part of such complex systems where articles use citations as a way to mention different contributions of other papers, resulting in a collective system.

The focus of this work is on the corpora created based on citation sentences. A citation sentence is a sentence in an article containing a citation and can contain zero or more *nuggets* (i.e., non-overlapping contributions) about the cited article. For example the following sentences are a few citation sentences that appeared in the NLP literature in past that talk about Resnik's work.

> *The STRAND system* **(Resnik, 1999)**, *for example, uses structural markup information from the pages, without looking at their content, to attempt to align them.*

> **Resnik (1999)** *addressed the issue of language identification for finding Web pages in the languages of interest.*

> *Mining the Web for bilingual text* **(Resnik, 1999)** *is not likely to provide sufficient quantities of high quality data..*

The set of citations is important to analyze because human summarizers have put their effort collectively but independently to read the target article and cite its important contributions. This has been shown in other work too (Elkiss et al., 2008; Nanba et al., 2004; Qazvinian and Radev, 2008; Mei and Zhai, 2008; Mohammad et al., 2009). In this work, we introduce a technique to summarize the set of citation sentences and cover the major contributions of the target paper. Our methodology first finds the set of keyphrases that represent important information units (i.e., nuggets), and then finds the best set of k sentences to cover more, and more important nuggets.

Our results confirm the effectiveness of the method and show that it outperforms other state of the art summarization techniques. Moreover, as shown in the paper, this method does not need to calculate the full cosine similarity matrix for a document cluster, which is the most time consuming part of the mentioned baseline methods.

1.1 Related Work

Previous work has used citations to produce summaries of scientific work (Qazvinian and Radev,

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 895–903,
Beijing, August 2010

2008; Mei and Zhai, 2008; Elkiss et al., 2008). Other work (Bradshaw, 2003; Bradshaw, 2002) benefits from citations to determine the content of articles and introduce “Reference Directed Indexing” to improve the results of a search engine.

In other work, (Nanba and Okumura, 1999) analyze citation sentences and automatically categorize citations into three groups using 160 predefined phrase-based rules to support a system for writing a survey. Previous research has shown the importance of the citation summaries in understanding what a paper contributes. In particular, (Elkiss et al., 2008) performed a large-scale study on citation summaries and their importance. Results from this experiment confirmed that the “Self Cohesion” (Elkiss et al., 2008) of a citation summary of an article is consistently higher than the that of its abstract and that citations contain additional information that does not appear in abstracts.

Kan et al. (2002) use annotated bibliographies to cover certain aspects of summarization and suggest using metadata and critical document features as well as the prominent content-based features to summarize documents. Kupiec et al. (1995) use a statistical method and show how extracts can be used to create summaries but use no annotated metadata in summarization.

Siddharthan and Teufel describe a new task to decide the scientific attribution of an article (Siddharthan and Teufel, 2007) and show high human agreement as well as an improvement in the performance of Argumentative Zoning (Teufel, 2005). Argumentative Zoning is a rhetorical classification task, in which sentences are labeled as one of Own, Other, Background, Textual, Aim, Basis, Contrast according to their role in the author’s argument. These all show the importance of citation summaries and the vast area for new work to analyze them to produce a summary for a given topic.

The Maximal Marginal Relevance (MMR) summarization method, which is based on a greedy algorithm, is described in (Carbonell and Goldstein, 1998). MMR uses the full similarity matrix to choose the sentences that are the least similar to the sentences already selected for the summary. We selected this method as one of our baseline methods, which we have explained in more details in Section 4.

2 Data

In order to evaluate our method, we use the ACL Anthology Network (AAN), which is a collection of papers from the Computational Linguistics journal and proceedings from ACL conferences and workshops and includes more than $13,000$ papers (Radev et al., 2009). We use 25 manually annotated papers from (Qazvinian and Radev, 2008), which are highly cited articles in AAN. Table 1 shows the ACL ID, title, and the number of citation sentences for these papers.

The annotation guidelines asked a number of annotators to read the citation summary of each paper and extract a list of the main contributions of that paper. Each item on the list is a non-overlapping contribution (nugget) perceived by reading the citation summary. The annotation strictly instructed the annotators to focus on the citing sentences to do the task and not their own background on the topic. Then, extracted nuggets are reviewed and those nuggets that have only been mentioned by 1 annotator are removed. Finally, the union of the rest is used as a set of nuggets representing each paper.

Table 2 lists the nuggets extracted by annotators for P03-1001.

3 Methodology

Our methodology assumes that each citation sentence covers 0 or more nuggets about the cited papers, and tries to pick sentences that maximize nugget coverage with respect to summary length.

These nuggets are essentially represented using keyphrases. Therefore, we try to extract significant keyphrases in order to represent nuggets each sentence contains. Here, the keyphrases are ex-

pressed using N-grams, and thus these building units are the key elements to our summarization. For each citation sentence d_i, our method first extracts a set of important keyphrases, D_i, and then tries to find sentences that have a larger number of important and non-redundant keyphrases. In order to take the first step, we extract statistically significantly frequent N-grams (up to $N = 4$) from each citing sentence and use them as the set of representative keyphrases for that citing sentence.

3.1 Automatic Keyphrase Extraction

A list of keyphrases for each citation sentence can be generated by extracting N-grams that occur significantly frequently in that sentence compared to a large corpus of such N-grams. Our method for such an extraction is inspired by the previous work by Tomokiyo and Hurst (Tomokiyo and Hurst, 2003).

A language model, $\mathcal{M}$, is a statistical model that assigns probabilities to a sequence of N-grams. Every language model is a probability distribution over all N-grams and thus the probabilities of all N-grams of the same length sum up to 1. In order to extract keyphrases from a text using statistical significance we need two language models. The first model is referred to as the *Background Model ($\mathcal{BM}$)* and is built using a large text corpus. Here we build the BM using the text of all the paper abstracts provided in AAN[1]. The second language model is called the *Foreground Model ($\mathcal{FM}$)* and is the model built on the text from which keyphrases are being extracted. In this work, the set of all citation sentences that cite a particular target paper are used to build a foreground language model.

Let g^i be an N-gram of size i and $C_{\mathcal{M}}(g^i)$ denote the count of g^i in the model $\mathcal{M}$. First, we extract the counts of each N-grams in both the background ($\mathcal{BM}$) and the foreground corpora ($\mathcal{FM}$).

[1] http://chernobog.si.umich.edu/clair/anthology/index.cgi

$$
\begin{aligned}
M_{\mathcal{BM}} &= \sum_{g^i \in \{\mathcal{BM} \cup \mathcal{FM}\}} 1 \\
N_{\mathcal{BM}} &= \sum_{g^i \in \{\mathcal{BM} \cup \mathcal{FM}\}} C_{\mathcal{BM}}(g^i) \\
N_{\mathcal{FM}} &= \sum_{g^i \in \mathcal{FM}} C_{\mathcal{FM}}(g^i) \\
\hat{p}_{\mathcal{FM}}(g^i) &= C_{\mathcal{FM}}(g^i)/N_{\mathcal{FM}} \\
\hat{p}_{\mathcal{BM}}(g^i) &= (C_{\mathcal{BM}}(g^i)+1)/(M_{\mathcal{BM}}+N_{\mathcal{BM}})
\end{aligned}
$$

The last equation is also known as Laplace smoothing (Manning and Schutze, 2002) and handles the N-grams in the foreground corpus that have a 0 occurrence frequency in the background corpus. Next, we extract N-grams from the foreground corpus that have significant frequencies compared to the frequency of the same N-grams in the background model and its individual terms in the foreground model.

To measure how randomly a set of consecutive terms are forming an N-gram, Tomokiyo and Hurst (Tomokiyo and Hurst, 2003) use pointwise divergence. In particular, for an N-gram of size i, $g^i = (w_1 w_2 \cdots w_i)$,

$$\delta_{g^i}(\mathcal{FM}^i \| \mathcal{FM}^1) = \hat{p}_{\mathcal{FM}}(g^i) \log\left(\frac{\hat{p}_{\mathcal{FM}}(g^i)}{\prod_{j=1}^{i} \hat{p}_{\mathcal{FM}}(w_j)}\right)$$

This equation shows the extent to which the terms forming g^i have occurred together randomly. In other words, it indicates the extent of information that we lose by assuming independence of each word by applying the unigram model, instead of the N-gram model.

In addition, to measure how randomly a sequence of words appear in the foreground model with respect to the background model, we use pointwise divergence as well. Here, pointwise divergence defines how much information we lose by assuming that g^i is drawn from the background model instead of the foreground model:

$$\delta_{g^i}(\mathcal{FM}^i \| \mathcal{BM}^i) = \hat{p}_{\mathcal{FM}}(g^i) \log\left(\frac{\hat{p}_{\mathcal{FM}}(g^i)}{\hat{p}_{\mathcal{BM}}(g^i)}\right)$$

(Corley and Mihalcea, 2005) applied or utilized lexical based word overlap measures.
{overlap measures, word overlap, lexical based, utilized lexical}

Table 4: Example: citation sentence for W05-1203 written by D06-1621, and its extracted bigrams.

We set the criteria of choosing a sequence of words as significant to be whether it has positive pointwise divergence with respect to both the background model, and individual terms of the foreground model. In other words we extract all g^i from $\mathcal{FM}$ for which the both properties are positive:

$$
\begin{aligned}
\delta_{g^i}(\mathcal{FM}^i \| \mathcal{BM}^i) &> 0 \\
\delta_{g^i}(\mathcal{FM}^i \| \mathcal{FM}^1) &\geq 0
\end{aligned}
$$

The equality condition in the second equation is specifically set to handle unigrams, in which $\hat{p}_{\mathcal{FM}}(g^i) = \prod_{j=1}^{i} \hat{p}_{\mathcal{FM}}(w_j)$.

In order to handle the text corpora and building the language models, we have used the CMU-Cambridge Language Model toolkit (Clarkson and Rosenfeld, 1997). We use the set of citation sentences for each paper to build foreground language models. Furthermore, we employ this tool and make the background model using nearly 11,000 abstracts from AAN. Table 3 summarizes some of the statistics about the background data.

Once keyphrases (significant N-grams) of each sentence are extracted, we remove all N-grams in which more than half of the terms are stopwords. For instance, we remove all stopword unigrams, if any, and all bigrams with at least one stopword in them. For 3-grams and 4-grams we use a threshold of 2 and 3 stopwords respectively. After that, the set of remaining N-grams is used to represent each sentence and to build summaries. Table 4 shows an example of a citation sentence from D06-1621 citing W05-1203 (Corley and Mihalcea, 2005), and its extracted bigrams.

3.2 Sentence Selection

After extracting the set of keyphrases for each sentence, d_i, the sentence is represented using its set of N-grams, denoted by D_i. Then, the goal is to pick sentences (sets) for each paper that cover more important and non-redundant keyphrases. Essentially, keyphrases that have been repeated in more sentences are more important and could represent more important nuggets. Therefore, sentences that contain more frequent keyphrases are more important. Based on this intuition we define the reward of building a summary comprising a set of keyphrases S as

$$f(S) = |S \cap A|$$

where A is the set of all keyphrases from sentences not in the summary.

The set function f has three main properties. First, it is non-negative. Second, it is monotone (i.e., For every set v we have $f(S+v) \geq f(S)$). Third, f is sub-modular. The submodularity means that for a set v and two sets $S \subseteq T$ we have

$$f(S+v) - f(S) \geq f(T+v) - f(T)$$

Intuitively, this property implies that adding a set v to S will increase the reward at least as much as it would to a larger set T. In the summarization setting, this means that adding a sentence to a smaller summary will increase the reward of the summary at least as much as adding it to a larger summary that subsumes it. The following theorem formalizes this and is followed by a proof.

Theorem 1 *The reward function f is submodular.*

Proof
We start by defining a gain function $\mathcal{G}$ of adding sentence (set) D_i to $\mathcal{S}_{k-1}$ where $\mathcal{S}_{k-1}$ is the set of keyphrases in a summary built using $k-1$ sentences, and D_i is a candidate sentence to be added:

$$\mathcal{G}(D_i, \mathcal{S}_{k-1}) = f(\mathcal{S}_{k-1} \cup D_i) - f(\mathcal{S}_{k-1})$$

Simple investigation through a Venn diagram proof shows that $\mathcal{G}$ can be re-written as

$$\mathcal{G}(D_i, \mathcal{S}_{k-1}) = |D_i \cap (\cup_{j \neq i} D_j) - \mathcal{S}_{k-1}|$$

Let's denote $D_i \cap (\cup_{j \neq i} D_j)$ by $\cap_i$. The following equations prove the theorem.

$$\begin{aligned}
&\mathcal{S}_{k-1} \subseteq \mathcal{S}_k \\
&\mathcal{S}'_{k-1} \supseteq \mathcal{S}'_k \\
&\cap_i \cap \mathcal{S}'_{k-1} \supseteq \cap_i \cap \mathcal{S}'_k \\
&\cap_i - \mathcal{S}_{k-1} \supseteq \cap_i - \mathcal{S}_k \\
&| \cap_i - \mathcal{S}_{k-1}| \geq | \cap_i - \mathcal{S}_k| \\
&\mathcal{G}(D_i, \mathcal{S}_{k-1}) \geq \mathcal{G}(D_i, \mathcal{S}_k) \\
&f(\mathcal{S}_{k-1} \cup D_i) - f(\mathcal{S}_{k-1}) \geq f(\mathcal{S}_k \cup D_i) - f(\mathcal{S}_k)
\end{aligned}$$

Here, $\mathcal{S}'_k$ is the set of all N-grams in the vocabulary that are not present in $\mathcal{S}_k$. The gain of adding a sentence, D_i, to an empty summary is a non-negative value.

$$\mathcal{G}(D_i, \mathcal{S}_0) = C \geq 0$$

By induction, we will get

$$\mathcal{G}(D_i, \mathcal{S}_0) \geq \mathcal{G}(D_i, \mathcal{S}_1) \geq \cdots \geq \mathcal{G}(D_i, \mathcal{S}_k) \geq 0$$

□

Theorem 1 implies the general case of submodularity:

$$\forall m, n, 0 \leq m \leq n \leq |D| \Rightarrow \mathcal{G}(D_i, \mathcal{S}_m) \geq \mathcal{G}(D_i, \mathcal{S}_n)$$

Maximizing this submodular function is an NP-hard problem (Khuller et al., 1999). A common way to solve this maximization problem is to start with an empty set, and in each iteration pick a set that maximizes the gain. It has been shown before in (Kulik et al., 2009) that if f is a submodular, nondecreasing set function and $f(\emptyset) = 0$, then such a greedy algorithm finds a set $\mathcal{S}$, whose gain is at least as high as $(1 - 1/e)$ of the best possible solution. Therefore, we can optimize the keyphrase coverage as described in Algorithm 1.

4 Experimental Setup

We use the annotated data described in Section 2. In summary, the annotation consisted of two parts: nugget extraction and nugget distribution analysis. Five annotators were employed to annotate the sentences in each of the 25 citation summaries and write down the nuggets (non-overlapping contributions) of the target paper. Then using these

Summary generated using bigram-based keyphrases	
ID	Sentence
P06-1048:1	Ziff-Davis Corpus Most previous work (Jing 2000; Knight and Marcu 2002; Riezler et al 2003; Nguyen et al 2004a; Turner and Charniak 2005; McDonald 2006) has relied on automatically constructed parallel corpora for training and evaluation purposes.
J05-4004:18	Between these two extremes, there has been a relatively modest amount of work in sentence simplification (Chandrasekar, Doran, and Bangalore 1996; Mahesh 1997; Carroll et al 1998; Grefenstette 1998; Jing 2000; Knight and Marcu 2002) and document compression (Daume III and Marcu 2002; Daume III and Marcu 2004; Zajic, Dorr, and Schwartz 2004) in which words, phrases, and sentences are selected in an extraction process.
A00-2024:9	The evaluation of sentence reduction (see (Jing, 2000) for details) used a corpus of 500 sentences and their reduced forms in human-written abstracts.
N03-1026:17	To overcome this problem, linguistic parsing and generation systems are used in the sentence condensation approaches of Knight and Marcu (2000) and Jing (2000).
P06-2019:5	Jing (2000) was perhaps the first to tackle the sentence compression problem.

nugget sets, each sentence was annotated with the nuggets it contains. This results in a sentence-fact matrix that helps with the evaluation of the summary. The summarization goal and the intuition behind the summarizing system is to select a few (5 in our experiments) sentences and cover as many nuggets as possible. Each sentence in a citation summary may contain 0 or more nuggets and not all nuggets are mentioned an equal number of times. Covering some nuggets (contributions) is therefore more important than others and should be weighted highly.

To capture this property, the pyramid score seems the best evaluation metric to use. We use the pyramid evaluation method (Nenkova and Passonneau, 2004) at the sentence level to evaluate the summary created for each set. We benefit from the list of annotated nuggets provided by the annotators as the ground truth of the summarization evaluation. These annotations give the list of nuggets covered by each sentence in each citation summary, which are equivalent to the *summarization content unit (SCU)* as described in (Nenkova and Passonneau, 2004).

The pyramid score for a summary is calculated as follows. Assume a pyramid that has n tiers, T_i, where tier $T_i > T_j$ if $i > j$ (i.e., T_i is not below T_j, and that if a nugget appears in more sentences, it falls in a higher tier.). Tier T_i contains nuggets that appeared in i sentences, and thus has weight i. Suppose $|T_i|$ shows the number of nuggets in tier T_i, and Q_i is the size of a subset of T_i whose members appear in the summary. Further suppose Q shows the sum of the weights of the facts that are covered by the summary. $Q = \sum_{i=1}^{n} i \times Q_i$. In addition, the optimal pyramid score for a summary with X facts, is

$$Max = \sum_{i=j+1}^{n} i \times |T_i| + j \times (X - \sum_{i=j+1}^{n} |T_i|)$$

where $j = \max_i(\sum_{t=i}^{n} |T_t| \geq X)$. The pyramid score for a summary is then calculated as follows.

$$P = \frac{Q}{Max}$$

This score ranges from 0 to 1, and a high score shows the summary contains more heavily weighted facts.

4.1 Baselines and Gold Standards

To evaluate the quality of the summaries generated by the greedy algorithm, we compare its pyramid score in each of the 25 citation summaries with those of a gold standard, a random summary, and four other methods. The gold standards are summaries created manually using 5 sentences. The 5 sentences are manually selected in a way to cover as many nuggets as possible with higher priority for the nuggets with higher frequencies. We also created random summaries using Mead (Radev et al., 2004). These summaries are basically a random selection of 5 sentences from the pool of sentences in the citation summary. Generally we expect the summaries created by the greedy method to be significantly better than random ones.

In addition to the gold and random summaries, we also used 4 baseline state of the art summarizers: LexRank, the clustering C-RR and C-LexRank, and Maximal Marginal Relevance (MMR). LexRank (Erkan and Radev, 2004) works based on a random walk on the cosine similarity of sentences and prints out the most frequently visited sentences. Said differently, LexRank first builds a network in which nodes are sentences and edges are cosine similarity values. It then uses the eigenvalue centralities to find the most central sentences. For each set, the top 5 sentences on the list are chosen for the summary.

The clustering methods, C-RR and C-LexRank, work by clustering the cosine similarity network of sentences. In such a network, nodes are sentences and edges are cosine similarity of node pairs. Clustering would intuitively put nodes with similar nuggets in the same clusters as they are more similar to each other. The C-RR method as described in (Qazvinian and Radev, 2008) uses a round-robin fashion to pick sentences from each cluster, assuming that the clustering will put the sentences with similar facts into the same clusters. Unlike C-RR, C-LexRank uses LexRank to find the most salient sentences in each cluster, and prints out the most central nodes of each cluster as summary sentences.

Finally, MMR uses the full cosine similarity matrix and greedily chooses sentences that are the least similar to those already selected for the summary (Carbonell and Goldstein, 1998). In particular,

$$MMR = \arg \min_{d_i \in D-A} \left[\max_{d_j \in A} Sim(d_i, d_j) \right]$$

where A is the set of sentences in the summary, initially set to $A = \emptyset$. This method is different from ours in that it chooses the least similar sentence to the summary in each iteration.

4.2 Results and Discussion

As mentioned before, we use the text of the abstracts of all the papers in AAN as the background, and each citation set as a separate foreground corpus. For each citation set, we use the method described in Section 3.1 to extract significant N-grams of each sentence. We then use the keyphrase set representation of each sentence to build the summaries using Algorithm 1. For each of the 25 citation summaries, we build 4 different summaries using unigrams, bigrams, 3-grams, and 4-grams respectively. Table 5 shows a 5-sentence summary created using algorithm 1 for the paper A00-1043 (Jing, 2000).

The pyramid scores for different methods are reported in Figure 1 together with the scores of gold standards, manually created to cover as many nuggets as possible in 5 sentences, as well as summary evaluations of the 4 baseline methods described above. This Figure shows how the keyphrase based summarization method when employing N-grams of size 3 or smaller, outperforms other baseline systems significantly. More importantly, Figure 1 also indicates that this method shows more stable results and low variation in summary quality when keyphrases of size 3 or smaller are employed. In contrast, MMR shows high variation in summary qualities making summaries that obtain pyramid scores as low as 0.15.

Another important advantage of this method is that we do not need to calculate the cosine similarity of the pairs of sentences, which would add a running time of $O(|D|^2|V|)$ in the number of documents, $|D|$, and the size of the vocabulary $|V|$ to the algorithm.

5 Conclusion and Future Work

This paper presents a summarization methodology that employs keyphrase extraction to find important contributions of scientific articles. The summarization is based on citation sentences and picks sentences to cover nuggets (represented by keyphrases) or contributions of the target papers. In this setting the best summary would have as few sentences and at the same time as many nuggets as possible. In this work, we use pointwise KL-divergence to extract statistically significant N-grams and use them to represent nuggets. We then apply a new set function for the task of summarizing scientific articles. We have proved that this function is submodular and concluded that a

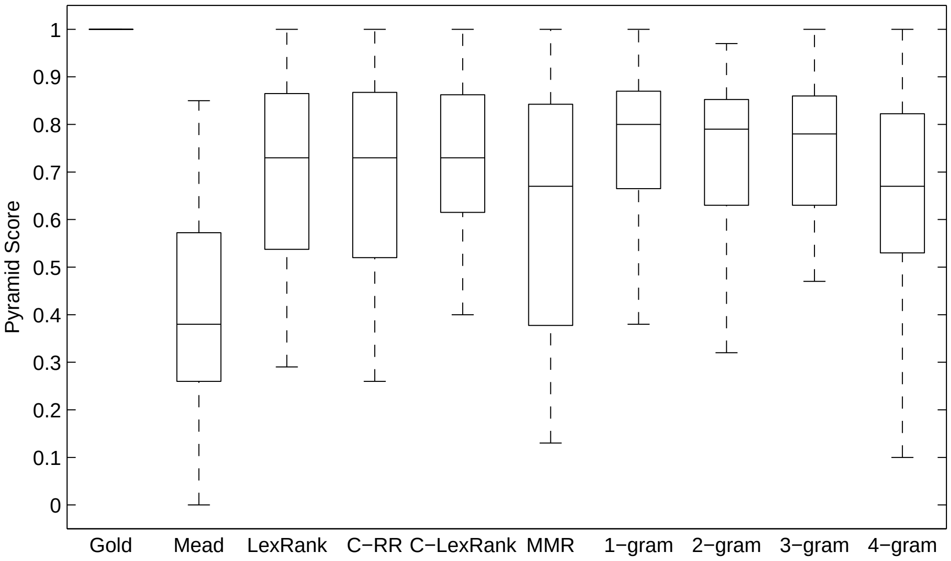

Figure 1: Evaluation Results (summaries with 5 sentences): The median pyramid score over 25 datasets using different methods.

greedy algorithm will result in a near-optimum set of covered nuggets using only 5 sentences. Our experiments in this paper confirm that the summaries created based on the presented algorithm are better than randomly generated summary, and also outperform other state of the art summarization methods in most cases. Moreover, we show how this method generates more stable summaries with lower variation in summary quality when N-grams of size 3 or smaller are employed.

A future direction for this work is to perform post-processing on the summaries and re-generate sentences that cover the extracted nuggets. However, the ultimate goal is to eventually develop systems that can produce summaries of entire research areas, summaries that will enable researchers to easily and quickly switch between fields of research.

One future study that will help us generate better summaries is to understand how nuggets are generated by authors. In fact, modeling the nugget coverage behavior of paper authors will help us identify more important nuggets and discover some aspects of the paper that would otherwise be too difficult by just reading the paper itself.

2D Trie for Fast Parsing

Xian Qian, Qi Zhang, Xuanjing Huang, Lide Wu

{xianqian, qz, xjhuang, ldwu}@fudan.edu.cn

Abstract

In practical applications, decoding speed is very important. Modern structured learning technique adopts template based method to extract millions of features. Complicated templates bring about abundant features which lead to higher accuracy but more feature extraction time. We propose Two Dimensional Trie (2D Trie), a novel efficient feature indexing structure which takes advantage of relationship between templates: feature strings generated by a template are prefixes of the features from its extended templates. We apply our technique to Maximum Spanning Tree dependency parsing. Experimental results on Chinese Tree Bank corpus show that our 2D Trie is about 5 times faster than traditional Trie structure, making parsing speed 4.3 times faster.

1 Introduction

In practical applications, decoding speed is very important. Modern structured learning technique adopts template based method to generate millions of features. Such as shallow parsing (Sha and Pereira, 2003), named entity recognition (Kazama and Torisawa,), dependency parsing (McDonald et al., 2005), etc.

The problem arises when the number of templates increases, more features generated, making the extraction step time consuming. Especially for maximum spanning tree (MST) dependency parsing, since feature extraction requires quadratic time even using a first order model. According to Bohnet's report (Bohnet, 2009), a fast feature extraction beside of a fast parsing algorithm is important for the parsing and training speed. He takes 3 measures for a 40X speedup, despite the same inference algorithm. One important measure is to store the feature vectors in file to skip feature extraction, otherwise it will be the bottleneck.

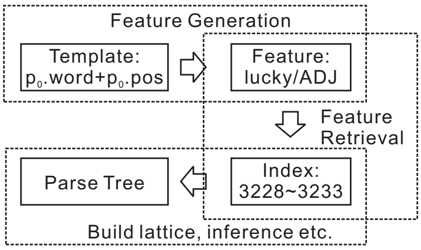

Figure 1: Flow chart of dependency parsing. p_0.*word*, p_0.*pos* denotes the word and POS tag of parent node respectively. Indexes correspond to the features conjoined with dependency types, e.g., *lucky/ADJ/OBJ*, *lucky/ADJ/NMOD*, etc.

Now we quickly review the feature extraction stage of structured learning. Typically, it consists of 2 steps. First, features represented by strings are generated using templates. Then a feature indexing structure searches feature indexes to get corresponding feature weights. Figure 1 shows the flow chart of MST parsing, where p_0.*word*, p_0.*pos* denote the word and POS tag of parent node respectively.

We conduct a simple experiment to investigate decoding time of MSTParser, a state-of-the-art java implementation of dependency parsing [1]. Chinese Tree Bank 6 (CTB6) corpus (Palmer and

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 904–912,
Beijing, August 2010

Step	Feature Generation	Index Retrieval	Other	Total
Time	300.27	61.66	59.48	421.41

Table 1: Time spent of each step (seconds) of MSTParser on CTB6 standard test data (2660 sentences). Details of the hardware and corpus are described in section 5

Xue, 2009) with standard train/development/test split is used for evaluation. Experimental results are shown in Table 1. The observation is that time spent of inference is trivial compared with feature extraction. Thus, speeding up feature extraction is critical especially when large template set is used for high accuracy.

General indexing structure such as Hash and Trie does not consider the relationships between templates, therefore they could not speed up feature generation, and are not completely efficient for searching feature indexes. For example, feature string s_1 generated by template "p$_0$.*word*" is prefix of feature s_2 from template "p$_0$.*word* + c$_0$.*word*" (word pair of parent and child), hence index of s_1 could be used for searching s_2. Further more, if s_1 is not in the feature set, then s_2 must be absent, its generation can be skipped.

We propose Two Dimensional Trie (2D Trie), a novel efficient feature indexing structure which takes advantage of relationship between templates. We apply our technique to Maximum Spanning Tree dependency parsing. Experimental results on CTB6 corpus show that our 2D Trie is about 5 times faster than traditional Trie structure, making parsing speed 4.3 times faster.

The paper is structured as follows: in section 2, we describe template tree which represents relationship between templates; in section 3, we describe our new 2D Trie structure; in section 4, we analyze the complexity of the proposed method and general string indexing structures for parsing; experimental results are shown in section 5; we conclude the work in section 6.

2 Template tree

2.1 Formulation of template

A template is a set of template units which are manually designed: $T = \{t_1, \dots, t_m\}$. For convenience, we use another formulation: $T = t_1 + \dots + t_m$. All template units appearing in this paper are described in Table 2, most of them are widely used. For example, "T = p$_0$.*word* + c$_0$.*word*$|^l$ " denotes the word pair of parent and child nodes, conjoined with their distance.

Unit	Meaning
p$_{-i}$/p$_i$	the i^{th} node left/right to parent node
c$_{-i}$/c$_i$	the i^{th} node left/right to child node
r$_{-i}$/r$_i$	the i^{th} node left/right to root node
n.*word*	word of node n
n.*pos*	POS tag of node n
n.*length*	word length of node n
$\|^l$	conjoin current feature with linear distance between child node and parent node
$\|_d$	conjoin current feature with direction of dependency (left/right)

Table 2: Template units appearing in this paper

2.2 Template tree

In the rest of the paper, for simplicity, let s_i be a feature string generated by template T_i.

We define the relationship between templates: T_1 is the **ancestor** of T_2 if and only $T_1 \subset T_2$, and T_2 is called the **descendant** of T_1. Recall that, feature string s_1 is prefix of feature s_2. Suppose $T_3 \subset T_1 \subset T_2$, obviously, the most efficient way to look up indexes of s_1, s_2, s_3 is to search s_3 first, then use its index id_3 to search s_1, and finally use id_1 to search s_2. Hence the relationship between T_2 and T_3 can be neglected.

Therefore we define **direct ancestor** of T_1: T_2 is a direct ancestor of T_1 if $T_2 \subset T_1$, and there is no template T' such that $T_2 \subset T' \subset T_1$. Correspondingly, T_1 is called the **direct descendant** of T_2.

Template graph $G = (V, E)$ is a directed graph that represents the relationship between templates, where $V = \{T_1, \dots, T_n\}$ is the template set, $E = \{e_1, \dots, e_N\}$ is the edge set. Edge from T_i to T_j exists, if and only if T_i is the direct ancestor of T_j. For templates having no ancestor, we add an empty template as their common direct ancestor, which is also the root of the graph.

The left part of Figure 2 shows a template graph for templates T_1 =p$_0$.*word*, T_2 =p$_0$.*pos* , T_3 =p$_0$.*word* + p$_0$.*pos*. In this example, T_3 has 2 direct ancestors, but in fact s_3 has only one prefix

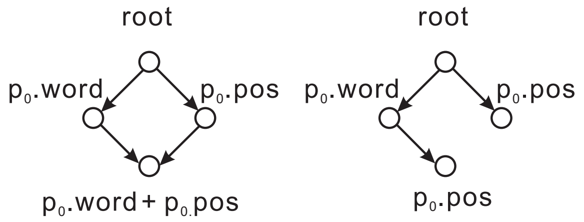

Figure 2: Left graph shows template graph for T_1 =p$_0$.*word*, T_2 =p$_0$.*pos* , T_3 =p$_0$.*word* + p$_0$.*pos*. Right graph shows the corresponding template tree, where each vertex saves the subset of template units that do not belong to its father

which depends on the order of template units in generation step. If $s_3 = s_1 + s_2$, then its prefix is s_1, otherwise its prefix is s_2. In this paper, we simply use the breadth-first tree of the graph for disambiguation, which is called **template tree**. The only direct ancestor T_1 of T_2 in the tree is called **father** of T_2, and T_2 is a **child** of T_1. The right part of Figure 2 shows the corresponding template tree, where each vertex saves the subset of template units that do not belong to its father.

2.3 Virtual vertex

Consider the template tree in the left part of Figure 3, red vertex and blue vertex are partially overlapped, their intersection is p$_0$.*word*, if string s from template T =p$_0$.*word* is absent in feature set, then both nodes can be neglected. For efficiently pruning candidate templates, each vertex in template tree is restricted to have exactly one template unit (except root). Another important reason for such restriction will be given in the next section.

To this end, virtual vertexes are created for multi-unit vertexes. For efficient pruning, the new virtual vertex should extract the most common template unit. A natural goal is to minimize the creation number. Here we use a simple greedy strategy, for the vertexes sharing a common father, the most frequent common unit is extracted as new vertex. Virtual vertexes are iteratively created in this way until all vertexes have one unit. The final template tree is shown in the right part of Figure 3, newly created virtual vertexes are shown in dashed circle.

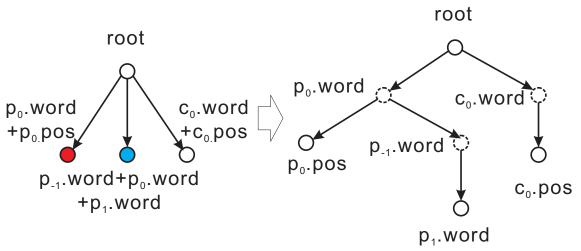

Figure 3: Templates that are partially overlapped: $T_{red} \cap T_{blue}$ =p$_0$.*word*, virtual vertexes shown in dashed circle are created to extract the common unit

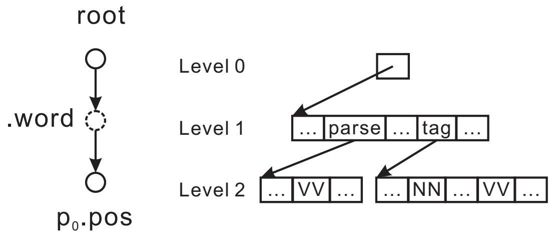

Figure 4: 2D Trie for single template, alphabets at level 1 and level 2 are the word set, POS tag set respectively

3 2D Trie

3.1 Single template case

Trie stores strings over a fixed alphabet, in our case, feature strings are stored over several alphabets, such as word list, POS tag list, etc. which are extracted from training corpus.

To illustrate 2D Trie clearly, we first consider a simple case, where only one template used. The template tree degenerates to a sequence, we could use a Trie like structure for feature indexing, the only difference from traditional Trie is that nodes at different levels could have different alphabets. One example is shown in Figure 4. There are 3 feature strings from template "p$_0$.*word* + p$_0$.*pos*": {*parse/VV, tag/VV, tag/VV*}. Alphabets at level 1 and level 2 are the word set, POS tag set respectively, which are determined by corresponding template vertexes.

As mentioned before, each vertex in template tree has exactly one template unit, therefore, at each level, we look up an index of a word or POS

Figure 5: Look up indexes of words and POS tags beforehand.

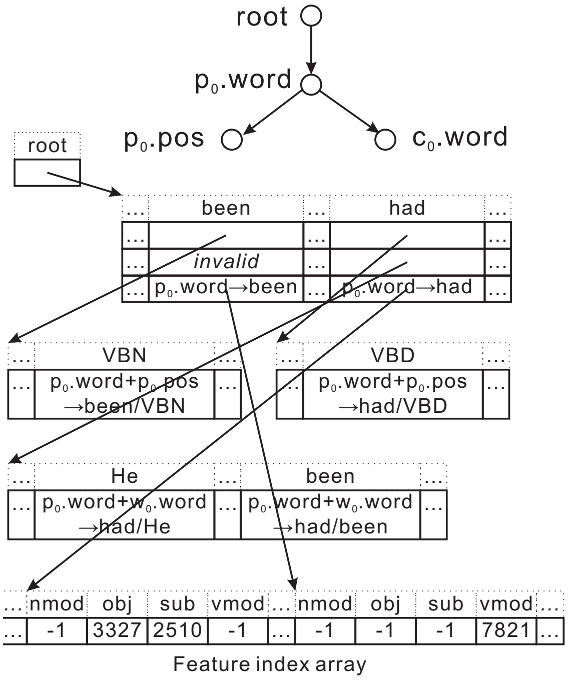

Figure 6: 2D trie for a general template tree. Dashed boxes are keys of columns, which are not stored in the structure

tag in sentence, not their combinations. Hence the number of alphabets is limited, and all the indexes could be searched beforehand for reuse, as shown in Figure 5, the token table is converted to a index table. For example, when generating features at position i of a sentence, template "r_0.*word* + r_1.*word*" requires index of $i+1^{th}$ word in the sentence, which could be reused for generation at position $i+1$.

3.2 General case

Generally, for vertex in template tree with K children, children of corresponding Trie node are arranged in a matrix of K rows and L columns, L is the size of corresponding alphabet. If the vertex is not virtual, i.e., it generates features, one more row is added at the bottom to store feature indexes. Figure 6 shows the 2D Trie for a general template tree.

3.3 Feature extraction

When extracting features for a pair of nodes in a sentence, template tree and 2D Trie are visited in breath first traversal order. Each time, an alphabet and a token index j from index table are selected according to current vertex. For example, POS tag set and the index of the POS tag of parent node are selected as alphabet and token index respectively for vertex "p_0.*pos*". Then children in the j^{th} column of the Trie node are visited, valid children and corresponding template vertexes are saved for further retrieval or generate feature indexes if the child is at the bottom and current Trie node is not virtual. Two queues are maintained to save the valid children and Trie nodes. Details of feature extraction algorithm are described in Algorithm 1.

3.4 Implementation

When feature set is very large, space complexity of 2D Trie is expensive. Therefore, we use Double Array Trie structure (Aoe, 1989) for implementation. Since children of 2D Trie node are arranged in a matrix, not an array, so each element of the base array has a list of bases, not one base in standard structure. For children that store features, corresponding bases are feature indexes. One example is shown in Figure 7. The root node has 3 bases that point to three rows of the child matrix of vertex "p_0.*word*" respectively. Number of bases in each element need not to be stored, since it can be obtained from template vertex in extraction procedure.

Building algorithm is similarly to Double Array Trie, when inserting a Trie node, each row of the child matrix is independently insert into base and check arrays using brute force strategy. The inser-

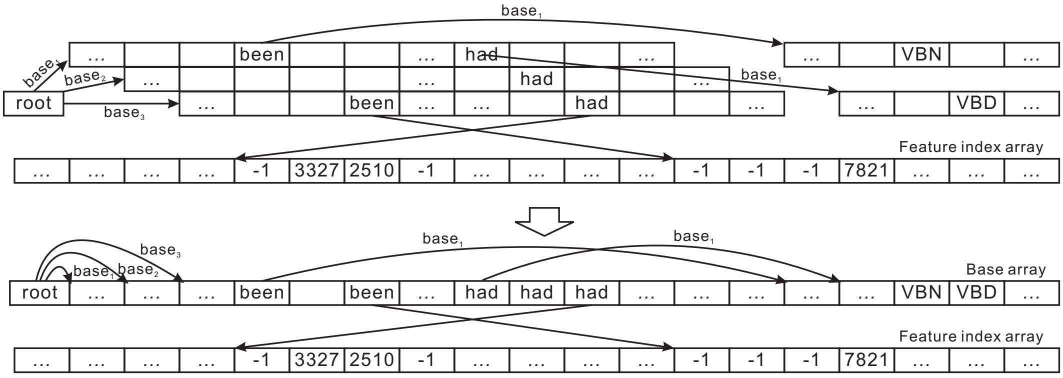

Figure 7: Build base array for 2D Trie in Figure 6. String in the box represents the key of the child. Blank boxes are the invalid children. The root node has 3 bases that point to three rows of the child matrix of vertex "p$_0$.*word*" respectively

```
Algorithm 1 Feature extraction using 2D Trie
Input: 2D Trie that stores features, template tree, template graph, a table storing token indexes, parent and child positions
Output: Feature index set $S$ of dependency from parent to child.
Create template vertex queue $Q_1$ and Trie node queue $Q_2$. Push roots of template tree and Trie into $Q_1, Q_2$ respectively. $S = \emptyset$
while $Q_1$ is not empty, do
    Pop a template vertex $T$ from $Q_1$ and a Trie node $N$ from $Q_2$. Get token index $j$ from index table according to $T$.
    for $i = 1$ to child number of $T$
        if child of $N$ at row $i$ column $j$ is valid,
            push it into $Q_2$ and push the $i^{th}$ child of $T$ into $Q_1$.
        else
            remove decedents of $i^{th}$ child of $T$ from template tree
        end if
    end for
    if $T$ is not virtual and the last child of $N$ in column $j$ is valid
            Enumerate dependency types, add valid feature indexes to $S$
    end if
end while
Return $S$.
```

tion repeats recursively until all features stored.

