For verb clustering, we adopted the best performing features of Sun and Korhonen (2009): automatically acquired verb subcategorization frames (SCFs) parameterized by their selectional preferences (SPs). We obtained these features using the SCF acquisition system of Preiss et al. (2007). The system tags and parses corpus data using the RASP parser and extracts SCFs from the resulting GRs using a rule-based classifier which identifies 168 SCF types for English verbs. It produces a lexical entry for each verb and SCF combination occurring in corpus data. We obtained SPs by clustering argument heads appearing in the subject and object slots of verbs in the resulting lexicon.

Our noun dataset consists of 2000 most frequent nouns in the BNC. Following previous works on semantic noun classification (Pantel and Lin, 2002; Bergsma et al., 2008), we used GRs as features for noun clustering. We employed all the argument heads and verb lemmas appearing in the subject, direct object and indirect object relations in the RASP-parsed BNC.

The feature vectors were first constructed from the corpus counts, and subsequently normalized by the sum of the feature values before applying clustering.

3.2.2 Clustering Algorithm

We use spectral clustering (SPEC) for both verbs and nouns. This technique has proved to be effective in previous verb clustering works (Brew and Schulte im Walde, 2002; Sun and Korhonen, 2009) and in related NLP tasks involving high dimensional data (Chen et al., 2006). We use the MNCut algorithm for SPEC which has a wide applicability and a clear probabilistic interpretation (Meila and Shi, 2001).

The task is to group a given set of words $W = \{w_n\}_{n=1}^{N}$ into a disjoint partition of K classes. SPEC takes a similarity matrix as input. We construct it using the Jensen-Shannon divergence (JSD) as a measure. The JSD between two feature vectors w and w' is $d_{jsd}(w, w') = \frac{1}{2}D(w||m) + \frac{1}{2}D(w'||m)$ where D is the Kullback-Leibler divergence, and m is the average of the w and w'.

The similarity matrix S is constructed where $S_{ij} = \exp(-d_{jsd}(w, w'))$. In SPEC, the similarities S_{ij} are viewed as weights on the edges ij of a graph G over W. The similarity matrix S is thus the adjacency matrix for G. The degree of a vertex i is $d_i = \sum_{j=1}^{N} S_{ij}$. A cut between two partitions A and A' is defined to be $\text{Cut}(A, A') = \sum_{m \in A, n \in A'} S_{mn}$.

The similarity matrix S is then transformed into a stochastic matrix P.

$$P = D^{-1}S \tag{1}$$

The degree matrix D is a diagonal matrix where $D_{ii} = d_i$.

It was shown by Meila and Shi (2001) that if P has the K leading eigenvectors that are piecewise constants[2] with respect to a partition I^* and their eigenvalues are not zero, then I^* minimizes the multiway normalized cut (MNCut):

$$\text{MNCut}(I) = K - \sum_{k=1}^{K} \frac{\text{Cut}(I_k, I_k)}{\text{Cut}(I_k, I)}$$

P_{mn} can be interpreted as the transition probability between the vertexes m, n. The criterion can thus be expressed as $\text{MNCut}(I) = \sum_{k=1}^{K}(1 - P(I_k \to I_k|I_k))$ (Meila, 2001), which is the sum of transition probabilities across different clusters. This criterion finds the partition where random walks are most likely to happen within the same cluster. In practice, the leading eigenvectors of P are not piecewise constants. However, we can extract the partition by finding the approximately equal elements in the eigenvectors using a clustering algorithm, such as K-Means.

Since SPEC has elements of randomness, we ran the algorithm multiple times and the partition that minimizes the distortion (the distances to cluster centroid) is reported. Some of the clusters obtained as a result of applying the algorithm to our noun and verb datasets are demonstrated in Figures 1 and 2 respectively. The noun clusters represent target concepts that we expect to be associated with the same source concept (some suggested source concepts are given in Figure 1, although the system only captures those implicitly).

[2] An eigenvector v is piecewise constant with respect to I if $v(i) = v(j) \forall i, j \in I_k$ and $k \in 1, 2...K$

Figure 2: Clustered verbs (source domains)

The verb clusters contain coherent lists of source domain vocabulary.

3.3 Selectional Preference Strength Filter

Following Wilks (1978), we take metaphor to represent a violation of selectional restrictions. However, not all verbs have an equally strong capacity to constrain their arguments, e.g. *remember, accept, choose* etc. are weak in that respect. We suggest that for this reason not all the verbs would be equally prone to metaphoricity, but only the ones exhibiting strong selectional preferences. We test this hypothesis experimentally and expect that placing this criterion would enable us to filter out a number of candidate expressions, that are less likely to be used metaphorically.

We automatically acquired selectional preference distributions for `Verb-Subject` and `Verb-Object` relations from the BNC parsed by RASP. We first clustered 2000 most frequent nouns in the BNC into 200 clusters using SPEC as described in the previous section. The obtained clusters formed our selectional preference classes. We adopted the selectional preference measure proposed by Resnik (1993) and successfully applied to a number of tasks in NLP including word sense disambiguation (Resnik, 1997). Resnik models selectional preference of a verb in probabilistic terms as the difference between the posterior distribution of noun classes in a particular relation with the verb and their prior distribution in that syntactic position regardless of the identity of the predicate. He quantifies this difference using the relative entropy (or Kullback-Leibler distance), defining the *selectional preference strength* (SPS) as follows.

$$S_R(v) = D(P(c|v)||P(c)) = \sum_c P(c|v) \log \frac{P(c|v)}{P(c)}, \quad (2)$$

where $P(c)$ is the prior probability of the noun class, $P(c|v)$ is the posterior probability of the noun class given the verb and R is the grammatical relation in question. SPS measures how strongly the predicate constrains its arguments.

We use this measure to filter out the verbs with weak selectional preferences. The optimal SPS threshold was set experimentally on a small held-out dataset and approximates to 1.32. We excluded expressions containing the verbs with preference strength below this threshold from the set of candidate metaphors.

4 Evaluation and Discussion

In order to prove that our metaphor identification method generalizes well over the seed set and goes far beyond synonymy, we compared its output to that of a baseline taking WordNet synsets to represent source and target domains. We evaluated the quality of metaphor tagging in terms of precision with the help of human judges.

4.1 Comparison against WordNet Baseline

The baseline system was implemented using synonymy information from WordNet to expand on the seed set. Assuming all the synonyms of the verbs and nouns in seed expressions to represent the source and target vocabularies respectively, the system searches for phrases composed of lexical items belonging to those vocabularies. For example, given a seed expression *stir excitement*, the baseline finds phrases such as *arouse fervour,* *stimulate agitation, stir turmoil* etc. However, it is not able to generalize over the concepts to broad semantic classes, e.g. it does not find other *feelings* such as *rage, fear, anger, pleasure* etc., which is necessary to fully characterize the target domain. The same deficiency of the baseline system manifests itself in the source domain vocabulary: the system has only the knowledge of direct synonyms of *stir*, as opposed to other verbs characteristic to the domain of *liquids*, e.g. *pour, flow, boil* etc., successfully identified by means of clustering.

To compare the **coverage** achieved by unsupervised clustering to that of the baseline in quantitative terms, we estimated the number of WordNet synsets, i.d. different word senses, in the metaphorical expressions captured by the two systems. We found that the baseline system covers only 13% of the data identified using clustering and does not go beyond the concepts present in the seed set. In contrast, most metaphors tagged by our method are novel and represent a considerably wider range of meanings, e.g. given the seed metaphors *stir excitement, throw remark, cast doubt* the system identifies previously unseen expressions *swallow anger, hurl comment, spark enthusiasm* etc. as metaphorical.