4 Complexity analysis

Let

- $|T|$ = number of templates
- $|t|$ = number of template units
- $|V|$ = number of vertexes in template tree, i.e, $|t|+$ number of virtual vertexes
- $|F|$ = number of features
- l = length of sentence
- $|f|$ = average length of feature strings

The procedure of 2D Trie for feature extraction consists of 2 steps: tokens in string table are mapped to their indexes, then Algorithm 1 is carried out for all node pairs of sentence. In the first step, we use double array Trie for efficient mapping. In fact, time spent is trivial compared with step 2 even by binary search. The main time spent of Algorithm 1 is the traversal of the whole template tree, in the worst case, no vertexes removed, so the time complexity of a sentence is $l^2|V|$, which is proportional to $|V|$. In other words, minimizing the number of virtual vertexes is important for efficiency.

For other indexing structures, feature generation is a primary step of retrieval. For each node

Structure	Generation	Retrieval
2D Trie	$l^2\|V\|$	
Hash / Trie	$l^2\|t\|$	$l^2\|f\|\|T\|$
Binary Search	$l^2\|t\|$	$l^2\|T\|\log\|F\|$

Table 3: Time complexity of different indexing structures.

pair of sentence, $|t|$ template units are processed, including concatenations of tokens and split symbols (split tokens in feature strings), boundary check (e.g, p$_{-1}$.*word* is out of boundary for beginning node of sentence). Thus the generation requires $l^2|t|$ processes. Notice that, time spent of each process varies on the length of tokens.

For feature string s with length $|s|$, if perfect hashing technique is adopted for index retrieval, it takes $|s|$ calculations to get hash value and a string comparison to check the string at the calculated position. So the time complexity is proportional to $|s|$, which is the same as Trie. Hence the total time for a sentence is $l^2|f||T|$. If binary search is used instead, $\log|F|$ string comparisons are required, complexity for a sentence is $l^2|T|\log|F|$.

Time complexity of these structures is summarized in Table 3.

5 Experiments

5.1 Experimental settings

We use Chinese Tree Bank 6.0 corpus for evaluation. The constituency structures are converted to dependency trees by Penn2Malt [2] toolkit and the standard training/development/test split is used. 257 sentences that failed in the conversion were removed, yielding 23316 sentences for training, 2060 sentences for development and 2660 sentences for testing respectively.

Since all the dependency trees are projective, a first order projective MST parser is naturally adopted. Online Passive Aggressive algorithm (Crammer et al., 2006) is used for fast training, 2 parameters, i.e, iteration number and C, are tuned on development data. The quality of the parser is measured by the labeled attachment score (LAS), i.e., the percentage of tokens with correct head and dependency type.

Group	IDs	#Temp.	#Vert.	#Feat.	LAS
1	1-2	72	91	$3.23M$	79.55%
2	1-3	128	155	$10.4M$	81.38%
3	1-4	240	275	$25.0M$	81.97%
4	1-5	332	367	$34.8M$	82.44%

Table 5: Parsing accuracy and number of templates, vertexes in template tree, features in decoding stage (zero weighted features are excluded) of each group.

We compare the proposed structure with Trie and binary search. We do not compare with perfect hashing, because it has the same complexity as Trie, and is often used for large data base retrieval, since it requires only one IO operation. For easy comparison, all feature indexing structures and the parser are implemented with C++. All experiments are carried out on a 64bit linux platform (CPU: Intel(R) Xeon(R) E5405, 2.00GHz, Memory: 16G Bytes). For each template set, we run the parser five times on test data and the averaged parsing time is reported.

5.2 Parsing speed comparison

To investigate the scalability of our method, rich templates are designed to generate large feature sets, as shown in Table 4. All templates are organized into 4 groups. Each row of Table 5 shows the details of a group, including parsing accuracy and number of templates, vertexes in template tree, and features in decoding stage (zero weighted features are excluded).

There is a rough trend that parsing accuracy increases as more templates used. Though such trend is not completely correct, the clear conclusion is that, abundant templates are necessary for accurate parsing.

Though algorithm described in section 2.3 for minimizing the number of virtual vertexes is heuristic, empirical results are satisfactory, number of newly created vertexes is only 10% as original templates. The reason is that complex templates are often extended from simple ones, their differences are often one or two template units.

Results of parsing time comparison are shown in Table 6. We can see that though time complexity of dynamic programming is cubic, parsing time of all systems is consistently dominated

	Conjoin templates in the row above with $\vert^l$			

Table 4: Templates used in Chinese dependency parsing.

by feature extraction. When efficient indexing structure adopted, i.e, Trie or Hash, time index retrieval is greatly reduced, about 4-5 times faster than binary search. However, general structures search features independently, their results could not guide feature generation. Hence, feature generation is still time consuming. The reason is that processing each template unit includes a series of steps, much slower than one integer comparison in Trie search.

On the other hand, 2D Trie greatly reduces the number of feature generations by pruning the template graph. In fact, no string concatenation occurs when using 2D Trie, since all tokens are converted to indexes beforehand. The improvement is significant, 2D Trie is about 5 times faster than Trie on the largest feature set, yielding 13.4 sentences per second parsing speed, about 4.3 times faster.

Space requirement of 2D Trie is about 2.1 times as binary search, and 1.7 times as Trie. One possible reason is that column number of 2D Trie (e.g. size of words) is much larger than standard double array Trie, which has only 256 children, i.e, range of a byte. Therefore, inserting a 2D Trie node is more strict, yielding sparser double arrays.

5.3 Comparison against state-of-the-art

Recent works on dependency parsing speedup mainly focus on inference, such as expected linear time non-projective dependency parsing (Nivre, 2009), integer linear programming (ILP) for higher order non-projective parsing (Martins et al., 2009). They achieve 0.632 seconds per sentence over several languages. On the other hand, Goldberg and Elhadad proposed splitSVM (Goldberg and Elhadad, 2008) for fast low-degree polynomial kernel classifiers, and applied it to transition based parsing (Nivre, 2003). They achieve 53 sentences per second parsing speed on English corpus, which is faster than our results, since transition based parsing is linear time, while for graph based method, complexity of feature extraction is quadratic. Xavier Lluís et al. (Lluís et al., 2009) achieve 8.07 seconds per sentence speed on CoNLL09 (Hajič et al., 2009) Chinese Tree Bank test data with a second order graphic model. Bernd Bohnet (Bohnet, 2009) also uses second order model, and achieves 610 minutes on CoNLL09 English data (2399 sentences, 15.3 second per sentence). Although direct comparison of parsing time is difficult due to the differences in data, models, hardware and implementations,

Group	Structure	Total	Generation	Retrieval	Other	Memory	sent/sec

these results demonstrate that our structure can actually result in a very fast implementation of a parser. Moreover, our work is orthogonal to others, and could be used for other learning tasks.

6 Conclusion

We proposed 2D Trie, a novel feature indexing structure for fast template based feature extraction. The key insight is that feature strings generated by a template are prefixes of the features from its extended templates, hence indexes of searched features can be reused for further extraction. We applied 2D Trie to dependency parsing task, experimental results on CTB corpus demonstrate the advantages of our technique, about 5 times faster than traditional Trie structure, yielding parsing speed 4.3 times faster, while using only 1.7 times as much memory.

Abstract

The problem addressed in this paper is to predict a user's numeric rating in a product review from the text of the review. Unigram and n-gram representations of text are common choices in opinion mining. However, unigrams cannot capture important expressions like "could have been better", which are essential for prediction models of ratings. N-grams of words, on the other hand, capture such phrases, but typically occur too sparsely in the training set and thus fail to yield robust predictors. This paper overcomes the limitations of these two models, by introducing a novel kind of bag-of-opinions representation, where an opinion, within a review, consists of three components: a root word, a set of modifier words from the same sentence, and one or more negation words. Each opinion is assigned a numeric score which is learned, by ridge regression, from a large, domain-independent corpus of reviews. For the actual test case of a domain-dependent review, the review's rating is predicted by aggregating the scores of all opinions in the review and combining it with a domain-dependent unigram model. The paper presents a constrained ridge regression algorithm for learning opinion scores. Experiments show that the bag-of-opinions method outperforms prior state-of-the-art techniques for review rating prediction.

1 Introduction

1.1 Motivation

Opinion mining and sentiment analysis has become a hot research area (Pang and Lee, 2008). There is ample work on analyzing the sentiments of online-review communities where users comment on products (movies, books, consumer electronics, etc.), implicitly expressing their *opinion polarities* (positive, negative, neutral), and also provide numeric *ratings* of products (Titov and McDonald, 2008b; Lerman et al., 2009; Hu and Liu, 2004; Titov and McDonald, 2008a; Pang and Lee, 2005; Popescu and Etzioni, 2005a). Although ratings are more informative than polarities, most prior work focused on classifying text fragments (phrases, sentences, entire reviews) by polarity. However, a product receiving mostly 5-star reviews exhibits better customer purchase behavior compared to a product with mostly 4-star reviews. In this paper we address the learning and prediction of numerical ratings from review texts, and we model this as a metric *regression* problem over an appropriately defined feature space.

Formally, the input is a set of rated documents (i.e., reviews), $\{\mathbf{x}_i, y_i\}_{i=1}^N$, where $\mathbf{x}_i$ is a sequence of word-level unigrams $(w_1, ..., w_l)$ and $y_i \in \mathbb{R}$ is a rating. The goal is to learn a function $f(\mathbf{x})$ that maps the word vector $\mathbf{x}$ into a numerical rating $\hat{y}$, which indicates both the polarity and strength of the opinions expressed in a document.

Numerical review rating prediction is harder than classifying by polarity. Consider the following example from Amazon book reviews:

The organization of the book is hard to follow and the chapter titles are not very helpful, so going back and trying to find information is quite *difficult*.

We note that there are many subjective words (*hard, helpful, difficult*) modified by opinion modifiers such as (*very, quite*) and negation words like (*not*). For rating prediction, considering opinion modifiers is crucial; *very helpful* is a much stronger sentiment than *helpful*. Negation words also need attention. As pointed out by Liu and Seneff (2009) we cannot simply reverse the polarity. For example, if we assign a higher positive score to *very helpful* than to *helpful*, simply reversing the sign of the scores would incorrectly suggest that *not helpful* is less negative than *not very helpful*.

The widely used unigram (bag-of-words) model (Pang and Lee, 2005; Snyder and Barzilay, 2007; Goldberg and Zhu, 2006; Ganu et al., 2009) cannot properly capture phrase patterns. Consider the following example: *not so helpful* vs. *not so bad*. In a unigram-based regression model each unigram gets a weight indicating its polarity and strength. High positive/negative weights are strongly positive/negative clues. It is reasonable to assign a positive weight to *helpful* and a negative weight to *bad*. The fundamental problem of unigrams arises when assigning a weight to *not*. If *not* had a strongly negative weight, the positive weight of *helpful* would be strongly reduced while the negative weight of *bad* would be amplified (by combining weights). This clearly fails to capture the true intentions of the opinion phrases. The same problem holds for *so*, which is an intensifier that should keep the same sign as the word it modifies. We refer to this limitation of the unigram model as **polarity incoherence**.

A promising way of overcoming this weakness is to include *n-grams*, generalizing the bag-of-words model into a bag-of-phrases model (Baccianella et al., 2009; Pang and Lee, 2008). However, regression models over the feature space of all n-grams (for either fixed maximal n or variable-length phrases) are computationally expensive in their training phase. Moreover and most importantly for our setting, including n-grams in the model results in a very high dimensional feature space: many features will then occur only very rarely in the training data. Therefore, it is difficult if not impossible to reliably learn n-gram weights from limited-size training sets. We refer to this problem as the **n-gram sparsity bottleneck**. In our experiments we investigate the effect of using bigrams and variable-length ngrams for improving review rating prediction.

1.2 Contribution

To overcome the above limitations of unigram and n-gram features, we have developed a novel kind of *bag-of-opinions* model, which exploits domain-independent corpora of opinions (e.g., all Amazon reviews), but is finally applied for learning predictors on domain-specific reviews (e.g., movies as rated in IMDB or Rottentomatoes). A document is represented as a bag of opinions each of which has three components: a root word, a set of modifier words and one or more negation words. In the phrase *not very helpful*, the opinion root is *helpful*, one (of potentially many) opinion modifier(s) is *very*, and a negation word is *not*. We enforce polarity coherence by the design of a learnable function that assigns a score to an opinion.

Our approach generalizes the cumulative linear offset model (CLO) presented in (Liu and Seneff, 2009). The CLO model makes several restrictive assumptions, most notably, that all opinion scores within one document are the same as the overall document rating. This assumption does not hold in practice, not even in reviews with extremely positive/negative ratings. For example, in a 5-star Amazon review the phrases *most impressive book* and *it helps explain* should receive different scores. Otherwise, the later transfer step to different domains would yield poor predictions. Due to this restriction, CLO works well on particular types of reviews that have pro/con entries listing characteristic major opinions about the object under review. For settings with individual reviews whose texts do not exhibit any specific structure, the CLO model faces its limitations.

In our bag-of-opinions method, we address the learning of opinion scores as a constrained ridge regression problem. We consider the opinion scores in a given review to be drawn from an unknown probability distribution (so they do not have to be the same within a document). We estimate the review rating based on a set of statistics (e.g., expectation, variance, etc.) derived from the scores of opinions in a document. Thus, our method has a sound statistical foundation and can be applied to arbitrary reviews with mixed opinion polarities and strengths. We avoid the n-gram sparsity problem by the limited-size structured feature space of *(root,modifiers,negators)* opinions.

We treat domain-independent and domain-dependent opinions differently in our system. In the first step we learn a bag-of-opinions model on a large dataset of online reviews to obtain scores for domain-independent opinions. Since the polarity of opinions is not bound to a topic, one can learn opinion scores from a pooled corpus of reviews for various categories, e.g., movies, books, etc., and then use these scored opinions for predicting the ratings of reviews belonging to a particular category. In order to also capture domain-dependent information (possibly complementary to the opinion lexicon used for learning domain-independent opinions), we combine the bag-of-opinions model with an unigram model trained on the domain-dependent corpus. Since domain-dependent training is typically limited, we model it using unigram models rather than bag-of-opinions. By combining the two models, even if an opinion does not occur in the domain-dependent training set but it occurs in a test review, we can still accurately predict the review rating based on the globally learned opinion score. In some sense our combined learning scheme is similar to smoothing in standard learning techniques, where the estimate based on a limited training set is smoothed using a large background corpus (Zhai and Lafferty, 2004).

In summary, the contributions of this paper are the following:

1. We introduce the bag-of-opinions model, for capturing the influence of n-grams, but in a structured way with root words, modifiers, and negators, to avoid the explosion of the feature space caused by explicit n-gram models.

2. We develop a constrained ridge regression method for learning scores of opinions from domain-independent corpora of rated reviews.

3. For transferring the regression model to newly given domain-dependent applications, we derive a set of statistics over opinion scores in documents and use these as features, together with standard unigrams, for predicting the rating of a review.

4. Our experiments with Amazon reviews from different categories (books, movies, music) show that the bag-of-opinions method outperforms prior state-of-the-art techniques.

2 Bag-of-Opinions Model

In this section we first introduce the bag-of-opinions model, followed by the method for learning (domain-independent) model parameters. Then we show how we annotate opinions and how we adapt the model to domain-dependent data.

2.1 Model Representation

We model each document as a bag-of-opinions $\{op_k\}_{k=1}^{K}$, where the number of opinions K varies among documents. Each opinion op_k consists of an opinion root w_r, $r \in S_R$, a set of opinion modifiers $\{w_m\}_{m=1}^{M}$, $m \in S_M$ and a set of negation words $\{w_z\}_{z=1}^{Z}$, $z \in S_Z$, where the sets S_R, S_M, S_Z are component index sets of opinion roots, opinion modifiers and negation words respectively. The union of these sets forms a global component index set $S \in \mathbb{N}^d$, where d is the dimension of the index space. The opinion root determines the prior polarity of the opinion. Modifiers intensify or weaken the strength of the prior polarity. Negation words strongly reduce or reverse the prior polarity. For each opinion, the set of negation words consists of at most a negation valence shifter like *not* (Kennedy and Inkpen, 2006) and its intensifiers like capitalization of the valence shifter. Each opinion component is associated with a score. We assemble the scores of opinion elements into an opinion-score by using a score function. For example, in the opinion *not very helpful*, the opinion root *helpful* determines the prior polarity positive say with a score 0.9, the modifier *very* intensifies the polarity say with a score 0.5. The prior polarity is further strongly reduced by the negation word *not* with e.g., a score -1.2. Then we sum up the scores to get a score of 0.2 for the opinion *not very helpful*.

Formally, we define the function $score(op)$ as a linear function of opinion components, which takes the form

$$\begin{aligned} score(op) &= sign(r)\beta_r x_r \\ &+ \sum_{m=1}^{M} sign(r)\beta_m x_m \\ &+ \sum_{z=1}^{Z} sign(r)\beta_z x_z \end{aligned} \quad (1)$$

where $\{x_z, x_m, x_r\}$ are binary variables denoting the presence or absence of negation words, modifiers and opinion root. $\{\beta_z, \beta_m, \beta_r\}$ are weights of each opinion elements. $sign(r) : w_r \rightarrow \{-1, 1\}$ is the opinion polarity function of the opinion root w_r. It assigns a value 1/-1 if an opinion root is positive/negative. Due to the semantics of opinion elements, we have constraints that $\beta_r \geq 0$ and $\beta_z \leq 0$. The sign of β_m is determined in the learning phase, since we have no prior knowledge whether it intensifies or weakens the prior polarity.

Since a document is modeled as a bag-of-opinions, we can simply consider the expectation of opinion scores as the document rating. If we assume the scores are uniformly distributed, the prediction function is then $f(\mathbf{x}) = \frac{1}{K}\sum_{k=1}^{K} score(op_k)$ which assigns the average of opinion scores to the document **x**.

2.2 Learning Regression Parameters

We assume that we can identify the opinion roots and negation words from a subjectivity lexicon. In this work we use MPQA (Wilson et al., 2005). In addition, the lexicon provides the prior polarity of the opinion roots. In the training phase, we are given a set of documents with ratings $\{\mathbf{x}_i, y_i\}_{i=1}^{N}$, and our goal is to find an optimal function f^* whose predictions $\{\hat{y}_i\}_{i=1}^{N}$ are as close as possibile to the original ratings $\{y_i\}_{i=1}^{N}$. Formally, we aim to minimize the following loss function:

$$L = \frac{1}{2N}\sum_{i=1}^{N}(f(\mathbf{x}_i) - y_i)^2 \quad (2)$$

where $f(\mathbf{x}_i)$ is modeled as the average score of opinions in review $\mathbf{x}_i$.

First, we rewrite $score(op)$ as the dot product $\langle \boldsymbol{\beta}, \mathbf{p}\rangle$ between a weight vector $\boldsymbol{\beta} = [\boldsymbol{\beta}_z, \boldsymbol{\beta}_m, \beta_r]$ and a feature vector $\mathbf{p} = [sign(r)\mathbf{x}_z, sign(r)\mathbf{x}_m, sign(r)x_r]$. In order to normalize the vectors, we rewrite the weight and feature vectors in the d dimensional vector space of all root words, modifiers and negation words. Then $\boldsymbol{\beta} = [..,\boldsymbol{\beta}_z, 0, .., \boldsymbol{\beta}_m, 0, .., \beta_r, 0..] \in R^d$ and $\mathbf{p} = [sign(r)\mathbf{x}_z, 0, .., sign(r)\mathbf{x}_m, 0, .., sign(r)x_r, ...] \in R^d$. The function $f(\mathbf{x_i})$ can then be written as the dot product $\langle \boldsymbol{\beta}, \mathbf{v_i}\rangle$, where $\mathbf{v_i} = \frac{1}{K_i}\sum_{k=1}^{K_i}\mathbf{p}_k$, with K_i the number of opinions in review $\mathbf{x_i}$. By using this feature representation, the learning problem is equivalent to:

$$\min_{\beta} \; L(\boldsymbol{\beta}) = \frac{1}{2N}\sum_{i=1}^{N}(\langle \boldsymbol{\beta}, \mathbf{v}_i\rangle + \beta_0 - y_i)^2$$

$s.t.$

$$\begin{aligned} &\beta_z \leq 0 \quad z \in S_Z \\ &\beta_r \geq 0 \quad r \in S_R \end{aligned} \quad (3)$$

where $\boldsymbol{\beta} \in R^d$, $\boldsymbol{\beta} = [\boldsymbol{\beta}_z, \boldsymbol{\beta}_m, \boldsymbol{\beta}_r]$. β_0 is the intercept of the regression function, which is estimated as the mean of the ratings in the training set. We define a new variable $\tilde{y}_i = y_i - \beta_0$.

In order to avoid overfitting, we add an $l2$ norm regularizer to the loss function with the parameter $\lambda > 0$.

$$LR(\boldsymbol{\beta}) = \frac{1}{2N}\sum_{i=1}^{N}(\langle \boldsymbol{\beta}, \mathbf{v}_i\rangle - \tilde{y}_i)^2 + \frac{\lambda}{2} \parallel \boldsymbol{\beta} \parallel_2^2$$

$s.t.$

$$\begin{aligned} &\beta_z \leq 0 \quad z \in S_Z \\ &\beta_r \geq 0 \quad r \in S_R \end{aligned} \quad (4)$$

We solve the above optimization problem by Algorithm 1 using coordinate descent. The procedure starts with $\boldsymbol{\beta}^0 = 0$, $\boldsymbol{\beta}^0 \in R^d$. Then it updates iteratively every coordinate of the vector $\boldsymbol{\beta}$ until convergence. Algorithm 1 updates every coordinate $\beta_j, j \in \{1, 2, ..., d\}$ of $\boldsymbol{\beta}$ by solving the following one-variable sub-problem:

$$min_{l_j \leq \beta_j \leq c_j} LR(\beta_1, ..., \beta_j, ..., \beta_d)$$

where l_j and c_j denote the lower and upper bounds of β_j. If $j \in S_Z$, $l_j = -\infty$ and $c_j = 0$. If $j \in S_R$, $l_j = 0$ and $c_j = \infty$. Otherwise both bounds are infinity.

According to (Luo and Tseng, 1992), the solution of this one-variable sub-problem is

$$\hat{\beta}_j = max\{l_j, min\{c_j, g_j\}\}$$

where

$$g_j = \frac{\frac{1}{N}\sum_{i=1}^{N} v_{ij}(\tilde{y}_i - \sum_{l \neq j} \beta_l v_l)}{\frac{1}{N}\sum_{i=1}^{N} v_{ij}^2 + \lambda}$$

Here g_j is the close form solution of standard ridge regression at coordinate j (for details see (Friedman et al., 2008)). We prove the convergence of Algorithm 1, by the following theorem using techniques in (Luo and Tseng, 1992).

Theorem 1 *A sequence of $\boldsymbol{\beta}$ generated by Algorithm 1 globally converges to an optimal solution $\beta^* \in \chi^*$ of problem (4), where χ^* is the set of optimal solutions.*

Proof: *Luo and Tseng (1992) show that coordinate descent for constrained quadratic functions in the following form converges to one of its global optimal solutions.*

$$\begin{array}{ll} min_{\boldsymbol{\beta}} & h(\boldsymbol{\beta}) = \langle \boldsymbol{\beta}, \mathbf{Q}\boldsymbol{\beta} \rangle / 2 + \langle \mathbf{q}, \boldsymbol{\beta} \rangle \\ s.t. & \mathbf{E}^T \boldsymbol{\beta} \geq \mathbf{b} \end{array}$$

where $\mathbf{Q}$ is a $d \times d$ symmetric positive-definite matrix, $\mathbf{E}$ is a $d \times d$ matrix having no zero column, $\mathbf{q}$ is a d-vector and $\mathbf{b}$ is a d-vector.

We rewrite LR in matrix form as

$$\begin{aligned} & \frac{1}{2N}(\tilde{\mathbf{y}} - \mathbf{V}\boldsymbol{\beta})^T(\tilde{\mathbf{y}} - \mathbf{V}\boldsymbol{\beta}) + \frac{\lambda}{2}\boldsymbol{\beta}^T\boldsymbol{\beta} \\ = & \frac{1}{2N}(\mathbf{V}\boldsymbol{\beta})^T(\mathbf{V}\boldsymbol{\beta}) + \frac{\lambda}{2}\boldsymbol{\beta}^T\boldsymbol{\beta} - \frac{1}{2N}((\mathbf{V}\boldsymbol{\beta})^T\tilde{\mathbf{y}} \\ & -\frac{1}{2N}\tilde{\mathbf{y}}^T(\mathbf{V}\boldsymbol{\beta})) + \frac{1}{2N}\tilde{\mathbf{y}}^T\tilde{\mathbf{y}} \\ = & \langle \boldsymbol{\beta}, \mathbf{Q}\boldsymbol{\beta} \rangle / 2 + \langle \mathbf{q}, \boldsymbol{\beta} \rangle + constant \end{aligned}$$

where

$$\mathbf{Q} = \mathbf{B}^T\mathbf{B}, \mathbf{B} = \begin{bmatrix} \sqrt{\frac{1}{N}}\mathbf{V} \\ \sqrt{\lambda}\mathbf{I}^{d \times d} \end{bmatrix}, \mathbf{q} = \frac{-1}{N}(\mathbf{V}^T\tilde{\mathbf{y}})$$

where $\mathbf{I}^{d \times d}$ is the identity matrix. Because $\lambda > 0$, all columns of $\mathbf{B}$ are linearly independent. As $\mathbf{Q} = \mathbf{B}^T\mathbf{B}$ and symmetric, $\mathbf{Q}$ is positive definite.

We define $\mathbf{E}$ as a $d \times d$ diagonal matrix with all entries on the main diagonal equal to 1 except $e_{ii} = -1, i \in S_Z$ and $\mathbf{b}$ is a d-vector with all entries equal to $-\infty$ except $b_i = 0$, for $i \in S_Z$ or $i \in S_R$.

Because the almost cyclic rule is applied to generate the sequence $\{\boldsymbol{\beta}^t\}$, the algorithm converges to a solution $\boldsymbol{\beta}^* \in \chi^*$.

Algorithm 1 Constrained Ridge Regression

```
Input: $\lambda$ and $\{\mathbf{v}_n, \tilde{y}_n\}_{n=1}^N$
Output: optimal $\boldsymbol{\beta}$
repeat
    for $j = 1, ..., d$ do
        $g_j = \frac{\frac{1}{N}\sum_{i=1}^{N} v_{ij}(\tilde{y}_i - \sum_{l \neq j} \beta_l v_l)}{\frac{1}{N}\sum_{i=1}^{N} v_{ij}^2 + \lambda}$
        $\hat{\beta}_j = \begin{cases} 0, & if\, j \in S_R\, and\, g_j < 0 \\ 0, & if\, j \in S_Z\, and\, g_j > 0 \\ g_j, & else \end{cases}$
    end for
until Convergence condition is satisfied
```

2.3 Annotating Opinions

The MPQA lexicon contains separate lexicons for subjectivity clues, intensifiers and valence shifters (Wilson et al., 2005), which are used for identifying opinion roots, modifiers and negation words. Opinion roots are identified as the positive and negative subjectivity clues in the subjectivity lexicon. In the same manner, intensifiers and valence shifters of the type {negation, shiftneg} are mapped to modifiers and negation words. Other modifier candidates are adverbs, conjunctions and modal verbs around opinion roots. We consider non-words modifiers as well, e.g., punctuations, capitalization and repetition of opinion roots. If the opinion root is a noun, adjectives are also included into modifier sets.

The automatic opinion annotation starts with locating the continous subjectivity clue sequence. Once we find such a sequence and at least one of the subjectivity clue is positive or negative, we search to the left up to 4 words for negation words and modifier candidates, and stop if encountering another opinion root. Similarly, we search to the right up to 3 unigrams for modifiers and stop if we find negation words or any other opinion roots. The prior polarity of the subjectivity sequence is determined by the polarity of the last subjectivity clue with either positive or negative polarity in the sequence. The other subjectivity clues in the same sequence are treated as modifiers.

2.4 Adaptation to Domain-Dependent Data

The adaptation of the learned (domain-independent) opinion scores to the target domain and the integration of domain-dependent unigrams is done in a second ridge-regression task. Note that this is a simpler problem than typical domain-adaptation, since we already know from the sentiment lexicon which are the domain-independent features. Additionally, its relatively easy to obtain a large mixed-domain corpus for reliable estimation of domain-independent opinion scores (e.g., use all Amazon product reviews). Furthermore, we need a domain-adaptation step since domain-dependent and domain-independent data have generally different rating distributions. The differences are mainly reflected in the intercept of the regression function (estimated as the mean of the ratings). This means that we need to scale the positive/negative mean of the opinion scores differently before using it for prediction on domain-dependent reviews. Moreover, other statistics further characterize the opinion score distribution. We use the variance of opinion scores to capture the reliability of the mean, multiplied by the negative sign of the mean to show how much it strengthens/weakens the estimation of the mean. The mean score of the dominant polarity (*major exp*) is also used to reduce the influence of outliers. Because positive and negative means should be scaled differently, we represent positive and negative values of the mean and *major exp* as 4 different features. Together with variance, they are the 5 statistics of the opinion score distribution. The second learning step on opinion score statistics and domain-dependent unigrams as features, re-weights the importance of domain-independent and domain-dependent information according to the target domain bias.

3 Experimental Setup

We performed experiments on three target domains of Amazon reviews: books, movies (DVDs), and music (CDs). For each domain, we use ca. 8000 Amazon reviews for evaluation; an additional set of ca. 4000 reviews are withheld for parameter tuning (regularization parameter, etc.). For learning weights for domain-independent opinions, we use a mixed-domain corpus of ca. 350,000 reviews from Amazon (electronics, books, dvds, etc.); this data is disjoint from the test sets and contains no reviews from the music domain. In order to learn unbiased scores, we select about the same number of positive and negative reviews (where reviews with more/less than 3 stars are regarded as positive/negative). The regularization parameters used for this corpus are tuned on withheld data with ca. 6000 thematically mixed reviews.[1].

We compare our method, subsequently referred to as *CRR-BoO* (Constrained Ridge Regression for Bag-of-Opinions), to a number of alternative state-of-the-art methods. These competitors are varied along two dimensions: 1) feature space, and 2) training set. Along the first dimension, we consider a) unigrams coined *uni*, b) unigrams and bigrams together, coined *uni+bi*, c) variable-length n-grams coined *n-gram*, d) the opinion model by (Liu and Seneff, 2009) coined *CLO* (cumulative linear offset model). As learning procedure, we use ridge regression for a), b), and d), and bounded cyclic regression, coined *BCR*, for c). Along the second - orthogonal - dimension, we consider 3 different training sets: i) domain-dependent training set coined *DD*, ii) the large mixed-domain training set coined *MD*, iii) domain-dependent training set and the large mixed-domain training set coined *DD+MD*. For the *DD+MD* training set, we apply our two stage approach for *CRR-BoO* and *CLO*, i.e., we use the mixed-domain corpus for learning the opinion scores in the first stage, and integrate unigrams from *DD* in a second domain-adaptation stage. We train the remaining feature models directly on the combination of the whole mixed-domain cor-

Table 1: Mean squared error for rating prediction methods on Amazon reviews.

pus and the training part of *DD*.

The CLO model is adapted as follows. Since bags-of-opinions generalize CLO, adjectives and adverbs are mapped to opinion roots and modifiers, respectively; negation words are treated the same as CLO. Subsequently we use our regression technique. As Amazon reviews do not contain pro and con entries, we learn from the entire review.

For BCR, we adapt the variable-length n-grams method of (Ifrim et al., 2008) to elastic-net-regression (Friedman et al., 2008) in order to obtain a fast regularized regression algorithm for variable-length n-grams. We search for significant n-grams by incremental expansion in backward direction (e.g., expand *bad* to *not bad*). BCR pursues a dense solution for unigrams and a sparse solution for n-grams. Further details on the BCR learning algorithm will be found on a subsequent technical report.

As for the regression techniques, we show only results with ridge regression (for all feature and training options except BCR). It outperformed ϵ-*support vector regression* (SVR) of libsvm (Chang and Lin, 2001), lasso (Tibshirani, 1996), and elastic net (Zou and Hastie, 2005) in our experiments.

4 Results and Discussion

Table 1 shows the mean square error (MSE) from each of the three domain-specific test sets. The error is defined as $MSE = \frac{1}{N}\sum_{i=1}^{N}(f(\mathbf{x}_i) - y_i)^2$. The right most two columns of the table show results for the full-fledge two-stage learning for our method and CLO, with domain-dependent weight learning and the domain adaptation step. The other models are trained directly on the given training sets. For the DD and DD+MD training sets, we use five-fold cross-validation on the domain-specific sets. For the MD training set, we take the domain-specific test sets as hold-out data for evaluation.

Table 1 clearly shows that our *CRR-BoO* method outperforms all alternative methods by a significant margin. Most noteworthy is the music domain, which is not covered by the mixed-domain corpus. As expected, unigrams only perform poorly, and adding bigrams leads only to marginal improvements. BCR pursues a dense solution for unigrams and a sparse solution for variable-length n-grams, but due to the sparsity of occurence of long n-grams, it filters out many interesting-but-infrequent ngrams and therefore performs worse than the dense solution of the *uni+bi* model. The CLO method of (Liu and Seneff, 2009) shows unexpectedly poor performance. Its main limitation is the assumption that opinion scores are identical within one document. This does not hold in documents with mixed opinion polarities. It also results in conflicts for opinion components that occur in both positive and negative documents. In contrast, *CRR-BoO* naturally captures the mixture of opinions as a bag of positive/negative scores. We only require that the mean of opinion scores equals the overall document rating.

The right most column of Table 1 shows that our method can be improved by learning opinion scores from the large mixed-domain corpus. How-

opinion	score
good	0.18
recommend	1.64
most difficult	-1.66
but it gets very good!	2.37
would highly recommend	2.73
would not recommend	-1.93

Table 2: Example opinions learned from the Amazon mixed-domain corpus.

ever, the high error rates of the models learned directly on the MD corpus show that direct training on the mixed-domain data can introduce a significant amount of noise into the prediction models. Although the noise can be reduced by learning from MD and DD together, the performance is still worse than when learning directly from the domain-dependent corpora. Additionally, when the domain is not covered by the mixed-domain corpus (e.g., music), the results are even worse. Thus, the two stages of our method (learning domain-independent opinion scores plus domain-adaptation) are decisive for a good performance, and the sentiment-lexicon-based BoO model leads to robust learning of domain-independent opinion scores.

Another useful property of BoO is its high interpretability. Table 2 shows example opinion scores learned from the mixed-domain corpus. We observe that the scores corelate well with our intuitive interpretation of opinions.

Our *CRR-BoO* method is highly scalable. Excluding the preprocessing steps (same for all methods), the learning of opinion component weights from the ca. 350,000 domain-independent reviews takes only 11 seconds.

5 Related Work

Rating prediction is modeled as an ordinal regression problem in (Pang and Lee, 2005; Goldberg and Zhu, 2006; Snyder and Barzilay, 2007). They simply use the bag-of-words model with regression algorithms, but as seen previously this cannot capture the expressive power of phrases. The resulting models are not highly interpretable. Baccianella et al. (2009) restrict the n-grams to the ones having certain POS patterns. However, the long n-grams matching the patterns still suffer from sparsity. The same seems to hold for sparse n-gram models (BCR in this paper) in the spirit of Ifrim et al. (2008). Although sparse n-gram models can explore arbitrarily large n-gram feature spaces, they can be of little help if the n-grams of interests occur sparsely in the datasets.

Since our approach can be regarded as learning a domain-independent sentiment lexicon, it is related to the area of automatically building domain-independent sentiment lexicons (Esuli and Sebastiani, 2006; Godbole et al., 2007; Kim and Hovy, 2004). However, this prior work focused mainly on the opinion polarity of opinion words, neglecting the opinion strength. Recently, the lexicon based approaches were extended to learn domain-dependent lexicons (Kanayama and Nasukawa, 2006; Qiu et al., 2009), but these approaches also neglect the aspect of opinion strength. Our method requires only the prior polarity of opinion roots and can thus be used on top of those methods for learning the scores of domain-dependent opinion components. The methods proposed in (Hu and Liu, 2004; Popescu and Etzioni, 2005b) can also be categorized into the lexicon based framework because their procedure starts with a set of seed words whose polarities are propagated to other opinion bearing words.

6 Conclusion and Future Work

In this paper we show that the bag-of-opinions (BoO) representation is better suited for capturing the expressive power of n-grams while at the same time overcoming their sparsity bottleneck. Although in this paper we use the BoO representation to model domain-independent opinions, we believe the same framework can be extended to domain-dependent opinions and other NLP applications which can benefit from modelling n-grams (given that the n-grams are decomposable in some way). Moreover, the learned model can be regarded as a domain-independent opinion lexicon with each entry in the lexicon having an associated score indicating its polarity and strength. This in turn has potential applications in sentiment summarization, opinionated information retrieval and opinion extraction.

Abstract

Emotion words have been well used as the most obvious choice as feature in the task of textual emotion recognition and automatic emotion lexicon construction. In this work, we explore features for recognizing word emotion. Based on Ren-CECps (an annotated emotion corpus) and MaxEnt (Maximum entropy) model, several contextual features and their combination have been experimented. Then PLSA (probabilistic latent semantic analysis) is used to get semantic feature by clustering words and sentences. The experimental results demonstrate the effectiveness of using semantic feature for word emotion recognition. After that, "word emotion components" is proposed to describe the combined basic emotions in a word. A significant performance improvement over contextual and semantic features was observed after adding word emotion components as feature.

1 Introduction

Textual emotion analysis is becoming increasingly important due to augmented communication via computer mediated communication (CMC). A possible application of textual emotion recognition is online chat system. An emotion feedback system can recognize users' emotion and give appropriate responses. Another application example is weblog emotion recognition and prediction. Blogspace consists of millions of users who maintain their online diaries, containing frequently-updated views and personal remarks about a range of issues. An emotion recognition and prediction system can understand the public's reaction to some social issues and predict emotion changes. It would be helpful for solving some psychological problems or giving early warnings, such as suicide or terrorism.

Textual emotion analysis also can improve the accuracy of other nonverbal modalities like speech or facial emotion recognition, and to improve human computer interaction systems. However, automatic recognition of emotion meaning from texts presents a great challenge. One of the reasons is the manifoldness of expressed emotions in words.

Emotion words have been well used as the most obvious choice as feature in the task of textual emotion recognition and automatic emotion lexicon construction (Virginia and Pablo, 2006; Tokuhisa et al., 2008, etc.). And there are many lexical resources developed for these tasks, such as GI (Stone et al., 1966), WordNet-Affect (Strapparava and Valitutti, 2004), NTU Sentiment Dictionary (Ku et al., 2006), Hownet (Dong and Dong, 2003), SentiWordnet (Esuli and Sebastiani, 2006). In these sentimental or affective lexicons, the words usually bear direct emotions or opinions, such as happy or sad, good or bad. Although they play a role in some applications, several problems of emotion expression in words have been ignored.

Firstly, there are a lot of sentences can evoke emotions without direct emotion words. For example,

(1) 春天在孩子们的眼里、在孩子们的心里。(Spring is in children's eyes, and in their hearts.)

In sentence (1), we may feel joy, love or expect delivered by the writer. But there are no direct emotion words can be found from lexicons. As Ortony (1987) indicates, besides words directly referring to emotion states (e.g., "fear", "cheerful") and for which an appropriate lexicon would help, there are words that act only as an indirect reference to emotions depending on the context. Strapparava et al. (2006) also address this issue. The authors believed that all words can potentially convey affective meaning, and they distinguished between words directly referring to emotion states (direct affective words) and those having only an indirect reference that depends on the context (indirect affective words).

The second problem is emotion ambiguity of words. The same word in different contexts may reflect different emotions. For example,

(2) 这是目前我**唯一**能做的。(This is currently the only thing I can do.)

(3) 他是我的**唯一**。(He is my only one.)

In sentence (2), the word "唯一 (only)" may express the emotion of anxiety or expect; but in sentence (3), the word "唯一 (only)" may express the emotion of love or expect. The emotion categories can not be determined without their certain contexts especially for the words with emotion ambiguity.

In addition, some words can express multiple emotions, such as "悲喜交加 (mingled feelings of joy and sorrow)". Statistics on an annotated emotion corpus (Ren-CECps [1], Chinese emotion corpus developed by Ren-lab) showed that 84.9% of all emotion words have one emotion, 15.1% have more than one emotions (Quan and Ren, 2010). Multi-emotion words are indispensable for expressing complex feelings in use of language.

In this work, we explore features for recognizing word emotion in sentences. Based on Ren-CECps and MaxEnt model, several contextual features and their combination have been experimented. Then PLSA (probabilistic latent semantic analysis) is used to get semantic feature by clustering word and sentence. The experimental results demonstrate the effectiveness of using semantic feature for word emotion recognition. After that, the notion of "word emotion components" is proposed to describe the combined basic emotions in a word. A significant performance improvement over only using contextual and semantic features was observed after adding word emotion components as feature and output in MaxEnt based model.

This paper is organized as follows. In section 2, based on Ren-CECps and MaxEnt, an exploration of using contextual feature for Chinese word emotion recognition is described. In section 3, using PLSA technique, the performance of adding semantic feature is presented. In section 4, the notion of "word emotion components" is proposed and the performance of using encoding feature is presented. In section 5, the discussions are described. Section 6 is conclusions.

2 Chinese Word Emotion Recognition

2.1 Related Works

There are many researches concerning computing semantics of words, while the researches on computing emotions of words are relatively less. Computing word emotions is a challenge task because the inherent of emotion is ambiguous and natural language is very rich in emotion terminology. Using the textual emotion information, several methods have been explored for computing lexical emotions. Wilson et al. (2009) proposed a two-step approach to classify word polarity out of context firstly, and then to classify word polarity in context with a wide variety of features. Strapparava et al. (2007) implemented a variation of Latent Semantic Analysis (LSA) to measure the similarities between direct affective terms and generic terms. Lee and Narayanan (2005) proposed a method of computing mutual information between a specific word and emotion category to measure how much information a word provides about a given emotion category (emotion salience). Based on structural similarity, Bhowmick (2008) computed the structural similarity of words in WordNet to distinguish the emotion words from the non-emotion words. Kazemzadeh (2008) measured similarity between word and emotion category based on interval type-2 fuzzy logic method. Takamura (2005) used a spin model to extract emotion polarity of words.

Different from the above researches, in this work, we explore which features are effective for word emotion recognition. The features include contextual feature, semantic feature and encoding feature.

[1] http://a1-www.is.tokushima-u.ac.jp/member /ren/Ren-CECps1.0/Ren-CECps1.0.html

2.2 Ren-CECps and MaxEnt based Chinese Word Emotion Recognition

Ren-CECps is constructed based on a relative fine-grained annotation scheme, annotating emotion in text at three levels: document, paragraph, and sentence. The all dataset consisted of 1,487 blog articles published at sina blog, sciencenet blog, etc. There are 11,255 paragraphs, 35,096 sentences, and 878,164 Chinese words contained in this corpus (more details can be found in (Quan and Ren, 2010)).

In the emotion word annotation scheme of Ren-CECps, direct emotion words and indirect emotion words in a sentence are all annotated. For example, in sentence (1) “春天 (spring)” and “孩子们 (the children)” are labeled. An emotion keyword or phrase is represented as a vector to record its intensities of the eight basic emotion classes (expect, joy, love, surprise, anxiety, sorrow, angry and hate). For instance, the emotion vector for the word “春天 (spring)” $\overrightarrow{w} = (0.1, 0.3, 0.3, 0.0, 0.0, 0.0, 0.0, 0.0)$ indicates the emotions of weak expect, joy and love. In this work, we focus on if a word contains some emotion(s) in a certain context. The analysis on emotion intensity of emotion words is included in our future work.

As word emotion is subjective entity, a word in a certain context may evoke multiple emotions in different people’s mind. A part of documents in Ren-CECps have been annotated by three annotators independently to measure agreement on the annotation of this corpus, which include 26 documents with a total of 805 sentences, 19,738 words. This part of corpus is used as testing corpus to evaluate the experimental results. (Section 5.1 shows the analysis on the annotation agreement on word emotion.)

MaxEnt modeling provides a framework for integrating information from many heterogeneous information sources for classification (Manning, 1999). MaxEnt principle is a well used technique provides probability of belongingness of a token to a class. In word emotion recognition, the MaxEnt estimation process produces a model in which each feature f_i is assigned a weight α_i. The deterministic model produces conditional probability (Berger, 1996), see equation (1) and (2). In experiments, we have used a Java based open-nlp MaxEnt toolkit [2].

$$p(e|context) = \frac{1}{Z(context)} \prod_i \alpha_i^{f_i(context,e)} \quad (1)$$

$$Z(context) = \sum \prod_i \alpha_i^{f_i(context,e)} \quad (2)$$

2.3 Contextual Features

The contextual features used in MaxEnt for Chinese word emotion recognition are described as follows:

Word Feature (WF): Word itself to be recognized.

N-words Feature (NF): To know the relationship between word emotion and its context, the surrounding words of length n for the word (w_i) to be recognized are used as feature: $(w_{i-n}...w_i...w_{i+n})$.

POS Feature (POSF): The part of speech of the current word and surrounding words are used as feature. We have used a Chinese segmentation and POS tagger (Ren-CMAS) developed by Ren-lab, which has an accuracy about 97%. The set of POS includes 35 classes.

Pre-N-words Emotion Feature (PNEF): The emotions of the current word may be influenced by the emotions of its previous words. So the emotions of previous n words are used as feature. The value of this feature for a word (w_i) is obtained only after the computation of the emotions for its previous words.

Pre-is-degree-word Feature (PDF), Pre-is-negative-word Feature (PNF), Pre-is-conjunction Feature (PCF): To determine if the previous word is a degree word, a negative word, or a conjunction may be helpful to identify word emotions. The degree word list (contains 1,039 words), negative word list (contains 645 words), and conjunction list (contains 297 words) extracted from Ren-CECps have been used.

2.4 The Performance of Using Contextual Feature

We use the documents in Ren-CECps that have been annotated by three annotators independently

[2] http://maxent.sourceforge.net/

as testing corpus. An output of word emotion(s) will be regarded as a correct result if it is in agreement with any one item of word emotion(s) provided by the three annotators. The numbers of training and testing corpus are shown in table 1. The accuracies are measured by F-value.

Table 1: Number of training and testing corpus

Number	Training	Testing
Documents	1,450	26
Sentences	33,825	805
Words	813,507	19,738
Emotion words	99,571	$2,271^*$

(*) At least agreed by two annotators.

Table 2 gives the results of F-value for different contextual features in the MaxEnt based Chinese word emotion recognition. The results of F-value include: (a) recognize emotion and unemotion words; (b) recognize the eight basic emotions for emotion words (complete matching); (c) recognize the eight basic emotions for emotion words (single emotion matching).

As shown in table 2, when we only use Word Feature(WF), the F-value of task (a) achieved a high value (96.3). However, the F-values of task (b) and (c) are relative low, that means the problem of recognizing the eight basic emotions for emotion words is a lot more difficult than the problem of recognizing emotion and unemotion words, so we focus on task (b) and (c).

When we experiment with Word Feature(WF) and N-words Feature (NF), we have observed that word feature (w_i) and a window of previous and next word (w_{i-1}, w_i, w_{i+1}) give the best results (a=96.5, b=50.4, c=69.0). Compared with (w_{i-1}, w_i, w_{i+1}), a larger window of previous and next two words ($w_{i-2}, w_{i-1}, w_i, w_{i+1}, w_{i+2}$) reduces the F-value. This demonstrates that w_i and w_{i-1}, w_i, w_{i+1} are effective features for word emotion recognition.

When POS Feature (POSF) is added, the F-value is increased. Especially the F-value is increased to (a=97.1, b=51.9, c=72.0) when pos_i and $pos_{i-1}, pos_i, pos_{i+1}$ are added.

We also find that Pre-N-words Emotion Feature (PNEF) ($pre\_e_0, ..., pre\_e_{i-1}$) increases the F-value, but previous one word emotion can not increases the F-value.

As can be seen from table 2, when only contextual features are used, the highest F-value is (a=97.1, b=53.0, c=72.7) when Pre-is-degree-word Feature (PDF), Pre-is-negative-word Feature (PNF), Pre-is-conjunction Feature (PCF) are added.

3 Semantic Feature

To know if semantic information is useful for emotion recognition, we have used probabilistic latent semantic analysis (PLSA) (Hofmann, 1999) to cluster words and sentences. PLSA clusters documents based on the term-document cooccurrence which results in semantic decomposition of the term-document matrix into a lower dimensional latent space. PLSA can be defined as:

$$P(s,w) = \sum_{z \in Z} P(z)P(s|z)P(w|z) \qquad (3)$$

where $p(s,w)$ is the probability of word w and sentence s co-occurrence, $P(s|z)$ is the probability of a sentence given a semantic class z, and $P(w|z)$ is the probability of a word given a semantic class z.

For word clustering, We made the assignment based on the maximum $p(z|w)$, if $p(z^{'}|w) =$ max $p(z|w)$, then w was assigned to $z^{'}$. Sentence clustering is similar to word clustering. Word clustering and sentence clustering are run separately. The word class_id and sentence class_id are used as semantic feature (SF), which including sentence class feature (SCF) and word class feature (WCF). PeenAspect implementation of PLSA has been used for our expriments [3].

Table 3 gives the results of F-value for combined all contextual features and semantic feature in the MaxEnt based Chinese word emotion recognition.

As can be seen from table 3, when SCF is used, the best result is obtained when the cluster number is 100; when WCF is used, the best result is obtained when the cluster number is 100 or 160. The results demonstrate the effectiveness of using SCF is a little higher than using WCF.

4 Encoding Feature: Emotion Components of Word

Researches on the psychology of concepts show that categories in the human mind are not simply sets with clearcut boundaries (Murphy, 2002; Hampton, 2007). Word emotions are certainly related to mental concepts. As for emotion states, most theorists appear to take a combinatorial view. Plutchik (1962), for example, talks about "mixed states", "dyads" and "triads" of primary emotions. Similarly, Averill (1975) argues for compound emotions based on more elementary ones. And one model, suggested by Ekman (1982) (emotion blends) and Plutchik (mixed states), is that emotions mix (Ortony, 1988). According to these researches, we use an encoding feature: emotion components of word.

"Emotion components of word" describes the combined basic emotions in a word, which is represented by eight binary digits, and each digit corresponding to a basic emotion class respectively. For example, the word "喜欢 (like)", its possible emotion components in a certain context is "01100000", which expresses the combined emotions by joy and love.

With the expression of emotion components of word, it is possible to distinguish direct emotion words and indirect emotion words. Those words always demonstrate similar emotion components in different contexts can be regarded as direct emotion words, accordingly, those words demonstrate different emotion components in different contexts can be regarded as indirect emotion words. With the expression of emotion components in word, the problem of expressing emotion ambiguity in words can be solved. The same word in different contexts may reflect different emotions, which can be expressed by different emotion components. The emotions of words with multiple emotions also can be expressed by emotion components.

Table 3: F-value for combined contextual features (CF) and semantic feature (SF) (including sentence class feature (SCF) and word class feature (WCF))

Feature type	Cluster number	F-value		
		(a)	(b)	(c)
CF+SCF	20	97.0	53.1	72.8
	40	97.0	53.4	72.7
	60	97.0	53.5	72.8
	80	97.0	52.9	72.5
	100	97.0	**53.6**	**73.1**
	120	97.0	53.1	72.7
	150	97.0	53.2	72.9
	180	97.0	53.4	73.1
CF+WCF	40	97.0	53.1	72.8
	100	97.0	**53.4**	**72.9**
	160	97.0	**53.4**	**72.9**
	220	97.0	53.3	72.9
	280	97.0	53.2	72.8
	370	97.0	53.1	72.8

The statistics of word emotion components in Ren-CECps show that there are a total of 68 emotion components in all of 22,095 annotated emotion words without repetitions. Figure 1 shows the growth curve of word emotion components number with emotion word number increase.

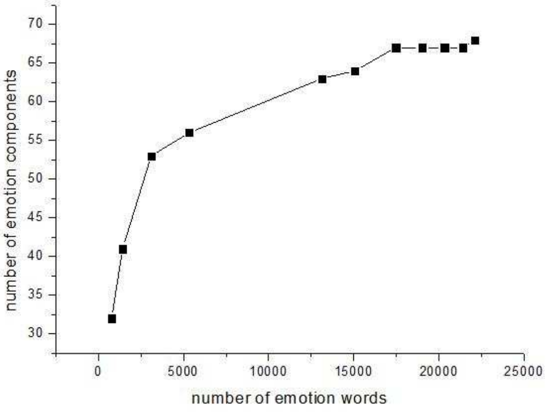

Figure 1: The growth curve of word emotion components

As can be seen from figure 1, the number increase of word emotion components shows a very slow growth rate with the number increase of emotion words. We can conclude that the space of word emotion components is a relatively small space.

In the model of MaxEnt based Chinese word emotion recognition, the Pre-N-words Emotion Feature (PNEF) and emotion output can be encoded to emotion components.

Pre-N-words Emotion Components Feature (PNECF): The emotion components of its previous words for a word (w_i). The value of this feature is obtained only after the computation of the emotion components for its previous words.

Table 4 gives the results of F-value for the combined contextual features and encoding feature.

As can be seen in table 4, when Pre-N-words Emotion Feature (PNEF) is replaced by Pre-N-words Emotion Components Feature (PNECF), and emotion components are output as results, F-value is increased up to (a=97.3, b=57.3, c=73.3). Then based on this result, we firstly trained a word emotion based model, then the word emotion outputs of this model are used as Pre-N-words Emotion Feature (PNEF) for the word emotion components based model. A significant F-value improvement of task (b) and (c) (b=62.5, c=73.7) over only using contextual and semantic features was observed after adding the combined word emotion and word emotion components as feature.

5 Discussion

5.1 Word Emotion Agreement on People's Judgments

The final aim of a human-computer interaction recognition system is to get the result close to people's judgments. As word emotion is inherently uncertain and subjective, here we report the annotation agreement on word emotion of Ren-CECps, which can be taken as an evaluation criteria for a algorithm.

To measure the annotation agreement of Ren-CECps, three annotators independently annotated 26 documents with a total of 805 sentences, 19,738 words. We use the following two metrics to measure agreement on word emotion annotation.

(1) Kappa coefficient of agreement (Carletta, 1996). It is a statistic adopted by the computa-

Table 4: F-value for the combined contextual features and encoding feature

tional linguistics community as a standard measure.

(2) Voting agreement. It is used to measure how much intersection there is between the sets of word emotions identified by the annotators. It includes majority-voting agreement ($Agreement_{MV}$) and all-voting agreement ($Agreement_{AV}$). $Agreement_{MV}$ is defined as follows. Let A, B and C be the sets of word emotion components annotated by annotators a, b and c respectively. The expert coder is the set of expressions that agreed by at least two annotators, see equation (4).

$$Agreement_{MV} = Avg(\frac{count(t_i = e_j)}{count(t_i)}) \quad (4)$$

In which, $t_i \in T$, $e_j \in E$, $T = A \bigcup B \bigcup C$, $E = (A \bigcap B) \bigcup (A \bigcap C) \bigcup (B \bigcap C)$.

Accordingly, the expert coder of $Agreement_{AV}$ is the set of expressions that agreed by all annotators.

The above two metrics are used to measure the agreements on: (a) determine if a word is an emotion or unemotion word; (b) determine the eight basic emotions for emotion words (complete emotion matching); (c) determine the eight basic emotions for emotion words (single matching). (b) and (c) are provided that at least two people to believe the word is an emotion word. Table 5 shows the agreements measured by the two metrics.

As shown in table 5, it is easier for annotators to agree at if a word contains emotion, but it is more difficult to agree on emotions or emotion components of a word. Compared with the agreement on people's judgments, our experiments gave promising results.

Table 5: Agreement of word emotion annotation measured by Kappa, Majority-voting (MV), and All-voting (AV)

Measure	Kappa	MV	AV
(a)	84.3	98.5	95.1
(b)	66.7	70.3	26.2
(c)	77.5	100	84.9

5.2 Error Analysis

Conducting an error analysis, we find that a lot of errors occur due to the recognition on multi-emotion words and indirect emotion words, especially in short sentences because the features can be extracted are too few. So more features should be considered from larger contexts, such as the topic emotion of paragraph or document.

There are some errors occur due to more than one emotion holders exist in one sentence, for example of sentence (4).

(4) 我发现女儿正看着她感兴趣的玩具。(I found that daughter was looking at the toys of her interest.)

In sentence (4), three annotators all agree that the emotion components of the word “感兴趣 (interest)” is “00000000” since they believe that this word is an unemotion word from the view of the writer. But our system give a result of “00100000” because the emotion holder “女儿 (daughter)” of the emotion word “感兴趣 (interest)” has not been considered in our algorithm. Therefore, the recognition of emotion holder is indispensable for an accurate emotion analysis system.

In addition, Chinese segmentation mistakes and phrasing error also cause errors.

6 Conclusions

Automatically perceive the emotions from text has potentially important applications in CMC (computer-mediated communication) that range from identifying emotions from online blogs to enabling dynamically adaptive interfaces. Therein words play important role in emotion expressions of text.

In this paper we explored features for recognizing word emotions in sentences. Different from previous researches on textual emotion recognition that based on affective lexicons, we believe that besides obvious emotion words referring to emotions, there are words can potentially convey emotions act only as an indirect reference. Also, quite often words that bear emotion ambiguity and multiple emotions are difficult to be recognized depending on emotion lexicons. Emotion of a word should be determined with its context.

Based on Ren-CECps (an annotated emotion corpus) and MaxEnt (Maximum entropy) model, we have experimented several contextual features and their combination, then using PLSA (probabilistic latent semantic analysis), semantic feature are demonstrated the effectiveness for word emotion recognition. A significant performance improvement over only using contextual and semantic features was observed after adding encoding feature (word emotion components). Determining intensity of word emotion and recognizing emotion of sentence or document based on word emotion are included in our future work.

Inducing Fine-Grained Semantic Classes via Hierarchical and Collective Classification

Abstract

Research in named entity recognition and mention detection has typically involved a fairly small number of semantic classes, which may not be adequate if semantic class information is intended to support natural language applications. Motivated by this observation, we examine the under-studied problem of semantic subtype induction, where the goal is to automatically determine which of a set of 92 fine-grained semantic classes a noun phrase belongs to. We seek to improve the standard supervised approach to this problem using two techniques: hierarchical classification and collective classification. Experimental results demonstrate the effectiveness of these techniques, whether or not they are applied in isolation or in combination with the standard approach.

1 Introduction

Semantic class determination refers to the task of classifying a noun phrase (NP), be it a name or a nominal, as one of a set of pre-defined semantic classes. A semantic class classifier is a basic text-processing component in many high-level natural language processing (NLP) applications, including information-extraction (IE) systems and question-answering (QA) systems. In recent years, supervised semantic class determination has been tackled primarily in the context of (1) *coreference resolution* (e.g., Ng (2007), Huang et al. (2009)), where semantic classes are induced and subsequently used to disallow coreference between semantically incompatible NPs, and (2) the *mention detection* task in the ACE evaluations (e.g., Florian et al. (2004; 2006)), where the goal is to identify the boundary of a *mention* (i.e., a noun phrase that belongs to one of the pre-defined ACE semantic classes), its mention type (e.g., pronoun, name), and its semantic class. The output of a mention detector is then used by downstream IE components, which typically include a coreference resolution system and a relation extraction system. Owing in part to its potentially large influence on downstream IE components, accurate semantic class determination is crucial.

Over the years, NLP researchers have focused on a relatively small number of semantic classes in both NE recognition and mention detection: seven classes in the MUC-6 and MUC-7 NE recognition task, four classes in the CoNLL 2002 and 2003 NE recognition shared task, and seven classes in the ACE 2005 mention detection task. Given that one of the uses of semantic class information is to support NLP applications, it is questionable whether this purpose can be adequately served by such a small number of semantic classes. For example, given the question "Which city was the first Olympic Games held in?", it would be helpful for a QA system to know which NEs are cities. However, virtually all of the existing NE recognizers and mention detectors can only determine whether an NE is a location or not.

Our goal in this paper is to tackle the under-studied problem of determining fine-grained semantic classes (henceforth *semantic subtypes*). More specifically, we aim to classify an NP as one of the 92 fine-grained, domain-independent semantic classes that are determined to be useful for supporting the development of QA and

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 931–939,
Beijing, August 2010

IE systems in the ACE and AQUAINT programs. These 92 semantic subtypes have been used to manually annotate the NPs in the *BBN Entity Type Corpus* (Weischedel and Brunstein, 2005). Given the availability of this semantic subtype-annotated corpus, we adopt a supervised machine learning approach to semantic subtype determination. Specifically, given (the boundary of) an NP, we train a classification model to determine which of the 92 semantic subtypes it belongs to.

More importantly, we seek to improve the standard approach to semantic subtype induction described above by proposing two techniques. The first technique, collective classification, aims to address a common weakness in the standard supervised learning paradigm, where a classifier classifies each instance independently of the others and is unable to exploit any relational information between a pair (or a subset) of the instances that may be helpful for classification. The second technique, hierarchical classification, exploits the observation that these 92 semantic subtypes can be grouped into a smaller number of coarse-grained semantic types (henceforth semantic supertypes). With this two-level hierarchy, learning can proceed in a sequential fashion: given an NP, we first determine its semantic supertype and then classify it as one of the semantic subtypes that fall under the predicted supertype in the hierarchy. Empirical results show that these two techniques, when applied in isolation to the standard learning approach to subtype induction, can significantly improve its accuracy, and the best result is achieved when they are applied in combination.

The rest of the paper is organized as follows. Section 2 provides an overview of the 92 semantic subtypes and the evaluation corpus. In Section 3, we present our baseline semantic subtype classification system. Sections 4 and 5 introduce collective classification and hierarchical classification respectively, and describe how these two techniques can be used to improve the baseline semantic subtype classifier. We show evaluation results in Section 6 and conclude in Section 7.

2 Semantic Subtypes

As noted before, each name and nominal in the *BBN Entity Type Corpus* is annotated with one of the 92 semantic subtypes. In our experiments, we use all the 200 Penn Treebank Wall Street Journal articles in the corpus, yielding 17,292 NPs that are annotated with their semantic subtypes.

Table 1 presents an overview of these subtypes. Since they have been manually grouped into 29 supertypes, we also show the supertypes in the table. More specifically, the first column shows the supertypes, the second column contains a brief description of a supertype, and the last column lists the subtypes that correspond to the supertype in the first column. In cases where a supertype contains only one subtype (e.g., PERSON), the supertype is not further partitioned into different subtypes; for classification purposes, we simply treat the subtype as identical to its supertype (and hence the two always have the same name). A detailed description of these supertypes and subtypes can be found in Weischedel and Brunstein (2005). Finally, we show the class distribution: the parenthesized number after each subtype is the percentage of the 17,292 NPs annotated with the subtype.

3 Baseline Classification Model

We adopt a supervised machine learning approach to train our baseline classifier for determining the semantic subtype of an NP. This section describes the details of the training process.

Training corpus. As mentioned before, we use the Wall Street Journal articles in the BBN Entity Type Corpus for training the classifier.

Training instance creation. We create one training instance for each annotated NP, NP_i, which is either a name or a nominal, in each training text. The classification of an instance is its annotated semantic subtype value, which is one of the 92 semantic subtypes. Each instance is represented by a set of 33 features[1], as described below.

1. Mention String (3): Three features are derived from the string of NP_i. Specifically, we employ the NP string as a feature. If NP_i contains more than one token, we create one feature for each of its constituent tokens. Finally, to distinguish the different senses of a nominal, we create

[1] As we will see, since we employ an exponential model, an instance may be represented by fewer than 33 features.

Supertype	Brief Description	Subtypes
PERSON	Proper names of people.	Person (9.2).
PERSON DESC	Any head word of a common noun referring to a person or group of people.	Person Desc (16.8).
NORP	This type is named after its subtypes: nationality, religion, political, etc.	Nationality (2.9), Religion (0.1), Political (0.6), Other (0.1).
FACILITY	Names of man-made structures, including infrastructure, buildings, monuments, camps, farms, mines, ports, etc.	Building (0.1), Bridge (0.02), Airport (0.01), Attraction (0.01), Highway Street (0.05), Other (0.1).
FACILITY DESC	Head noun of a noun phrase describing buildings, bridges, airports, etc.	Building (0.5), Bridge (0.05), Airport (0.01), Highway Street (0.2), Attraction (0.02), Other (0.5).
ORGANIZATION	Names of companies, government agencies, educational institutions and other institutions.	Government (3.6), Corporation (8.3), Political (0.5), Educational (0.3), Hotel (0.04), City (0.01), Hospital (0.01), Religious (0.1), Other (0.7).
ORG DESC	Heads of descriptors of companies, educational institutions and other governments, government agencies, etc.	Government (2.1), Corporation (4.3), Political (0.2), Educational (0.1), Religious (0.1), Hotel (0.1), City (0.01), Hospital (0.02), Other (0.7).
GPE	Names of countries, cities, states, provinces, municipalities, boroughs.	Country (4.2), City (3.2), State Province (1.4), Other (0.1).
GPE DESC	Heads of descriptors of countries, cities, states, provinces, municipalities.	Country (0.8), City (0.3), State Province (0.3), Other (0.1).
LOCATION	Names of locations other than GPEs. E.g., mountain ranges, coasts, borders, planets, geo-coordinates, bodies of water.	River (0.03), Lake Sea Ocean (0.05), Region (0.2), Continent (0.1), Other (0.2).
PRODUCT	Name of any product. It does not include the manufacturer).	Food (0.01), Weapon (0.02), Vehicle (0.2), Other (0.2).
PRODUCT DESC	Descriptions of weapons and vehicles only. Cars, buses, machine guns, missiles, bombs, bullets, etc.	Food (0.01), Weapon (0.2), Vehicle (0.97), Other (0.02).
DATE	Classify a reference to a date or period.	Date (7.99), Duration (1.9), Age (0.5), Other (0.4).
TIME	Any time ending with A.M. or P.M.	Time (0.5).
PERCENT	Percent symbol or the actual word percent.	Percent (2.07).
MONEY	Any monetary value.	Money (2.9).
QUANTITY	Used to classify measurements. E.g., 4 miles, 4 grams, 4 degrees, 4 pounds, etc.	1D (0.11), 2D (0.08), 3D (0.1), Energy (0.01), Speed (0.01), Weight (0.1), Other (0.04).
ORDINAL	All ordinal numbers. E.g., First, fourth.	Ordinal (0.6).
CARDINAL	Numerals that provide a count or quantity.	Cardinal (5.1).
EVENT	Named hurricanes, battles, wars, sports events, and other named events.	War (0.03), Hurricane (0.1), Other (0.24).
PLANT	Any plant, flower, tree, etc.	Plant (0.2).
ANIMAL	Any animal class or proper name of an animal, real or fictional.	Animal (0.7).
SUBSTANCE	Any chemicals, elements, drugs, and foods. E.g., boron, penicillin, plutonium.	Food (1.1), Drug (0.46), Chemical (0.23), Other (0.9).
DISEASE	Any disease or medical condition.	Disease (0.6).
LAW	Any document that has been made into a law. E.g., Bill of Rights, Equal Rights.	Law (0.5).
LANGUAGE	Any named language.	Language (0.2).
CONTACT INFO	Address, phone.	Address (0.01), Phone (0.04).
GAME	Any named game.	Game (0.1).
WORK OF ART	Titles of books, songs and other creations.	Book (0.16), Play (0.04), Song (0.03), Painting (0.01), Other (0.4).

Table 1: The 92 semantic subtypes and their corresponding supertypes.

a feature whose value is the concatenation of the head of NP_i and its WordNet sense number.[2]

2. Verb String (3): If NP_i is governed by a verb, the following three features are derived from the governing verb. First, we employ the string of the governing verb as a feature. Second, we create a feature whose value is the semantic role of the

[2] We employ the sense number that is manually annotated for each NP in the WSJ corpus as part of the OntoNotes project (Hovy et al., 2006).

governing verb.[3] Finally, to distinguish the different senses of the governing verb, we create a feature whose value is the concatenation of the verb and its WordNet sense number.

3. Semantic (5): We employ five semantic features. First, if NP_i is an NE, we create a feature whose value is the NE label of NP_i, as determined by the Stanford CRF-based NE recognizer (Finkel et al., 2005). However, if NP_i is a nominal, we create a feature that encodes the WordNet semantic class of which it is a hyponym, using the manually determined sense of NP_i.[4] Moreover, to improve generalization, we employ a feature whose value is the WordNet synset number of the head noun of a nominal. If NP_i has a governing verb, we also create a feature whose value is the WordNet synset number of the verb. Finally, if NP_i is a nominal, we create a feature based on its *WordNet equivalent concept*. Specifically, for each entity type defined in ACE 2005[5], we create a list containing all the word-sense pairs in WordNet (i.e., synsets) whose glosses are compatible with that entity type.[6] Then, given NP_i and its sense, we use these lists to determine if it belongs to any ACE 2005 entity type. If so, we create a feature whose value is the corresponding entity type.

4. Morphological (8). If NP_i is a nominal, we create eight features: prefixes and suffixes of length one, two, three, and four.

5. Capitalization (4): We create four capitalization features to determine whether NP_i `IsAllCap`, `IsInitCap`, `IsCapPeriod`, and `IsAllLower` (see Bikel et al. (1999)).

6. Gazetteers (8): We compute eight gazetteer-based features, each of which checks whether NP_i is in a particular gazetteer. The eight dictionaries contain pronouns (77 entries), common words and words that are not names (399.6k), person names (83.6k), person titles and honorifics (761), vehicle words (226), location names (1.8k), company names (77.6k), and nouns extracted from WordNet that are hyponyms of PERSON (6.3k).

7. Grammatical (2): We create a feature that encodes the part-of-speech (POS) sequence of NP_i obtained via the Stanford POS tagger (Toutanova et al., 2003). In addition, we have a feature that determines whether NP_i is a nominal or not.

We employ maximum entropy (MaxEnt) modeling[7] for training the baseline semantic subtype classifier. MaxEnt is chosen because it provides a *probabilistic* classification for each instance, which we will need to perform collective classification, as described in the next section.

4 Collective Classification

One weakness of the baseline classification model is that it classifies each instance independently. In particular, the model cannot take into account relationships between them that may be helpful for improving classification accuracy. For example, if two NPs are the same string in a given document, then it is more likely than not that they have the same semantic subtype according to the "one sense per discourse" hypothesis (Gale et al., 1992). Incorporating this kind of *relational* information into the feature set employed by the baseline system is not an easy task, since each feature characterizes only a single NP.

To make use of the relational information, one possibility is to design a new learning procedure. Here, we adopt a different approach: we perform collective classification, or joint probabilistic inference, on the output of the baseline model. The idea is to treat the output for each NP, which is a probability distribution over the semantic subtypes, as its *prior* label/class distribution, and convert it into a *posterior* label/class distribution by exploiting the available relational information as an additional piece of evidence. For this purpose, we will make use of *factor graphs*. In this section, we first give a brief overview of factor graphs[8], and show how they can be used to perform joint

[3] We also employ the semantic role that is manually annotated for each NP in the WSJ corpus in OntoNotes.

[4] The semantic classes we considered are person, location, organization, date, time, money, percent, and object.

[5] The ACE 2005 entity types include person, organization, GPE, facility, location, weapon, and vehicle.

[6] Details of how these lists are constructed can be found in Nicolae and Nicolae (2006).

[7] We use the MaxEnt implementation available at http://homepages.inf.ed.ac.uk/s0450736/maxent_toolkit.html

[8] See Bunescu and Mooney (2004) and Loeliger (2004) for a detailed introduction to factor graphs.

inference for semantic subtype determination.

4.1 Factor Graphs

Factor graphs model optimization problems of an objective function g, which is a real-valued function of n random variables $X_1, ..., X_n$. We assume that g can be decomposed into a product of m *factors*. In other words, $g(X_1, ..., X_n) = f_1(s_1(X_1, ..., X_n)) ... f_m(s_m(X_1, ..., X_n))$, where each factor f_k is a real-valued function of some subset of $X_1, ..., X_n$, denoted as $s_k(X_1, ..., X_n)$. Each f_k can be thought of as a feature function that computes the *compatibility* of an assignment of values to the variables in $s_k(X_1, ..., X_n)$ with respect to a user-defined feature. Hence, a larger function value is more desirable, as it corresponds to a more compatible assignment of values to the variables involved.

A factor graph consists of two types of nodes: variable nodes and factor nodes. Each random variable X_i is represented by a variable node, and each factor f_k is represented by a factor node. Each factor node f_k is connected only to the nodes corresponding to s_k. This results in a bipartite graph, where edges exist only between a variable node and a factor node.

Given this graph, there are several methods for finding an optimal assignment of the random variables $X_1, ..., X_n$ such that the objective function g is maximized. Exact inference using the sum-product algorithm (Kschischang et al., 2001) is possible if there are no cycles in the graph; otherwise a belief propagation algorithm, such as loopy belief propagation (Murphy et al., 1999), can be applied. Although there are no cycles in our factor graphs, we choose to use loopy belief propagation as our inferencer, since it performs approximate inference and is therefore computationally more efficient than an exact inferencer.

4.2 Application to Subtype Inference

To apply joint inference to semantic subtype induction, we create one factor graph for each test document, where each variable node is random variable X_i over the set of semantic subtype labels L and represents an NP, NP$_i$, in the document. To retain the prior probabilities over the semantic subtype labels $l_q \in L$ obtained from the baseline classification model, each variable node is given a factor $f(X_i) = P(X_i = l_q)$. If no additional factors that model the relation between two nodes/instances are introduced, maximizing the objective function for this graph (by maximizing the product of factors) will find an assignment identical to the one obtained by taking the most probable semantic subtype label assigned to each instance by the baseline classifier.

Next, we exploit the relationship between two random variables. Specifically, we want to encourage the inference algorithm to assign the same label to two variables if there exists a relation between the corresponding NPs that can provide strong evidence that they should receive the same label. To do so, we create a *pairwise* factor node that connects two variable nodes if the aforementioned relation between the underlying NPs is satisfied. However, to implement this idea, we need to address two questions.

First, *which relation between two NPs can provide strong evidence that they have the same semantic subtype?* We exploit the coreference relation. Intuitively, the coreference relation is a reasonable choice, as coreferent entities are likely to have the same semantic subtype. Here, we naively posit two NPs as coreferent if at least one of the following conditions is satisfied: (1) they are the same string after determiners are removed; (2) they are aliases (i.e., one is an acronym or abbreviation of the other); and (3) they are both proper names and have at least one word in common (e.g., "Delta" and "Delta Airlines").[9]

Second, *how can we define a pairwise factor, f_{pair}, so that it encourages the inference algorithm to assign the same label to two nodes?* One possibility is to employ the following definition:

$$\begin{aligned} & f_{pair}(X_i, X_j) \\ = \; & P(X_i = l_p, X_j = l_q), \text{where } \; l_p, l_q \in L \\ = \; & \begin{cases} 1 & \text{if } l_p = l_q \\ 0 & \text{otherwise} \end{cases} \end{aligned}$$

In essence, f_{pair} prohibits the assignment of different labels to the two nodes it connects. In our

[9] The third condition can potentially introduce many false positives, positing "Bill Clinton" and "Hillary Clinton" as coreferent, for instance. However, this kind of false positives does not pose any problem for us, since the two NPs involved belong to the same semantic subtype (i.e., PERSON).

experiments, however, we "improve" f_{pair} by incorporating semantic supertype information into its definition, as shown below:

$$\begin{aligned} & f_{pair}(X_i, X_j) \\ =\ & P(X_i = l_p, X_j = l_q), \text{where } \ l_p, l_q \in L \\ =\ & \begin{cases} P_{sup}(sup(l_p)|\text{NP}_i)P_{sup}(sup(l_q)|\text{NP}_j) & \text{if } l_p = l_q \\ 0 & \text{otherwise} \end{cases} \end{aligned}$$

In this definition, $sup(l_q)$ is the supertype of l_q according to the semantic type hierarchy shown in Section 2, and $P_{sup}(sup(l_q)|\text{NP}_j)$ is the probability that NP$_j$ belongs to $sup(l_q)$ according to the semantic supertype classification model P_{sup} (see Section 5 for details on how this model can be trained). In essence, we estimate the joint probability by (1) assuming that the two events are independent, and then (2) computing each event using supertype information. Intuitively, this definition allows f_{pair} to favor those label assignments that are more compatible with the predictions of P_{sup}.

After graph construction, we apply an inferencer to compute a marginal probability distribution over the labels for each node/instance in the graph by maximizing the objective function g, and output the most probable label for each instance according to its marginal distribution.

5 Hierarchical Classification

The pairwise factor f_{pair} defined above exploits supertype information in a *soft* manner, meaning that the most probable label assigned to an NP by an inferencer is not necessarily consistent with its predicted supertype (e.g., an NP may receive Hotel as its subtype even if its supertype is PERSON). In this section, we discuss how to use supertype information for semantic subtype classification in a *hard* manner so that the predicted subtype is consistent with its supertype.

To exploit supertype information, we first train a model, P_{sup}, for determining the semantic supertype of an NP using MaxEnt. This model is trained in essentially the same way as the baseline model described in Section 3. In particular, it is trained on the same set of instances using the same feature set as the baseline model. The only difference is that the class value of each training instance is the semantic supertype of the associated NP rather than its semantic subtype.

Next, we train 29 supertype-specific classification models for determining the semantic subtype of an NP. For instance, the ORGANIZATION-specific classification model will be used to classify an NP as belonging to one of its subtypes (e.g., Government, Corporation, Political agencies). A supertype-specific classification model is trained much like the baseline model. Each instance is represented using the same set of features as in the baseline, and its class label is its semantic subtype. The only difference is that the model is only trained only on the subset of the instances for which it is intended. For instance, the ORGANIZATION-specific classification model is trained only on instances whose class is a subtype of ORGANIZATION.

After training, we can apply the supertype classification model and the supertype-specific subtype classification model to determine the semantic subtype of an NP in a hierarchical fashion. Specifically, we first employ the supertype model to determine its semantic supertype. Then, depending on this predicted semantic supertype, we use the corresponding subtype classification model to determine its subtype.