4.2 Comparison with Human Judgements

In order to access the **quality** of metaphor identification by both systems we used the help of human annotators. The annotators were presented with a set of randomly sampled sentences containing metaphorical expressions as annotated by the system and by the baseline. They were asked to mark the tagged expressions that were metaphorical in their judgement as correct.

The annotators were encouraged to rely on their own intuition of metaphor. However, we also provided some guidance in the form of the following definition of metaphor[3]:

1. For each verb establish its meaning in context and try to imagine a more basic meaning of this verb on other contexts. Basic meanings normally are: (1) more concrete; (2) related to bodily action; (3) more precise (as opposed to vague); (4) historically older.
2. If you can establish the basic meaning that is distinct from the meaning of the verb in this context, the verb is likely to be used metaphorically.

CKM 391 Time and time again he would stare at the ground, hand on hip, if he thought he had received a bad call, and then **swallow his anger** and play tennis.
AD9 3205 He tried to **disguise the anxiety** he felt when he found the comms system down, but Tammuz was nearly hysterical by this stage.
AMA 349 We will **halt the reduction** in NHS services for long-term care and community health services which support elderly and disabled patients at home.
ADK 634 **Catch their interest** and **spark their enthusiasm** so that they begin to see the product's potential.
K2W 1771 The committee heard today that gangs regularly **hurled** abusive **comments** at local people, making an unacceptable level of noise and leaving litter behind them.

Figure 3: Sentences tagged by the system (metaphors in bold)

We had 5 volunteer annotators who were all native speakers of English and had no or sparse linguistic knowledge. Their agreement on the task was 0.63 in terms of κ (Siegel and Castellan, 1988), whereby the main source of disagreement was the presence of highly lexicalized metaphors, e.g. verbs such as *adopt, convey, decline* etc. We then evaluated the system performance against their judgements in terms of *precision*. Precision measures the proportion of metaphorical expressions that were tagged correctly among the ones that were tagged. We considered the expressions tagged as metaphorical by at least three annotators to be correct. As a result our system identifies metaphor with the precision of 0.79, whereas the baseline only attains 0.44. Some examples of sentences annotated by the system are shown in Figure 3.

Such a striking discrepancy between the performance levels of the clustering approach and the baseline can be explained by the fact that a large number of metaphorical senses are included in WordNet. This means that in WordNet synsets source domain verbs are mixed with more abstract terms. For example, the metaphorical sense of *shape* in *shape opinion* is part of the synset (*de-*

[3] taken from the annotation procedure of Shutova and Teufel (2010) that is in turn partly based on the work of Pragglejaz Group (2007).

termine, shape, mold, influence, regulate). This results in the baseline system tagging literal expressions as metaphorical, erroneously assuming that the verbs from the synset belong to the source domain.

The main source of confusion in the output of our clustering method was the conventionality of some metaphorical expressions, e.g. *hold views, adopt traditions, tackle a problem*. The system is capable of tracing metaphorical etymology of conventional phrases, but their senses are highly lexicalized. This lexicalization is reflected in the data and affects clustering in that conventional metaphors are sometimes clustered together with literally used terms, e.g. *tackle a problem* and *resolve a problem*, which may suggest that the latter are metaphorical. It should be noted, however, that such errors are rare.

Since there is no large metaphor-annotated corpus available, it was impossible for us to reliably evaluate the *recall* of the system. However, the system identified a total number of 4456 metaphorical expressions in the BNC starting with a seed set of only 62, which is a promising result.

5 Related Work

One of the first attempts to identify and interpret metaphorical expressions in text automatically is the approach of Fass (1991). Fass developed a system called met*, capable of discriminating between literalness, metonymy, metaphor and anomaly. It does this in three stages. First, literalness is distinguished from non-literalness using selectional preference violation as an indicator. In the case that non-literalness is detected, the respective phrase is tested for being a metonymic relation using hand-coded patterns (such as CONTAINER-for-CONTENT). If the system fails to recognize metonymy, it proceeds to search the knowledge base for a *relevant analogy* in order to discriminate metaphorical relations from anomalous ones. E.g., the sentence in (5) would be represented in this framework as (*car,drink,gasoline*), which does not satisfy the preference (*animal,drink,liquid*), as *car* is not a hyponym of *animal*. met* then searches its knowledge base for a triple containing a hypernym of both the actual argument and the desired argument and finds (*thing,use,energy_source*), which represents the metaphorical interpretation.

Birke and Sarkar (2006) present a sentence clustering approach for non-literal language recognition implemented in the TroFi system (Trope Finder). This idea originates from a similarity-based word sense disambiguation method developed by Karov and Edelman (1998). The method employs a set of seed sentences, where the senses are annotated, computes similarity between the sentence containing the word to be disambiguated and all of the seed sentences and selects the sense corresponding to the annotation in the most similar seed sentences. Birke and Sarkar (2006) adapt this algorithm to perform a two-way classification: literal vs. non-literal, and they do not clearly define the kinds of tropes they aim to discover. They attain a performance of 53.8% in terms of f-score.

The method of Gedigan et al. (2006) discriminates between literal and metaphorical use. They trained a maximum entropy classifier for this purpose. They obtained their data by extracting the lexical items whose frames are related to MOTION and CURE from FrameNet (Fillmore et al., 2003). Then they searched the PropBank Wall Street Journal corpus (Kingsbury and Palmer, 2002) for sentences containing such lexical items and annotated them with respect to metaphoricity. They used PropBank annotation (arguments and their semantic types) as features to train the classifier and report an accuracy of 95.12%. This result is, however, only a little higher than the performance of the naive baseline assigning majority class to all instances (92.90%). These numbers can be explained by the fact that 92.00% of the verbs of MOTION and CURE in the Wall Street Journal corpus are used metaphorically, thus making the dataset unbalanced with respect to the target categories and the task notably easier.

Both Birke and Sarkar (2006) and Gedigan et al. (2006) focus only on metaphors expressed by a verb. As opposed to that the approach of Krishnakumaran and Zhu (2007) deals with verbs, nouns and adjectives as parts of speech. They use hyponymy relation in WordNet and word bigram counts to predict metaphors at the sentence level. Given an IS-A metaphor (e.g. *The world is a stage*[4]) they verify if the two nouns involved are in hyponymy relation in WordNet, and if this is not the case then this sentence is tagged as containing a metaphor. Along with this they consider expressions containing a verb or an adjective used metaphorically (e.g. *He planted good ideas in their minds* or *He has a fertile imagination*). Hereby they calculate bigram probabilities of verb-noun and adjective-noun pairs (including the hyponyms/hypernyms of the noun in question). If the combination is not observed in the data with sufficient frequency, the system tags the sentence containing it as metaphorical. This idea is a modification of the selectional preference view of Wilks. However, by using bigram counts over verb-noun pairs as opposed to verb-object relations extracted from parsed text Krishnakumaran and Zhu (2007) loose a great deal of information. The authors evaluated their system on a set of example sentences compiled from the Master Metaphor List (Lakoff et al., 1991), whereby highly conventionalized metaphors (they call them *dead metaphors*) are taken to be negative examples. Thus, they do not deal with literal examples as such: essentially, the distinction they are making is between the senses included in WordNet, even if they are conventional metaphors, and those not included in WordNet.

6 Conclusions and Future Directions

We presented a novel approach to metaphor identification in unrestricted text using unsupervised methods. Starting from a limited set of metaphorical seeds, the system is capable of capturing the regularities behind their production and annotating a much greater number and wider range of previously unseen metaphors in the BNC.