6 Evaluation

For evaluation, we partition the 200 Wall Street Journal Articles in the BBN Entity Type corpus into a training set and a test set following a 80/20 ratio. As mentioned before, each text in the Entity Type corpus has its NPs annotated with their semantic subtypes. Test instances are created from these texts in the same way as the training instances described in Section 3. To investigate whether we can benefit from hierarchical and collective classifications, we apply these two techniques to the Baseline classification model in isolation and in combination, resulting in the four sets of results in Tables 2 and 3.

The Baseline results are shown in the second column of Table 2. Due to space limitations, it is not possible to show the result for each semantic subtype. Rather, we present semantic supertype results, which are obtained by micro-averaging the corresponding semantic subtype results and are expressed in terms of recall (R), precision (P), and F-measure (F). Note that only those semantic

Table 3: Results for Baseline with collective classification and Baseline with both techniques.

supertypes with non-zero scores are shown. As we can see, only 16 of the 29 supertypes have non-zero scores.[10] Among the "traditional" semantic types, the Baseline yields good performance for PERSON, but only mediocre performance for ORGANIZATION and GPE. While additional experiments are needed to determine the reason, we speculate that this can be attributed to the fact that PERSON and PERSON DESC have only one semantic subtype (which is the supertype itself), whereas ORGANIZATION and GPE have nine and four subtypes, respectively. The classification accuracy is shown in the last row of the table. As we can see, the Baseline achieves an accuracy of 81.56.

Results obtained when hierarchical classification is applied to the Baseline are shown in the third column of Table 2. In comparison to the Baseline, accuracy rises from 81.56 to 82.60. This represents an error reduction of 5.6%, and the difference between these two accuracies is statistically significant at the $p = 0.04$ level.[11]

[10] The 13 supertypes that have zero scores are all under-represented classes, each of which accounts for less than one percent of the instances in the dataset.

[11] All significance test results in this paper are obtained using Approximate Randomization (Noreen, 1989).

1	3	7	4	2	5	6
81.4	75.8	83.3	83.7	84.1	85.2	85.6

80.4	78.3	83.9	86.5	86.7		
81.8	76.2	85.2	87.6			
75.4	83.4	84.6				
66.2	80.9					

Table 4: Results of feature analysis.

Results obtained when collective classification alone is applied to the Baseline are shown in the second column of Table 3. In this case, the prior probability distribution over the semantic subtypes that is needed to create the factor associated with each node in the factor graph is simply the probabilistic classification of the test instance that the node corresponds to. In comparison to the Baseline, accuracy rises from 81.56 to 83.70. This represents an error reduction of 11.6%, and the difference is significant at the $p = 0.01$ level. Also, applying collective classification to the Baseline yields slightly better results than applying hierarchical classification to the Baseline, and the difference in their results is significant at the $p = 0.002$ level.

Finally, results obtained when both hierarchical and collective classification are applied to the Baseline are shown in the third column of Table 3. In this case, the prior distribution needed to create the factor associated with each node in the factor graph is provided by the supertype-specific classification model that is used to classify the test instance in hierarchical classification. In comparison to the Baseline, accuracy rises from 81.56 to 85.08. This represents an error reduction of 19.1%, and the difference is highly significant ($p < 0.001$). Also, applying both techniques to the Baseline yields slightly better results than applying only collective classification to the Baseline, and the difference in their results is significant at the $p = 0.003$ level.

6.1 Feature Analysis

Next, we analyze the effects of the seven feature types described in Section 3 on classification accuracy. To measure feature performance, we take the best-performing system (i.e., Baseline combined with both techniques), begin with all seven feature types, and iteratively remove them one by one so that we get the best accuracy. The results are shown in Table 4. Across the top line, we list the numbers representing the seven feature classes. The feature class that corresponds to each number can be found in Section 3, where they are introduced. For instance, “2” refers to the features computed based on the governing verb. The first row of results shows the system performance after removing just one feature class. In this case, removing the sixth feature class (Gazetteers) improves accuracy to 85.6, while removing the mention string features reduces accuracy to 81.4. The second row repeats this, after removing the gazetteer features.

Somewhat surprisingly, using only mention string, semantic, and grammatical features yields the best accuracy (87.6). This indicates that gazetteers, morphological features, capitalization, and features computed based on the governing verb are not useful. Removing the grammatical features yields a 3% drop in accuracy. After that, accuracy drops by 4% when semantic features are removed, whereas a 18% drop in accuracy is observed when the mention string features are removed. Hence, our analysis suggests that the mention string features are the most useful features for semantic subtype prediction.

7 Conclusions

We examined the under-studied problem of semantic subtype induction, which involves classifying an NP as one of 92 semantic classes, and showed that two techniques — hierarchical classification and collective classification — can significantly improve a baseline classification model trained using an off-the-shelf learning algorithm on the BBN Entity Type Corpus. In particular, collective classification addresses a major weakness of the standard feature-based learning paradigm, where a classification model classifies each instance independently, failing to capture the relationships among subsets of instances that might improve classification accuracy. However, collective classification has not been extensively applied in the NLP community, and we hope that our work can increase the awareness of this powerful technique among NLP researchers.

Abstract

Model minimization has been shown to work well for the task of unsupervised part-of-speech tagging with a dictionary. In (Ravi and Knight, 2009), the authors invoke an integer programming (IP) solver to do model minimization. However, solving this problem exactly using an integer programming formulation is intractable for practical purposes. We propose a novel two-stage greedy approximation scheme to replace the IP. Our method runs fast, while yielding highly accurate tagging results. We also compare our method against standard EM training, and show that we consistently obtain better tagging accuracies on test data of varying sizes for English and Italian.

1 Introduction

The task of unsupervised part-of-speech (POS) tagging with a dictionary as formulated by Merialdo (1994) is: given a raw word sequence and a dictionary of legal POS tags for each word type, tag each word token in the text. A common approach to modeling such sequence labeling problems is to build a bigram Hidden Markov Model (HMM) parameterized by *tag-bigram* transition probabilities $P(t_i|t_{i-1})$ and *word-tag* emission probabilities $P(w_i|t_i)$. Given a word sequence w and a tag sequence t, of length N, the joint probability $P(w,t)$ is given by:

$$P(w,t) = \prod_{i=1}^{N} P(w_i|t_i) \cdot P(t_i|t_{i-1}) \qquad (1)$$

We can train this model using the Expectation Maximization (EM) algorithm (Dempster and Rubin, 1977) which learns $P(w_i|t_i)$ and $P(t_i|t_{i-1})$ that maximize the likelihood of the observed data. Once the parameters are learnt, we can find the best tagging using the Viterbi algorithm.

$$\hat{t} = \arg\max_{t} P(w,t) \qquad (2)$$

Ravi and Knight (2009) attack the Merialdo task in two stages. In the first stage, they search for a minimized transition model (i.e., the smallest set of tag bigrams) that can explain the data using an integer programming (IP) formulation. In the second stage, they build a smaller HMM by restricting the transition parameters to only those tag bigrams selected in the minimization step. They employ the EM algorithm to train this model, which prunes away some of the emission parameters. Next, they use the pruned emission model along with the original transition model (which uses the full set of tag bigrams) and retrain using EM. This alternating EM training procedure is repeated until the number of tag bigrams in the Viterbi tagging output does not change between subsequent iterations. The final Viterbi tagging output from their method achieves state-of-the-art accuracy for this task. However, their minimization step involves solving an integer program, which can be very slow, especially when scaling to large-scale data and more complex tagging problems which use bigger tagsets. In this paper, we present a novel method that optimizes the same objective function using a fast greedy model selection strategy. Our contributions are summarized below:

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 940–948,
Beijing, August 2010

- We present an efficient two-phase greedy-selection method for solving the minimization objective from Ravi and Knight (2009), which runs much faster than their IP.

- Our method easily scales to large data sizes (and big tagsets), unlike the previous minimization-based approaches and we show runtime comparisons for different data sizes.

- We achieve very high tagging accuracies comparable to state-of-the-art results for unsupervised POS tagging for English.

- Unlike previous approaches, we also show results obtained when testing on the entire Penn Treebank data (973k word tokens) in addition to the standard 24k test data used for this task. We also show the effectiveness of this approach for Italian POS tagging.

2 Previous work

There has been much work on the unsupervised part-of-speech tagging problem. Goldwater and Griffiths (2007) also learn small models employing a fully Bayesian approach with sparse priors. They report 86.8% tagging accuracy with manual hyperparameter selection. Smith and Eisner (2005) design a *contrastive estimation* technique which yields a higher accuracy of 88.6%. Goldberg et al. (2008) use linguistic knowledge to initialize the the parameters of the HMM model prior to EM training. They achieve 91.4% accuracy. Ravi and Knight (2009) use a Minimum Description Length (MDL) method and achieve the best results on this task thus far (91.6% word token accuracy, 91.8% with random restarts for EM). Our work follows a similar approach using a model minimization component and alternate EM training.

Recently, the integer programming framework has been widely adopted by researchers to solve other NLP tasks besides POS tagging such as semantic role labeling (Punyakanok et al., 2004), sentence compression (Clarke and Lapata, 2008), decipherment (Ravi and Knight, 2008) and dependency parsing (Martins et al., 2009).

3 Model minimization formulated as a Path Problem

The complexity of the model minimization step in (Ravi and Knight, 2009) and its proposed approximate solution can be best understood if we formulate it as a path problem in a graph.

Let $w = w_0, w_1, \ldots, w_N, w_{N+1}$ be a word sequence where $w_1, \ldots, w_N$ are the input word tokens and $\{w_0, w_{N+1}\}$ are the $start/end$ tokens. Let $T = \{T_1, \ldots, T_K\} \bigcup \{T_0, T_{K+1}\}$ be the fixed set of all possible tags. T_0 and T_{K+1} are special tags that we add for convenience. These would be the $start$ and end tags that one typically adds to the HMM lattice. The tag dictionary D contains entries of the form (w_i, T_j) for all the possible tags T_j that word token w_i can have. We add entries (w_0, T_0) and (w_{K+1}, T_{K+1}) to D. Given this input, we now create a directed graph $G(V, E)$. Let $C_0, C_1 \ldots, C_{K+1}$ be columns of nodes in G, where column C_i corresponds to word token w_i. For all $i = 0, \ldots, N+1$ and $j = 0, \ldots, K+1$, we add node $C_{i,j}$ in column C_i if $(w_i, T_j) \in D$. Now, $\forall i = 0, \ldots, N$, we create directed edges from every node in C_i to every node in C_{i+1}. Each of these edges $e = (C_{i,j}, C_{i+1,k})$ is given the label (T_j, T_k) which corresponds to a tag bigram. This creates our directed graph. Let $l(e)$ be the tag bigram label of edges $e \in E$. For every path P from $C_{0,0}$ to $C_{N+1,K+1}$, we say that P uses an edge label or tag bigram (T_j, T_k) if there exists an edge e in P such that $l(e) = (T_j, T_k)$. We can now formulate the the optimization problem as: *Find the smallest set S of tag bigrams such that there exists at least one path from $C_{0,0}$ to $C_{N+1,K+1}$ using only the tag bigrams in S.* Let us call this the Minimal Tag Bigram Path (MinTagPath) problem.

Figure 1 shows an example graph where the input word sequence is $w_1, \ldots, w_4$ and $T = \{T_1, \ldots, T_3\}$ is the input tagset. We add the start/end word tokens $\{w_0, w_5\}$ and corresponding tags $\{T_0, T_4\}$. The edges in the graph are instantiated according to the word/tag dictionary D provided as input. The node and edge labels are also illustrated in the graph. Our goal is to find a path from $C_{0,0}$ to $C_{5,4}$ using the smallest set of tag bigrams.

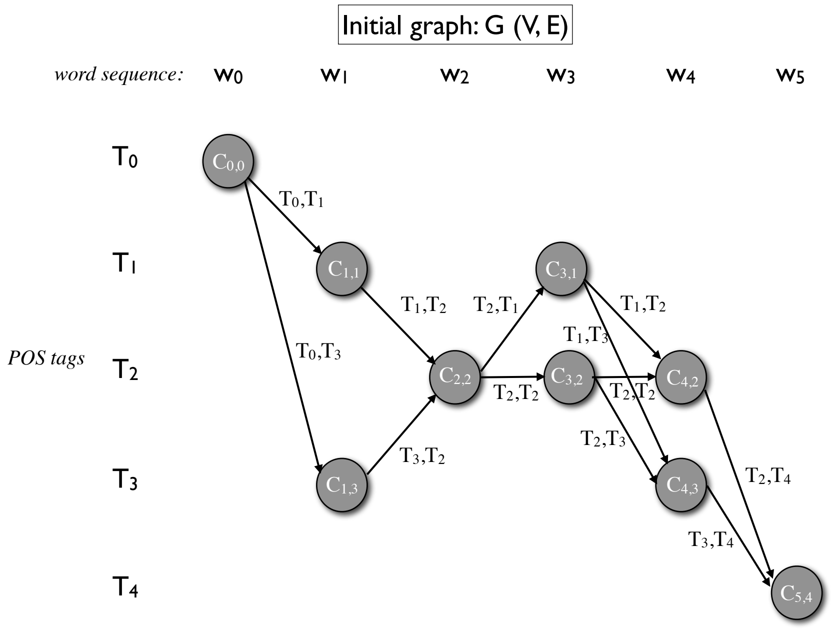

Figure 1: Graph instantiation for the MinTagPath problem.

4 Problem complexity

Having defined the problem, we now show that it can be solved in polynomial time even though the number of paths from $C_{0,0}$ to $C_{N+1,K+1}$ is exponential in N, the input size. This relies on the assumption that the tagset T is fixed in advance, which is the case for most tagging tasks.[1] Let B be the set of all the tag bigram labels in the graph, $B = \{l(e), \forall e \in E\}$. Now, the size of B would be at most $K^2 + 2K$ where every word could be tagged with every possible tag. For $m = 1 \ldots |B|$, let B^m be the set of subsets of B each of which have size m. Algorithm 1 optimally solves the MinTagPath problem.

Algorithm 1 Brute Force solution to MinTagPath

```
for $m = 1$ to $|B|$ do
  for $s_i \in \mathcal{B}^m$ do
    Use Breadth First Search (BFS) to check if $\exists$ path $P$ from $C_{0,0}$ to $C_{N+1,K+1}$ using only the tag bigrams in $s_i$.
    if $P$ exists then
      return $s_i, m$
    end if
  end for
end for
```

Algorithm 1 basically enumerates all the possible subsets of B, from the smallest to the largest, and checks if there is a path. It exits the first time a path is found and therefore finds the smallest possible set s_i of size m such that a path exists that uses only the tag bigrams in s_i. This implies the correctness of the algorithm. To check for path existence, we could either throw away all the edges from E not having a label in s_i, and then execute a Breadth-First-Search (BFS) or we could traverse only the edges with labels in s_i during BFS. The running time of Algorithm 1 is easy to calculate. Since, in the worst case we go over all the subsets of size $m = 1, \ldots, |B|$ of B, the number of iterations we can perform is at most $2^{|B|}$, the size of the powerset $\mathcal{P}$ of B. In each iteration, we do a BFS through the lattice, which has $O(N)$ time complexity[2] since the lattice size is linear in N and BFS is linear in the lattice size. Hence the running time is $\leq 2^{|B|} \cdot O(N) = O(N)$. Even though this shows that MinTagPath can be solved in polynomial time, the time complexity is prohibitively large. For the Penn Treebank, $K = 45$ and the

[1] If K, the size of the tagset, is a variable as well, then we suspect the problem is NP-hard.

[2] Including throwing away edges or not.

worst case running time would be $\approx 10^{13.55} \cdot N$. Clearly, for all practical purposes, this approach is intractable.

5 Greedy Model Minimization

We do not know of an efficient, exact algorithm to solve the MinTagPath problem. Therefore, we present a simple and fast two-stage greedy approximation scheme. Notice that an optimal path P (or any path) *covers* all the input words i.e., every word token w_i has one of its possible taggings in P. Exploiting this property, in the first phase, we set our goal to cover all the word tokens using the least possible number of tag bigrams. This can be cast as a set cover problem (Garey and Johnson, 1979) and we use the set cover greedy approximation algorithm in this stage. The output tag bigrams from this phase might still not allow any path from $C_{0,0}$ to $C_{N+1,K+1}$. So we carry out a second phase, where we greedily add a few tag bigrams until a path is created.

5.1 Phase 1: Greedy Set Cover

In this phase, our goal is to cover all the word tokens using the least number of tag bigrams. The covering problem is exactly that of set cover. Let $U = \{w_0, \ldots, w_N + 1\}$ be the set of elements that needs to be covered (in this case, the word tokens). For each tag bigram $(T_i, T_j) \in B$, we define its corresponding covering set S_{T_i,T_j} as follows:

$$\begin{aligned} S_{T_i,T_j} \;=\; \{w_n \;:\; & ((w_n, T_i) \in D \\ & \wedge (C_{n,i}, C_{n+1,j}) \in E \\ & \wedge l(C_{n,i}, C_{n+1,j}) = (T_i, T_j)) \\ \bigvee \; & ((w_n, T_j) \in D \\ & \wedge (C_{n-1,i}, C_{n,j}) \in E \\ & \wedge l(C_{n-1,i}, C_{n,j}) = (T_i, T_j))\} \end{aligned}$$

Let the set of covering sets be X. We assign a cost of 1 to each covering set in X. The goal is to select a set $CHOSEN \subseteq X$ such that $\bigcup_{S_{T_i,T_j} \in CHOSEN} = U$, minimizing the total cost of $CHOSEN$. This corresponds to covering all the words with the least possible number of tag bigrams. We now use the greedy approximation algorithm for set cover to solve this problem. The pseudo code is shown in Algorithm 2.

Algorithm 2 Set Cover : Phase 1

```
Definitions
Define $CAND$ : Set of candidate covering sets in the current iteration
Define $U_{rem}$ : Number of elements in $U$ remaining to be covered
Define $E_{S_{T_i,T_j}}$ : Current effective cost of a set
Define $Itr$ : Iteration number

Initializations
LET $CAND = X$
LET $CHOSEN = \emptyset$
LET $U_{rem} = U$
LET $Itr = 0$
LET $E_{S_{T_i,T_j}} = \frac{1}{|S_{T_i,T_j}|}, \forall\ S_{T_i,T_j} \in CAND$

while $U_{rem} \neq \emptyset$ do
  $Itr \leftarrow Itr + 1$
  Define $\hat{S}_{Itr} = \underset{S_{T_i,T_j} \in CAND}{\text{argmin}} E_{S_{T_i,T_j}}$
  $CHOSEN = CHOSEN \bigcup \hat{S}_{Itr}$
  Remove $\hat{S}_{Itr}$ from $CAND$
  Remove all the current elements in $\hat{S}_{Itr}$ from $U_{rem}$
  Remove all the current elements in $\hat{S}_{Itr}$ from every $S_{T_i,T_j} \in CAND$
  Update effective costs, $\forall\ S_{T_i,T_j} \in CAND$, $E_{S_{T_i,T_j}} = \frac{1}{|S_{T_i,T_j}|}$
end while
return $CHOSEN$
```

For the graph shown in Figure 1, here are a few possible covering sets S_{T_i,T_j} and their initial effective costs $E_{S_{T_i,T_j}}$.

- $S_{T_0,T_1} = \{w_0, w_1\}$, $E_{S_{T_0,T_1}} = 1/2$
- $S_{T_1,T_2} = \{w_1, w_2, w_3, w_4\}$, $E_{S_{T_1,T_2}} = 1/4$
- $S_{T_2,T_2} = \{w_2, w_3, w_4\}$, $E_{S_{T_2,T_2}} = 1/3$

In every iteration Itr of Algorithm 2, we pick a set $\hat{S}_{Itr}$ that is most cost effective. The elements that $\hat{S}_{Itr}$ covers are then removed from all the remaining candidate sets and U_{rem} and the effectiveness of the candidate sets is recalculated for the next iteration. The algorithm stops when all elements of U i.e., all the word tokens are covered. Let, $B_{CHOSEN} = \{(T_i, T_j) : S_{T_i,T_j} \in$

$CHOSEN\}$, be the set of tag bigrams that have been chosen by set cover. Now, we check, using BFS, if there exists a path from $C_{0,0}$ to $C_{N+1,K+1}$ using only the tag bigrams in B_{CHOSEN}. If not, then we have to add tag bigrams to B_{CHOSEN} to enable a path. To accomplish this, we carry out the second phase of this scheme with another greedy strategy (described in the next section).

For the example graph in Figure 1, one possible solution $B_{CHOSEN} = \{(T_0, T_1), (T_1, T_2), (T_2, T_4)\}$.

5.2 Phase 2: Greedy Path Completion

We define a graph $G_{CHOSEN}(V', E') \subseteq G(V, E)$ that contains the edges $e \in E$ such $l(e) \in B_{CHOSEN}$.

Let $B_{CAND} = B \setminus B_{CHOSEN}$, be the current set of candidate tag bigrams that can be added to the final solution which would create a path. We would like to know how many *holes* a particular tag bigram (T_i, T_j) can fill. We define a hole as an edge e such that $e \in G \setminus G_{CHOSEN}$ and there exists $e', e'' \in G_{CHOSEN}$ such that $tail(e') = head(e) \wedge tail(e) = head(e'')$.

Figure 2 illustrates the graph G_{CHOSEN} using tag bigrams from the example solution to Phase 1 (Section 5.1). The dotted edge $(C_{2,2}, C_{3,1})$ represents a hole, which has to be filled in the current phase in order to complete a path from $C_{0,0}$ to $C_{5,4}$.

In Algorithm 3, we define the effectiveness of a candidate tag bigram $H(T_i, T_j)$ to be the number of holes it covers. In every iteration, we pick the most effective tag bigram, fill the holes and recalculate the effectiveness of the remaining candidate tag bigrams.

Algorithm 3 returns B_{FINAL}, the final set of chosen tag bigrams. It terminates when a path has been found.

Algorithm 3 Greedy Path Complete : Phase 2

```
Define $B_{FINAL}$ : Final set of tag bigrams selected by the two-phase greedy approach

LET $B_{FINAL} = B_{CHOSEN}$
LET $H(T_i, T_j) = |\{e\}|$ such that $l(e) = (T_i, T_j)$ and $e$ is a hole, $\forall\ (T_i, T_j) \in B_{CAND}$

while $\nexists$ path $P$ from $C_{0,0}$ to $C_{N+1,K+1}$ using only $(T_i, T_j) \in B_{CHOSEN}$ do
  Define $(\hat{T_i}, \hat{T_j}) = \underset{(T_i,T_j) \in B_{CAND}}{\text{argmax}} H(T_i, T_j)$
  $B_{FINAL} = B_{FINAL} \bigcup (\hat{T_i}, \hat{T_j})$
  Remove $(\hat{T_i}, \hat{T_j})$ from $B_{CAND}$
  $G_{CHOSEN} = G_{CHOSEN} \bigcup \{e\}$ such that $l(e) = (T_i, T_j)$
  $\forall\ (T_i, T_j) \in B_{CAND}$, Recalculate $H(T_i, T_j)$
end while
return $B_{FINAL}$
```

5.3 Fitting the Model

Once the greedy algorithm terminates and returns a minimized grammar of tag bigrams, we follow the approach of Ravi and Knight (2009) and fit the minimized model to the data using the alternating EM strategy. The alternating EM iterations are terminated when the change in the size of the observed grammar (i.e., the number of unique tag bigrams in the tagging output) is $\leq 5\%$. We refer to our entire approach using greedy minimization followed by EM training as MIN-GREEDY.

6 Experiments and Results

6.1 English POS Tagging

Data: We use a standard test set (consisting of 24,115 word tokens from the Penn Treebank) for the POS tagging task (described in Section 1). The tagset consists of 45 distinct tag labels and the dictionary contains 57,388 word/tag pairs derived from the entire Penn Treebank. Per-token ambiguity for the test data is about 1.5 tags/token. In addition to the standard 24k dataset, we also train and test on larger data sets of 48k, 96k, 193k, and the entire Penn Treebank (973k).

Methods: We perform comparative evaluations for POS tagging using three different methods:

1. **EM**: Training a bigram HMM model using EM algorithm.

2. **IP**: Minimizing grammar size using integer programming, followed by EM training (Ravi and Knight, 2009).

3. **MIN-GREEDY**: Minimizing grammar size using the Greedy method described in Sec-

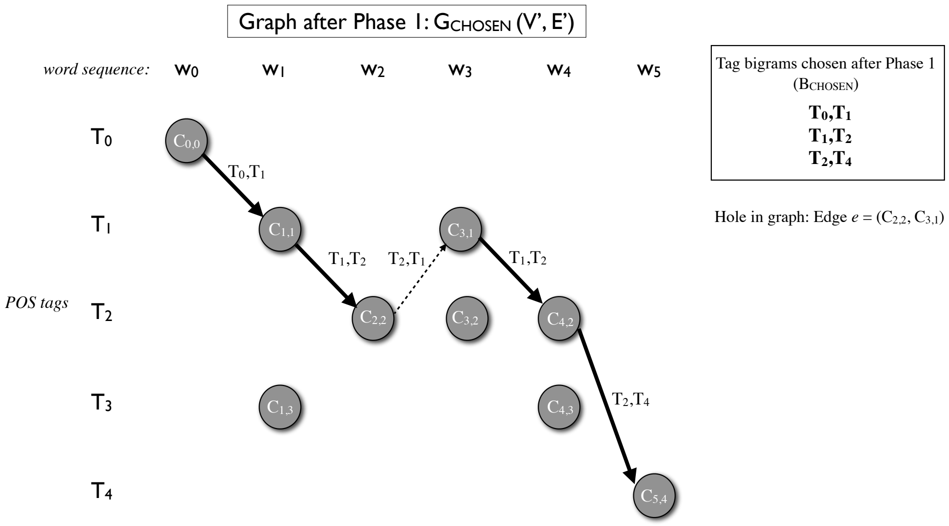

Figure 2: Graph constructed with tag bigrams chosen in Phase 1 of the MIN-GREEDY method.

tion 5, followed by EM training.

Results: Figure 3 shows the tagging performance (word token accuracy %) achieved by the three methods on the standard test (24k tokens) as well as Penn Treebank test (PTB = 973k tokens). On the 24k test data, the MIN-GREEDY method achieves a high tagging accuracy comparable to the previous best from the IP method. However, the IP method does not scale well which makes it infeasible to run this method in a much larger data setting (the entire Penn Treebank). MIN-GREEDY on the other hand, faces no such problem and in fact it achieves high tagging accuracies on all four datasets, consistently beating EM by significant margins. When tagging all the 973k word tokens in the Penn Treebank data, it produces an accuracy of 87.1% which is much better than EM (82.3%) run on the same data.

Ravi and Knight (2009) mention that it is possible to interrupt the IP solver and obtain a suboptimal solution faster. However, the IP solver did not return any solution when provided the same amount of time as taken by MIN-GREEDY for any of the data settings. Also, our algorithms were implemented in Python while the IP method employs the best available commercial software package (CPLEX) for solving integer programs.

Figure 4 compares the running time efficiency for the IP method versus MIN-GREEDY method as we scale to larger datasets. Since the IP solver shows variations in running times for different datasets of the same size, we show the average running times for both methods (for each row in the figure, we run a particular method on three different datasets with similar sizes and average the running times). The figure shows that the greedy approach can scale comfortably to large data sizes, and a complete run on the entire Penn Treebank data finishes in just 1485 seconds. In contrast, the IP method does not scale well—on average, it takes 93 seconds to finish on the 24k test (versus 34 seconds for MIN-GREEDY) and on the larger PTB test data, the IP solver runs for

Test set	**Efficiency** (average running time in secs.)	
	IP	MIN-GREEDY
24k test	93.0	34.3
48k test	111.7	64.3
96k test	397.8	93.3
193k test	2347.0	331.0
PTB (973k) test	*	1485.0

Figure 4: Comparison of MIN-GREEDY versus MIN-GREEDY approach in terms of *efficiency* (average running time in seconds) for different data sizes. All the experiments were run on a single machine with a 64-bit, 2.4 GHz AMD Opteron 850 processor.

Method	**Tagging accuracy (%)** when training & testing on:				
	24k	*48k*	*96k*	*193k*	*PTB (973k)*
EM	81.7	81.4	82.8	82.0	82.3
IP	91.6	89.3	89.5	91.6	*
MIN-GREEDY	91.6	88.9	89.4	89.1	87.1

Figure 3: Comparison of tagging accuracies on test data of varying sizes for the task of unsupervised English POS tagging with a dictionary using a 45-tagset. *(* IP method does not scale to large data).*

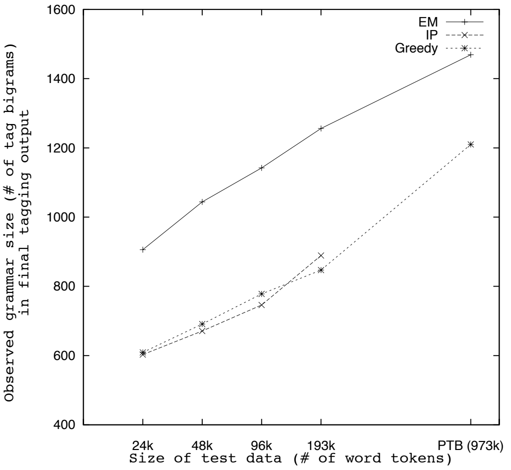

Figure 5: Comparison of observed grammar size (# of tag bigram types) in the final tagging output from EM, IP and MIN-GREEDY.

more than 3 hours without returning a solution.

It is interesting to see that for the 24k dataset, the greedy strategy finds a grammar set (containing only 478 tag bigrams). We observe that MIN-GREEDY produces 452 tag bigrams in the first minimization step (phase 1), and phase 2 adds another 26 entries, yielding a total of 478 tag bigrams in the final minimized grammar set. That is almost as good as the optimal solution (459 tag bigrams from IP) for the same problem. But MIN-GREEDY clearly has an advantage since it runs much faster than IP (as shown in Figure 4). Figure 5 shows a plot with the size of the observed grammar (i.e., number of tag bigram types in the final tagging output) versus the size of the test data for EM, IP and MIN-GREEDY methods. The figure shows that unlike EM, the other two approaches reduce the grammar size considerably and we observe the same trend even when scaling to larger data. Minimizing the grammar size helps remove many spurious tag combinations from the grammar set, thereby yielding huge improvements in tagging accuracy over the EM method (Figure 3). We observe that for the 193k dataset, the final observed grammar size is greater for IP than MIN-GREEDY. This is because the alternating EM steps following the model minimization step add more tag bigrams to the grammar.

Test set	**Average Speedup**	**Optimality Ratio**
24k test	2.7	0.96
48k test	1.7	0.98
96k test	4.3	0.98
193k test	7.1	0.93

Figure 6: *Average speedup* versus *Optimality ratio* computed for the model minimization step (when using MIN-GREEDY over IP) on different datasets.

We compute the optimality ratio of the MIN-GREEDY approach with respect to the grammar size as follows:

$$\text{Optimality ratio} \quad = \quad \frac{\text{Size of IP grammar}}{\text{Size of MIN-GREEDY grammar}}$$

A value of 1 for this ratio implies that the solution found by MIN-GREEDY algorithm is exact. Figure 6 compares the optimality ratio versus average speedup (in terms of running time) achieved in the minimization step for the two approaches. The figure illustrates that our solution is nearly optimal for all data settings with significant speedup.

The MIN-GREEDY algorithm presented here can also be applied to scenarios where the dictionary is incomplete (i.e., entries for all word types are not present in the dictionary) and rare words

Method	Tagging accuracy (%)	Number of unique tag bigrams in final tagging output
EM	83.4	1195
IP	88.0	875
MIN-GREEDY	88.0	880

Figure 7: Results for unsupervised Italian POS tagging with a dictionary using a set of 90 tags.

take on all tag labels. In such cases, we can follow a similar approach as Ravi and Knight (2009) to assign tag possibilities to every unknown word using information from the known word/tag pairs present in the dictionary. Once the completed dictionary is available, we can use the procedure described in Section 5 to minimize the size of the grammar, followed by EM training.

6.2 Italian POS Tagging

We also compare the three approaches for Italian POS tagging and show results.

Data: We use the Italian CCG-TUT corpus (Bos et al., 2009), which contains 1837 sentences. It has three sections: newspaper texts, civil code texts and European law texts from the JRC-Acquis Multilingual Parallel Corpus. For our experiments, we use the POS-tagged data from the CCG-TUT corpus, which uses a set of 90 tags. We created a tag dictionary consisting of 8,733 word/tag pairs derived from the entire corpus (42,100 word tokens). We then created a test set consisting of 926 sentences (21,878 word tokens) from the original corpus. The per-token ambiguity for the test data is about 1.6 tags/token.

Results: Figure 7 shows the results on Italian POS tagging. We observe that MIN-GREEDY achieves significant improvements in tagging accuracy over the EM method and comparable to IP method. This also shows that the idea of model minimization is a general-purpose technique for such applications and provides good tagging accuracies on other languages as well.

7 Conclusion

We present a fast and efficient two-stage greedy minimization approach that can replace the integer programming step in (Ravi and Knight, 2009). The greedy approach finds close-to-optimal solutions for the minimization problem. Our algorithm runs much faster and achieves accuracies close to state-of-the-art. We also evaluate our method on test sets of varying sizes and show that our approach outperforms standard EM by a significant margin. For future work, we would like to incorporate some linguistic constraints within the greedy method. For example, we can assign higher costs to unlikely tag combinations (such as "SYM SYM", etc.).

Our greedy method can also be used for solving other unsupervised tasks where model minimization using integer programming has proven successful, such as word alignment (Bodrumlu et al., 2009).

Abstract

Active learning has been applied to different NLP tasks, with the aim of limiting the amount of time and cost for human annotation. Most studies on active learning have only simulated the annotation scenario, using prelabelled gold standard data. We present the first active learning experiment for Word Sense Disambiguation with human annotators in a realistic environment, using fine-grained sense distinctions, and investigate whether AL can reduce annotation cost and boost classifier performance when applied to a real-world task.

1 Introduction

Active learning has recently attracted attention as having the potential to overcome the knowledge acquisition bottleneck by limiting the amount of human annotation needed to create training data for statistical classifiers. Active learning has been shown, for a number of different NLP tasks, to reduce the number of manually annotated instances needed for obtaining a consistent classifier performance (Hwa, 2004; Chen et al., 2006; Tomanek et al., 2007; Reichart et al., 2008).

The majority of such results have been achieved by simulating the annotation scenario using prelabelled gold standard annotations as a stand-in for real-time human annotation. Simulating annotation allows one to test different parameter settings without incurring the cost of human annotation. There is, however, a major drawback: we do not know whether the results of experiments performed using hand-corrected data carry over to real-world scenarios in which individual human annotators produce noisy annotations. In addition, we do not know to what extent error-prone annotations mislead the learning process. A systematic study of the impact of erroneous annotation on classifier performance in an active learning (AL) setting is overdue. We need to know a) whether the AL approach can really improve classifier performance and save annotation time when applied in a real-world scenario with noisy data, and b) whether AL works for classification tasks with fine-grained or complex annotation schemes and a low inter-annotator agreement.

In this paper we bring active learning to life in the context of frame semantic annotation of German texts within the SALSA project (Burchardt et al., 2006). Specifically, we apply AL methods for learning to assign semantic frames to predicates, following Erk (2005) in treating frame assignment as a Word Sense Disambiguation task. Under our fine-grained annotation scheme, annotators have to deal with a high level of ambiguity, resulting in low inter-annotator agreement for some word senses. This fact, along with the potential for wrong annotation decisions or possible biases from individual annotators, results in an annotation environment in which we get noisy data which might mislead the classifier. A second characteristic of our scenario is that there is no gold standard for the newly annotated data, which means that evaluation is not straightforward. Finally, we have multiple annotators whose decisions on particular instances may diverge, raising the question of which annotations should be used to guide the AL process. This paper thus investigates whether active learning can be successfully applied in a real-world scenario with the particular challenges described above.

Section 2 of the paper gives a short overview of the AL paradigm and some related work, and Section 3 discusses the multi-annotator scenario. In Section 4 we present our experimental design and describe the data we use. Section 5 presents results, and Section 6 concludes.

2 Active Learning

The active learning approach aims to reduce the amount of manual annotation needed to create training data sufficient for developing a classifier with a given performance. At each iteration of the AL cycle, the actual knowledge state of the learner guides the learning process by determining which instances are chosen next for annotation. The main goal is to advance the learning process by selecting instances which provide important information for the machine learner.

In a typical active learning scenario, a small set of manually labelled seed data serves as the initial training set for the classifier (learner). Based on the predictions of the classifier, a large pool of unannotated instances is queried for the next instance (or batch of instances) to be presented to the human annotator (sometimes called the oracle). The underlying active learning algorithm controlling the learning process tries to select the most informative instances in order to get a strong boost in classifier performance. Different methods can be used for determining informativity of instances. We use uncertainty sampling (Cohn et al., 1995) in which "most informative" instances are those for which the classifier has the lowest confidence in its label predictions. The rough intuition behind this selection method is that it identifies instance types which have yet to be encountered by the classifier. The learning process proceeds by presenting the selected instances to the human annotator, who assigns the correct label. The newly-annotated instances are added to the seed data and the classifier is re-trained on the new data set. The newly trained classifier now picks the next instances, based on its updated knowledge, and the process repeats. If the learning process can provide precisely that information which the classifier still needs to learn, a smaller number of instances should suffice to achieve the same accuracy as on a larger training set of randomly selected training examples.

Active learning has been applied to a number of natural language processing tasks like POS tagging (Ringger et al., 2007), NER (Laws and Schütze, 2008; Tomanek and Hahn, 2009), syntactic parsing (Osborne and Baldridge, 2004; Hwa, 2004), Word Sense Disambiguation (Chen et al., 2006; Chan and Ng, 2007; Zhu and Hovy, 2007; Zhu et al., 2008) and morpheme glossing for language documentation (Baldridge and Palmer, 2009). While most of these studies successfully show that the same classification accuracy can be achieved with a substantially smaller data set, these findings are mostly based on simulations using gold standard data.

For our task of Word Sense Disambiguation (WSD), mixed results have been achieved. AL seems to improve results in a WSD task with coarse-grained sense distinctions (Chan and Ng, 2007), but the results of (Dang, 2004) raise doubts as to whether AL can successfully be applied to a fine-grained annotation scheme, where Inter-Annotator Agreement (IAA) is low and thus the consistency of the human annotations decreases. In general, AL has been shown to reduce the cost of annotation when applied to classification tasks where a single human annotator predicts labels for new data points with a reasonable consistency and accuracy. It is not clear whether the same settings can be applied to a multi-annotator environment where IAA is low.

3 Active Learning in a realistic task including multiple annotators

Another possible difference between active learning simulations and real-world scenarios is the multi-annotator environment. In such a setting, two or more annotators assign labels to the same instances, which are then merged to check for conflicting decisions from different annotators. This is standard practise in many annotation projects doing fine-grained semantic annotation with a high level of ambiguity, and it necessitates that all annotators work on the same data set.

Replicating an active learning simulation on hand-corrected data, starting with a fixed set of seed data and fixed parameter settings, using the same algorithm, will always result in the same training set selected from the pool. Human annotators, however, will assign different labels to the same instances, thus influencing the selection of the next instance from the pool. This means that individual annotators might end up with very different sets of annotated data, depending on factors like their interpretation of the annotation guidelines, an implicit bias towards a particular label, or simply errors made during annotation.

There is not much work addressing this problem. (Donmez and Carbonell, 2008) consider modifications of active learning to accommodate variability of annotators. (Baldridge and Palmer, 2009) present a real-world study with human annotators in the context of language documentation. The task consists of producing interlinear glossed text, including morphological and grammatical analysis, and can be described as a sequence labelling task. Annotation cost is measured as the actual time needed for annotation. Among other settings, the authors compare the performance of two annotators with different grades of expertise. The classifier trained on the data set created by the expert annotator in an active learning setting does obtain a higher accuracy on the gold standard. For the non-expert annotator, however, the active learning setting resulted in a lower accuracy than for a classifier trained on a randomly selected data set. This finding suggests that the quality of annotation needs to be high enough for active learning to actually work, and that annotation noise is a problem for AL.

There are two problems arising from this:

1. It is not clear whether active learning will work when applied to noisy data
2. It is not straightforward to apply active learning to a real-world scenario, where low IAA asks for multiple annotators

In our experiment we address these questions by systematically investigating the impact of annotation noise on classifier performance and on the composition of the training set. The next section presents the experimental design and the data used in our experiment.

4 Experimental Design

In the experiment we annotated 8 German causation nouns, namely *Ausgang, Anlass, Ergebnis, Resultat, Grund, Konsequenz, Motiv, Quelle* (outcome, occasion, effect, result, reason, consequence, motive, source of experience). These nouns were chosen because they exhibit a range of difficulty in terms of the number of senses they have in our annotation scheme. They all encode subtle distinctions between different word senses, but some of them are clearly easier to disambiguate than others. For instance, although *Ausgang* has 9 senses, they are easier to distinguish for humans than the 4 senses of *Konsequenz*.

Six annotators participated in the experiment. While all annotators were trained, having at least one year experience in frame-semantic annotation, one of the annotators is an expert with several years of training and working experience in the Berkeley FrameNet Project. This annotator also defined the frames (word senses) used in our experiment.

Prior to the experiment, all annotators were given 100 randomly chosen sentences. After annotating the training data, problematic cases were discussed to make sure that the annotators were familiar with the fine-grained distinctions between word senses in the annotation scheme. The data sets used for training were adjudicated by two of the annotators (one of them being the expert) and then used as a gold standard to test classifier performance in the active learning process.

4.1 Data and Setup

For each lemma we extracted sentences from the Wahrig corpus[1] containing this particular lemma. The annotators had to assign word senses to 300 instances for each target word, split into 6 packages of 50 sentences each. This resulted in 2,400 annotated instances per annotator (14,400 annotated instances in total). The annotation was done

[1] The Wahrig corpus includes more than 113 mio. sentences from German newspapers and magazines covering topics such as politics, science, fashion, and others.

Table 1: 8 causation nouns and their word senses (numbers in brackets give the distribution of word senses in the gold standard (100 sentences); CXN: constructions, MWE: multi-word expressions; note that Ergebnis and Resultat are synonyms and therefore share the same set of frames.)

using a Graphical User Interface where the sentence was presented to the annotator, who could choose between all possible word senses listed in the GUI. The annotators could either select the frame by mouse click or use keyboard shortcuts. For each instance we recorded the time it took the annotator to assign an appropriate label. To ease the reading process the target word was highlighted.

As we want to compare time requirements needed for annotating random samples and sentences selected by active learning, we had to control for training effects which might speed up the annotation. Therefore we changed the annotation setting after each package, meaning that the first annotator started with 50 sentences randomly selected from the pool, then annotated 50 sentences selected by AL, followed by another 50 randomly chosen sentences, and so on. We divided the annotators into two groups of three annotators each. The first group started annotating in the random setting, the second group in the AL setting. The composition of the groups was changed for each lemma, so that each annotator experienced all different settings during the annotation process. The annotators were not aware of which setting they were in.

Pool data For the random setting we randomly selected three sets of sentences from the Wahrig corpus which were presented for annotation to all six annotators. This allows us to compare annotation time and inter-annotator agreement between the annotators. For the active learning setting we randomly selected three sets of 2000 sentences each, from which the classifier could pick new instances during the annotation process. This means that for each trial the algorithm could select 50 instances out of a pool of 2000 sentences. On any given AL trial each annotator uses the same pool as all the other annotators. In an AL simulation with fixed settings and gold standard labels this would result in the same subset of sentences selected by the classifier. For our human annotators, however, due to different annotation decisions the resulting set of sentences is expected to differ.

Sampling method Uncertainty sampling is a standard sampling method for AL where new instances are selected based on the confidence of the classifier for predicting the appropriate label. During early stages of the learning process when the classifier is trained on a very small seed data set, it is not beneficial to add the instances with the lowest classifier confidence. Instead, we use a dynamic version of uncertainty sampling (Rehbein and Ruppenhofer, 2010), based on the confidence of a maximum entropy classifier[2], taking into account how much the classifier has learned so far. In each iteration one new instance is selected from the pool and presented to the oracle. After annotation the classifier is retrained on the new data set. The modified uncertainty sampling results in a more robust classifier performance during early stages of the learning process.

5 Results

The basic idea behind active learning is to select the most informative instances for annotation. The intuition behind "more informative" is that these instances support the learning process, so we might need fewer annotated instances to achieve a comparable classifier performance, which could decrease the cost of annotation. On the other hand, "more informative" also means that these instances might be more difficult to annotate, so it is only fair to assume that they might need more time for annotation, which increases annotation cost. To answer the question of whether AL reduces annotation cost or not we have to check a) how long it took the annotators to assign labels to the AL samples compared to the randomly selected instances, and b) how many instances we need to achieve the best (or a sufficient) performance in each setting. Furthermore, we want to investigate the impact of active learning on the distribution of the resulting training sets and study the correlation between the performance of the classifier trained on the annotated data and these factors: the difficulty of the annotation task (assessed by IAA), expertise and individual properties of the annotators.

5.1 Does AL speed up the annotation process when working with noisy data?

Table 2 reports annotation times for each annotator and target for random sampling (R) and uncertainty sampling (U). For 5 out of 8 targets the time needed for annotating in the AL setting (averaged over all annotators) was higher than for annotating the random samples. To investigate whether this might be due to the length of the sentences in the samples, Table 2 shows the average sentence length for random samples and AL samples for each target lemma. Overall, the sentences selected by the classifier during AL are longer (26.2 vs. 28.1 token per sentence), and thus may take the annotators more time to read.[3] However, we could not find a significant correlation (Spearman rank correlation test) between sentence length and annotation time, nor between sentence length and classifier confidence.

The three target lemmas which took longer to annotate in the random setting are *Ergebnis* (result), *Grund* (reason) and *Quelle* (source of experience). This observation cannot be explained by sentence length. While sentence length for *Ergebnis* is nearly the same in both settings, for *Grund* and *Quelle* the sentences picked by the classifier in the AL setting are significantly longer and therefore should have taken more time to annotate. To understand the underlying reason for this we have to take a closer look at the distribution of word senses in the data.

5.2 Distribution of word senses in the data

In the literature it has been stated that AL implicitly alleviates the class imbalance problem by extracting more balanced data sets, while random sampling tends to preserve the sense distribution present in the data (Ertekin et al., 2007). We could not replicate this finding when using noisy data to guide the learning process. Table 3 shows the distribution of word senses for the target lemma *Ergebnis* a) in the gold standard, b) in the random samples, and c) in the AL samples.

The variance in the distribution of word senses in the random samples and the gold standard can

[3] The correlation between sentence length and annotation time is not obvious, as the annotators only have to label one target in each sentence. For ambiguous sentences, however, reading time may be longer, while for the clear cases we do not expect a strong effect.

Table 4: Avg. classifier performance (acc.) over all annotators for the 8 target lemmas when training on 50, 100 and 150 annotated instances for random samples and uncertainty samples

be explained by low inter-annotator agreement caused by the high level of ambiguity for the target lemmas. The frame distribution in the data selected by uncertainty sampling, however, crucially deviates from those of the gold standard and the random samples. A disproportionately high 66% of the instances selected by the classifier have been assigned the label Operating_result by the human annotators. This is the more surprising as this frame is fairly easy for humans to distinguish.

The classifier, however, proved to have serious problems learning this particular word sense and thus repeatedly selected more instances of this frame for annotation. As a result, the distribution of word senses in the training set for the uncertainty samples is highly skewed, having a negative effect on the overall classifier performance. The high percentage of instances of the "easy-to-decide" frame Operating_result explains why the instances for *Ergebnis* took less time to annotate in the AL setting. Thus we can conclude that annotating the same number of instances on average takes more time in the AL setting, and that this effect is not due to sentence length.

5.3 What works, what doesn't, and why

For half of the target lemmas *(Motiv, Konsequenz, Quelle, Ausgang),* we did obtain best results in the AL setting (Table 4). For *Ausgang* and *Motiv* AL gives a substantial boost in classifier performance of 5% and 7% accuracy, while the gains for *Konsequenz* and *Quelle* are somewhat smaller with 2% and 1%, and for *Grund* the highest accuracy was reached on both the AL and the random sample.

Figure 1 (top row) shows the learning curves for *Resultat*, our worst-performing lemma, for the classifier trained on the manually annotated samples for each individual annotator. The solid black line represents the majority baseline, obtained by assigning the most frequent word sense in the gold standard to all instances. For both random and AL settings, results are only slightly above the baseline. The curves for the AL setting show how erroneous decisions can mislead the classifier, resulting in classifier accuracy below the baseline for two of the annotators, while the learning curves for these two annotators on the random samples show the same trend as for the other 4 annotators.

For *Konsequenz* (Figure 1, middle), the classifier trained on the AL samples yields results over the baseline after around 25 iterations, while in the random sampling setting it takes at least 100 iterations to beat the baseline. For *Motiv* (Figure 1, bottom row), again we observe far higher results in the AL setting. A possible explanation for why AL seems to work for *Ausgang, Motiv* and *Quelle* might be the higher IAA[4] (κ 0.825, 0.789, 0.768) as compared to the other target lemmas. This, however, does not explain the good results achieved on the AL samples for *Konsequenz,* for which IAA was quite low with κ 0.554.

Also startling is the fact that AL seems to work particularly well for one of the annotators (A_6, Figure 1) but not for others. Different possible explanations come to mind: (a) the accuracy of the annotations for this particular annotator, (b) the

[4] IAA was computed on the random samples, as the AL samples do not include the same instances.

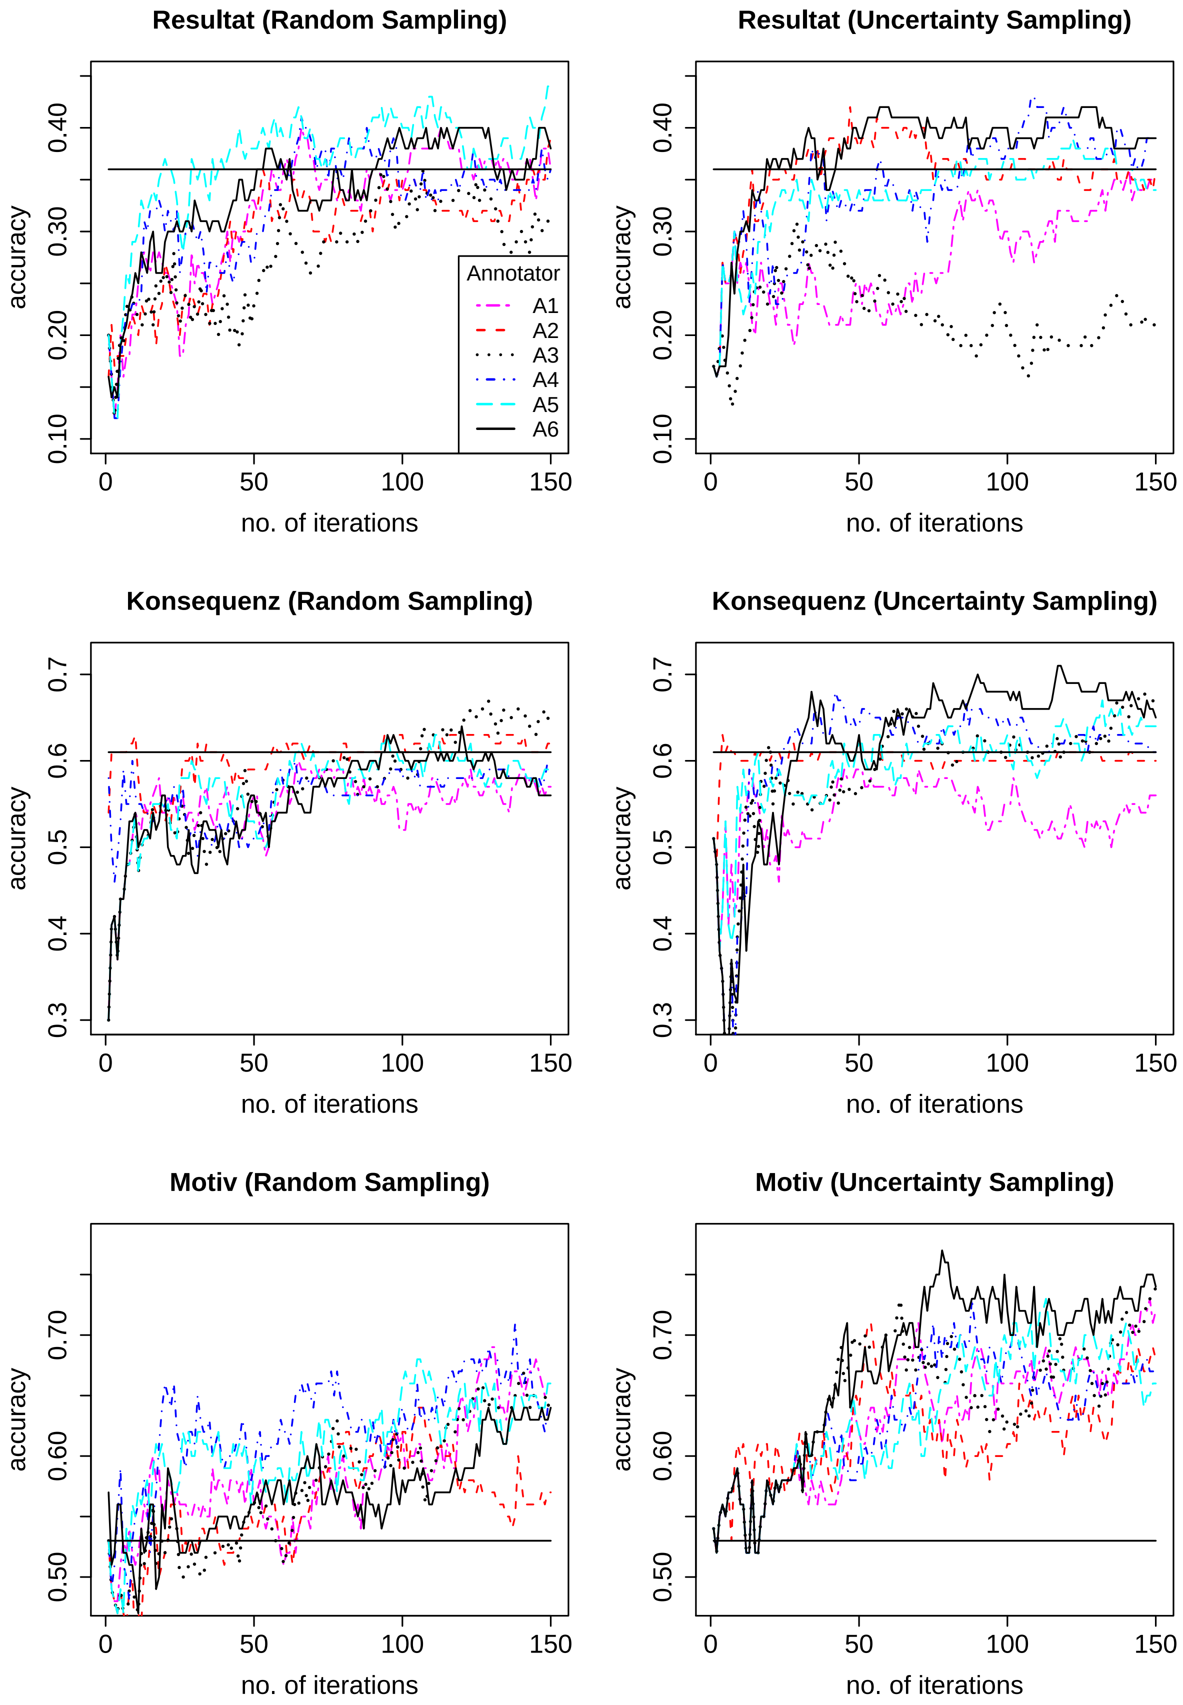

Figure 1: Active learning curves for Resultat, Konsequenz and Motiv (random sampling versus uncertainty sampling; the straight black line shows the majority baseline)

Konsequenz	A1	A2	A3	A4	A5	A6
human	0.80	0.72	0.89	0.73	0.89	0.76
maxent	0.60	0.63	0.67	0.60	0.63	0.64

Table 5: Acc. for human annotators against the adjudicated random samples and for the classifier

instances selected by the classifier based on the annotation decisions of the individual annotators, and (c) the distribution of frames in the annotated training sets for the different annotators.

To test (a) we evaluated the annotated random samples for *Konsequenz* for each annotator against the adjudicated gold standard. Results showed that there is no strong correlation between the accuracy of the human annotations and the performance of the classifier trained on these annotations. The annotator for whom AL worked best had a medium score of 0.76 only, while the annotator whose annotations were least helpful for the classifier showed a good accuracy of 0.80 against the gold standard.

Next we tested (b) the impact of the particular instances in the AL samples for the individual annotators on classifier performance. We took all instances in the AL data set from A_6, whose annotations gave the greatest boost to the classifier, removed the frame labels and gave them to the remaining annotators for re-annotation. Then we trained the classifier on each of the re-annotated samples and compared classifier performance. Results for 3 of the remaining annotators were in the same range or even higher than the ones for A_6 (Figure 2). For 2 annotators, however, results remained far below the baseline.

This again shows that the AL effect is not directly dependent on the accuracy of the individual annotators, but that particular instances are more informative for the classifier than others. Another crucial point is (c) the distribution of frames in the samples. In the annotated samples for A_1 and A_2 the majority frame for *Konsequenz* is Causation, while in the samples for the other annotators Response was more frequent. In our test set Response also is the most frequent frame, therefore it is not surprising that the classifiers trained on the samples of A_3 to A_6 show a higher performance. This means that high-quality annotations (identified by IAA) do not necessarily provide the information from which the classifier benefits most, and that in a realistic annotation task addressing the class imbalance problem (Zhu and Hovy, 2007) is crucial.

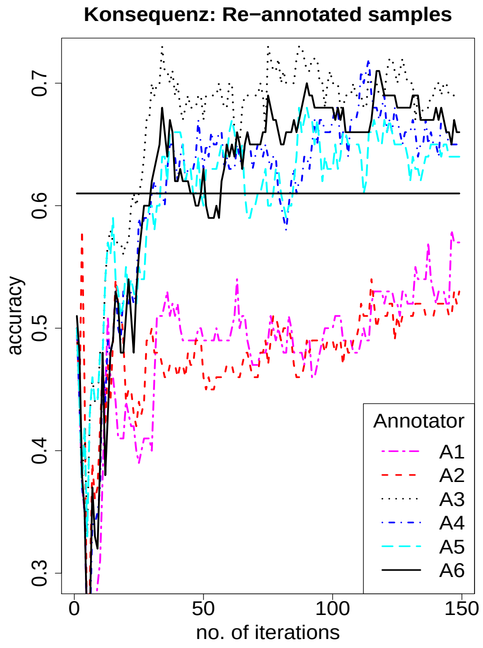

Figure 2: Re-annotated instances for Konsequenz (AL samples from annotator A_6)

6 Conclusions

We presented the first experiment applying AL in a real-world scenario by integrating the approach in an ongoing annotation project. The task and annotation environment pose specific challenges to the AL paradigm. We showed that annotation noise caused by biased annotators as well as erroneous annotations mislead the classifier and result in skewed data sets, and that for this particular task no time savings are to be expected when applied to a realistic scenario. Under certain conditions, however, classifier performance can improve over the random sampling baseline even on noisy data and thus yield higher accuracy in the active learning setting. Critical features which seem to influcence the outcome of AL are the amount of noise in the data as well as the distribution of frames in training- and test sets. Therefore, addressing the class imbalance problem is crucial for applying AL to a real annotation task.

Computing EM-based Alignments of Routes and Route Directions as a Basis for Natural Language Generation

Michael Roth and **Anette Frank**
Department of Computational Linguistics
Heidelberg University
{mroth,frank}@cl.uni-heidelberg.de

Abstract

Route directions are natural language (NL) statements that specify, for a given navigational task and an automatically computed route representation, a sequence of actions to be followed by the user to reach his or her goal. A corpus-based approach to generate route directions involves (i) the selection of elements along the route that need to be mentioned, and (ii) the induction of a mapping from route elements to linguistic structures that can be used as a basis for NL generation.

This paper presents an Expectation-Maximization (EM) based algorithm that aligns geographical route representations with semantically annotated NL directions, as a basis for the above tasks. We formulate one basic and two extended models, the latter capturing special properties of the route direction task. Although our current data set is small, both extended models achieve better results than the simple model and a random baseline. The best results are achieved by a combination of both extensions, which outperform the random baseline and the simple model by more than an order of magnitude.

1 Introduction

The purpose of route directions is to inform a person, who is typically not familiar with his current environment, of how to get to a designated goal. Generating such directions poses difficulties on various conceptual levels such as planning the route, selecting landmarks (i.e., recognizable buildings or structures) and splitting the task into appropriate single instructions of how to navigate along the route using the selected landmarks as reference points.

Previously developed natural language generation (NLG) systems make use of simple heuristics for the task of content selection for route directions (Dale et al., 2005; Roth and Frank, 2009). In our work, we aim for a corpus-based approach that can be flexibly modeled after natural, human-produced directions for varying subtasks (e.g., indoor vs. outdoor navigation), and that facilitates multilingual extensions. By employing salient landmarks and allowing for variation in NL realization, such a system is expected to generate natural sounding directions that are easier to memorize and easier to follow than directions given by a classical route planner or navigation system.

NLG for route directions crucially differs from other generation tasks such as document summarization (Mani, 2001) in that the selection and ordering of input structures for language generation is heavily situation-dependent, i.e., dependent on the specific properties of a given route to be followed.

In line with a corpus-based NLG approach, we propose to automatically align geographical route representations as produced by a route planner with an annotated corpus of NL directions given by humans for the respective routes. The induced alignments will (i) serve to identify which elements of a route to select for verbalization, and (ii) deliver correspondences between route segments and linguistic input structures that can be used as a basis for statistical NL generation. We investi-

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 958–966,
Beijing, August 2010

gate a minimally supervised method for inducing such alignments to ensure maximal flexibility for adaptations to different scenarios.

The remainder of this paper is structured as follows: In Section 2 we discuss related work. Section 3 introduces the task, and the representation formats and resources we use. Section 4 introduces a basic Expectation-Maximization model and two extensions for the alignment task. Section 5 outlines the experiments and presents the evaluation results. In Section 6 we conclude and discuss future work.

2 Related Work

Various aspects of route directions have been subject of research in computational linguistics, ranging from instructional dialogues in MapTask (Anderson et al., 1991) to recent work on learning to follow route directions (Vogel and Jurafsky, 2010). However, little work has been done on generating NL directions based on data from Geographical Information Systems (Dale et al., 2005; Roth and Frank, 2009).

NLG systems are typically realized as pipeline architectures (Reiter and Dale, 2000). As a first step, they compute a set of messages that represent the information to be conveyed to a user, given a specific communicative task (*Content Selection*). Selecting appropriate content for a task can be defined heuristically, by manually crafted rules or by learning content selection rules automatically from corpus data. Previous work by Dale et al. (2005) and Roth and Frank (2009) on generating NL directions used hand-crafted heuristics. Duboue and McKeown (2003) were the first to model content selection as a machine learning task, in which selection rules are induced from pairs of human-written text and associated sets of database entries. They induce baseline selection rules from exact matches of NL expressions with database entries; in addition, class-based rules are computed by matching database entry types against NL expressions, using statistical co-occurrence clusters. Barzilay and Lapata (2005) incorporate the interplay between multiple events and entities when learning content selection rules using a special link function.

Recent work by Liang et al. (2009) focuses on modeling grounded language, by aligning real-world representations with NL text that references corresponding world states. They show how a generative model can be used to segment text into utterances and to identify relevant facts with minimal supervision. Both tasks are handled jointly in a unified framework by training a hierarchical semi-Markov model on pairs of text and world states, thereby modeling sequencing effects in the presentation of facts. While their work is not primarily concerned with NLG, the learned correspondences and their probabilities could be applied to induce content selection rules and linguistic mappings in a NLG task. The approach is shown to be effective in scenarios typical for NLG settings (weather forecasts, RoboCup sportscasting, NFL recaps) that differ in the amount of available data, length of textual descriptions, and density of alignments.

In the following, we will adapt ideas from their EM-based approach to align (segments of) route representations and NL route directions in a minimally supervised manner. We will investigate increasingly refined models that are tailored to the nature of our task and underlying representations. In particular, we extend their approach by exploiting semantic markup in the NL direction corpus.

3 Aligning Routes and Directions

In this work we explore the possibility of using an implementation of the EM algorithm (Dempster et al., 1977) to learn correspondences between (segments of) the geographical representation of a route and linguistic instructions of how to follow this route in order to arrive at a designated goal. We are specifically interested in identifying which parts of a route are realized in natural language and which kinds of semantic constructions are used to express them.

As a data source for inducing such correspondences we use a parallel corpus of route representations and corresponding route directions that were collected in a controlled experiment for navigation in an urban street network (cf. Schuldes et al. (2009)). For the alignment task, the routes were compiled to a specification format that has been realized in an internal version of an online route planner. Figure 1 displays the route rep-

Figure 1: A (partial) route representation of the route segment displayed on the right.

resentation for a small route segment (a junction connecting 'Hauptstraße' and 'Leyergasse'). The corresponding part of a NL route direction is displayed in Figure 2. The route representation and the NL direction share some common concepts: For example, both contain references to a landmark called "Sudpfanne" (marked as [1]) and a street named "Leyergasse" (marked as [2]). Using pairs of route representations and directions, we aim to automatically induce alignments between such correspondences. In the following we describe our data in more detail.

3.1 Route Representation Format

The route representation format we use (illustrated in Figure 1) is an extended version of the *OpenGIS Location Service (OpenLS) Implementation Standards*, a set of XML-based representations specified by the Open Geospatial Consortium[1]. Previous approaches on extending the latter with landmarks in an interoperable way have been presented by Neis and Zipf (2008). The representation format of our data has been developed in close collaboration with researchers from Geoinformatics at Heidelberg University[2] and adopts ideas previously proposed in the *Cognitive OpenLS* specification by Hansen et al. (2006). The resulting specification will be implemented in an extended (internal) version of the online route planner OpenRouteService.org.

Our work revolves around two kinds of elements in this format: so-called *maneuvers*, i.e., elements that describe a decision point including the required action and the following route segment, and *landmarks* that occur along the route. For the alignment task we focus on the following types of attributes that are part of the XML specification, specified here as **Attribute (Element)**:

directionOfTurn (Maneuver) – the direction of movement for the current maneuver, i.e., "left", "right" or "straight"

[1] http://www.opengeospatial.org/standards/is

[2] Chair of GIScience, Alexander Zipf, http://www.geog.uni-heidelberg.de/lehrstuehle/gis/

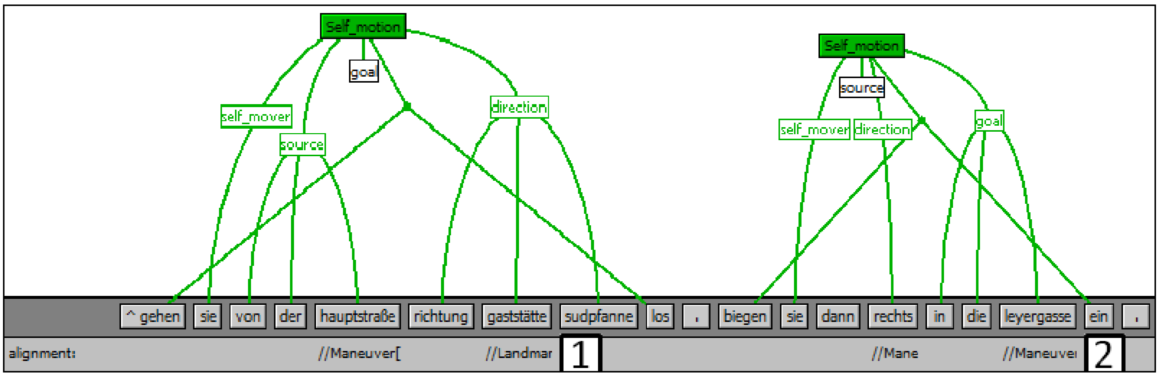

Figure 2: Directions for the route segment displayed in Figure 1 annotated with frame-semantic markup and alignment information. The directions translate to "You start walking from Hauptstraße towards Gaststätte Sudpfanne, then you turn right onto Leyergasse"

junctionType (Maneuver) – the type of junction at the current maneuver, e.g., "intersection", "crossing"

name (JunctionCategory) – the name of the junction at the current maneuver, e.g., "Hauptstraße/Leyergasse"

name (NextSegment) – the name of the street of the next route segment, e.g., "Hauptstraße"

streetName (RouteBranch) – the street name of a branch along which the route continues, e.g., "Leyergasse"

streetName (NoRouteBranch) – the street name of a branch that is not part of the route, e.g., "Kisselgasse"

name (Landmark) – the name of a landmark, e.g., "Hotel Sudpfanne"

spatialRelation (UsedLandmark) – the spatial relation between a landmark and the current maneuver, e.g., "left", "right", "before"

3.2 A Parallel Corpus of Route Directions

The corpus of route directions used in this work is a subset of the data collected by Schuldes et al. (2009) in a desk-based experiment. To elicit NL route directions, subjects were shown a web application that guided them along a route by means of a 2D animation. Subsequently they had to write NL route directions in German for the shown routes. The subjects were allowed to use all information displayed by the web application: named places, buildings, bridges and street names, etc. The resulting directions were POS-tagged with TreeTagger (Schmid, 1997), dependency-parsed with XLE (Maxwell and Kaplan, 1993), and manually revised. Additionally, we annotated frame-semantic markup (Fillmore et al., 2003) and gold standard alignments to the route representation using the SALTO annotation tool (Burchardt et al., 2006).

Frame semantic markup. The texts are annotated with an inventory of 4 frames relevant for directions (SELF_MOTION, PERCEPTION, BEING_LOCATED, LOCATIVE_RELATION), with semantic roles (*frame elements*) such as DIRECTION, GOAL, PATH, LOCATION. Figure 2 illustrates a typical example for the use of the SELF_MOTION frame, once with the elements SOURCE and DIRECTION, and once with the elements DIRECTION and GOAL. Our alignment model uses the frame semantic annotation as structuring information.

Gold standard alignments. For evaluation we constructed gold alignments. We asked two annotators to align text parts with corresponding attributes in the respective route representation[3]. The information about corresponding attributes was added to a single word by manually insert-

[3] The alignments have not been double annotated, hence no measure for inter-annotator agreement can be provided.

	#S	#W	#FE	#aligned FE
avg. per direction	8	98	28	14 (50%)
overall	412	5298	1519	750

Table 1: Corpus statistics: number of sentences (S), words (W), frame elements (FE) and alignments.

	#attributes	#aligned attr.
avg. per route	115	14 (12%)
overall	921	

Table 2: Corpus statistics: total number and percentage of relevant attribute alignments.

ing XPATH expressions that unambiguously refer to the aligned attribute in the route representation format. For learning the alignment model, the annotations were spread to all words in the span of the respective frame element.

Corpus statistics. We made use of a corpus of 54 NL directions collected for 8 routes in an urban street network. Tables 1 and 2 give some statistics about the number of words (W) and frame elements (FE) in the parallel corpus. Comparing the total number of relevant attributes (as listed in Section 3.1) and attributes annotated in the gold alignments (aligned attr.) we note that only 12% are actually mentioned in NL directions. Thus it is necessary to select the most salient attributes to avoid the generation of overly redundant text.

4 Alignment Model

For the induction of alignments between (parts of) route structures and semantic representations, we adopt ideas from the models presented in Liang et al. (2009) (cf. Section 2).

We start from a basic *frame alignment model.* It specifies a conditional probability distribution $\mathrm{p}(f|a)$ for the alignment to a frame element f of type f_t (e.g., source, goal, direction) in the frame-semantic annotation layer given an attribute a of type a_t (e.g., streetName, directionOfTurn) in the route representation format. Note that this model does not take into account the actual value a_v of the attribute a nor the words that are annotated as part of f. We assume that the frame annotation represents a reliable segmentation for this alignment. This allows us to omit modeling segmentation explicitly.

As extensions to the basic frame alignment model, we specify two further models that capture properties that are specific to the task of direction alignment. As route directions are typically presented in a linear order with respect to the route, we incorporate an additional *distance model* λ in our alignment. We further account for *word choice* within a frame element as an additional factor. The word choice model $\mathrm{p}(w|a)$ will exploit attribute type and value information in the route representations that are reflected in word choice in the linguistic instructions. Both extensions are inspired by and share similarities with models that have been successfully applied in work on text alignment for the task of machine translation (Vogel et al., 1996; Tiedemann, 2003).

Our full model is a distribution over frame elements f and words w that factorizes the three above mentioned parts under the assumption of independence between each component and each attribute:

$$\mathrm{p}(f,w|a) = \mathrm{p}(f|a)\lambda(\mathrm{dist}(f,a))\,\mathrm{p}(w|a) \quad (1)$$

The individual models are described in more detail in the following subsections.

4.1 Frame Alignment Model

This basic frame alignment model specifies the probabilities $\mathrm{p}(f|a)$ for aligning an attribute a of type a_t (i.e., one of the types listed in Section 3.1) to a frame element f labeled as type f_t. This alignment model is initialized as a uniform distribution over f and trained using a straight-forward implementation of the EM algorithm, following the well-known IBM Model 1 for alignment in machine translation (Brown et al., 1993). The expectation step (E-step) computes expected counts given occurrences of f_t and a_t under the assumption that all alignments are independent 1:1 correspondences:

$$\mathrm{count}(f_t,a_t) = \frac{\sum_{\{\langle f',a'\rangle|f'_t=f_t\wedge a'_t=a_t\}}\mathrm{p}(f'|a')}{\sum_{\{\langle f',y\rangle|f'_t=f_t\}}\mathrm{p}(f'|y)} \quad (2)$$

The probabilities are re-estimated to maximize the overall alignment probability by normalizing the estimated counts (M-step):

$$\mathrm{p}(f|a) = \frac{\mathrm{count}(f_t, a_t)}{\sum_x \mathrm{count}(x_t, a_t)} \tag{3}$$

4.2 Distance Model

We hypothesize that the order of route directions tends to be consistent with the order of maneuvers encoded by the route representation. We include this information in our alignment model by defining a distance measure $\mathrm{dist}(f, a)$ between the relative position of a frame element f in the text and the relative position of an attribute a in the route representation. The probabilities are specified in form of a distance distribution $\lambda(i)$ over normalized distances $i \in [0 : 1]$ and learned during EM training. The weights are initialized as a uniform distribution and re-estimated in each M-step by normalizing the estimated counts:

$$\lambda(i) = \frac{\sum_{\{\langle x,y\rangle |\, \mathrm{dist}(x,y)=i\}} \mathrm{count}(x, y)}{\sum_{\{\langle x,y\rangle\}} \mathrm{count}(x, y)} \tag{4}$$

4.3 Word Choice Model

We define a word choice model for word usage within a frame element. This additional factor is necessary to distinguish between various occurrences of the same type of frame element with different surface realizations. For example, assuming that the frame alignment model correctly aligns directionOfTurn attributes to a frame element of type DIRECTION, the word choice model will provide an additional weight for the alignment between the value of an attribute (e.g., “left”) and the corresponding words within the frame element (e.g., “links”). Similarly to the word choice model within fields in (Liang et al., 2009), our model specifies a distribution over words given the attribute a. Depending on whether the attribute is typed for strings or categorial values, two different distributions are used.

String Attributes. For string attributes, we determine a weighting factor based on the longest common subsequence ratio (LCSR). The reason for using this measure is that we want to allow for spelling variants and the use of synonymous common nouns in the description of landmarks and street names (e.g., “Main St.” vs. “Main Street”, “Texas Steakhouse” vs. “Texas Restaurant”). The weighting factor $\mathrm{p}_{\mathrm{str}}(w|a)$ for an alignment pair $\langle f, a\rangle$ is a constant in the E-step and is calculated as the LCSR of the considered attribute value a_v and the content words $w = \mathrm{cw}(f)$ in an annotated frame element f divided by the sum over the LCSR values of all alignment candidates for a:

$$\mathrm{p}_{\mathrm{str}}(w|a) = \frac{\mathrm{LCSR}(a_v, w)}{\sum_x \mathrm{LCSR}(a_v, \mathrm{cw}(x))} \tag{5}$$

Categorial Attributes. We define categorial attributes as attributes that can only take a finite and prescribed set of values. For these we do not expect to find matching strings in NL directions as the attribute values are defined independently of the language in use (e.g., values for directionOfTurn are “left”, “right” and “straight”. However, the directions in our data set are in German, thus containing the lexemes “links”, “rechts” und “geradeaus” instead). As the set of values $\{a_v \in \mathbb{D}_{a_t}\}$ for a categorial attribute type a_t is finite, we can define and train probability distributions over words for each of them during EM training. The models are initialized as uniform distributions and are used as a weighting factor in the E-Step. We re-calculate the parameters of a distribution $\mathrm{p}_{cat}(w|a)$ in each EM iteration by normalizing the estimated counts during M-step:

$$\mathrm{p}_{\mathrm{cat}}(w|a) = \frac{\mathrm{count}(a_v, w)}{\sum_x \mathrm{count}(a_v, x)} \tag{6}$$

5 Experiments and Results

5.1 Setting

We test the performance of different combinations of these EM-based models on our data, starting from a simple baseline model (**EM**), combined with the distance (**EM+dst**) and word choice models (**EM+wrd**) and finally the full model (**Full**). We perform additional experiments to examine the impact of different corpus sizes and an alignment threshold (**+thld**).

EM is a baseline model that consists of a simple EM implementation for aligning attributes and frame elements (equation (3)).

EM+dst consists of the simple EM model and the additional distance factor (equation (4)).

Model	P (+thld)	R (+thld)	F_1 (+thld)
Random	2.7 (2.7)	3.9 (3.9)	3.2 (3.2)
EM	2.0 (3.6)	2.9 (3.7)	2.34 (3.6)
EM+dst	7.3 (11.6)	10.8 (11.7)	8.7 (11.6)
EM+wrd	26.8 (36.3)	39.5 (35.5)	32.0 (35.9)
Full	28.9 (38.9)	42.5 (37.9)	34.4 (38.4)

Table 3: Precision (P), Recall (R) and F_1 measure results with and without threshold (+thld) on the alignment task (all numbers in percentages).

EM+wrd consists of the simple EM model with the word choice model (equations (5) and (6), respectively).

Full is the full alignment model including distance and word choice as described in Section 4 (cf. equation (1)).

We use the data set described in Section 3. The predictions made by the different models are evaluated against the gold standard alignments (cf. Tables 1 and 2). We run a total number of 30 iterations[4] of EM training on the complete data set to learn the parameters of the probability distributions. From the set of all possible 1-to-1 alignments, we select the most probable alignments according to the model in a way that no attribute and no frame element is aligned twice.

5.2 Results

We measure precision as the number of predicted alignments also annotated in the gold standard divided by the total number of alignments generated by our model. Recall is measured as the number of correctly predicted alignments divided by the total number of alignment annotations. As baselines we consider a random baseline (obtained from the average results measured over 1,000 random alignment runs) and the simple EM model.