Our system is the first of its kind and it is capable of identifying metaphorical expressions with a high precision (0.79). By comparing its coverage to that of a WordNet baseline, we proved that our method goes far beyond synonymy and generalizes well over the source and target domains. Although at this stage we tested our system on verb-subject and verb-object metaphors only, we are convinced that the described identification techniques can be similarly applied to a wider range of syntactic constructions. Extending the system to deal with more parts of speech and types of phrases is part of our future work.

One possible limitation of our approach is that it is seed-dependent, which makes the recall of the system questionable. Thus, another important future research avenue is the creation of a more diverse seed set. We expect that a set of expressions representative of the whole variety of common metaphorical mappings, already described in linguistics literature, would enable the system to attain a very broad coverage of the corpus. Master Metaphor List (Lakoff et al., 1991) and other existing metaphor resources could be a sensible starting point on a route to such a dataset.

Acknowledgments

We are very grateful to our anonymous reviewers for their useful feedback on this work and the volunteer annotators for their interest, time and help. This research is funded by generosity of Cambridge Overseas Trust (Katia Shutova), Dorothy Hodgkin Postgraduate Award (Lin Sun) and the Royal Society, UK (Anna Korhonen).

Abstract

Thanks to its simplicity, social tagging system has accumulated huge amount of user contributed tags. However, user contributed tags lack explicit hierarchical structure, while many tag-based applications would benefit if such a structure presents. In this work, we explore the structure of tags with a directed and easy-to-evaluate relation, named as the subsumption relation. We propose three methods to discover the subsumption relation between tags. Specifically, the tagged document's content is used to find the relations, which leads to better result. Besides relation discovery, we also propose a greedy algorithm to eliminate the redundant relations by constructing a Layered Directed Acyclic Graph (Layered-DAG) of tags. We perform quantitative evaluations on two real world data sets. The results show that our methods outperform hierarchical clustering-based approach. Empirical study of the constructed Layered-DAG and error analysis are also provided.

1 Introduction

In this work, we aim at exploring the structure of social tags. Social tagging is widely used in Web-based services, in which a user could use any word to annotate an object. Thanks to its simplicity, services with social tagging features have attracted a lot of users and have accumulated huge amount of annotations. However, comparing to taxonomies, social tagging has an inherent shortcoming, that there is no explicit hierarchical relations between tags. Figure 1 (a) shows an example of the commonly used flat tag cloud, in which only the popularity of a tag is concerned. Kome et al. (2005) argued that implicit hierarchical relations exist in social tags. Previous literature shows that organizing tags in hierarchical structures will help tag-based Information Retrieval applications (Begelman et al., 2006; Brooks and Montanez, 2006).

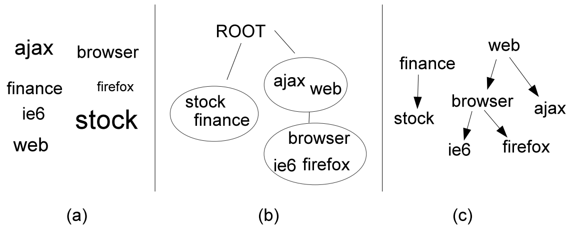

Figure 1: Examples of (a) flat tag cloud, (b) hierarchical clusters, and (c) subsumption relations.

Hierarchical clustering could reveal the similarity relations of tags. Figure 1 (b) shows an example of a typical hierarchical clustering of tags. While clusters can capture similarity between tags, problems still remain: First, clusters mix different relations, such as synonyms and hypernyms. Second, clusters also ignore the direction of relations, for example, the direction in browser → firefox. Third, it is hard to evaluate the correctness of clustering. Specifically, it is hard to tell if two tags are similar or not. In practice, directed and easy-to-evaluate relations between tags are preferred, such as Figure 1 (c).

In this work, we explore the structure of social tags by discovering a directed and easy-to-evaluate relation between tags, named *subsumption relation*. A tag t_a subsumes t_b, if and only if wherever t_b is used, we can also replace it

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 1011–1019,
Beijing, August 2010

with t_a. Unlike *similar-to*, subsumption relation is asymmetric, and its correctness is easier to assess. Then, we propose three ways to discover the subsumption relations, through tag-tag, tag-word and tag-reason co-occurrences respectively. In the third way, A tag's *reason* is defined as the word in the content that explains the using of the tag. We employ the Tag Allocation Model (TAM) proposed by Si et al. (2010) to find the reason for each tag. Besides subsumption relation discovery, we also propose a greedy algorithm to remove the redundant relations. The removal is done by constructing a Layered Directed Acyclic Graph (Layered-DAG) of tags with the subsumption relations.

We carried out the experiments on two real world data sets. The results of quantitative evaluation showed that tag-reason based approach outperformed other two methods and a commonly used hierarchical clustering-based method. We also do empirical study on the output of Layered-DAG construction.

The contribution of this paper can be summarized as follows:

1. We explore the structure of social tags by a clearly defined subsumption relation. We propose methods to discover the subsumption relation automatically, leveraging both the co-occurred tags and the content of annotated document.
2. We propose an algorithm to eliminate the redundant relations by constructing a Layered-DAG of tags.
3. We perform both empirical and quantitative evaluation of proposed methods on two real world data sets.

The rest of the paper is organized as follows: Section 2 surveys the related work; Section 3 defines the subsumption relation we used, and proposes methods for relation discovery; Section 4 proposes a greedy algorithm for Layered-DAG construction; Section 5 explains the experimental settings and shows the evaluation results. Section 6 concludes the paper.

2 Related Work

To explore the hierarchical relations between tags, an intuitive way is to cluster the tags into hierarchical clusters. Wu et al. (2006b) used a factorized model, namely Latent Semantic Analysis, to group tags into non-hierarchical topics for better recommendation. Brooks et al. (2006) argued that performing Hierarchical Agglomerative Clustering (HAC) on tags can improve the collaborative tagging system. Later, HAC on tags was also used for improving personalized recommendation (Shepitsen et al., 2008). Heymann et al. (2006) clustered tags into a tree by a similarity-based greedy tree-growing method. They evaluated the obtained trees empirically, and reported that the method is simple yet powerful for organizing tags with hierarchies. Based on Heymann et al.'s work, Schwarzkopf et al. (2007) proposed an approach for modeling users with the hierarchy of tags. Begelman et al. (2006) used top-down hierarchical clustering, instead of bottom-up HAC, to organize tags, and argued that tag hierarchies improve user experiences in their system. Most of the hierarchical clustering algorithms rely on the symmetric similarity between tags, while the discovered relations are hard to evaluate quantitatively, since one cannot distinguish similar from not-similar with a clear boundary.

People have also worked on bridging social tagging systems and ontologies. An ontology defines relations between entities. Peter Mika (2005) proposed an extended scheme of social tagging that includes actors, concepts and objects, and used tag co-occurrences to construct an ontology from social tags. Wu et al. (2006a) used hierarchical clustering to build ontology from tags that also use similar-to relations. Later, ontology schemes that fits social tagging system were proposed, such as (Van Damme et al., 2007) and (Echarte et al., 2007), which mainly focused on the relation between tags, objects and users, rather than between tags themselves. Alexandre Passant (2007) mapped tags to domain ontologies manually to improve information retrieval in social media. To construct tag ontology automatically, Angeletou et al. (2007) used ontologies built by domain experts to find relations between tags, but observed a very low coverage. Specia et al. (2007) proposed an integrated framework for organizing tags by existing ontologies, but no experiment was performed. Kim et al. (2008) summarized the state-of-the-art methods to model tags with semantic annotations.

Before social tagging was invented, Sanderson et al. (1999) proposed to use *subsumption* relation to organize words in text hierarchically. Schmitz et al. (2006) followed the idea to use subsumption relation for organizing Flickr [1] tag, where tag-tag co-occurrences are used for discover the relations. We follow the idea of subsumption relation in this paper, and explore alternative ways for relation discovery.

3 Subsumption Relations in Tags

In this section, we define the subsumption relation used in our study, and propose three methods to discover the subsumption relations.

3.1 Definitions

First, we introduce the symbols used through out the paper: A tag is denoted as $t \in T$, where T is the set of all tags. To distinguish from words, we use `fixed-width` to represent the example tags. An annotated document is denoted as $d \in D$, where D is the set of all documents. The words in d are denoted as a set $\{w_{d_i}\}$, where $i \in [1, |d|]$, and $|d|$ is the number of words in d.

Inspired by (Sanderson and Croft, 1999), we define the subsumption relation between t_a and t_b as follows: t_a **subsumes** t_b**, means that wherever the tag** t_b **is used,** t_a **can also be used without ambiguity**. The subsumption relation between t_a and t_b is denoted as $t_a \rightarrow_s t_b$.

Subsumption relation is directional, that is, $t_a \rightarrow_s t_b$ does not imply $t_b \rightarrow_s t_a$. For example, `literature` $\rightarrow_s$ `chineseliterature`, since for any document annotated with `chineseliterature`, we can also annotate it with `literature`. However, if we swapped the two tags, the statement would not hold.

Subsumption relation is more strict than similarity. For example, during the time of Haiti earthquake, the tag `earthquake` is close to `haiti` in similarity, but none of them implies the use of the other one: document annotated with `earthquake` may refer to the earthquake in China, while document annotated with `haiti` may mean the traveling experience in Haiti.

Note that the subsumption has transitivity property, that $t_a \rightarrow_s t_b$ and $t_b \rightarrow_s t_c$ means $t_a \rightarrow_s t_c$, which corresponds to our intuition. For instance, `naturaldisaster` $\rightarrow_s$ `earthquake` and `disaster`$\rightarrow_s$`naturaldisaster` means `disaster` $\rightarrow_s$`earthquake`.

3.2 Discover Subsumption Relation

We discover the subsumption relations by estimating the probability $p(t_a|t_b)$. The motivation is, if $t_a \rightarrow_s t_b$ and t_b is used, it would be more likely to see t_a. So, by sorting all (t_a, t_b) pairs by $p(t_a|t_b)$ in descending order, top-ranked pairs are more likely to have subsumption relations.

In this work, we present three methods to estimate the probability $p(t_a|t_b)$, using tag-tag, tag-word and tag-reason co-occurrences respectively. By using tag-word and tag-reason co-occurrences, we leverage the content of the annotated document for subsumption relation discovery.

3.2.1 Tag-Tag Co-occurrences Approach

The most intuitive way to estimate $p(t_a|t_b)$ is via tag-tag co-occurrences. Specifically, we use the following formula:

$$p(t_a|t_b) = \frac{N_d(t_a, t_b)}{N_d(t_b)}, \qquad (1)$$

where $N_d(t_a, t_b)$ is the number of documents that are annotated by both t_a and t_b, and $N_d(t_b)$ is the number of documents annotated by t_b. We denote the tag-tag co-occurrences approach as TAG-TAG.

The use of TAG-TAG can be found in previous literature for organizing tags for photos(Schmitz, 2006). One of TAG-TAG's benefits is that it does not rely on the content of the annotated document, thus it can be applied to tags for non-text objects, such as images and music. However, when coming to text documents, this benefit is also a shortcoming, that TAG-TAG makes no use of the content when it is available.

Using TAG-TAG for subsumption relation discovery relies on an implication, that if a user has annotated d with t_b, he would also annotate all tags that subsumes t_b. The implication may not always hold in real world situations. For example,

[1] http://www.flickr.com. An image sharing site that allows users to annotate images with tags

a novel reader would use tags such as scifi and mystery to organize his collections, but he is not likely to annotate each of his collection as novel or book, since they are too obvious for him. We name the problem as the *omitted-tag problem*.

3.2.2 Tag-Word Co-occurrences Approach

When the content of the annotated document is available, using it for estimating $p(t_a|t_b)$ is a natural thought. The content is expected to be complete and information-rich whether or not the user has omitted any tags. We use the following formula to estimate $p(t_a|t_b)$ by tag-word co-occurrences:

$$\begin{aligned} p(t_a|t_b) &= \sum_{w \in W} p(t_a|w)p(w|t_b) \\ &= \sum_{w \in W} \frac{N_d(t_a, w)}{N_d(w)} \frac{N_d(t_b, w)}{N_d(t_b)}, \end{aligned} \quad (2)$$

where $N_d(t_a, w)$ is the number of documents that contains both tag t_a and word w, and $N_d(w)$ is the number of documents that contains the word w. We denote this approach as TAG-WORD.

Instead of computing tag-tag co-occurrences directly, TAG-WORD uses words in the document as a bridge to estimate $p(t_a|t_b)$. By introducing words, the estimation is less affected by the omitted-tag problem, Take the novel reader example again: Although he does not use the tag novel too often, the words in book descriptions would suggest the using of novel, according to all other documents annotated by novel.

While using the content may weaken the omitted-tag problem, it also brings the noise in text to the estimation. Not every word in the content is related to one of the tags. To the opposite, most words are functional words or that about other aspects of the document. $p(t_a|t_b)$ estimated by using all words may largely depends on these irrelevant words.

3.2.3 Tag-Reason Co-occurrences Approach

To focus on the words that are highly relevant to the interested tags, we propose the third method that uses tag-reason co-occurrences. The *reason* is defined as the word(s) that can explain the using of a tag in the document. For example, the tag scifi for a book could be explained by the words "robot", "Asimov" in the book description. If the reason of each tag could be identified, the noise in content-based $p(t_a|t_b)$ could be reduced.

Si et al. (2010) proposed a probabilistic model for content-based social tags, named Tag Allocation Model (TAM). TAM introduces a latent variable r for each tag in the data set, known as the reason variable. The value of r can be a word in the corresponding document, or a global noise variable μ. Allowing the reason of tags to be a global noise makes TAM deal with content-irrelevant tags and mistakenly annotated tags effectively. The likelihood that a document d is annotated by tag t is given as:

$$\begin{aligned} p(t|d) &= \sum_{w \in d} p(t|r = w)p(r = w|d)p(s = 0) \\ &+ p(t|\mu)p(r = \mu)p(s = 1), \end{aligned} \quad (3)$$

where r is the reason of the tag t, $r \in \{w_{di}|i \in [0, |d|]\} \cup \{\mu\}$, μ is the global noise variable. s is the source of reason t, $s = 0$ means the source is the content of the document, while $s = 1$ means the source is the global noise variable μ. TAM can be trained use Gibbs sampling method. For the details of TAM, please refer to (Si and Sun, 2010).

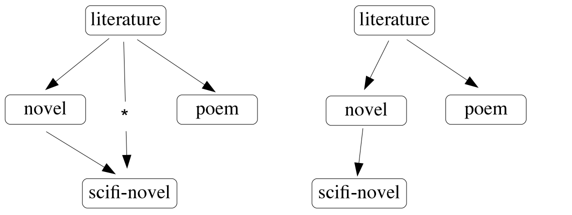
With a trained TAM, we can infer $p(t|r)$, the probability of seeing a tag t when using r as the reason, and $p(r|t)$, the probability of choosing r as the reason for tag t. With these probabilities, we can estimate $p(t_a|t_b)$ by

$$p(t_a|t_b) = \sum_{r \in W} p(t_a|r)p(r|t_b). \quad (4)$$

Note that we use only word reasons ($r \in W$), ignoring the noise reason μ completely. We denote this approach as TAG-REASON.