The results in Table 3 show that the simple EM model performs below the random baseline. The individual extended models achieve significant improvement over the simple model and the random baseline. While the distance model has a smaller impact, the influence of the word choice model is considerable. Applying the full model yields further performance gains. We note that for all models recall is higher compared to precision.

# directions	Precison	Recall	F_1
1	28.94%	42.31%	34.38%
2	29.04%	41.90%	34.31%
3	29.01%	42.18%	34.38%
4	28.75%	41.81%	34.07%
5	29.36%	42.69%	34.79%
6	30.18%	43.91%	35.77%

Table 4: Average results when using only a specific number of directions for each route with the model Full (-thld).

One of the reasons for this phenomenon may be that the EM-based models align as many attributes as possible to frame elements in the route directions. In our gold standard, however, only around 12% of all relevant attributes correspond to frame elements in the route directions (cf. Section 3.2). We estimate this quota from a part of the corpus and use it as an alignment threshold, i.e., for evaluation we select the best alignments proposed by the models, until we reach the threshold. With this we achieve a F_1 measure of 38.40% in a 6-fold cross validation test. This represents an improvement of 3.97 points and considerably boosts precision, yielding overall balanced precision (38.90%) and recall (37.92%).

A general problem of the current setup is the small amount of available data. With a total of 54 route directions, the data consists of 6 to 8 directions for each route. We compute a learning curve by using only exactly 1 to 6 directions per route to examine whether performance improves with increasing data size. The results are computed as an average over multiple runs with different data partitions (see Table 4). The results indicate small but consistent improvements with increasing data sizes, however, the differences are minimal. Thus we are not able to conclude at this point whether performance increases are possible with the addition of more data.

5.3 Error Analysis

In an error analysis on the results of the full model, we found that 363 out of 784 (46%) misalign-

[4] This number was determined by experiments as a general heuristics.

ments are related to attributes not aligned in our gold standard. This is due to the fact that not all relevant attributes are realized in natural language directions. By addressing this problem in the model Full+threshold, we are able to reduce these errors, as evidenced by a gain of almost 10 points in precision and 4 points in F_1 measure.

We further observe that the word choice model does not correctly reflect the distribution of categorial attributes in the parallel corpus. In the data, we observe that humans often aggregate multiple occurrences of the same attribute value into one single utterance. An example of such a phenomenon can be seen with the attribute type 'directionOfTurn': Even though "straight" is the most common value for this attribute, it is only realized in directions in 33 (5%) cases (compared to 65% and 47% for "left" and "right" respectively). While our EM implementation maximizes the likelihood for all alignment probabilities based on expected counts, many pairs are not – or not frequently – found in the corpus. This results in the model often choosing incorrect alignments for categorial attributes and makes up for 23% of the misaligned attributes in total.

We found that further 5% of the attributes are misaligned with frame elements containing pronouns that actually refer to a different attribute. As our word choice model does not account for the use of anaphora, none of the affected frame elements are aligned correctly. Given the genre of our corpus, integrating simple heuristics to resolve anaphora (e.g., binding to the closest preceding mention) could solve this problem for the majority of the cases.

6 Conclusion

We presented a weakly supervised method for aligning route representations and natural language directions on the basis of parallel corpora using EM-based learning. Our models adopt ideas from Liang et al. (2009) with special adaptations to the current application scenario. As a major difference to their work, we make use of frame-semantic annotations on the NL side as a basis for segmentation.

While we can show that the extended models significantly outperform a simple EM-based model, the overall results are still moderate. We cannot draw a direct comparison to the results presented in Liang et al. (2009) due to the different scenarios and data sets. However, the corpus they used for the NFL recaps scenario is the closest to ours in terms of available data size and percentage of aligned records (in our case attributes). For this kind of corpus, they achieve an F_1 score of 39.9% with the model that is closest to ours (Model 2'). Their model achieves higher performance for scenarios with more available data and a higher percentage of alignments. Thus we expect that our model benefits from additional data sets, which we plan to gather in web-based settings.

Still, we do not expect to achieve near to perfect alignments due to speaker variation, a factor we also observe in the current data. As our ultimate goal is to generate NL instructions from given route representations, we can nevertheless make use of imperfectly aligned data for the compilation of high-confidence rules to compute semantic input structures for NLG. Following previous work by Barzilay and Lee (2002), we can also exploit the fact that our data consists of multiple directions for each route to identify alternative realization patterns for the same route segments. In addition, (semi-)supervised models could be used to assess the gain we may achieve in comparison to the minimally supervised setting.

However, we still see potential for improving our current models by integrating refinements based on the observations outlined above: Missing alignment targets on the linguistic side – especially due to anaphora, elliptical or aggregating constructions – constitute the main error source. We aim to capture these phenomena within the linguistic markup in order to provide hidden alignment targets. Also, our current model only considers frame elements as alignment targets. This can be extended to include their verbal predicates.

A Multiple-Domain Ontology Builder

Sara Salem **Samir AbdelRahman**

Abstract

The interpretation of a multiple-domain text corpus as a single ontology leads to misconceptions. This is because some concepts may be syntactically equal; though, they are semantically lopsided in different domains. Also, the occurrences of a domain concept in a large multiple-domain corpus may not gauge correctly the concept significance. This paper tackles the mentioned problems and proposes a novel ontology builder to extract separate domain specific ontologies from such a corpus**.** The builder contribution is to sustain each domain specific concepts and relations to get precise answers for user questions. We extend a single ontology builder named Text2Onto to apply our thought. We fruitfully enhance it to answer, more precisely, questions on a subset of AQUAINT corpus.

1 Introduction

Domain ontology is a knowledge representation of the domain as a set of concepts and relations. Ontology notion always presents handy semantic solutions for various hot research areas such as Semantic Web, Informational Retrieval, and Question Answering.

Currently, automatic ontology builders presume that the given corpus has a single domain. When used with a multiple-domain corpus, these builders generate 1 large ontology for the whole corpus. Dramatically, this causes 2 domain misconception problems. First, the ontology conceptual model becomes imprecise for the common concepts in various domains having different semantics. Second, the relevance weights assigned to the concepts do not measure precisely their significance in specific domains.

This paper presents a promising solution for the mentioned problems. The proposed solution is an integrated 2-layer ontology builder. The ontology layers are: 1) the conceptual layer, which has the key concepts and relations of each separate domain, and 2) the general layer, which maintains the general domain information regarding related persons, organizations, locations, and dates. Our proposed 2-layer ontology improves the extracted answers for single-domain and cross-domain questions. We successfully prove our thought against Text2Onto builder.

Ontology extraction from a domain corpus has been targeted by many researchers. The core extraction approaches can be classified into 3 approaches. The first approach is to build the ontology from scratch (Buitelaar et al., 2004; Cimiano and Völker, 2005). The second approach is to extend a predefined general ontology, such as WordNet, with possible application domain concepts and relations (Navigli and Velardi, 2004). The last approach is to build ontology as a composition of other predefined ontologies (Cimiano et al., 2006). Moreover, as an ontology building design decision, the resultant ontology is either a single layer ontology or a multi-layered ontology (Benslimane et al., 2000; Dumontier and Villanueva-Rosales, 2007).

The paper is organized as follows: Section 2 introduces some related systems; Section 3 explains the misconceptions due to extracting a single ontology from a multiple-domain corpus; Section 4 describes our proposed builder; Section 5 illustrates our Question Answering system, which is used for the evaluation; Section 6 states our evaluation results; and Section 7 draws our conclusion and directions for the future work.

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 967–975,
Beijing, August 2010

2 Related Work

There are 3 main approaches for ontology building, namely building from scratch, extending a general ontology, or building an ontology as a composition of other predefined ontologies.

Text2Onto (Cimiano and Völker, 2005) applies the first approach. It is a framework for learning ontologies automatically from textual data. It implements diverse linguistic and statistical techniques to extract domain concepts and relations. It combines results from different techniques, and it represents the extracted ontology elements in a so called Probabilistic Ontology Model (POM), which assigns a confidence value for each learnt element.

OntoLT (Buitelaar et al., 2004) is another example of building from scratch. It is a Protégé[1] plug-in that extracts ontology from text by defining a set of mapping rules. The rules map certain linguistic structures in an annotated text into ontological elements. The extracted elements are validated by the user before being inserted into the ontology.

OntoLearn (Navigli and Velardi, 2004) employs the second approach. It is a framework for trimming and extending general purpose ontologies, like WordNet, with specific domain terminologies and taxonomies. It extracts domain terminologies, and it uses a relevance measure to keep out non-relevant terms. OntoLearn uses a novel technique, called SSI, to assign a domain specific term to the correct sense in a general ontology.

The third approach is proposed in (Cimiano et al., 2006). It presents a system that integrates several heterogeneous semantic sources into 1 ontology, which is used to extract answers for user queries from various knowledge sources.

As a design decision, the ontology may consist of a single layer or of multiple layers. Benslimane et al. (2000) apply the multiple-layer approach for manually generating a set of interrelated ontology layers; each layer models a spatial domain specific function. Also, Dumontier and Villanueva-Rosales (2007) suggest a 3-layer ontology design. The first layer (primitive layer) defines the basic domain concepts and relations. The second layer (complex layer) imposes more complex domain restrictions on the primitive layer. The top layer (application layer) maintains application specific restrictions.

Our builder constructs a layered ontology from scratch. Its main distinguished features are: 1) generating separate domain specific ontologies from a multiple-domain corpus, 2) extracting general domain information, in addition to core domain conceptual information, and 3) it is an automatic multi-layered ontology builder, unlike other automatic builders, which generate single layer ontologies.

Our system can extend current builders, which extract ontologies from textual data, allowing them to handle a multiple-domain corpus. We selected Text2Onto because it is an automatic ontology builder, and it implements a variety of algorithms to extract many types of ontology elements. We use a news corpus as a multiple-domain corpus since it contains documents from different domains like Politics, Sports, Arts, and Finance.

3 Ontology Misconceptions

Building a single ontology for a given corpus is a familiar method. However, when dealing with a multiple-domain corpus, the builder usually suffers from the following 2 problems:

First, the ontology conceptual model becomes imprecise in the definition of common concepts that are semantically lopsided in different domains. For example, the concept "wall street" in the Finance domain is defined as a financial institution, and it is in the Arts domain defined as a movie. It is inaccurate to define the concept with 2 totally different meanings in 1 ontology. It is also incorrect to ignore a definition of them. When using Text2Onto for that example, it generates only 1 definition for "wall street" as a subclass-of "institution".

Second, when weighing concepts in a multiple-domain corpus, the relevance weights assigned to the concepts do not indicate the significance of each concept in a certain domain. As a result, some core domain specific concepts may have low weights with respect to the whole corpus. For example the concept "trading" has a low weight in a multiple-domain corpus; although, it is a main concept in the Finance domain (Section 6.2). This gives wrong indication of the concept importance to the user.

[1] http://protege.stanford.edu/

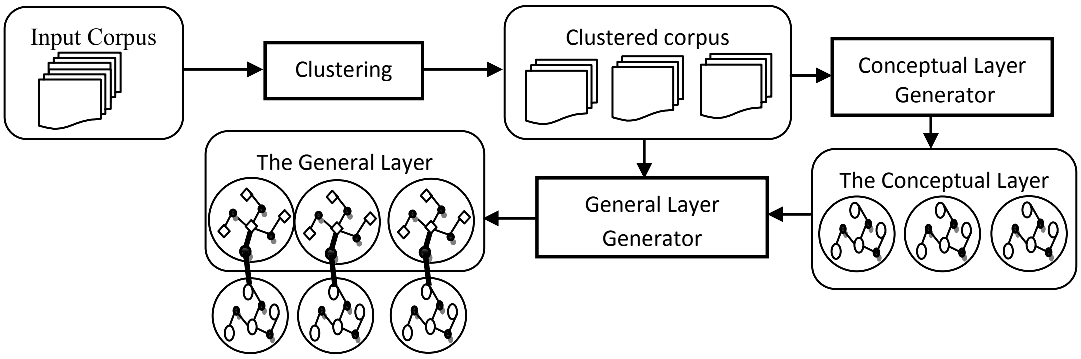

Figure 1. The Multiple-Domain Ontology Builder.

4 The Proposed Ontology Builder

Our builder aims to extract precise ontologies, which model possible knowledge in a multiple-domain corpus. A domain corpus, mostly, not only contains information about the core domain concepts and their relations, but it also contains general domain information such as dates of events and names of persons, locations, or organizations participating in the domain. Existing ontology builders either ignore this general information or they provide a limited implementation to extract it.

4.1 System Overview

The input to our builder (Figure 1) is a multiple-domain corpus. The first step is the ***clustering operation***, which divides the given corpus documents into clusters that are different among each other with high internal similarity. The next step is the ***conceptual layer generation***. In this step, we use Text2Onto to extract a separate ontology for each domain. Finally, the ***general layer generator*** uses each domain corpus and the conceptual layer ontology to extract relations among the concepts and the Named Entities in that domain.

4.2 The Conceptual Layer

The first step in constructing the conceptual layer is the clustering operation. We separate a multiple-domain corpus into various domain specific corpora such that the domain concepts are weighted based on their significance in that domain; also, the common concepts in different domains are separated. We favored a hierarchical clustering technique over a flat clustering one. That was because the number of resulting clusters should be known as a parameter in the latter. However, the number of corpus domains might be unknown in our case.

We employ the agglomerative hierarchical clustering technique (Manning et al., 2008). The technique starts with each document as a singleton cluster, and then it successively merges pairs of similar clusters until all clusters are merged into 1 cluster. We use the vector space model (Manning et al., 2008) to represent each document as a vector of terms' weights. The weight of a term *w* in a document *d* is calculated using the TF-IDF measure (Equation 1).

$$TFIDF(w,d) = TF(w,d) * log\frac{N}{DF(w)} \qquad (1)$$

Where *N* is the corpus size, *TF (w,d)* is the number of occurrences of the term *w* in the document *d*, and *DF (w)* is the number of documents containing the term *w*.

The similarity between 2 documents is calculated using the Cosine Similarity measure (Equation 2).

$$cosine(d1,d2) = \frac{V(d1) \, . \, V(d2)}{||V(d1)|| * ||V(d2)||} \qquad (2)$$

Where *V(d)* is the terms' weights vector for the document *d*, ||*V(d)*|| is the Euclidean length of the vector *V(d)*, and the numerator is the dot product of the 2 vectors.

The similarity between 2 clusters is calculated using the UPGMA measure (Steinbach et al., 2000) (Equation 3).

$$sim(C1, C2) = \frac{\sum_{\substack{d1 \in C1 \\ d2 \in C2}} cosine(d1, d2)}{size(C1) * size(C2)} \qquad (3)$$

We use the UPGMA measure to cluster a subset of DMOZ[2] data (1322 documents, in 4 domains), and it performs F-Measure of 0.86. Steinbach et al. (2000) describe how to calculate F-Measure for a hierarchy of clusters.

The combination similarity is the similarity of 2 merged clusters. We use this measure to cut the clusters hierarchy into M clusters by grouping ones having a minimum combination similarity of the threshold value €[3]. After clustering, we use Text2Onto to generate an ontology for each cluster (domain).

4.3 The General Layer

Text2Onto performs well in extracting ontology elements such as concepts, sub-class-of relations, instance-of relations, and part-of relations. Unfortunately, it performs inaccurately in extracting general domain information such as Named Entities and numeric information. There are 3 reasons for such misconception. First, proper nouns are not extracted as concepts. Second, numeric data is ignored. Third, restricted patterns are applied for the relations of Named Entities, that include only verb relations like [(NP |PNP) *verb* (NP|PNP)] and instance-of relations like [NP *such as* PNP], [*such* NP *as* PNP], and [PNP (NP)].

Because of the above reasons, we propose a highly flexible pattern based relation extractor. In our system, a pattern is a sequence of tags in the form of a regular expression. The possible tags are the normal POS tags like NN, VB, JJ, IN besides the following 5 tags CONCEPT, PERSON, LOCATION, ORGANIZATION, and DATE. This criterion is called Mixed Tagging. Currently, dates are the only data containing numbers extracted by our builder, but we can easily extend it to handle more numeric data.

The Mixed Tagging operation inputs are a document and the related conceptual ontology (Figure 2). The operation output is a mixed tagged document. The tagged text is then provided to the Relations Extractor to take out all relations matching our current predefined patterns. Example patterns are listed in Table 1; the first 2 patterns are verb relations, and the last 2 are noun relations.

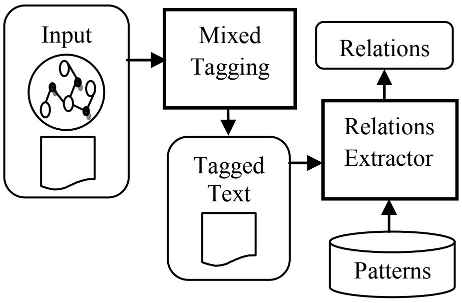

Figure 2. The General Relations Extraction.

The regular expression ([.{1,12}]){0,5} is used to limit the maximum number of tokens between the subject, the object, and the relation to 5 tokens. The expression [NN.?.?] matches any noun tag, and [VB.?] matches any verb tag.

After extracting the relations in all domain documents, the domain general ontology is created. It imports the corresponding conceptual ontology to model the relations among Named Entities and concepts.

([PERSON]) ([.{1,12}]){0,5}**([VB.?])+** ([.{1,12}]){0,5}**([CONCEPT])**
([ORGANIZATION])([.{1,12}]){0,5} **([DATE])**([.{1,12}]){0,5}**([VB.?])+**
([PERSON])([.{1,12}]){0,5} **([NN.?.?])+**([.{1,12}]){0,5}**([DATE])**
([NN.?.?])+([.{1,12}]){0,5}**([PERSON])** ([.{1,12}]){0,5}**([ORGANIZATION])**

Table 1. Sample Relation Patterns.

5 Question Answering System

Based on (Brank et al., 2005), a generated ontology can be evaluated using 4 different ways: 1) by a human who assesses it based on specific criteria, 2) by a comparison with the source data, 3) by a comparison with a golden standard, or 4) by using the ontology in an application and measuring the application performance. We chose the last option because the manual human assessment and the comparison with the source data are time consuming. Also, there is no golden standard ontology for a multiple-domain corpus.

Recently, researchers have studied the use of ontologies to extract answers to the user questions. AquaLog (Lopez et al., 2007) and

[2] http://www.dmoz.org/

[3] For clustering 600 AQUAINT documents, we use €=0.55 resulting in 7 Clusters (Secion 6.4).

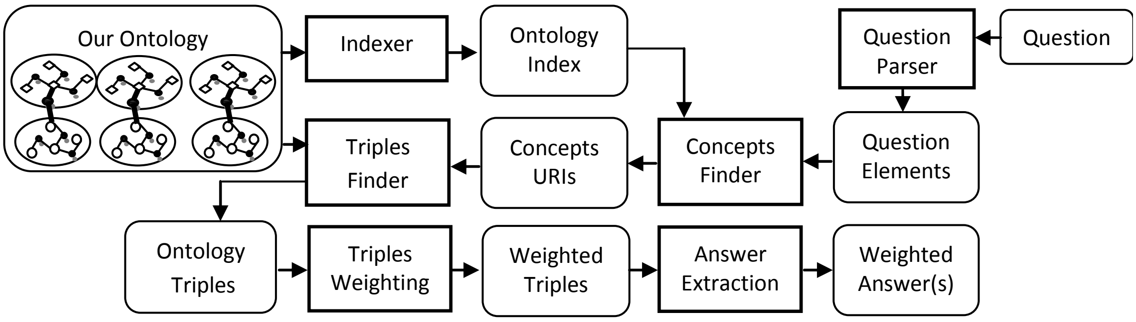

Figure 3. The Question Answering System.

PowerAqua (Lopez et al., 2009) are both ontology based Question Answering systems. PowerAqua extracts answers from various ontologies available on the web, unlike AquaLog, which extracts answers from 1 configurable ontology.

5.1 System Description

We implemented our simple Question Answering system handling who, when, where, and what questions. In the following, we describe the components of the system (Figure 3).

The Indexer: to make it easier for the system to locate the question concepts, an index is generated for our layered ontology. All concepts in different ontologies containing a certain stem are grouped in an index entry in the index file. The form of an index entry is as follows:

Stem,(Concept URI)+

The Question Parser: this component parses the user question, and it extracts 4 elements from it. First, the answer type; it can be PERSON, LOCATION, ORGANIZATION, DATE, or ANY based on the question type such as who, where, when, or what. Second, the answer restriction; it is used to limit the answers of *what* questions. For example, the answers for "what sport …?" question are restricted only to the sport types. Third, the question target; it defines the thing in which the question is interested. The fourth element is the relation; it contains the main verb(s) in the question. As an example, the elements of the question "*What sport does Jennifer Capriati play?*" are: the answer type (ANY), the restriction (sport), the question target (Jennifer Capriati), and the relation (play).

For a compound (2-clause) question such as "*What countries have Rhodes Scholars come from* ***and*** *has the Hale Bopp comet visible?*", each question clause is parsed as a separate question; finally, the answer extraction step intersects the answers of both clauses.

The Concepts Finder: using the ontology index, it locates concepts containing the stems of the question target and the restriction (if exists).

The Triples Finder: it extracts the triples which contain the question target concepts either as subjects or as objects. If the question is a definition question like "What is something?", the triple finder extracts only the sub-class-of triples.

The Triples Weighting: the triples are weighted based on their similarity to the question using our similarity criterion (Equation 4):

$$sim(Q,T) = \frac{\sum_{\substack{a\in Q \\ b\in T}} Lin(a,b)}{L(Q) * L(T)} \qquad (4)$$

Where Q and T are sets of the bag-of-words for the question relation and the triple relation respectively, *Lin(a,b)* is a measure for the semantic similarity between *a* and *b* based on WordNet (Lin, 1998), and *L(x)* is the number of elements in the set *x*.

The Answer Extraction: this component first filters out the triples mismatching the expected answer type. Then, if there is no restriction element, it extracts the answer from the weighted triples by considering the triple object if the question target is the subject, and vice versa. The extracted answer from a triple is assigned the same triple weight. If the question has a restriction element, the answer(s) will be limited to the sub concepts of the restriction element. A weight (Equation 5) is assigned to each sub concept *s* based on its similarity to the extracted triples as follows:

$$W(s) = \frac{\sum_{T \in R} sim(S,T)}{L(R)} \qquad (5)$$

Where *R* is the set of extracted triples, *S* and *T* are the sets of bag-of-words for the sub concept and the triple relation respectively, *sim(S,T)* is calculated using Equation 4, and *L(R) is* the number of elements in *R*.

For a compound question, the list of resulting answers contains only the common answers extracted for the 2 clauses.

6 Evaluation and Discussion

In our evaluation, we assess: 1) the enhancement of the concepts' weights in a specific domain corpus, 2) the enhancement of modeling common concepts in different domains with different semantics, and 3) the performance of our Question Answering system. The assessment is done through a comparison between our approach and Text2Onto.

In the development of our builder, we used Text2Onto[4], Stanford Part-Of-Speech Tagger (POS Tagger)[5], Stanford Named Entity Recognizer (NER)[6], and Jena[7]. In the Question Answering system, we also used the Java WordNet Similarity Library (JWSL)[8]; it implements the Lin measure.

6.1 Data Set

Our evaluation is based on the AQUAINT[9] corpus (Graff, 2002). It is an English news corpus containing documents from the New York Times News Service, the Xinhua News Service, and the Associated Press Worldstream News Service. The Question Answering track in TREC[10] (The Text REtrieval Conference) provides a set of questions on AQUAINT corpus along with their answers.

6.2 Concepts Weights Enhancement

For this experiment, we generated a corpus for the 3 domains, namely Finance, Sports, and Movies, from AQUAINT documents, such that each domain has equal number of documents. We measured the concepts' significance weights when using Text2Onto to generate a single ontology for the whole corpus and when using our builder to generate 3 different domains ontologies. We consider 3 measures implemented in Text2Onto, namely the Relative Term Frequency (RTF), the Entropy, and the TF-IDF.

The RTF for a concept *w* is the probability of the concept occurrence in the corpus (Equation 6).

$$p(w) = \frac{No.of\ occurences\ of\ w}{No.of\ all\ corpus\ concepts} \qquad (6)$$

The entropy and the normalized entropy for a concept *w* are calculated as follows (Equations 7 and 8 respectively):

$$Ent(w) = p(w) * \log p(w) \qquad (7)$$

$$N\big(Ent(w)\big) = \frac{Ent(w)}{Min\ Ent - Max\ Ent} \qquad (8)$$

In Section 4.2, we mention how to calculate the TF-IDF value for a term *w* in a document *d* (Equation 1). The TF-IDF weight and the normalized TF-IDF weight for a concept *w* in the whole corpus are calculated as follows (Equations 9 and 10 respectively):

$$TFIDF(w) = \frac{\sum_{d \in D} TFIDF(w,d)}{N} \qquad (9)$$

$$N\big(TFIDF(w)\big) = \frac{TFIDF(w)}{\sqrt{\sum_{ci \in C} TFIDF(ci)^2}} \qquad (10)$$

Where *D* is the set of documents containing *w*, *N* is the corpus size, and *C* is the set of all concepts in the corpus.

Since the concept weight is proportional to its occurrences in the corpus with respect to the other concepts, the fair distribution of the occurrences leads to precise weight calculation. In the specific domain corpus, the distribution is more reasonable than in multiple-domain corpus.

Table 2. Concepts Weights Comparison between Our Builder and Text2Onto.

This fact can be verified easily from Table 2. The 3 measures give higher weights in the domain specific ontologies than in a single ontology for the whole corpus.

6.3 Modeling Common Concepts

To study the enhancement in modeling common concepts having different meaning in different domains, we chose 5 concepts as samples (Table 3). For each concept, we selected documents from AQUAINT and from the Wikipedia concerning the concepts in 2 different domains.

In this experiment, the single ontology generated by Text2Onto contains only 1 definition for each concept namely wall_street *is_a* institution, marijuana *is_a* drug, bear *is_a* mammal, jaguar *is_a* cat, and world_war *is_a* war. On the other hand, our builder maintains both concept definitions in different ontologies.

Concept	Definition 1	Definition 2
Wall Street	A financial Institution	A movie
Marijuana	A drug	A song
The bear	A Mammal	A movie
Jaguar	A big cat	A car
World War	A war	A museum

Table 3. Sample of Lopsided Concepts.

6.4 Question Answering Enhancement

The experiment includes common concepts definition questions, single-domain questions, and cross-domain questions.

To illustrate the effect of the common concepts misconception problem solved by our builder against Text2Onto, we generated 5 definition questions for the 5 concepts in Table 3, like "what is wall street?", "what is marijuana?"…etc.

For the single-domain questions, we used a subset of AQUAINT corpus composed of 600 documents clustered into 7 domains using combination similarity threshold value of 0.55. We selected 60 factoid questions from TREC 2004 questions having their answers in these documents. Examples of single-domain questions are:

- *Who discovered prions?*
- *When was the IFC established?*

In addition to factoid questions, TREC 2004 also includes list questions. The answers of each question are aggregated from multiple documents. We used these questions in generating 10 cross-domain questions. Each question combines 2 of TREC list questions such that the 2 list questions are in different domains. Examples of these questions are:

- *What cities have an Amtrak terminal and have Crip gangs?*
- *What countries are Burger King located in and have IFC financed projects?*

Evaluation Criteria: the accuracy (A) (Equation 11) is used for evaluating single-domain questions because each factoid question has only 1 correct answer.

$$A = \frac{No.of\ correct\ answers}{No.of\ questions} \qquad (11)$$

The definition and cross-domain questions have multiple correct answers. The average Precision (P), Recall (R), and F-Measure (F) (Equations 12, 13, and 14 respectively) of all questions are used for our evaluation.

$$P = \frac{No.of\ correct\ answers}{No.of\ retrieved\ answers} \qquad (12)$$

$$R = \frac{No.of\ correct\ answers}{No.of\ actual\ answers} \qquad (13)$$

$$F = \frac{2 * P * R}{P + R} \qquad (14)$$

Table 4 shows that, in the definition questions, we achieve F-Measure of 1, while Text2Onto achieves 0.5. This is because our builder maintains the 2 different definitions of each concept, unlike Text2Onto, which contains only one.

Questions Type	Our Ontology	Text2Onto Ontology

Definition Questions	P=1.0
	R=1.0
	F=1.0
		P=0.5
		R=0.5
		F=0.5

Single-Domain	A=68%	A=0.05%

Cross-Domain	P=0.49
	R=0.59
	F=0.44
		P=0
		R=0
		F=0

Table 4. Question Answering Evaluation.

In the single-domain questions, using our ontology, we could answer 41 questions while using Text2Onto ontology we could answer only 3 questions ("what particle is a quark?", "what are prions made of?", and "What is the treatment of cataract?"). The low coverage of Named Entities in Text2Onto hinders it from answering correctly any question of types Who, When, and Where. This indicates the enhancement introduced by the proposed general layer for modeling accurately more domain information. In the cross-domain questions, we achieve F-Measure of 0.44. None of the cross-domain questions are answered using Text2Onto ontology due to the mentioned Named Entity coverage problem.

Although our results are better than Text2Onto, there is a room for more improvements. There are 4 main sources for retrieving wrong or incomplete answers (Table 5). Some relations are not extracted because their elements (subject, relation, and object) are not near enough from each other in the text, so none of our patterns or Text2Onto patterns could match them. This is the source of 65% of the errors. Missed Named Entities or wrongly tagged ones cause 16% of the errors. Some relations are not extracted because co-reference has not been handled yet. That leads to 12% of the total errors. Finally, in the factoid questions, we consider the answer with the highest weight to be the correct answer; 7% of the answers are extracted but with lower weights.

Error Type	Error percentage
No matching pattern	65%
NER Error	16%
Co-Reference	12%
Low answer weight	7%

Table 5. Answer Error Sources.

Based on the mentioned experiments, our builder outperforms Text2Onto in Question Answering. In addition, it can be used skillfully to enhance other Natural Language Processing applications such as Information Retrieval from multiple-domain data. Our initial results using 220 queries on 600 AQUAINT documents records 0.35 F-Measure against Lucene[11], which achieves 0.18.

7 Conclusion and Future Work

This paper presents the misconception problems when interpreting a multiple-domain corpus in a single ontology. A novel ontology builder is presented handling these problems by generating separate domain ontologies describing core and general domain information.

Currently, we hand on improving our builder relation extractor to answer more TREC questions by automatically learning patterns from text and by handling co-reference. Moreover, we are working to enhance the performance of our Information Retrieval system.

Weakly Supervised Morphology Learning for Agglutinating Languages Using Small Training Sets

Ksenia Shalonova

University of Bristol
ksenia@cs.bris.ac.uk

Bruno Golénia
Computer Science,
University of Bristol
csbsgg@bristol.ac.uk

Abstract

The paper describes a weakly supervised approach for decomposing words into all morphemes: stems, prefixes and suffixes, using wordforms with marked stems as training data. As we concentrate on under-resourced languages, the amount of training data is limited and we need some amount of supervision in the form of a small number of wordforms with marked stems. In the first stage we introduce a new Supervised Stem Extraction algorithm (SSE). Once stems have been extracted, an improved unsupervised segmentation algorithm GBUMS (Graph-Based Unsupervised Morpheme Segmentation) is used to segment suffix or prefix sequences into individual suffixes and prefixes. The approach, experimentally validated on Turkish and isiZulu languages, gives high performance on test data and is comparable to a fully supervised method.

1 Introduction

The major function of morphological analysis is decomposition of words into their constituents - stems and prefixes/suffixes. In recent years Machine Learning approaches were used for word decomposition. There is a number of both unsupervised morphology learning systems that use ”raw” wordforms as training data (Creutz and Lagus, 2002; Goldsmith, 2001; Kazakov and Manandhar, 2001) and supervised morphology learning systems using segmented wordforms into stems and affixes as training data (Oflazer et al., 2001). The supervised morphology learning systems are usually based on two-level morphology (Koskenniemmi, 1983). There is also a weakly supervised approach that uses, for example, wordpairs as input, and this was applied mainly to fusional languages for stem extraction (Erjavec and Dzeroski, 2004). Our project concerns developing speech technology for under-resourced languages. For this type of applications we need a relatively fast, cheap (i.e. does not require large training sets), almost knowledge-free approach that gives high performance. We have chosen to use wordforms with marked stems as training data in order to fulfill the criteria mentioned above.

Morphological analysis is used in many practical Natural Language Processing applications such as Machine Translation, Text Mining, spellcheckers etc. Our near-term goal is the integration of the morphology learning algorithms into the language-independent Text-to-Speech (TTS) system for improvement of grapheme-to-phoneme rules, stress prediction and tone assignment. In particular, the morphology learning algorithms described in this paper will be incorporated into the available isiZulu TTS system for automatic prediction of lexical tones. In the isiZulu language lexical tone assignment depends on the morpheme boundary. The current isiZulu TTS system is tone-deaf due to the lack of morphological decomposition. A number of perception tests will be carried out in order to evaluate which performance of morphology decomposition is acceptable for TTS and will improve the quality of the synthesised speech. It seems that the unsupervised morphology learning systems can be relatively easy to implement from scratch, but their performance probably cannot be regarded as high enough to improve the performance of the synthesized speech. In order to overcome this problem we present a novel synthesis of supervised and unsupervised induction techniques for morphology learning.

Our approach consists of two parts: the new supervised stem extraction algorithm for agglutinat-

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 976–983,
Beijing, August 2010

ing languages and the improved version of the unsupervised algorithm for segmenting affix sequences. In (Shalonova et al., 2009) the authors presented the function learning approach called TASR (Tree of Aligned Suffix Rules) for extracting stems in fusional languages given wordpairs (word in grammatical form - word in basic form). While this algorithm gives good performance for Russian and English, it gives quite poor performance for agglutinating languages as shown in Section 4. A new approach for stem extraction in agglutinating languages is required for two main reasons. Firstly, suffix (or prefix) sequences in agglutinating languages can be much longer than in fusional languages and TASR does not seem to be efficient on long affix sequences as it does not generalise data in the efficient way and generates too many specific rules. This leads to poor performance on unseen data. Secondly, in some agglutinating languages it could be easier for native speakers to provide a stem (i.e. to provide a list of wordforms with annotated stems), whereas in highly inflective fusional languages the stem is often strongly bound with suffix sequences, and providing a proper stem requires high linguistic expertise. TASR approach is more appropriate for word-and-paradigm or realizational morphology that focuses on the whole word form rather than on word segmentation. For example, in Russian the infinitive verb *govorit'* ('to speak') generates a set of grammatical forms or a paradigm - *govorivshij*, *govor'aschij*, *govorim* etc.

The second part of our approach is the improved version of GBUAS algorithm (Shalonova et al., 2009) that provides affix segmentation given unannotated affix sequences. Given stem boundaries in the training set, our method splits the input word into all morphemes: stems and prefixes/suffixes. Our two-stage approach is tested on the under-resourced language isiZulu containing both prefixes and suffixes, as well as on Turkish containing only suffixes. Turkish is the most commonly spoken of the Turkic languages (over 77 million people). isiZulu is the Bantu language with about 10 million speakers and it is the most widely spoken home language in South Africa. Both Turkish and isiZulu use agglutination to form new words from noun and verb stems. In comparison to Turkish, isiZulu is a tonal language. In contrast to East Asian languages, in isiZulu there are three steps for tone assignment: lexical, morphemic and terraced. For TTS the lexical and morphemic tones will need to be recovered from the lexicon and the grammar as the orthography has no tone marking. The terraced tone relation can in general be recovered and marked automatically from the tone sequence with a finite state model.

2 Stem Extraction Algorithm

The Stem Extraction Algorithm (SSE) is the supervised algorithm for stem extraction. The training data for the SSE represent wordforms with the marked stem boundaries. During the training stage we collect a set of all possible stem extraction rules from training data and assign precision measures to each rule. Each rule is of the form *L_R* where "_" is the stem boundary, L and R are the left and right graphemic contexts of a stem boundary of different lengths. We differentiate prefix *Lpref_Rstem* and suffix *Lstem_Rsuff* stem extraction rules that correspond to the rules containing the left-hand stem boundary and the right-hand stem boundary respectively. For example, the Turkish word *yer* ('earth') with the marked word boundary #ye_r# generates the following *Lstem_Rsuff* rules: #ye_r#, #ye_r, ye_r#, #ye_, ye_r, e_r#, _r#, ye_, e_r, _r, and e_, where the symbol '#' signifies the word initial and final positions. We are implementing similar feature vectors used for automatic pronunciation prediction based on the focal grapheme (in our case it is a stem boundary) and left/right graphemic contexts of different length (Davel and Barnard, 2008). The idea of implementing expanding context in NLP tasks is usually applied for two-level data like grapheme-to-phoneme mapping rules (Torkkola, 1993), whereas in our case we use it for one-level data.

The precision measure for each rule is calculated by the formula $p/(p+n+\varepsilon)$ where p and n are the number of positive and negative examples, and ε is used to cover the cases where there are no negative examples. A high precision is desirable and this occurs when there are high values of p and low values of n (i.e. many positive examples and few negative examples). Using negative examples in contrast to using only rule frequencies (or positive examples) improves the performance of the algorithm.

Definition 1. *The number of positive examples for the rule Lstem_Rsuff (or rule Lpref_Rstem) is the number of training instances of $Stem\_Suffixes$ (or $Prefixes\_Stem$) containing the substring L_R.*

Definition 2. *The number of negative examples for rule Lstem_Rsuff (or Lpref_Rstem) is the number of training instances $Stem\_Suffixes$ (or $Prefixes\_Stem$) such that $Stem + Suffixes$ (or $Prefixes + Stem$) contains substring L+R and $Stem\_Suffixes$ (or $Prefixes\_Stem$) does not contain substring L_R where '+' denotes string concatenation.*

In the above definitions '_' is a stem boundary.

Example 1. *Suppose we have only three isiZulu verbs: zi_bek_e, zi_nak_eke and a_hlul_eke. For the $Lstem\_Rsuff$ rule* ***'ek_e'****, the word zi_bek_e generates one positive example and the two other words zi_nak_eke and a_hlul_eke generate one negative example each.*

The approach given in Algorithm 1 aims to find the unique longest rule-pair '$Lpref\_Rstem$ and $Lstem\_Rsuff$' with the highest precision that is applied to the input wordform for stem extraction. In case the language does not have prefixes like Turkish, the longest rule $Lstem\_Rsuff$ with the highest precision is applied. The decision of using either a rule-pair or just a single suffix rule is influenced by prior knowledge that a particular language has got either both prefixes and suffixes like isiZulu or only suffixes like Turkish. From now on we will use the term 'rulepair' in application both to the rulepair '$Lpref\_Rstem$ and $Lstem\_Rsuff$' in case of isiZulu and to the rulepair ' and $Lstem\_Rsuff$' with an empty first element in case of Turkish.

Algorithm 1 Choosing rule pair for stem extraction.

```
input W = raw wordform; $P$ and $S$ are sets of unique $Lpref\_Rstem$ and $Lstem\_Rsuff$ rules
output $result\_rule\_pair$

$result\_rule\_pair \leftarrow \emptyset$
iMaxlength $\leftarrow \infty$
repeat
  $(p1,s1) \leftarrow$ getrulepair (P $\times$ S, W, iMaxlength)
  $(p2,s2) \leftarrow$ getrulepair (P $\times$ S $\setminus$ $(p1,s1)$, W, iMaxlength)
  iMaxlength $\leftarrow$ length$(p1,s1)$
until $(p1,s1) = \emptyset$ or precision $(p1,s1) \neq$ precision$(p2,s2)$ or length $(p1,s1) \neq$ length$(p2,s2)$
$result\_rule\_pair \leftarrow (p1,s1)$

function getrulepair(PS, W, iMaxlength)
ilength $\leftarrow 0$
r $\leftarrow \emptyset$
for all $(p,s) \in PS$ do
  if $(p,s)$ matches W then
    if length$(p,s) < iMaxlength$ and length$(p,s) >$ ilength then
      ilength $\leftarrow$ length$(p,s)$
      $r \leftarrow (p,s)$
    else
      if length$(p,s) =$ ilength and precision$(p,s) >$ precision$(r)$ then
        $r \leftarrow (p,s)$
      end if
    end if
  end if
end for
return $r$
end function
```

The search is carried out on the set of rule pairs matching an input raw wordform. The set is sorted by length first, and then by precision measure within each length category.