With the help of TAM, TAG-REASON covers the problems of the TAG-WORD method in two aspects: First, instead of using all words, TAG-REASON emphasizes on the really relevant words, which are the reasons identified by TAM. Second, by ignoring the noise variable μ, TAG-REASON is less affected by the content-irrelevant noise tags, such as thingstodo or myown.

After $p(t_a|t_b)$ is estimated for each $(t_a, t_b) \in T \times T$, we use the top-$n$ pairs with largest $p(t_a|t_b)$



(a) Directed Acyclic Graph (b) Layered Directed Acyclic Graph

Figure 2: DAG and Layered-DAG

as the final set of discovered subsumption relations.

4 Remove Redundancy with Layered-DAG Construction

The discovered subsumption relations connect all tags into a directed graph $G = \{V, E\}$, where V is the set of nodes, with each node is a tag; E is the set of edges, an edge e_{t_a,t_b} from t_a to t_b means $t_a \rightarrow_s t_b$. Furthermore, we define the weight of each edge w_e as the probability $p(t_a|t_b)$.

Recalling that subsumption relation has transitivity property, to avoid the cyclic references in G, we would like to turn G into a Directed Acyclic Graph (DAG). Further, DAG may also contains redundant information. Figure 2 (a) shows a part of a DAG. Note the edge marked as "*", which is perfectly correct, but does not provide extra information, since `literature` $\rightarrow_s$ `novel` and `novel` $\rightarrow_s$ `scifi-novel` have already implied that `literature` $\rightarrow_s$ `novel`. We would like to remove these redundant relations, turning a DAG into the form of Figure 2 (b).

We define Layered-DAG formally as follows: For a DAG G, when given any pair of nodes, if every path that can connect them has equal length, G is a Layered-DAG. Layered-DAG prohibits edges that link cross layers, such like edge "*" in Figure 2 (a). Constructing a Layered-DAG from the discovered relations can eliminate the redundant information.

Given a set of subsumption relations, multiple Layered-DAGs may be constructed. In particular, we want to find the Layered-DAG that maximizes the sum of all edges' weights. Weight maximization implies two concerns: First, when we need to remove a relation to resolve the conflicts or redundancy, the one with lower weight is prefered. Second, when more than one valid Layered-DAGs are available, we want to use the one that contains as many edges as possible.

```
Layered-DAG Construction Algorithm
Input: A set of weighted relations, $R = \{t_a \rightarrow_s t_b | t_a \in T, t_b \in T\}$,
$w_{t_a \rightarrow_s t_b} > 0$
Output: A Layered-DAG of tags $G^* = \{V^*, E^*\}$
 1:  $V^* = \{\}$
 2:  while $R \neq \varnothing$
 3:    if $V^* = \varnothing$
 4:      choose $t_a \rightarrow_s t_b \in R$ with highest weight.
 5:      $E^* \Leftarrow t_a \rightarrow_s t_b$
 6:      $V^* \Leftarrow t_a, V^* \leftarrow t_b$.
 7:      remove $t_a \rightarrow_s t_b$ from $R$.
 8:    else
 9:      $C \Leftarrow \{t_a \rightarrow_s t_b | t_a \rightarrow_s t_b \in R, \{t_a, t_b\} \cap V^* \neq \varnothing\}$
10:      for $t_a \rightarrow_s t_b \in C$ in descending weight order
11:        if adding $t_a \rightarrow_s t_b$ to $G^*$ keeps $G^*$ a Layered-DAG.
12:          $E^* \Leftarrow t_a \rightarrow_s t_b$
13:          $V^* \Leftarrow t_a, V^* \leftarrow t_b$.
14:          break
15:        endif
16:        remove $t_a \rightarrow_s t_b$ from $R$.
17:      endfor
18:    endif
19:  endwhile
20:  output $G^*$
```

Figure 3: A greedy algorithm for constructing Layered-DAG of tags

Finding and proving an optimal algorithm for maximum Layered-DAG construction are beyond the scope of this paper. Here we present a greedy algorithm that works well in practice, as described in Figure 3.

The proposed algorithm starts with a minimal Layered-DAG G^* that contains only the highest weighted relation in R (Steps 1-8). Then, it moves an edge in G to G^* once a time, ensuring that adding the new edge still keeps G^* a valid Layered-DAG (Step 11), and the new edge has the highest weights among all valid candidates (Steps 9-10).

5 Experiments

In this section, we show the experimental results of proposed methods. Specifically, we focus on the following points:

- The quality of discovered subsumption relations by different methods.
- The characteristics of wrong subsumption relations discovered.
- The effect of Layered-DAG construction on the quality of relations.
- Empirical study of the resulted Layered-DAG.

Name	N	$\bar{N}_{tag}$	$\bar{N}_{content}$
BLOG	100,192	2.78	332.87
BOOK	110,371	8.51	204.76

Table 1: Statistics of the data sets. N is the number of documents. $\bar{N}_{tag}$ is the mean number of tags per document. $\bar{N}_{content}$ is the mean number of words per document.

5.1 Data Sets

We use two real world social tagging data sets. The first data set, named BLOG, is a collection of blog posts annotated by blog authors, which is crawled from the web. The second data set, named BOOK, is from a book collecting and sharing site[2], which contains description of Chinese books and user contributed tags. Table 1 lists the basic statistics of the data sets.

The two data sets have different characteristics. Documents in BLOG are longer, not well written, and the number of tags per document is small. To the opposite, documents in BOOK are shorter but well written, and there are more tags for each document.

5.2 Discovered Subsumption Relations

5.2.1 Experimental Settings

For BLOG, we use the tags that have been used more than 10 times; For BOOK, we use the tags that have been used more than 50 times. We perform 100 iterations of Gibbs sampling when training the TAM model, with first 50 iterations as the burn-in iterations. All the estimation methods require proper smoothing. Here we use additive smoothing for all methods, which adds a very small number (0.001 in our case) to all raw counts. Sophisticated smoothing method could be employed, but is out of the scope of this paper.

5.2.2 Evaluation

We use *precision* and *coverage* to evaluate the discovered relations at any given cut-off threshold n. First, we sort the discovered relations by their weights in descending order. Then, we take the top-n relations, discarding the others. For the remaining relations, precision is computed as N_c/n, N_c is the number of correct relations in the top-n list; coverage is computed as $N_t/|T|$, where N_t is the number of unique tags appeared in the top-n list, and $|T|$ is the total number of tags.

To get N_c, the number of correct relations, we need a standard judgement of the correctness of relations, which involves human labeling. To minimize the bias in human assessment, we use **pooling**, which is a widely accepted method in Information Retrieval research (Voorhees and Harman, 2005). Pooling works as follows: First, relations obtained by different methods are mixed together, creating a pool of relations. Second, the pool is shuffled, so that the labeler cannot identify the source of a single relation. Third, annotators are requested to label the relations in the pool as correct or incorrect, based on the definition of subsumption relation. After all relations in the pool are labeled, we use them as the standard judgement to evaluate each method's output.

Precision measures the proportion of correct relations, while coverage measures the proportion of tags that are connected by the relations. The cutoff threshold n affects both precision and coverage: the larger the n, the lower the precision, and the higher the coverage.

5.2.3 Baseline methods

Besides TAG-TAG, TAG-WORD and TAG-REASON, we also include the method described in (Heymann and Garcia-Molina, 2006) as a baseline, denoted as HEYMANN. HEYMANN method was designed to find similar-to relation rather than subsumption relation. The similar-to relation is symmetric, while subsumption relation is more strict and asymmetric. In our experiments, we use the same evaluation process to evaluate TAG-TAG, TAG-WORD, TAG-REASON and HEYMANN, in which only subsumption relations will be marked as correct.

5.2.4 Results

For each method, we set the cut-off threshold n from 1 to 500, so as to plot the psrecision-coverage curves. The result is shown in Figure 4. The larger the area under the curve, the better the method's performance.

We have three observations from Figure 4. First, TAG-REASON has the best performance

(a) BLOG

(b) BOOK

Figure 4: The precision and coverage of TAG-TAG, TAG-WORD, TAG-REASON and HEYMANN methods. The larger the area under the curve, the better the result. The cut-off threshold $n \in [1, 500]$.

BLOG			BOOK		
Insufficient	Reversed	Irrelevant	Insufficient	Reversed	Irrelevant
childedu $\rightarrow_s$ father childedu $\rightarrow_s$ grandma emotion$\rightarrow_s$warm childedu$\rightarrow_s$child education$\rightarrow_s$child	stock $\rightarrow_s$ security stock $\rightarrow_s$ financial delicious$\rightarrow_s$taste delicious$\rightarrow_s$food earthquake$\rightarrow_s$disaster	travel$\rightarrow_s$building emotion $\rightarrow_s$time emotion$\rightarrow_s$original culture$\rightarrow_s$spring poem$\rightarrow_s$night	textbook $\rightarrow_s$ exam history $\rightarrow_s$ military piano$\rightarrow_s$scores history$\rightarrow_s$culture novel$\rightarrow_s$love	English $\rightarrow_s$ foreignlang biography$\rightarrow_s$people jpbuilding$\rightarrow_s$jpculture novel$\rightarrow_s$pureliterature ancientgreek$\rightarrow_s$greek	japan $\rightarrow_s$lightnovel building$\rightarrow_s$textbook sales$\rightarrow_s$O japan $\rightarrow_s$ shower photo$\rightarrow_s$umbrella
Total 52%	Total 14%	Total 34%	Total 37%	Total 48%	Total 15%

Table 2: Examples of mistakes and the percentage of each mistake type.

on both data sets: On the BOOK data set, TAG-REASON outperforms others by a marked margin; On the BLOG data set, TAG-REASON has higher precision when coverage is smaller (which means within top-ranked relations), and has comparable precision to TAG-TAG when coverage increases. Second, similarity-based clustering method (namely HEYMANN) performed worse than others, suggesting it may not be adequate for discovering subsumption relation. Third, while also using content information, TAG-WORD performs poorer than both TAG-REASON and TAG-TAG, which suggests that noise in the content would prevent TAG-WORD from getting the correct estimation of $p(t_a|t_b)$.

To summarize, by leveraging *relevant* content, TAG-REASON could discover better subsumption relations than just using tag-tag co-occurrences and similarity-based hierarchical clustering.

5.2.5 Mistakes in Discovered Relations

We also studied the type of mistakes in subsumption relation discovery. To our observation, a mistakenly discovered relation $t_a \rightarrow_s t_b$ falls into one of the following categories:

1. **insufficient** t_a relates with t_b, but using t_b does not implies the using of t_a in all cases.
2. **reversed** $t_b \rightarrow_s t_a$ is correct, while $t_a \rightarrow_s t_b$ is not.
3. **irrelevant** There is no obvious connection between t_a and t_b.

We collected all incorrect relations discovered by the TAG-REASON method. Then, the type of mistake for each relation is labeled manually. The result is shown in Table 2, along with selected examples of each type.

Table 2 shows different error patterns for BLOG and BOOK. In BLOG, most of the mistakes are of the type *insufficient*. Taking "`education` $\rightarrow_s$ `child`" for example, annotating a document as `child` does not imply that it is about child education, it may about food or clothes for a child. In BOOK, most of the mistakes are *reversed* mistakes, which is a result of the omitted-tag problem discussed in Section 3.2.1.

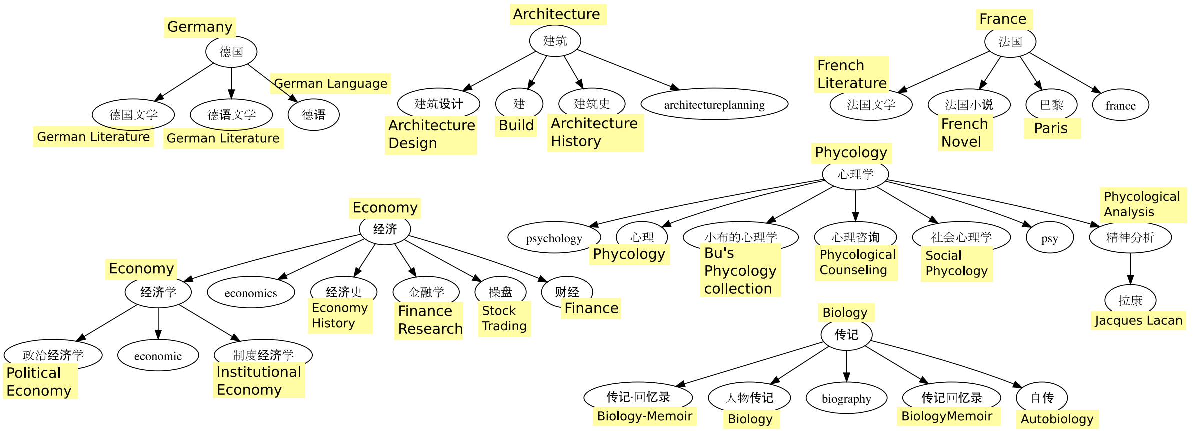

Figure 5: Part of the constructed Layered-DAG from the BOOK data set.

	BLOG		BOOK	
Method	Precision	Coverage	Precision	Coverage
TAG-TAG	-4.7%	$+7.9\%$	-7.4%	$+12.5\%$
TAG-WORD	0%	0%	-9.0%	$+2.2\%$
TAG-REASON	-3.6%	$+5.4\%$	-0.9%	$+5.4\%$

Table 3: The effects on precision and coverage by Layered-DAG construction

5.3 Layered-DAG Construction

Using the algorithm introduced in Section 4, we constructed Layered-DAGs from the discovered relations. Constructing Layered-DAG will remove certain relations, which will decrease the precision and increase the coverage. Table 3 shows the changes of precision and coverage brought by Layered-DAG construction. In most of the cases, the increasing of coverage is more than the decreasing of precision.

As a representative example, we show part of a constructed Layered-DAG from the BOOK data set in Figure 5, since the whole graph is too big to fit in the paper. All tags in Chinese are translated to English.

6 Conclusion and Future Work

In this paper, we explored the structure of social tags by discovering subsumption relations. First, we defined the subsumption relation $t_a \rightarrow_s t_b$ as t_a can be used to replace t_b without ambiguity. Then, we cast the subsumption relation identification problem to the estimation of $p(t_a|t_b)$. We proposed three methods, namely TAG-TAG, TAG-WORD and TAG-REASON, while the last two leverage the content of document to help estimation. We also proposed an greedy algorithm for constructing a Layered-DAG from the discovered relations, which helps minimizing redundancy.

We performed experiments on two real world data sets, and evaluated the discovered subsumption relations quantitatively by pooling. The results showed that the proposed methods outperform similarity-based hierarchical clusteing in finding subsumption relations. The TAG-REASON method, which uses only the relevant content to the tags, has the best performance. Empirical study showed that Layered-DAG construction works effectively as expected.

The results suggest two directions for future work: First, more ways for $p(t_a|t_b)$ estimation could be explored, for example, combining TAG-TAG and TAG-REASON; Second, external knowledge, such as the Wikipedia and the WordNet, could be exploited as background knowledge to improve the accuracy.