For example, if rulepairs have the following length-precision values:
'4-0.5,'4-0.5','4-0.2'

'3-0.4','3-0.3'
'2-0.3'
rulepair with the value 3-0.4 is selected.

The rulepair matches the input word if *Lpref_Rstem* and *Lstem_Rsuff* rules can be applied without contradicting each other. For example, the rule pair '#a_hl' and 'l_eke' matches the word *a_hlul_eke*, whereas the rule pair '#a_hlulek' and 'le_ke' does not match this word. For each input wordform the set of its own rulepair candidates is generated. The search in the algorithm among these rulepairs starts from the longest rulepairs, and this allows more specific rules and exceptions to be applied first, whereas the more general rules are applied if no specific rules cover the input wordform.

3 Graph-Based Unsupervised Morpheme Segmentation

In this section we extend GBUMS (Graph-Based Unsupervised Morpheme Segmentation) that segments sequences of prefixes and suffixes (Golénia et al., 2009). We propose an extension of GBUMS which uses the graph structure of GBUMS through a brute-force method. Our experiments showed the improved results on training set and allowed GBUMS to be run on the test sets for two languages: Turkish and isiZulu.

The algorithm GBUMS was originally developed in (Shalonova et al., 2009) under the name GBUSS (Graph-Based Unsupervised Suffix Segmentation) to extract suffix sequences efficiently and it was applied to Russian and Turkish languages on training sets. We refer to prefixes and suffixes generally as morphemes. GBUMS uses a morpheme graph in a bottom-up way. Similar to Harris (Harris, 1955), the algorithm is based on letter frequencies. However, when Harris uses successor and predecessor frequencies, they use position-independent *n*-gram statistics to merge single letters into morphemes until a stopping criterion is fulfilled.

In the morpheme graph, each node represents a morpheme and each directed edge the concatenation of two morphemes labelled with the frequencies in a M-corpus (see Figure 1). M-corpus is a list of morpheme sequences

Definition 3. *Let* $M = \{m_i | 1 \leq i \leq |M|\}$ *be a set of morphemes, let* f_i *be the frequency with which morpheme* m_i *occurs in a M-corpus of morpheme sequences, let* $v_i = (m_i, f_i)$ *for* $1 \leq i \leq n$*, and let* $f_{i,j}$ *denote the number of morpheme sequences in the corpus in which morpheme* m_i *is followed by morpheme* m_j*. The* morpheme graph $G = (V, E)$ *is a directed graph with vertices or nodes* $V = \{v_i | 1 \leq i \leq |V|\}$ *and edges* $E = \{(v_i, v_j) | f_{i,j} > 0\}$*. We treat* $f_{i,j}$ *as the label of the edge from* v_i *to* v_j*.*

In *G*, each node is initialised with a letter according to a M-corpus, then one by one, nodes are merged to create the real morphemes. To merge nodes, an evaluation function is required. In (Golénia et al., 2009), Golenia et al. employed the *Morph_Lift* evaluation function based on its relation to the *lift* of a rule for association rules in data mining (Brin et al., 1997).

Definition 4. *Morph_Lift is defined for a pair of morphemes* m_1 *and* m_2 *as follows:*

$$Morph\_Lift(m_1, m_2) = \frac{f_{1,2}}{f_1 + f_2} \quad (1)$$

From now on, we know how to merge nodes. Now, we need to figure out the most important part of GBUMS, which is the stopping criterion. The stopping criterion is to prevent overgeneralisation. In other words, the algorithm needs to be stopped before getting the initial M-corpus (since no merging is possible). This criterion is based on the Bayesian Information Criterion (BIC) and Jensen-Shannon divergence (Li, 2001).

BIC is used for selecting a model (set of morphemes) which fits a data set (M-Corpus) without being too complex. We want to point out that BIC is related to MDL. BIC is a trade-off between the maximum likelihood, the parameters of the model (probability and length of each morpheme) and the number of elements in the data set (frequency of each morpheme). A smaller value of BIC corresponds to a better model fit. The maximum of the Jensen-Shannon divergence is used in order to analyse the increase of log-likelihood among all possible models. The Jensen-Shannon divergence is defined as follows (Dagan et al., 1997):

Definition 5. *The* Jensen-Shannon divergence *is defined for two morphemes* m_1 *and* m_2 *as the de-*

crease in entropy between the concatenated and the individual morphemes:

$$D_{JS}(m_1,m_2) = H(m_1 \cdot m_2) - \frac{L_{m_1}H(m_1) + L_{m_2}H(m_2)}{N} \tag{2}$$

where $H(m) = -P(m)\log_2 P(m)$ $N = \sum_m Freq(m)$ *and* L_m *is the string length of* m*.*

Stopping criterion *requires that* $\Delta BIC < 0$ *which translates to:*

$$\max_{m_1,m_2} D_{JS}(m_1,m_2) \leq 2\log_2 N \tag{3}$$

Algorithm 2 The GBUMS morpheme segmentation algorithm

```
input M-Corpus = List of Strings
output M-CorpusSeg = List of Strings
  M-CorpusSeg $\leftarrow$ SegmentInLetters(M-Corpus);
  Graph $\leftarrow$ InitialiseGraph(M-CorpusSeg);
  repeat
    Max $\leftarrow$ 0;
    for all (p,q) $\in$ Graph do
      ML_Max $\leftarrow$ Morph_Lift(p, q);
      if ML_Max $>$ Max then
        Max $\leftarrow$ ML_Max;
        pMax $\leftarrow$ p;
        qMax $\leftarrow$ q;
      end if
    end for
    Graph $\leftarrow$ MergeNodes(Graph, pMax, qMax);
    M-CorpusSeg $\leftarrow$ DeleteBoundaries(M-CorpusSeg, Label(pMax), Label(qMax));
    Graph $\leftarrow$ AdjustGraph(M-corpusSeg, Graph);
  until StoppingCriterion(pMax, qMax, Max)
```

After several merging iterations, the output of the algorithm is the graph shown in Figure 1. The GBUMS is presented in Algorithm 2.

Note that the M-Corpus is completely segmented at the beginning of the algorithm. Then, the boundaries in the segmented M-Corpus are removed step by step according to a pair found in the graph with the maximum value for *Morph_Lift*. When the stopping criterion is fulfilled, the segmented M-Corpus represents the morpheme sequences.

At this point we present our extension of GBUMS based on a brute-force heuristic which scores every possible segmentation of an input morpheme sequence using graph values. We consider the morpheme graph as a model where each morpheme sequence can be extracted by the *MGraph* function (eq. 4).

Definition 6. *We define MGraph of a morpheme sequence without boundaries x as follows:*

$$MGraph(x) = \arg\max_{t \subseteq x} \frac{1}{N_t - C_t} \sum_{m \in t} L_m log(f_m + 1) \tag{4}$$

where

- *t is a morpheme sequence with boundaries of x,*
- *m is a morpheme of t,*
- *f_m is the frequency of the morpheme m,*
- *N_t is the number of morphemes existing in the graph,*
- *C_t is the number of morphemes existing and contiguous in the graph.*

Firstly, as a post-processing procedure the *MGraph* function improves the performance on training data. Secondly, it permits the identification of unseen morphemes. That is why the model generated by GBUMS can be run on test data sets.

Example 2. *Let our final morpheme graph be as shown in Figure 1 where nodes represent suffixes and their frequencies.*
Let x="ekwe" be our input suffix sequence that we want to segment into individual suffixes. We split this input sequence into all possible substrings from individual characters up to size of the input string length: e-k-w-e, e-k-we, e-kw-e, ek-w-e, ..., ekwe.
Using equation 4, we evaluate each substring and select the one with the highest score as the correct segmentation. Here, we have 7 potential segmentations with a score higher than 0 (MGraph > 0), e.g: e-k-w-e $= (\log(3)+\log(3))/2 = 1.0986$*, ek-w-e* $=(2\log(4)+\log(3))/2 = 1.9356$ *and ek-we* $=$

$2\log(4) = 2.7726$.
Consequently, ek-we is chosen as the correct segmentation for the substring "ekwe".

We would like to highlight that our new method can identify unseen cases with M-Graph, for instance, in the previous example suffix "we" was not present in the training graph, but was correctly extracted.

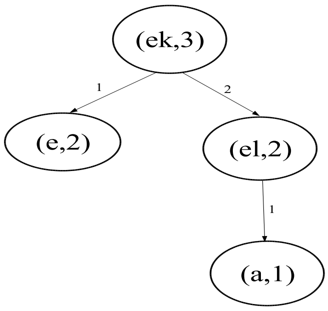

Figure 1: Example of a suffix subgraph in the training phase for isiZulu.

4 Results

Our experiments were based on Turkish data containing 1457 verbs and 2267 nouns, and isiZulu data containing 846 nouns and 931 verbs, with one single unambiguous segmentation per word.[1] Both isiZulu and Turkish data were uniquely sampled from the most frequent word lists.

Our first experiments compared TASR and the new SSE algorithm for stem extraction (10-fold cross validation assumes the following training and test set sizes: training sets containing 1311 wordforms for verbs and 2040 wordforms for nouns; test sets containing 146 wordforms for verbs and 227 wordforms for nouns). As can be seen from the Table 1, the performance of the SSE algorithm on Turkish data is much higher than that of TASR on the same dataset. As we mentioned in Section 1, TASR is not suitable for agglutinating languages with long suffix sequences. Although TASR algorithm gives an excellent performance on Russian, for most Turkish words it fails to extract proper stems.

	Test	FMea
TASR	Nouns	20.7±6.8
	Verbs	12.6±5.9
SSE	Nouns	84.3±3.2
	Verbs	82.1±3.7

Table 1: Comparison of TASR and SSE for Turkish using 10-fold cross validation.

Our next experiments evaluated the performance of GBUMS on its own given unsegmented suffix sequences from Turkish nouns and verbs as training data. The performance on these training data increased by approximately 3-4 % in comparison to the results presented in (Shalonova et al., 2009). We would like to point out that the results in (Shalonova et al., 2009) are based on training data rather than on test data, whereas in the current paper we run our algorithms on test (or unseen) data. Our final experiments examined performance on the test sets and were run both on Turkish and isiZulu data. We compared our approach with Morfessor run both in supervised and in unsupervised mode. Although Morfessor is known as one of the best unsupervised morphology learning systems, it is possible to run it in the supervised mode as well (Spiegler et al., 2008). The training data for SSE+ GBUMS contained wordforms with marked stems. During training stage the SSE algorithm was collecting information about stem boundaries and the GBUMS algorithm was run on unlabelled suffix and prefix sequences from the same training set. The test stage for the SSE+GBUMS approach was run on "raw" wordforms by applying the SSE algorithm first for stem extraction and then running GBUMS algorithm for segmenting prefix or suffix sequences after the SSE has extracted stems. Training data for supervised Morfessor used the same wordforms as for the SSE+GBUMS training set and contained wordforms segmented into stems and affixes (i.e. words segmentated into all morphemes were given as training data). The test data for supervised Morfesor were the same as those used for SSE+GBUMS. Morfessor in unsupervised mode was run on "raw" wordforms as training data. To evaluate our current work we ap-

[1] In agglutinating languages some wordforms even within one POS category can have several possible segmentations.

	Verbs	26.9±5.0

Table 3: Comparison of Morfessor and SSE+GBUMS for isiZulu using 10-fold cross validation.

plied the SSE+GBUMS approach for the under-resourced agglutinating language isiZulu containing both prefixes and suffixes and for Turkish containing only suffixes. The results show (Table 2 and Table 3) that our weakly supervised approach is comparable with the supervised Morfessor and decisively outperforms the unsupervised Morfessor. We think that it is useful to point out that unsupervised morphology learning systems in general require much larger training sets for better performance. F-measure is the harmonic mean of precision and recall, whereas precision is the proportion of true morpheme boundaries among the boundaries found, recall is the proportion of boundaries found among the true boundaries. In our experiments the GBUMS algorithm had no restrictions on affix length (Shalonova et al., 2009), but if there were restrictions, performance could be better. For isiZulu nouns our approach significantly outperformed supervised Morfessor, whereas for Turkish verbs SSE+GBUMS performed much worse. The best overall results obtained by GBUMS were based on the isiZulu nouns where about **53%** of all affixes were single letter affixes, whereas the worst results our approach gave for Turkish verbs where only about **12%** of affixes are composed of one letter. It is important to notice that the GBUMS algorithm, which is completely unsupervised, gives better results for extracting one letter affixes compared to Morfessor.

5 Conclusions

In the paper we described a weakly supervised approach for learning morphology in agglutinating languages. We were successful in our ultimate goal of synthesis of supervised and unsupervised induction techniques by achieving high performance on small amount of training data. Our weakly supervised approach is comparable with the supervised morphology learning system. As we are working with the languages for which linguistic resources are very limited (in particular words with morpheme boundaries), the developed method fulfills our goals of providing key components for speech and language products for such under-resourced languages. We speculate that the current performance might be improved by adding a small amount of completely ”raw” data to the training set.

The integration of our algorithms into working TTS systems is of key importance. As our near-term goal is the integration of morphology learning component into the currently working isiZulu TTS system, we will have to analyse the necessity of a Part of Speech Tagger (POS) and morphological disambiguation. In agglutinating languages some wordforms can be segmented in different ways (i.e. have different surface forms) and Machine Learning approaches normally select the most probable segmentation, and therefore our morphology disambiguation can be important. Morphological disambiguation for TTS can be considered a less complex problem than full morphological disambiguation as it can be linked, for example, to lexical tone disambiguation that may not require the full POS tag set. We intend to carry out user perception tests in order to evaluate the possible improvement in the isiZulu TTS quality after morphology information is added.

6 Acknowledgment

We would like to thank Kemal Oflazer from Sabanci University in Istanbul for his help and the Turkish data. We also thank Viktor Zimu and Etienne Barnard from CSIR in Pretoria for providing us isiZulu data. We also thank Roger Tucker for his support in the project. The work was sponsored by the EPSRC Grant EP/E010857/1 'Learning the morphology of complex synthetic languages'.

Multi-Document Summarization via the Minimum Dominating Set

Chao Shen and **Tao Li**
School of Computing and Information Sciences
Florida Internation University
{cshen001|taoli}@cs.fiu.edu

Abstract

Multi-document summarization has been an important problem in information retrieval. It aims to distill the most important information from a set of documents to generate a compressed summary. Given a sentence graph generated from a set of documents where vertices represent sentences and edges indicate that the corresponding vertices are similar, the extracted summary can be described using the idea of graph domination. In this paper, we propose a new principled and versatile framework for multi-document summarization using the minimum dominating set. We show that four well-known summarization tasks including generic, query-focused, update, and comparative summarization can be modeled as different variations derived from the proposed framework. Approximation algorithms for performing summarization are also proposed and empirical experiments are conducted to demonstrate the effectiveness of our proposed framework.

1 Introduction

As a fundamental and effective tool for document understanding and organization, multi-document summarization enables better information services by creating concise and informative reports for a large collection of documents. Specifically, in multi-document summarization, given a set of documents as input, the goal is to produce a condensation (i.e., a generated summary) of the content of the entire input set (Jurafsky and Martin, 2008). The generated summary can be generic where it simply gives the important information contained in the input documents without any particular information needs or query/topic-focused where it is produced in response to a user query or related to a topic or concern the development of an event (Jurafsky and Martin, 2008; Mani, 2001).

Recently, new summarization tasks such as update summarization (Dang and Owczarzak, 2008) and comparative summarization (Wang et al., 2009a) have also been proposed. Update summarization aims to generate short summaries of recent documents to capture new information different from earlier documents and comparative summarization aims to summarize the differences between comparable document groups.

In this paper, we propose a new principled and versatile framework for multi-document summarization using the *minimum dominating set*. Many known summarization tasks including generic, query-focused, update, and comparative summarization can be modeled as different variations derived from the proposed framework. The framework provides an elegant basis to establish the connections between various summarization tasks while highlighting their differences.

In our framework, a sentence graph is first generated from the input documents where vertices represent sentences and edges indicate that the corresponding vertices are similar. A natural method for describing the extracted summary is based on the idea of graph domination (Wu and Li, 2001). *A dominating set* of a graph is a subset of vertices such that every vertex in the graph is either in the subset or adjacent to a vertex in the subset; and

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 984–992,
Beijing, August 2010

a minimum dominating set is a dominating set with the minimum size. The minimum dominating set of the sentence graph can be naturally used to describe the summary: it is *representative* since each sentence is either in the minimum dominating set or connected to one sentence in the set; and it is with *minimal redundancy* since the set is of minimum size. Approximation algorithms are proposed for performing summarization and empirical experiments are conducted to demonstrate the effectiveness of our proposed framework. Though the dominating set problem has been widely used in wireless networks, this paper is the first work on using it for modeling sentence extraction in document summarization.

The rest of the paper is organized as follows. In Section 2, we review the related work about multi-document summarization and the dominating set. After introducing the minimum dominating set problem in graph theory in Section 3, we propose the minimum dominating set based framework for multi-document summarization and model the four summarization tasks including generic, query-focused, update, and comparative summarization in Section 4. Section 5 presents the experimental results and analysis, and finally Section 6 concludes the paper.

2 Related Work

Generic Summarization For generic summarization, a saliency score is usually assigned to each sentence and then the sentences are ranked according to the saliency score. The scores are usually computed based on a combination of statistical and linguistic features. MEAD (Radev et al., 2004) is an implementation of the centroid-based method where the sentence scores are computed based on sentence-level and inter-sentence features. SumBasic (Nenkova and Vanderwende, 2005) shows that the frequency of content words alone can also lead good summarization results. Graph-based methods (Erkan and Radev, 2004; Wan et al., 2007b) have also been proposed to rank sentences or passages based on the PageRank algorithm or its variants.

Query-Focused Summarization In query-focused summarization, the information of the given topic or query should be incorporated into summarizers, and sentences suiting the user's declared information need should be extracted. Many methods for generic summarization can be extended to incorporate the query information (Saggion et al., 2003; Wei et al., 2008). Wan et al. (Wan et al., 2007a) make full use of both the relationships among all the sentences in the documents and relationship between the given query and the sentences by manifold ranking. Probability models have also been proposed with different assumptions on the generation process of the documents and the queries (Daumé III and Marcu, 2006; Haghighi and Vanderwende, 2009; Tang et al., 2009).

Update Summarization and Comparative Summarization Update summarization was introduced in Document Understanding Conference (DUC) 2007 (Dang, 2007) and was a main task of the summarization track in Text Analysis Conference (TAC) 2008 (Dang and Owczarzak, 2008). It is required to summarize a set of documents under the assumption that the reader has already read and summarized the first set of documents as the main summary. To produce the update summary, some strategies are required to avoid redundant information which has already been covered by the main summary. One of the most frequently used methods for removing redundancy is Maximal Marginal Relevance(MMR) (Goldstein et al., 2000). Comparative document summarization is proposed by Wang et. al. (Wang et al., 2009a) to summarize the differences between comparable document groups. A sentence selection approach is proposed in (Wang et al., 2009a) to accurately discriminate the documents in different groups modeled by the conditional entropy.

The Dominating Set Many approximation algorithms have been developed for finding minimum dominating set for a given graph (Guha and Khuller, 1998; Thai et al., 2007). Kann (Kann, 1992) shows that the minimum dominating set problem is equivalent to set cover problem, which is a well-known NP-hard problem. Dominating set has been widely used for clustering in wireless networks (Chen and Liestman, 2002; Han and Jia, 2007). It has been used to find topic words for hierarchical summarization (Lawrie et al., 2001), where a set of topic words is extracted as a dominating set of word graph. In our work, we use the minimum dominating set to formalize the sentence extraction for document summarization.

3 The Minimum Dominating Set Problem

Given a graph $G =< V, E >$, *a dominating set* of G is a subset S of vertices with the following property: each vertex of G is either in the dominating set S, or is adjacent to some vertices in S.

Problem 3.1. *Given a graph G, the minimum dominating set problem (MDS) is to find a minimum size subset S of vertices, such that S forms a dominating set.*

MDS is closely related to the set cover problem (SC), a well-known NP-hard problem.

Problem 3.2. *Given F, a finite collection* $\{S_1, S_2, \dots, S_n\}$ *of finite sets, the set cover problem (SC) is to find the optimal solution*

$$F^* = \arg\min_{F' \subseteq F} |F'| \; s.t. \bigcup_{S' \in F'} S' = \bigcup_{S \in F} S.$$

Theorem 3.3. *There exists a pair of polynomial time reduction between MDS and SC.*

So, MDS is also NP-hard and it has been shown that there are no approximate solutions within $c \log |V|$, for some $c > 0$ (Feige, 1998; Raz and Safra, 1997).

3.1 An Approximation Algorithm

A greedy approximation algorithm for the SC problem is described in (Johnson, 1973). Basically, at each stage, the greedy algorithm chooses the set which contains the largest number of uncovered elements.

Based on Theorem 3.3, we can obtain a greedy approximation algorithm for MDS. Starting from an empty set, if the current subset of vertices is not the dominating set, a new vertex which has the most number of the adjacent vertices that are not adjacent to any vertex in the current set will be added.

Proposition 3.4. *The greedy algorithm approximates SC within* $1 + \ln s$ *where s is the size of the largest set.*

It was shown in (Johnson, 1973) that the approximation factor for the greedy algorithm is no more than $H(s)$, the s-th harmonic number:

$$H(s) = \sum_{k=1}^{s} \frac{1}{k} \leq \ln s + 1$$

Corollary 3.5. *MDS has a approximation algorithm within* $1 + \ln \Delta$ *where* Δ *is the maximum degree of the graph.*

Corollary 3.5 follows directly from Theorem 3.3 and Proposition 3.4.

4 The Summarization Framework

4.1 Sentence Graph Generation

To perform multi-document summarization via minimum dominating set, we need to first construct a sentence graph in which each node is a sentence in the document collection. In our work, we represent the sentences as vectors based on tf-isf, and then obtain the cosine similarity for each pair of sentences. If the similarity between a pair of sentences s_i and s_j is above a given threshold λ, then there is an edge between s_i and s_j.

For generic summarization, we use all sentences for building the sentence graph. For query-focused summarization, we only use the sentences containing at least one term in the query. In addition, when a query q is involved, we assign each node s_i a weight, $w(s_i) = d(s_i, q) = 1 - \cos(s_i, q)$, to indicate the distance between the sentence and the query q.

After building the sentence graph, we can formulate the summarization problem using

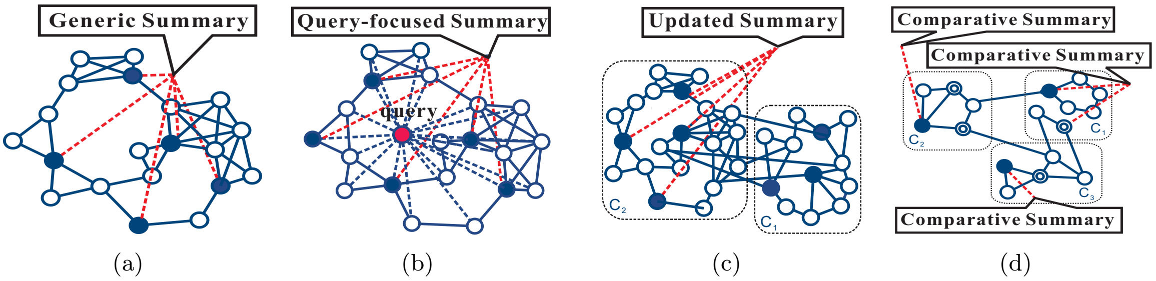

Figure 1: Graphical illustrations of multi-document summarization via the minimum dominating set. (a): The minimum dominating set is extracted as the generic summary. (b):The minimum weighted dominating set is extracted as the query-based summary. (c):Vertices in the right rectangle represent the first document set C_1, and ones in the left represent the second document set where update summary is generated. (d):Each rectangle represents a group of documents. The vertices with rings are the dominating set for each group, while the solid vertices are the complementary dominating set, which is extracted as comparative summaries.

the minimum dominating set. A graphical illustration of the proposed framework is shown in Figure 1.

4.2 Generic Summarization

Generic summarization is to extract the most representative sentences to capture the important content of the input documents. Without taking into account the length limitation of the summary, we can assume that the summary should represent all the sentences in the document set (i.e., every sentence in the document set should either be extracted or be similar with one extracted sentence). Meanwhile, a summary should also be as short as possible. Such summary of the input documents under the assumption is exactly the minimum dominating set of the sentence graph we constructed from the input documents in Section 4.1. Therefore the summarization problem can be formulated as the minimum dominating set problem.

However, usually there is a length restriction for generating the summary. Moreover, the MDS is NP-hard as shown in Section 3. Therefore, it is straightforward to use a greedy approximation algorithm to construct a subset of the dominating set as the final summary. In the greedy approach, at each stage, a sentence which is optimal according to the local criteria will be extracted. Algorithm 1 describes an approximation algorithm for generic summarization. In Algorithm 1, G is the sentence graph, $L(S)$ is the length of the summary, W is the maximal length of the summary, and $ADJ(v) = \{v'|(v', v) \in E(G)\}$ is the set of vertices which are adjacent to the vertex v. A graphical illustration of generic summarization using the minimum dominating set is shown in Figure 1(a).

Algorithm 1 Algorithm for Generic Summarization

```
INPUT: G, W
OUTPUT: S
$S = \emptyset$
$T = \emptyset$
while $L(S) < W$ and $V(G)! = S$ do
    for $v \in V(G) - S$ do
        $s(v) = |\{ADJ(v) - T\}|$
    $v^* = \arg\max_v s(v)$
    $S = S \cup \{v^*\}$
    $T = T \cup ADJ(v^*)$
```

4.3 Query-Focused Summarization

Letting G be the sentence graph constructed in Section 4.1 and q be the query, the query-focused summarization can be modeled as

$$D^* = \arg\min_{D \subseteq G} \sum_{s \in D} d(s, q) \qquad (1)$$
$$\text{s.t. } D \text{ is a dominating set of } G.$$

Note that $d(s, q)$ can be viewed as the weight of vertex in G. Here the summary length is minimized implicitly, since if $D' \subseteq D$, then

$\sum_{s \in D'} d(s,q) \leq \sum_{s \in D} d(s,q)$. The problem in Eq.(1) is exactly a variant of the minimum dominating set problem, i.e., the minimum weighted dominating set problem (MWDS).

Similar to MDS, MWDS can be reduced from the weighted version of the SC problem. In the weighted version of SC, each set has a weight and the sum of weights of selected sets needs to be minimized. To generate an approximate solution for the weighted SC problem, instead of choosing a set i maximizing $|SET(i)|$, a set i minimizing $\frac{w(i)}{|SET(i)|}$ is chosen, where $SET(i)$ is composed of uncovered elements in set i, and $w(i)$ is the weight of set i. The approximate solution has the same approximation ratio as that for MDS, as stated by the following theorem (Chvatal, 1979).

Theorem 4.1. *An approximate weighted dominating set can be generated with a size at most* $1+\log\Delta\cdot|OPT|$, *where* Δ *is the maximal degree of the graph and* OPT *is the optimal weighted dominating set.*

Accordingly, from generic summarization to query-focused summarization, we just need to modify line 6 in Algorithm 1 to

$$v^* = \arg\min_{v} \frac{w(v)}{s(v)}, \tag{2}$$

where $w(v)$ is the weight of vertex v. A graphical illustration of query-focused summarization using the minimum dominating set is shown in Figure 1(b).

4.4 Update Summarization

Give a query q and two sets of documents C_1 and C_2, update summarization is to generate a summary of C_2 based on q, given C_1. Firstly, summary of C_1, referred as D_1 can be generated. Then, to generate the update summary of C_2, referred as D_2, we assume D_1 and D_2 should represent all query related sentences in C_2, and length of D_2 should be minimized.

Let G_1 be the sentence graph for C_1. First we use the method described in Section 4.3 to extract sentences from G_1 to form D_1. Then we expand G_1 to the whole graph G using the second set of documents C_2. G is then the graph presentation of the document set including C_1 and C_2. We can model the update summary of C_2 as

$$D^* = \arg\min_{D_2} \textstyle\sum_{s \in D_2} w(s) \tag{3}$$
$$\text{s.t. } D_2 \cup D_1 \text{ is a dominating set of } G.$$

Intuitively, we extract the smallest set of sentences that are closely related to the query from C_2 to complete the partial dominating set of G generated from D_1. A graphical illustration of update summarization using the minimum dominating set is shown in Figure 1(c).

4.5 Comparative Summarization

Comparative document summarization aims to summarize the differences among comparable document groups. The summary produced for each group should emphasize its difference from other groups (Wang et al., 2009a).

We extend our method for update summarization to generate the discriminant summary for each group of documents. Given N groups of documents $C_1, C_2, \ldots, C_N$, we first generate the sentence graphs $G_1, G_2, \ldots, G_N$, respectively. To generate the summary for $C_i, 1 \leq i \leq N$, we view C_i as the update of all other groups. To extract a new sentence, only the one connected with the largest number of sentences which have no representatives in any groups will be extracted. We denote the extracted set as the complementary dominating set, since for each group we obtain a subset of vertices dominating those are not dominated by the dominating sets of other groups. To perform comparative summarization, we first extract the standard dominating sets for $G_1, \ldots, G_N$, respectively, denoted as $D_1, \ldots, D_N$. Then we extract the so-called complementary dominating set CD_i for G_i by continuing adding vertices in G_i to find the dominating set of $\cup_{1 \leq j \leq N} G_j$ given $D_1, \ldots, D_{i-1}, D_{i+1}, \ldots, D_N$. A graphical illustration of comparative summarization is shown in Figure 1(d).

5 Experiments

We have conducted experiments on all four summarization tasks and our proposed methods based on the minimum dominating set have outperformed many existing methods. For the generic, topic-focused and update summarization tasks, the experiments are perform the DUC data sets using ROUGE-2 and ROUGE-SU (Lin and Hovy, 2003) as evaluation measures. For comparative summarization, a case study as in (Wang et al., 2009a) is performed. Table 1 shows the characteristics of the data sets. We use DUC04 data set to evaluate our method for generic summarization task and DUC05 and DUC06 data sets for query-focused summarization task. The data set for update summarization, (i.e. the main task of TAC 2008 summarization track) consists of 48 topics and 20 newswire articles for each topic. The 20 articles are grouped into two clusters. The task requires to produce 2 summaries, including the initial summary (TAC08 A) which is standard query-focused summarization and the update summary (TAC08 B) under the assumption that the reader has already read the first 10 documents.

We apply a 5-fold cross-validation procedure to choose the threshold λ used for generating the sentence graph in our method.

5.1 Generic Summarization

We implement the following widely used or recent published methods for generic summarization as the baseline systems to compare with our proposed method (denoted as MDS). (1) Centroid: The method applies MEAD algorithm (Radev et al., 2004) to extract sentences according to the following three parameters: centroid value, positional value, and first-sentence overlap. (2) LexPageRank: The method first constructs a sentence connectivity graph based on cosine similarity and then selects important sentences based on the concept of eigenvector centrality (Erkan and Radev, 2004). (3) BSTM: A Bayesian sentence-based topic model making use of both the term-document and term-sentence associations (Wang et al., 2009b).

Our method outperforms the simple Centroid method and another graph-based LexPageRank, and its performance is close to the results of the Bayesian sentence-based topic model and those of the best team in the DUC competition. Note however that, like clustering or topic based methods, BSTM needs the topic number as the input, which usually varies by different summarization tasks and is hard to estimate.

5.2 Query-Focused Summarization

We compare our method (denoted as MWDS) described in Section 4.3 with some recently published systems. (1) TMR (Tang et al., 2009): incorporates the query information into the topic model, and uses topic based score and term frequency to estimate the importance of the sentences. (2) SNMF (Wang et al., 2008): calculates sentence-sentence similarities by sentence-level semantic analysis, clusters the sentences via symmetric non-negative matrix factorization, and extracts the sentences based on the clustering result. (3) Wiki (Nastase, 2008): uses Wikipedia as external knowledge to expand query and builds the connection between the query and the sentences in documents.

Table 3 presents the experimental comparison of query-focused summarization on the two datasets. From Table 3, we observe that our method is comparable with these systems. This is due to the good interpretation of the summary extracted by our method, an ap-

proximate minimal dominating set of the sentence graph. On DUC05, our method achieves the best result; and on DUC06, our method outperforms all other systems except the best team in DUC. Note that our method based on the minimum dominating set is much simpler than other systems. Our method only depends on the distance to the query and has only one parameter (i.e., the threshold λ in generating the sentence graph).

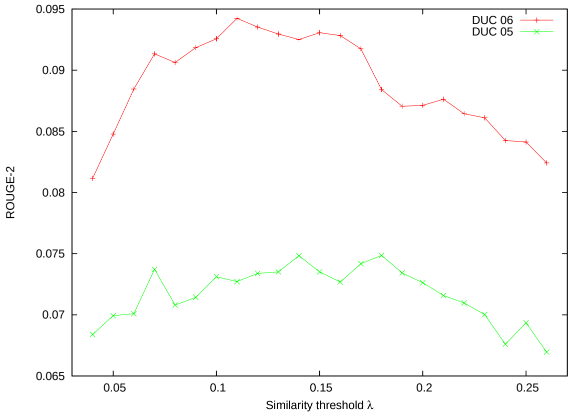

Figure 2: ROUGE-2 vs. threshold λ

We also conduct experiments to empirically evaluate the sensitivity of the threshold λ. Figure 2 shows the ROUGE-2 curve of our MWDS method on the two datasets when λ varies from 0.04 to 0.26. When λ is small, edges fail to represent the similarity of the sentences, while if λ is too large, the graph will be sparse. As λ is approximately in the range of $0.1 - 0.17$, ROUGE-2 value becomes stable and relatively high.

5.3 Update Summarization

Table 5 presents the experimental results on update summarization. In Table 5, 'TAC Best" and "TAC Median" represent the best and median results from the participants of TAC 2008 summarization track in the two tasks respectively according to the TAC 2008 report (Dang and Owczarzak, 2008). As seen from the results, the ROUGE scores of our methods are higher than the median results. The good results of the best team typically come from the fact that they utilize advanced natural language processing (NLP) techniques to resolve pronouns and other anaphoric expressions. Although we can spend more efforts on the preprocessing or language processing step, our goal here is to demonstrate the effectiveness of formalizing the update summarization problem using the minimum dominating set and hence we do not utilize advanced NLP techniques for preprocessing. The experimental results demonstrate that our simple update summarization method based on the minimum dominating set can lead to competitive performance for update summarization.

5.4 Comparative Summarization

We use the top six largest clusters of documents from TDT2 corpora to compare the summary generated by different comparative summarization methods. The topics of the six document clusters are as follows: topic 1: Iraq Issues; topic 2: Asia's economic crisis; topic 3: Lewinsky scandal; topic 4: Nagano Olympic Games; topic 5: Nuclear Issues in Indian and Pakistan; and topic 6: Jakarta Riot. From each of the topics, 30 documents are extracted

Topic	Complementary Dominating Set	Discriminative Sentence Selection	Dominating Set
1	$\cdots$ U.S. Secretary of State Madeleine Albright arrives to consult on the stand-off between the **United Nations and Iraq**.	**the U.S. envoy to the United Nations**, Bill Richardson, $\cdots$ play down China's refusal to support threats of **military force against Iraq**	The United States and Britain do not trust **President Saddam** and wants *cdots*warning of serious consequences if **Iraq** violates the accord.
2	**Thailand's currency**, the baht, **dropped through a key psychological level** of $\cdots$ amid a regional sell-off sparked by escalating **social unrest in Indonesia**.	Earlier, driven largely by **the declining yen**, **South Korea's stock market fell** by $\cdots$, while the **Nikkei 225 benchmark index dipped** below 15,000 in the morning $\cdots$	*In the fourth quarter, IBM Corp. earned $2.1 billion, up 3.4 percent from $2 billion a year earlier.*
3	$\cdots$ attorneys representing **President Clinton and Monica Lewinsky.**	The following night **Isikoff** $\cdots$, where he directly followed the recitation of the top-10 list: "Top 10 **White House Jobs That Sound Dirty.**"	In Washington, Ken Starr's grand jury continued its investigation of the **Monica Lewinsky matter**.
4	Eight women and six men were named Saturday night as the first **U.S. Olympic Snowboard Team** as their sport gets set to make its debut in **Nagano, Japan**.	*this tunnel is finland's cross country version of tokyo's alpine ski dome, and olympic skiers flock from russia, $\cdots$, france and austria this past summer to work out the kinks $\cdots$*	If the skiers the **men's super-G** and the **women's downhill** on Saturday, they will be back on schedule.
5	**U.S. officials** have announced **sanctions** Washington will impose on **India and Pakistan** for conducting **nuclear tests**.	The **sanctions** would stop all foreign aid except for humanitarian purposes, **ban military sales to India** $\cdots$	And **Pakistan's prime minister** says his country will sign the **U.N.'s comprehensive ban on nuclear tests** if **India** does, too.
6	$\cdots$ remain in force around **Jakarta**, and at the Parliament building where **thousands of students staged a sit-in** Tuesday $\cdots$.	"**President Suharto** has given much to his country over the past 30 years, raising **Indonesia's** standing in the world $\cdots$	*What were the students doing at the time you were there, and what was the reaction of the students to the troops?*

Table 4: A case study on comparative document summarization. Some unimportant words are skipped due to the space limit. The bold font is used to annotate the phrases that are highly related with the topics, and italic font is used to highlight the sentences that are not proper to be used in the summary.

randomly to produce a one-sentence summary. For comparison purpose, we extract the sentence with the maximal degree as the baseline. Note that the baseline can be thought as an approximation of the dominating set using only one sentence. Table 4 shows the summaries generated by our method (complementary dominating set (CDS)), discriminative sentence selection (DSS) (Wang et al., 2009a) and the baseline method. Our CDS method can extract discriminative sentences for all the topics. DSS can extract discriminative sentences for all the topics except topic 4. Note that the sentence extracted by DSS for topic 4 may be discriminative from other topics, but it is deviated from the topic Nagano Olympic Games. In addition, DSS tends to select long sentences which should not be preferred for summarization purpose. The baseline method may extract some general sentences, such as the sentence for topic 2 and topic 6 in Table 4.

6 Conclusion

In this paper, we propose a framework to model the multi-document summarization using the minimum dominating set and show that many well-known summarization tasks can be formulated using the proposed framework. The proposed framework leads to simple yet effective summarization methods. Experimental results show that our proposed methods achieve good performance on several multi-document document tasks.

Corpus-based Semantic Class Mining: Distributional vs. Pattern-Based Approaches

Abstract

Main approaches to corpus-based semantic class mining include *distributional similarity* (DS) and *pattern-based* (PB). In this paper, we perform an empirical comparison of them, based on a publicly available dataset containing 500 million web pages, using various categories of queries. We further propose a frequency-based rule to select appropriate approaches for different types of terms.

1 Introduction

Computing the semantic relationship between terms, which has wide applications in natural language processing and web search, has been a hot topic nowadays. This paper focuses on corpus-based semantic class mining (Lin 1998; Pantel and Lin 2002; Pasca 2004; Shinzato and Torisawa, 2005; Ohshima, et al., 2006; Zhang et al., 2009), where *peer terms* (or *coordinate terms*) are discovered from a corpus.