Abstract

Zulu is an indigenous language of South Africa, and one of the eleven official languages of that country. It is spoken by about 11 million speakers. Although it is similar in size to some Western languages, e.g. Swedish, it is considerably under-resourced. This paper presents a new open-source morphological corpus for Zulu named *Ukwabelana corpus*. We describe the agglutinating morphology of Zulu with its multiple prefixation and suffixation, and also introduce our labeling scheme. Further, the annotation process is described and all single resources are explained. These comprise a list of 10,000 labeled and 100,000 unlabeled word types, 3,000 part-of-speech (POS) tagged and 30,000 raw sentences as well as a morphological Zulu grammar, and a parsing algorithm which hypothesizes possible word roots and enumerates parses that conform to the Zulu grammar. We also provide a POS tagger which assigns the grammatical category to a morphologically analyzed word type. As it is hoped that the corpus and all resources will be of benefit to any person doing research on Zulu or on computer-aided analysis of languages, they will be made available in the public domain from http://www.cs.bris.ac.uk/Research/MachineLearning/Morphology/Resources/.

1 Introduction

Zulu (also known as isiZulu) is a Bantu language of South Africa, classified as S.30 in Guthrie's classification scheme (Guthrie, 1971). Since 1994, it has been recognized as one of the eleven official languages of South Africa. It has a written history of about 150 years: the first grammar was published by Grout (1859), and the first dictionary by Colenso (1905). There are about 11 million mother-tongue speakers, who constitute approximately 23% of South Africa's population, making Zulu the country's largest language.

Zulu is highly mutually intelligible with the Xhosa, Swati and Southern Ndebele languages, and with Ndebele of Zimbabwe (Lanham, 1960), to the extent that all of these can be considered dialects or varieties of a single language, Nguni. Despite its size, Zulu is considerably *under-resourced*, compared to Western languages with similar numbers of speakers, e.g. Swedish. There are only about four regular publications in Zulu, there are few published books, and the language is not used as a medium of instruction.

This of course is partly due to the short time-span of its written history, but the main reason, of course, is the apartheid history of South Africa: for most of the twentieth century resources were allocated to Afrikaans and English, the two former official languages, and relatively few resources to the indigenous Bantu languages. Since 1994, Zulu has had a much larger presence in the media, with several television programs being broadcast in Zulu every day. Yet much needs to be done in order to improve the resources available to Zulu speakers and students of Zulu.

The aim of the project reported in this paper was to establish a Zulu corpus, named the *Ukwabelana corpus*[1], consisting of morphologically labeled words (that is, word types) and part-of-speech (POS) tagged sentences. Along with the labeled corpus, unlabeled words and sentences, a morphological grammar, a semi-automatic mor-

[1] *Ukwabelana* means 'to share' in Zulu where the 'k' is pronounced voiced like a [g].

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 1020–1028,
Beijing, August 2010

phological analyzer and a *POS tagger* for morphologically analyzed words will be provided.

The sources used for the corpus were limited to fictional works and the Zulu Bible. This means that there is not a wide variety of registers, and perhaps even of vocabulary items. This defect will have to be corrected in future work.

The *Ukwabelana corpus* can be used to develop and train automatic morphological analyzers, which in turn tag a large corpus of written Zulu, similar to the Brown corpus or the British National Corpus. Moreover, the list of POS tagged sentences is an essential step towards building an automatic syntactic tagger, which still does not exist for Zulu, and a tagged corpus of Zulu. Such a corpus would be beneficial to language researchers as it provides them with examples of actual usage, as opposed to elicited or invented examples, which may be artificial or unlikely to occur in real discourse. This would greatly improve the quality of Zulu dictionaries and grammars, most of which rely heavily on the work of Doke (1927) and Doke, Malcom and Sikakana (1958), with little in the way of innovation. Morphological tagging is also useful for practical computational applications like predictive text, spell-checking, grammar checking and machine translation; in the case of Zulu, where a large percentage of grammatical information is conveyed by prefixes and suffixes rather than by separate words, it is essential. For example, in English, the negative is expressed by means of a separate word *'not'*, but in Zulu the negative is constructed using a prefix-and-suffix combination on the verb, and this combination differs according to the mood of the verb (indicative, participial or subjunctive). The practical computational applications mentioned could have a very great impact on the use of Zulu as a written language, as spell-checking and grammar checking would benefit proofreaders, editors and writers. Machine translation could aid in increasing the number of texts available in Zulu, thus making it more of a literary language, and allowing it to become established as a language of education. The use of Zulu in public life could also increase. Currently, the tendency is to use English, as this is the language that reaches the widest audience. If high-quality automatic translation becomes available, this would no longer be necessary. As it is hoped that the *Ukwabelana corpus* will be of benefit to any person doing research on Zulu or on computer-aided analysis of languages, it will be made available as the first morphologically analysed corpus of Zulu in the public domain.

2 Related work

In this section, we will give an overview of linguistic research on Nguni languages, following the discussions in van der Spuy (2001), and thereafter a summary of computational approaches to the analysis of Zulu.

2.1 Linguistic research on Nguni languages

The five Nguni languages Zulu, Xhosa, South African Ndebele, Swati, and Zimbabwean Ndebele are highly mutually intelligible, and for this reason, works on any of the other Nguni languages are directly relevant to an analysis of Zulu.

There have been numerous studies of Nguni grammar, especially its morphology; in fact, the Nguni languages probably rival Swahili and Chewa for the title of most-studied Bantu language. The generative approach to morphological description (as developed by Aronoff (1976), Selkirk (1982), Lieber (1980), Lieber (1992)) has had very little influence on most of the work that has been done on Nguni morphology.

Usually, the descriptions have been atheoretical or structuralist. Doke's paradigmatic description of the morphology (Doke, 1927; Doke, 1935) has remained the basis for linguistic work in the Southern Bantu languages. Doke (1935) criticized previous writers on Bantu grammars for basing their classification, treatment and terminology on their own mother tongue or Latin. His intention was to create a grammatical structure for Bantu which did not conform to European or classical standards. Nevertheless, Doke himself could not shake off the European mindset: he treated the languages as if they had inflectional paradigms, with characteristics like subjunctive or indicative belonging to the whole word, rather than to identifiable affixes; in fact, he claimed (1950) that Bantu languages are "inflectional with [just] a tendency to agglutination", and assumed that the morphology was linear not hierarchical. Most subsequent linguistic studies and reference grammars of the Southern Bantu languages have been directed at refining or redefining Doke's categories from a paradigmatic perspective.

Important Nguni examples are Van Eeden (1956), Van Wyk (1958), Beuchat (1966), Wilkes (1971), Nkabinde (1975), Cope (1984), Davey (1984), Louw (1984), Ziervogel et al. (1985), Gauton (1990), Gauton (1994), Khumalo (1992), Poulos and Msimang (1998), Posthumus (1987), Posthumus (1988), Posthumus (1988) and Posthumus (2000). Among the very few generative morphological descriptions of Nguni are Lanham (1971), Mbadi (1988) and Du Plessis (1993). Lanham (1971) gives a transformational analysis of Zulu adjectival and relative forms. This analysis can be viewed as diachronic rather than synchronic. Mbadi (1988) applies Lieber (1980) and Selkirk's percolation theory (Selkirk, 1982) to a few Xhosa morphological forms. Du Plessis (1993) gives a hierarchical description of the morphology of the verb, but he assumes that derivation is syntactical rather than lexical.

In short, there has been no thorough-going generative analysis of the morphology which has treated the Nguni languages as agglutinative rather than inflectional.