Existing approaches to semantic class mining could roughly be divided into two categories: *distributional similarity* (*DS*), and *pattern-based* (*PB*). The first type of work (Hindle, 1990; Lin 1998; Pantel and Lin 2002) is based on the distributional hypothesis (Harris, 1985), saying that terms occurring in analogous (lexical or syntactic) *contexts* tend to be similar. DS approaches basically exploit *second-order* co-occurrences to discover strongly associated concepts. In pattern-based approaches (Hearst 1992; Pasca 2004; Shinzato and Torisawa, 2005; Ohshima, et al., 2006; Zhang et al., 2009), patterns are applied to discover specific relationships between terms, from the general *first-order* co-occurrences. For example, "*NP such as NP, NP..., and NP*" is a popular and high-quality pattern for extracting peer terms (and also hyponyms). Besides the natural language patterns, some HTML tag tree patterns (e.g., the drop down list) are also effective in semantic class mining.

It is worth-noting that the word "*pattern*" also appears in some DS approaches (Pasca et al., 2006; Tanev and Magnini, 2006; Pennacchiotti and Pantel, 2009), to represent the *context* of a term or a term-pair, e.g., "(invent, subject-of)" for the term "Edison", and "- starring -" for the term-pair "(The Terminal, Tom Hanks)". Although "*patterns*" are utilized, we categorize them as DS approaches rather than PB, because they match the DS framework well. In this paper, *PB* only refers to the approaches that utilize patterns to exploit *first-order* co-occurrences. And the patterns in DS approaches are called *contexts* in the following part of this paper.

Progress has been made and promising results have been reported in the past years for both DS and PB approaches. However, most previous research work (some exceptions are discussed in related work) involves solely one category of approach. And there is little work studying the comparison of their performance for different types of terms (we use "*term*" to represent a single word or a phrase).

In this paper, we make an empirical study of this problem, based on a large-scale, publicly available dataset containing 500 million web pages. For each approach *P*, we build a *term-similarity graph* *G*(*P*), with vertices representing terms, and edges being the confidence that the two terms are peers. Approaches are compared by the quality of their corresponding term graphs.

[*] Work done during an internship at Microsoft

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 993–1001,
Beijing, August 2010

We measure the quality of a term graph by set expansion. Two query sets are adopted: One contains 49 semantic classes of named entities and 20220 trials (queries), collected by Pantel et al. (2009) from Wikipedia[2]; and the other contains 100 queries of five lexical categories (proper nouns, common nouns, verbs, adjectives, and adverbs), built in this paper for studying the performance comparison on different term types. With the dataset and the query sets, we study the comparison of DS and PB. Key observations and preliminary conclusions are,

- ***DS vs. PB***: DS approaches perform much better on common nouns, verbs, adjectives, and adverbs; while PB generates higher-quality semantic classes for proper nouns.
- ***Lexical vs. Html-tag patterns***: If only lexical patterns are adopted in PB, the performance drops significantly; while the performance only becomes slightly worse with only Html-tag patterns being included.
- ***Corpus-size***: For proper nouns, PB beats DS even based on a much smaller corpus; similarly, for other term types, DS performs better even with a smaller corpus.

Given these observations, we further study the feasibility of selecting appropriate approaches for different term types to obtain better results. A simple and effective frequency-based rule is proposed for approach-selection. Our online semantic mining system (*NeedleSeek*)[3] adopts both PB and DS to build semantic classes.

2 Related Work

Existing efforts for semantic class mining has been done upon various types of data sources, including text-corpora, search-results, and query logs. In corpus-based approaches (Lin 1998; Lin and Pantel 2001; Pantel and Lin 2002; Pasca 2004; Zhang et al., 2009), semantic classes are obtained by the offline processing of a corpus which can be unstructured (e.g., plain text) or semi-structured (e.g., web pages). Search-results-based approaches (Etzioni et al., 2004; Kozareva et al., 2008; Wang and Cohen, 2008) assume that multiple terms (or, less often, one term) in a semantic class have been provided as *seeds*. Other terms in the class are retrieved by sending queries (constructed according to the seeds) to a web search engine and mining the search results. Query logs are exploited in (Pasca 2007; Komachi and Suzuki, 2008; Yamaguchi 2008) for semantic class mining. This paper focuses on corpus-based approaches.

As has been mentioned in the introduction part, primarily two types of methodologies are adopted: DS and PB. Syntactic context information is used in (Hindle, 1990; Ruge, 1992; Lin 1998; Lin and Pantel, 2001; Pantel and Lin, 2002) to compute term similarities. The construction of syntactic contexts requires sentences to be parsed by a dependency parser, which may be extremely time-consuming on large corpora. As an alternative, lexical context (such as text window) has been studied (Pantel et al., 2004; Agirre et al., 2009; Pantel et al., 2009). In the pattern-based category, a lot of work has been done to discover term relations by sentence lexical patterns (Hearst 1992; Pasca 2004), HTML tag patterns (Shinzato and Torisawa, 2005), or both (Shi et al., 2008; Zhang et al., 2009). In this paper, our focus is not one specific methodology, but the comparison and combination of them.

A small amount of existing work is related to the comparison or combination of multiple methods. Pennacchiotti and Pantel (2009) proposed a feature combination framework (named ensemble semantic) to combine features generated by different extractors (distributional and "pattern-based") from various data sources. As has been discussed in the introduction, in our terminology, their "pattern-based" approaches are actually DS for term-pairs. In addition, their study is based on three semantic classes (actors, athletes, and musicians), all of which are proper nouns. Differently, we perform the comparison by classifying terms according to their lexical categories, based on which additional insights are obtained about the pros and cons of each methodology. Pantel et al., (2004) proposed, in the scenario of extracting *is-a* relations, one pattern-based approach and compared it with a baseline syntactic distributional similarity method (called *syntactic co-occurrence* in their paper). Differently, we study the comparison in a different scenario (semantic class mining). In addition, they did not differentiate the lexical types of terms in the study. The third difference is that we proposed a rule for method-selection while they did not. In (Pasca and Durme,

[2] http://www.wikipedia.org/

[3] http://needleseek.msra.cn/

2008), clusters of distributional similar terms were adopted to expand the labeled semantic classes acquired from the "such as | including" pattern. Although both patterns and distributional similarity were used in their paper, they did not do any comparison about their performance. Agirre et al. (2009) compared DS approaches with WordNet-based methods in computing word similarity and relatedness; and they also studied the combination of them. Differently, the methods for comparison in our paper are DS and PB.

3 Similarity Graph Construction

A key operation in corpus-based semantic class mining is to build a term similarity graph, with vertices representing terms, and edges being the similarity (or distance) between terms. Given the graph, a clustering algorithm can be adopted to generate the final semantic classes. Now we describe the state-of-the-art DS and PB approaches for computing term similarities.

3.1 Distributional Similarity

DS approaches are based on the distributional hypothesis (Harris, 1985), which says that terms appearing in analogous contexts tend to be similar. In a DS approach, a term is represented by a feature vector, with each feature corresponding to a context in which the term appears. The similarity between two terms is computed as the similarity between their corresponding feature vectors. Different approaches may have different ways of 1) defining a context, 2) assigning feature values, or 3) measuring the similarity between two feature vectors.

Contexts	Text window (window size: 2, 4)
	Syntactic
Feature value	PMI
Similarity measure	Cosine, Jaccard

Table 1. DS approaches implemented in this paper

Mainly two kinds of contexts have been extensively studied: *syntactic context* and *lexical context*. The construction of *syntactic contexts* relies on the syntactic parsing trees of sentences, which are typically the output of a syntactic parser. Given a syntactic tree, a syntactic context of a term *w* can be defined as the parent (or one child) of *w* in the tree together with their relationship (Lin, 1998; Pantel and Lin, 2002; Pantel et al., 2009). For instance, in the syntactic tree of sentence "*this is an interesting read for anyone studying logic*", one context of the word "logic" can be defined as "*study V:obj:N*". In this paper, we adopt Minipar (Lin, 1994) to parse sentences and to construct syntactic trees.

One popular *lexical context* is *text window*, where a context *c* for a term *w* in a sentence *S* is defined as a substring of the sentence containing but removing *w*. For example, for sentence "$\ldots w_1 w_2 w_3 w w_4 w_5 w_6 \ldots$", a text window context (with size 4) of *w* can be "$w_2 w_3 w_4 w_5$". It is typically time-consuming to construct the syntactic trees for a large-scale dataset, even with a lightweight syntactic parser like Minipar. The construction of lexical contexts is much more efficient because it does not require the syntactic dependency between terms. Both contexts are studied in this paper.

After defining contexts for a term *w*, the next step is to construct a feature vector for the term: $F(w)=(\mathrm{f}_{w1}, \mathrm{f}_{w2} \ldots, \mathrm{f}_{w,m})$, where *m* is the number of distinct contexts, and $\mathrm{f}_{w,c}$ is the feature value of context *c* with respect to term *w*. Among all the existing approaches, the dominant way of assigning feature values (or context values) is computing the pointwise mutual information (PMI) between the feature and the term,

$$\mathrm{f}_{w,c} = \mathrm{PMI}_{w,c} = \log \frac{F(w,c) \cdot F(*,*)}{F(w,*) \cdot F(*,c)} \qquad (3.1)$$

where $F(w,c)$ is the frequency of context *c* occurring for term *w*, $F(w,*)$ is the total frequency of all contexts for term *w*, $F(*,c)$ is the frequency of context *c* for all terms, and $\mathrm{F}(*,*)$ is the total frequency of all context for all terms. They are calculated as follows respectively,

$$\begin{aligned} F(w,*) &= \textstyle\sum_{j=1}^{m} F(w,j) \\ F(*,c) &= \textstyle\sum_{i=1}^{n} F(i,c) \qquad (3.2) \\ F(*,*) &= \textstyle\sum_{i=1}^{n} \sum_{j=1}^{m} F(i,j) \end{aligned}$$

where *m* and *n* are respectively the distinct numbers of contexts and terms.

Following state-of-the-art, we adopt PMI in this paper for context weighting.

Given the feature vectors of terms, the similarity of any two terms is naturally computed as the similarity of their corresponding feature vectors. Cosine similarity and Jaccard similarity (weighted) are implemented in our experiments,

$$Cosine(\vec{x}, \vec{y}) = \frac{\sum_i x_i y_i}{\sqrt{\sum_i {x_i}^2} \cdot \sqrt{\sum_i {y_i}^2}} \qquad (3.3)$$

$$Jaccard(\vec{x},\vec{y}) = \frac{\sum_i \min(x_i,y_i)}{\sum_i x_i + \sum_i y_i - \sum_i \min(x_i,y_i)} \quad (3.4)$$

Jaccard similarity is finally used in presenting our experimental results (in Section 6), because it achieves higher performance.

3.2 Pattern-based Approaches

In PB approaches, a list of carefully-designed (or automatically learned) patterns is exploited and applied to a text collection, with the hypothesis that the terms extracted by applying each of the patterns to a specific piece of text tend to be similar. Two categories of patterns have been studied in the literature: sentence lexical patterns, and HTML tag patterns. Table-2 lists some popular patterns utilized in existing semantic class mining work (Heast 1992; Pasca 2004; Kozareva et al., 2008; Zhang et al., 2009). In the table, "T" means a term (a word or a phrase). Exactly the same set of patterns is employed in implementing our pattern-based approaches in this paper.

Type	Pattern
Lexical	T {, T}*{,} (and|or) {other} T
	(such as | including) T (and|,|.)
	T, T, T {,T}*
Tag	<ul> <li> T </li> … <li> T </li> </ul>
	<ol> <li> T </li> … <li> T </li> </ol>
	<select> <option> T …<option> T </select>
	<table> <tr> <td> T </td> … <td> T </td> </tr> ... </table>
	Other Html-tag repeat patterns

Table 2. Patterns employed in this paper (Lexical: sentence lexical patterns; Tag: HTML tag patterns)

We call the set of terms extracted by applying a pattern one time as a *raw semantic class* (RASC). The term similarity graph needs to be built by aggregating the information of the extracted RASCs.

One basic idea of estimating term similarity is to count the number of RASCs containing both of them. This idea is extended in the state-of-the-art approaches (Zhang et al., 2009) to distinguish the reliability of different patterns and to punish term similarity contributions from the same domain (or site), as follows,

$$Sim(a,b) = \sum_{i=1}^{m} \log(1 + \sum_{j=1}^{k_i} w(P(C_{i,j}))) \quad (3.5)$$

where $C_{i,j}$ is a RASC containing both term a and term b, $P(C_{i,j})$ is the pattern via which the RASC is extracted, and $w(P)$ is the weight of pattern P. The above formula assumes all these RASCs belong to m sites (or domains) with $C_{i,j}$ extracted from a page in site i, and k_i being the number of RASCs corresponding to site i.

In this paper, we adopt an extension of the above formula which considers the frequency of a single term, as follows,

$$Sim^*(a,b) = Sim(a,b) \cdot \sqrt{IDF(a) \cdot IDF(b)} \quad (3.6)$$

where $IDF(a)$=log(1+N/$N(a)$), N is the total number of RASCs, and $N(a)$ is the number of RASCs containing a. In the experiments, we simply set the weight of every pattern type to be the same value (1.0).

4 Compare PB and DS

We compare PB and DS by the quality of the term similarity graphs they generated. The quality of a term graph is measured by set expansion: Given a list of *seed* terms (e.g., S={*lent*, *epiphany*}) belonging to a semantic class, our task is to find other members of this class, such as *advent*, *easter*, and *christmas*.

In this section, we first describe our set expansion algorithm adopted in our study. Then DS and PB are compared in terms of their set-expansion performance. Finally we discuss ways of selecting appropriate approaches for different types of seeds to get better expansion results.

4.1 Set Expansion Algorithm

Having at hand the similarity graph, set expansion can be implemented by selecting the terms most similar to the seeds. So given a query Q={s_1, s_2, …, s_k}, the key is to compute $f(t,Q)$, the similarity between a term t and the seed-set Q. Naturally, we define it as the weighted average similarity between t and every seed in Q,

$$f(t,Q) = \sum_{i=1}^{k} w_i \cdot Sim(t,s_i) \quad (4.1)$$

where w_i is the weight of seed s_i, which can be a constant value, or a function of the frequency of term s_i in the corpus. Although Formula 3.6 can be adopted directly for calculating $Sim(t,s_i)$, we use the following rank-based formula because it generate better expansion results.

$$Sim(t,s_i) = \frac{1}{\log(\lambda + r(t,s_i))} \quad (4.2)$$

where $r(t,s_i)$ is the rank of term t among the neighbors of s_i.

In our experiments, we fix w_i=1 and λ=10.

4.2 Compare DS with PB

In order to have a comprehensive comparison of the two approaches, we intentionally choose terms of diverse types and do experiments based on various data scales. We classify terms into 5 types by their lexical categories: proper nouns, common nouns, verbs, adjectives, and adverbs. The data scales for experiments are from one million to 500 million web pages. Please refer to sections 5.1 and 5.2 for more details about the corpora and seeds used for experiments.

Experimental results (refer to Section 6) will show that, for proper nouns, the ranking of approaches (in terms of performance) is:

$$PB > PB\text{-}HtmlTag > DS \approx PB\text{-}Lexical$$

While for common nouns, verbs, adjectives, and adverbs, we have:

$$DS > PB$$

Here "PB-lexical" means only the lexical patterns of Table 2 are adopted. Similarly, "PB-HtmlTag" represents the PB approach with only Html-tag patterns being utilized.

Please pay attention that this paper by no means covers all PB or DS approaches (although we have tried our best to include the most popular ones). For PB, there are of course other kinds of patterns (e.g., patterns based on deeper linguistic analysis). For DS, other types of contexts may exist in addition to those listed in Table 1. So in interpreting experimental results, making observations, and drawing preliminary conclusions, we only means the patterns in Table 2 for PB and Table 1 for DS. It will be an interesting future work to include more DS and PB approaches in the study.

In order to understand why PB performs so well in dealing with proper nouns while so badly for other term categories, we calculated the frequency of each seed term in the extracted *RASCs*, the output of the pattern-matching algorithm. We define the *normalized frequency* of a term to be its frequency in the RASCs divided by the frequency in the sentences of the original documents (with duplicate sentences merged). Then we define the *mean normalized frequency* (MNF) of a seed set *S*, as follows,

$$MNF(S) = \frac{\sum_{t \in S} F_{norm}(t)}{|S|} \tag{4.3}$$

where $F_{norm}(t)$ is the normalized frequency of *t*.

The MNF values for the five seed sets are listed in Table 3, where we can see that proper nouns have the largest MNF values, followed by common nouns. In other words, the patterns in Table 2 capture the relations of more proper nouns than other term categories.

Seed Categories	Terms	MNF
Proper nouns	40	0.2333
Common nouns	40	0.0716
Verbs	40	0.0099
Adjectives	40	0.0126
Adverbs	40	0.0053

Table 3. MNF values of different seed categories

As mentioned in the introduction, the PB and DS approaches we studied capture first-order and second-order term co-occurrences respectively. Some existing work (e.g., Edmonds, 1997) showed that second-order co-occurrence leads to better results for detecting synonymy. Considering that a high proportion of coordinate terms of verbs, adjectives, and adverbs are their synonyms and antonyms, it is reasonable that DS behaves better for these term types because it exploits second-order co-occurrence. For PB, different from the standard way of dealing with first-order co-occurrences where statistics are performed on all pairs of near terms, a *subset* of co-occurred terms are *selected* in PB by specific patterns. The patterns in Table-2 help detecting coordinate proper nouns, because they are frequently occurred together obeying the patterns in sentences or web pages. But it is not the case for other term types. It will be interesting to study the performance of PB when more pattern types are added.

4.3 Approach Selection

Having observed that the two approaches perform quite differently on every type of queries we investigated, we hope we can improve the expansion performance by smartly selecting an approach for each query. In this section, we propose and study several approach-selection methods, by which we hope to gain some insights about the possibility and effectiveness of combining DS and PB for better set expansion.

Oracle selection: In order to get an insight about the upper bound that we could obtain when combing the two methods, we implement an oracle that chooses, for each query, the approach that generates better expansion results.

Frequency-based selection: It is shown in Table 3 that the *mean normalized frequency* of proper nouns is much larger than other terms. Motivated by this observation, we select a set expansion methodology for each query as follows: Select PB if the normalized frequency values of all terms in the query are larger than 0.1; otherwise choose DS.

We demonstrate, in Section 6.3, the effectiveness of the above selection methods.

5 Experimental Setup

5.1 Dataset and Exp. Environment

We adopt a public-available dataset in our experiments: ClueWeb09[4]. This is a very large dataset collected by Carnegie Mellon University in early 2009 and has been used by several tracks of the Text Retrieval Conference (TREC)[5]. The whole dataset consists of 1.04 billion web pages in ten languages while only those in English, about 500 million pages, are used in our experiments. The reason for selecting such a dataset is twofold: First, it is a corpus large enough for conducting web-scale experiments and getting meaningful results. Second, since it is publicly available, it is possible for other researchers to reproduce the experiments in the paper.

Corpora	Docs (millions)	Sentences (millions)	Description
Clue500	500	13,000	All En pages in ClueWeb09
Clue050	50	1,600	ClueWeb09 category B
Clue010	10	330	Sampling from Clue050
Clue001	1	42	Sampling from Clue050

Table 4. Corpora used in experiments

To test the impact of corpus size on set expansion performance, four corpora are derived from the dataset, as outlined in Table 4. The Clue500 corpus contains all the 500 million English web pages in the dataset; while Clue050 is a subset of ClueWeb09 (named category B) containing 50 million English web pages. The remaining two corpora are respectively the 1/5 and 1/50 random sampling of web pages from Clue050.

Documents in the corpora are stored and processed in a cluster of 40 four-core machines.

5.2 Query Sets

We perform our study using two query sets.

WikiGold: It was collected by Pantel et al. (2009) from the “List of” pages in Wikipedia and used as the gold standard in their paper. This gold standard consists of 49 entity sets, and 20220 trials (used as queries) of various numbers of seeds. Most seeds in the query set are named entities. Please refer to Pantel et al. (2009) for details of the gold standard.

Mix100: This query set consists of 100 queries in five categories: verbs, adjectives, adverbs, common nouns, and proper nouns. There are 20 queries in every category and two seeds in every query. The query set was built by the following steps: First, 20 terms of each category were randomly selected from a term list (which is constructed by part-of-speech tagging the Clue050 corpus and removing low-frequency terms), and were treated as the first seed of the each query. Then, we manually added one additional seed for each query. The reason for utilizing two seeds instead of one is the observation that a large portion of the terms selected in the previous step belong to multiple categories. For example, “*colorful*” is both an adjective and a proper noun (a Japanese manga).

5.3 Results Labeling

No human labeling efforts are needed for the expansion results of the WikiGold query set. Every returned term is automatically judged to be “Good” (otherwise “Bad”) if it appears in the corresponding gold standard entity set.

For Mix100, the search results of various approaches are merged and labeled by three human labelers. Each labeler assigns each term in the search results a label of “Good”, “Fair” or “Bad”. The labeling agreement values (measured by percentage agreement) between labelers I and II, I and III, II and III are respectively 0.82, 0.81, and 0.81. The ultimate judgment of each result term is obtained from the three labelers by majority voting. In the case of three labelers giving mutually different results (i.e., one “Good”, one “Fair” and one “Bad”), the ultimate judgment is set to “Fair” (the average).

5.4 Evaluation Metrics

After removing seeds from the expansion results, we adopt the following metrics to evaluate the

[4] http://boston.lti.cs.cmu.edu/Data/clueweb09/

[5] http://trec.nist.gov/

results of each query. The evaluation score on a query set is the average over all the queries.

Precision@*k*: The percentage of relevant (good or fair) terms in the top-*k* expansion results (terms labeled as "Fair" are counted as 0.5)

Recall@*k*: The ratio of relevant terms in the top-*k* results to the total number of relevant terms

R-Precision: Precision@R where *R* is the total number of terms labeled as "Good"

Mean average precision (MAP): The average of precision values at the positions of all good or fair results

6 Experimental Results

6.1 Overall Performance Comparison

Table 5 lists the performance (measured by MAP, R-precision, and the precisions at ranks 25, 50, and 100) of some key approaches on corpus Clue050 and query set WikiGold. The results of query set Mix100 are shown in Table 6. In the results, *TWn* represents the DS approach with text-window of size *n* as contexts, *Syntactic* is the DS approach with syntactic contexts, *PB-Lexical* means only the lexical patterns of Table 2 are adopted, and *PB-HtmlTag* represents the PB approach with only Html-tag patterns utilized.

Approach	MAP	R-Prec	P@25	P@50	P@100
TW2	0.218	0.287	0.359	0.278	0.204
TW4	0.152	0.210	0.325	0.244	0.173
Syntactic	0.170	0.247	0.314	0.242	0.178
PB-Lexical	0.227	0.276	0.352	0.272	0.190
PB-HtmlTag	0.354	0.417	0.513	0.413	0.311
PB	**0.362**	**0.424**	**0.520**	**0.418**	**0.314**
Pantel-24M	N/A	0.264	0.353	0.298	0.239
Pantel-120M	N/A	0.356	0.377	0.319	0.250
Pantel-600M	N/A	0.404	0.407	0.347	0.278

Table 5. Performance comparison on the Clue050 corpus (query set: WikiGold)

It is shown that PB gets much higher evaluation scores than other approaches on the *WikiGold* query set and the proper-nouns category of *Mix100*. While for other seed categories in *Mix100*, TW2 return significantly better results. We noticed that most seeds in *WikiGold* are proper nouns. So the experimental results tend to indicate that the performance comparison between state-of-the-art DS and PB approaches depends on the types of terms to be mined, specifically, DS approaches perform better in mining semantic classes of common nouns, verbs, adjectives, and adverbs; while state-of-the-art PB approaches are more suitable for mining semantic classes of proper nouns. The performance of PB is low in dealing with other types of terms (especially adverbs). The performance of PB drops significantly if only lexical patterns are used; and the HtmlTag-only version of PB performs only slightly worse than PB.

The observations are verified by the precision-recall graph in Figure 1 on Clue500. The results of the *syntactic* approach on Clue500 are not included, because it is too time-consuming to parse all the 500 million web pages by a dependency parser (even using a high-performance parser like Minipar). It took overall about 12,000 CPU-hours to parse all the sentences in Clue050 by Minipar.

Query types & Approaches		MAP	P@5	P@10	P@20
Proper Nouns	TW2	0.302	0.835	0.810	0.758
	PB	**0.336**	**0.920**	**0.838**	**0.813**
Common Nouns	TW2	**0.384**	**0.735**	**0.668**	**0.595**
	PB	0.212	0.640	0.548	0.485
Verbs	TW2	**0.273**	**0.655**	**0.543**	**0.465**
	PB	0.176	0.415	0.373	0.305
Adjectives	TW2	**0.350**	**0.655**	**0.563**	**0.473**
	PB	0.120	0.335	0.285	0.234
Adverbs	TW2	**0.432**	**0.605**	**0.505**	**0.454**
	PB	0.043	0.100	0.095	0.089

Table 6. Performance comparison on different query types (Corpus: Clue050; query set: Mix100)

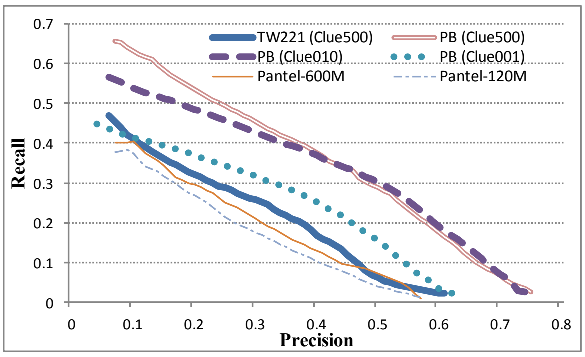

Figure 1. Precision and recall of various approaches (query set: WikiGold)

The methods labeled Pantel-24M etc. (in Table 5 and Figure 1) are the approaches presented in (Pantel et al., 2009) on their corpus (called Web04, Web20, and Web100 in the paper) containing respectively 24 million, 120 million, and 600 million web pages. Please pay attention that their results and ours may not be directly comparable, because different corpora and set-expansion algorithms were used. Their results are listed here for reference purpose only.

6.2 Corpus Size Effect

Table 7 shows the performance (measured by MAP) of two approaches on query set *Mix100*, by varying corpus size. We observed that the performance of TW2 improves rapidly along with the growth of corpus size from one million to 50 million documents. From Clue050 to Clue500, the performance is slightly improved.

Query types & Approaches		Clue001	Clue010	Clue050	Clue500
Proper Nouns	TW2	0.209	0.265	0.302	**0.311**
	PB	**0.355**	0.351	0.336	0.327
Common Nouns	TW2	0.259	0.348	0.384	**0.393**
	PB	0.200	**0.234**	0.212	0.205
Verbs	TW2	0.224	0.268	0.273	**0.278**
	PB	0.101	0.134	**0.176**	0.148
Adjectives	TW2	0.309	0.326	0.350	**0.353**
	PB	0.077	**0.158**	0.120	0.129
Adverbs	TW2	0.413	0.423	0.432	**0.437**
	PB	0.028	0.058	0.043	**0.059**

Table 7. Effect of different corpus size (query set: Mix100; metric: MAP)

For PB, however, the performance change is not that simple. For proper nouns, the best performance (in terms of MAP) is got on the two small corpora Clue001 and Clue010; and the score does not increase when corpus size grows. Different observations are made on WikiGold (see Figure 1), where the performance improves a lot with the data growth from Clue001 to Clue010, and then stabilizes (from Clue010 to Clue500). For other term types, the MAP scores do not grow much after Clue010. To our current understanding, the reason may be due to the two-fold effect of incorporating more data in mining: *bringing useful information as well as noise*. Clue001 contains enough information, which is fully exploited by the PB approach, for expanding the proper-nouns in Mix100. So the performance of PB on Clue001 is excellent. The named entities in WikiGold are relatively rare, which requires a larger corpus (Clue010) for extracting peer terms from. But when the corpus gets larger, we may not be able to get more useful information to further improve results quality.

Another interesting observation is that, for proper nouns, the performance of PB on Clue001 is even much better than that of TW2 on corpus Clue500. Similarly, for other query types (common nous, verbs, adjectives, and adverbs), TW2 easily beats PB even with a much smaller corpus.

6.3 Approach Selection

Here we demonstrate the experimental results of combining DS and PB with the methods we proposed in Section 4.3. Table 8 shows the combination of PB and TW2 on corpus Clue050 and query set Mix100. The overall performance relies on the number (or percentage) of queries in each category. Two ways of mixing the queries are tested: avg(4:1:1:1:1) and avg(1:1:1:1:1), where the numbers are the proportion of proper nouns, common nouns, verbs, adjectives, and adverbs.

Approach	Avg (1:1:1:1:1)			Avg (4:1:1:1:1)		
	P@5	P@10	P@20	P@5	P@10	P@20
TW2	0.697	0.618	0.548	0.749	0.690	0.627
PB	0.482	0.428	0.385	0.646	0.581	0.545
Oracle	0.759	0.663	0.591	0.836	0.759	0.695
Freq-based	0.721	0.633	0.570	0.799	0.723	0.671

Table 8. Experiments of combining both approaches (Corpus: Clue050; query set: Mix100)

The expansion performance is improved a lot with our frequency-based combination method. As expected, oracle selection achieves great performance improvement, which shows the large potential of combining DS and PB. Similar results (omitted due to space limitations) are observed on the other corpora.

Our online semantic mining system (*NeedleSeek*, http://needleseek.msra.cn) adopts both PB and DS for semantic class construction.

7 Conclusion

We compared two mainstream methods (DS and PB) for semantic class mining, based on a dataset of 500 million pages and using five term types. We showed that PB is clearly adept at extracting semantic classes of proper nouns; while DS is relatively good at dealing with other types of terms. In addition, a small corpus is sufficient for each approach to generate better semantic classes of its "favorite" term types than those obtained by its counterpart on a much larger corpus. Finally, we tried a frequency-based method of combining them and saw apparent performance improvement.

Metaphor Identification Using Verb and Noun Clustering

Ekaterina Shutova, Lin Sun and Anna Korhonen
Computer Laboratory, University of Cambridge

Abstract

We present a novel approach to automatic metaphor identification in unrestricted text. Starting from a small seed set of manually annotated metaphorical expressions, the system is capable of harvesting a large number of metaphors of similar syntactic structure from a corpus. Our method is distinguished from previous work in that it does not employ any hand-crafted knowledge, other than the initial seed set, but, in contrast, captures metaphoricity by means of verb and noun clustering. Being the first to employ unsupervised methods for metaphor identification, our system operates with the precision of 0.79.

1 Introduction

Besides enriching our thought and communication with novel imagery, the phenomenon of metaphor also plays a crucial structural role in our use of language. Metaphors arise when one concept is viewed in terms of the properties of the other. Below are some examples of metaphor.

(1) How can I *kill* a process? (Martin, 1988)

(2) Inflation has *eaten up* all my savings. (Lakoff and Johnson, 1980)

(3) He *shot down* all of my arguments. (Lakoff and Johnson, 1980)

(4) And then my heart with pleasure *fills*,
And *dances* with the daffodils.[1]

In metaphorical expressions seemingly unrelated features of one concept are associated with another concept. In the computer science metaphor in (1) the *computational process* is viewed as something *alive* and, therefore, its forced termination is associated with the act of killing. Lakoff and Johnson (1980) explain metaphor as a systematic association, or a *mapping*, between two concepts or conceptual domains: the *source* and the *target*. The metaphor in (3) exemplifies a mapping of a concept of *argument* to that of *war*. The *argument*, which is the target concept, is viewed in terms of a *battle* (or a *war*), the source concept. The existence of such a link allows us to talk about arguments using the war terminology, thus giving rise to a number of metaphors.

Characteristic to all areas of human activity (from poetic to ordinary to scientific) and, thus, to all types of discourse, metaphor becomes an important problem for natural language processing (NLP). In order to estimate the frequency of the phenomenon, Shutova and Teufel (2010) conducted a corpus study on a subset of the British National Corpus (BNC) (Burnard, 2007) representing various genres. They manually annotated metaphorical expressions in this data and found that 241 out of 761 sentences contained a metaphor, whereby in 164 phrases metaphoricity was introduced by a verb. Due to such a high frequency of their use, a system capable of recognizing and interpreting metaphorical expressions in unrestricted text would become an invaluable component of any semantics-oriented NLP application.

Automatic processing of metaphor can be clearly divided into two subtasks: *metaphor identification* (distinguishing between literal and metaphorical language in text) and *metaphor interpretation* (identifying the intended literal meaning of a metaphorical expression). Both of them have been repeatedly attempted in NLP.

To date the most influential account of metaphor identification is that of Wilks (1978).

[1] "I wandered lonely as a cloud", William Wordsworth, 1804.

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 1002–1010,
Beijing, August 2010

According to Wilks, metaphors represent a violation of selectional restrictions in a given context. Consider the following example.

(5) My car *drinks* gasoline. (Wilks, 1978)

The verb *drink* normally takes an *animate* subject and a *liquid* object. Therefore, *drink* taking a *car* as a subject is an anomaly, which may as well indicate metaphorical use of *drink*.

This approach was automated by Fass (1991) in his met* system. However, Fass himself indicated a problem with the method: it detects any kind of non-literalness or anomaly in language (metaphors, metonymies and others), i.e., it overgenerates with respect to metaphor. The techniques met* uses to differentiate between those are mainly based on hand-coded knowledge, which implies a number of limitations. In a similar manner manually created knowledge in the form of WordNet (Fellbaum, 1998) is employed by the system of Krishnakumaran and Zhu (2007), which essentially differentiates between highly lexicalized metaphors included in WordNet, and novel metaphorical senses.

Alternative approaches (Gedigan et al., 2006) search for metaphors of a specific domain defined a priori (e.g. MOTION metaphors) in a specific type of discourse (e.g. Wall Street Journal). In contrast, the scope of our experiments is the whole of the British National Corpus (BNC) (Burnard, 2007) and the domain of the expressions we identify is unrestricted. However, our technique is also distinguished from the systems of Fass (1991) and Krishnakumaran and Zhu (2007) in that it does not rely on any hand-crafted knowledge, but rather captures metaphoricity in an unsupervised way by means of verb and noun clustering.

The motivation behind the use of clustering methods for metaphor identification task lies in the nature of metaphorical reasoning based on association. Compare, for example, the target concepts of *marriage* and *political regime*. Having quite distinct meanings, both of them are cognitively mapped to the source domain of *mechanism*, which shows itself in the following examples:

(6) Our relationship is not really *working*.

(7) Diana and Charles did not succeed in *mending* their marriage.

(8) The *wheels* of Stalin's regime were *well oiled* and already *turning*.

We expect that such relatedness of distinct target concepts should manifest itself in the examples of language use, i.e. target concepts that are associated with the same source concept should appear in similar lexico-syntactic environments. Thus, clustering concepts using grammatical relations (GRs) and lexical features would allow us to capture their relatedness **by association** and harvest a large number of metaphorical expressions beyond our seed set. For example, the sentence in (6) being part of the seed set should enable the system to identify metaphors in both (7) and (8).

In summary, our system (1) starts from a seed set of metaphorical expressions exemplifying a range of source–target domain mappings; (2) performs unsupervised noun clustering in order to harvest various target concepts associated with the same source domain; (3) by means of unsupervised verb clustering creates a source domain verb lexicon; (4) searches the BNC for metaphorical expressions describing the target domain concepts using the verbs from the source domain lexicon.

We tested our system starting with a collection of metaphorical expressions representing verb-subject and verb-object constructions, where the verb is used metaphorically. We evaluated the precision of metaphor identification with the help of human judges. In addition to this we compared our system to a baseline built upon WordNet, whereby we demonstrated that our method goes far beyond synonymy and captures metaphors not directly related to any of those seen in the seed set.

2 Experimental Data

2.1 Seed Phrases

We used the dataset of Shutova (2010) as a seed set. Shutova (2010) annotated metaphorical expressions in a subset of the BNC sampling various genres: literature, newspaper/journal articles, essays on politics, international relations and history, radio broadcast (transcribed speech). The dataset consists of 62 phrases that are single-word metaphors representing verb-subject and verb-object relations, where a verb is used metaphorically. The seed phrases include e.g. *stir excitement, reflect enthusiasm, accelerate change, grasp theory, cast doubt, suppress memory, throw remark* (verb - direct object constructions) and *campaign surged, factor shaped [..], tension mounted, ideology embraces, changes operated, approach focuses, example illustrates* (subject - verb constructions).

2.2 Corpus

The search space for metaphor identification was the British National Corpus (BNC) that was parsed using the RASP parser of Briscoe et al. (2006). We used the grammatical relations output of RASP for BNC created by Andersen et al. (2008). The system searched the corpus for the source and target domain vocabulary within a particular grammatical relation (verb-object or verb-subject).

3 Method

Starting from a small seed set of metaphorical expressions, the system implicitly captures the associations that underly their production and comprehension. It generalizes over these associations by means of unsupervised verb and noun clustering. The obtained clusters then represent potential source and target concepts between which metaphorical associations hold. The knowledge of such associations is then used to annotate metaphoricity in a large corpus.

3.1 Clustering Motivation

Abstract concepts that are associated with the same source domain are often related to each other on an intuitive and rather structural level, but their meanings, however, are not necessarily synonymous or even semantically close. The results of previous research on corpus-based lexical semantics suggest that the linguistic environment in which a lexical item occurs can shed light on its meaning. A number of works have shown that it is possible to automatically induce semantic word classes from corpus data via clustering of contextual cues (Pereira et al., 1993; Lin, 1998; Schulte im Walde, 2006). The consensus is that the lexical items exposing similar behavior in a large body of text most likely have the same meaning. However, the concepts of *marriage* and *political regime*, that are also observed in similar lexico-syntactic environments, albeit having quite distinct meanings are likewise assigned by such methods to the same cluster. In contrast to concrete concepts, such as *tea, water, coffee, beer, drink, liquid*, that are clustered together due to **meaning similarity**, abstract concepts tend to be clustered together **by association** with the same source domain. It is the presence of this association that explains the fact that they share common contexts. We exploit this idea for identification of new target domains associated with the same source domain. We then use unsupervised verb clustering to collect source domain vocabulary, which in turn allows us to harvest a large number of new metaphorical expressions.

3.2 Verb and Noun Clustering

Since Levin (1993) published her classification, there have been a number of attempts to automatically classify verbs into semantic classes using supervised and unsupervised approaches (Lin, 1998; Brew and Schulte im Walde, 2002; Korhonen et al., 2003; Schulte im Walde, 2006; Joanis et al., 2008; Sun and Korhonen, 2009). Similar methods were also applied to acquisition of noun classes from corpus data (Rooth et al., 1999; Pantel and Lin, 2002; Bergsma et al., 2008).

We adopt a recent verb clustering approach of Sun and Korhonen (2009), who used rich syntactic and semantic features extracted using a shallow parser and a clustering method suitable for the resulting high dimensional feature space. When Sun and Korhonen evaluated their approach on 204 verbs from 17 Levin classes, they obtained 80.4 F-measure (which is high in particular for an unsupervised approach). We apply this approach to a much larger set of 1610 verbs: all the verb forms appearing in VerbNet (Kipper et al., 2006) with the exception of highly infrequent ones. In addition, we adapt the approach to noun clustering.

3.2.1 Feature Extraction

Our verb dataset is a subset of VerbNet compiled as follows. For all the verbs in VerbNet we extracted their occurrences (up to 10,000) from the raw corpus data collected originally by Korhonen et al. (2006) for construction of VALEX lexicon. Only the verbs found in this data more than 150 times were included in the experiment.