2.2 Computational approaches to analyzing Zulu

In the last decade, various computational approaches for Zulu have been reported. Based on the *Xerox finite-state toolbox* by Beesley and Karttunen (2003), Pretorius and Bosch (2003) developed a prototype of a computational morphological analyzer for Zulu. Using a semi-automated process, a morphological lexicon and a rule-base were built incrementally. Later work (Pretorius and Bosch, 2007) dealt with overgeneration of the Zulu finite-state tool concerning locative formation from nouns and verbal extensions to verb roots. Pretorius and Bosch (2009) also used cross-linguistic similarities and dissimilarities of Zulu to bootstrap a morphological analyser for Xhosa. Joubert et al. (2004) followed a bootstrapping approach to morphological analysis. A simple framework uses morpheme lists, morphophonological and morphosyntactic rules which are learnt by consulting an *oracle*, in their case a linguistic expert who corrects analyses. The framework then revises its grammar so that the updated morpheme lists and rules do not contradict previously found analyses. Botha and Barnard (2005) compared two approaches for gathering Zulu text corpora from the World Wide Web. They drew the conclusion that using commercial search engines for finding Zulu websites outperforms webcrawlers even with a carefully selected starting point. They saw the reason for that in the fact that most documents on the internet are in one of the world's dominant languages. Bosch and Eiselen (2005) presented a spell checker for Zulu based on morphological analysis and regular expressions. It was shown that after a certain threshold for the lexicon size performance could only be improved by incrementally extending morphological rules. Experiments were performed for basic and complex Zulu verbs and nouns, and large numbers of words still were not recognized. Spiegler et al. (2008) performed experiments where they tested four machine learning algorithms for morphological analysis with different degrees of supervision. An unsupervised algorithm analyzed a raw word list, two semi-supervised algorithms were provided with word stems and subsequently segmented prefix and suffix sequences, and the supervised algorithm used a language model of analysed words which was applied to new words. They experimentally showed that there is a certain trade-off between the usage of labeled data and performance. They also reckoned that computational analysis improves if words of different grammatical categories are analysed separately since there exist homographic morphemes across different word categories.

3 Zulu morphology

Zulu is an agglutinative language, with a complex morphology. It presents an especial problem for computational analysis, because words usually incorporate both prefixes and suffixes, and there can be several of each. This makes it hard to identify the root by mechanical means, as the root could be the first, second, third, or even a later morpheme in a word. The complexities involved are exacerbated by the fact that a considerable number of affixes, especially prefixes, have allomorphic forms. This is largely brought about by the fact that Zulu has a prohibition against sequences of vowels, so that a prefix whose canonical form is *nga-* will have an allomorph *ng-* before roots that begin with vowels. Given a sequence *nga-*, then, it is possible that it constitutes an entire morpheme, or the beginning of a morpheme like the verb root *ngabaz-* 'to be uncertain', or a morpheme *ng-* followed by a vowel-commencing root like *and-* 'to increase'. Furthermore, many morphemes are homographs, so that the prefix *nga-* could represent either the potential mood morpheme or a form of the negative that occurs in subordinate clauses; and the sequence *ng-* could be the allomorph of either of these, or of a number of homographic morphemes *ngi-*, which represent the first person singular in various moods. Besides these phonologically conditioned allomorphs, there are also morphologically conditioned ones, for example the locative prefix *e-* has an allomorph *o-* that occurs in certain morphological circumstances. Certain morpheme sequences also exhibit syncretism, so that while most nouns take a sequence of prefixes known as the initial vowel and the noun prefix, as in *i-mi-zi* 'villages', nouns of certain classes, like class 5, syncretise these two prefixes, as in *i-gama* 'name', where the prefix *i-* represents both the initial vowel and the noun prefix.

Like all other Bantu languages, Zulu divides its nouns into a number of classes. The class is often identifiable from the noun prefix that is attached to the noun, and it governs the *agreement* of all words that modify the noun, as well as of predicates of which the noun is a subject. Object agreement may also be marked on the predicate. Two examples of this agreement are given below.

Example 1.

Leso si-tshudeni e-si-hle e-ngi-si-fundis-ile si-phas-e kahle.
that student who-AGR-good who-I-him-teach-PAST AGR-pass-PAST well.
'That good student whom I taught passed well.'

Example 2.

Lowo m-fundi o-mu-hle e-ngi-m-fundis-ile u-phas-e kahle.
that learner who-AGR-good who-I-him-teach-PAST AGR-pass-PAST well.
'That good learner whom I taught passed well.'

The differences in agreement morphology in the two sentences is brought about because the nouns *sitshudeni* and *mfundi* belong to different classes. Canonici (1996) argues that a noun should be assigned to a class by virtue of the agreement that it takes. In terms of this criterion, there are twelve noun classes in Zulu. These classes are numbered 1–7, 9, 10, 11, 14, 15. The numbering system was devised by Meinhof (1906), and reflects the historical affinities between Zulu and other Bantu languages: Zulu lacks classes 8, 12 and 13, which are found in other Bantu languages. In the labels used on the database, morphemes that command or show agreement have been labeled as <*xn*>, where *x* is a letter or sequence of letters, and *n* is a number: thus the morpheme *m-* in *mfundi* is labeled <*n1*>, as it marks the noun as belonging to noun class *1*. The morpheme *si-* in *engisifundisile* is marked <*o7*>, as it shows object agreement with a noun of class *7*.

Zulu *predicatives* may be either verbal or non-verbal – the latter are referred to in the literature as copulatives. Copulatives usually consist of a predicative prefix and a base, which may be a noun, an adjective, or a prepositional, locative or adverbial form. There may also be various tense, aspect and polarity markers. They translate the English verb 'be', plus its complement – Zulu has no direct equivalent of 'be'; the verb *-ba*, which has the closest meaning, is probably better translated as 'become'. Examples of copulative forms are *ubenguthisha* 'he was a teacher', *zimandla* 'they are strong', *basekhaya* 'they are at home'. Predicatives may occur in a variety of moods, tenses, aspects and polarities; these are usually distinguished by the affixes attached to the base form. Thus in *engasesendlini* '(s)he no longer being in the house', the initial prefix *e-* indicates third person singular, class 1, participial mood; the prefix *nga-* denotes negative; the first prefix *se-* denotes continuative aspect; the second prefix *se-* is the locative prefix; *n-* shows that the noun belongs to class 9; *dl-* is the noun root meaning 'house', an allomorph of the canonical form *-dlu*; and *-ini* is the locative suffix. Thus in typical agglutinative manner, each affix contributes a distinctive part of the meaning of the word as a whole. This characteristic of the language was exploited in the labeling system used for the morphological corpus: labels were designed so as to indicate the grammatical function of the morpheme. A person searching for past tense negative verbs, for example, could simply search for the combination of <*past* >, <*neg*> and <*vr*>. A complete list of morphemes, allomorphs and their labels is provided along with the corpus and other resources.

According to the Dokean grammatical tradition (Doke, 1927), Zulu has a large number of parts of speech. This is because what would be separate words in other languages are often prefixes in Zulu, and also because various subtypes of determiner are given individual names. The parts of speech recognised in the corpus are: noun, verb, adjective, pronoun, adverb, conjunction, prepositional, possessive, locative, demonstrative, presentative, quantitative, copulative and relative.

Adjective includes the traditional Dokean adjective (a closed class of roots which take noun prefixes as their agreement prefixes) and the predicative form of the Dokean relative, which is seen as an open class of adjectives (cf. van der Spuy (2006)). *Pronouns* are the personal pronouns, which may also (sometimes in allomorphic form) be used as agreement morphemes in quantifiers. Adverbs may be forms derived from adjectives by prefixing *ka-* to the root, or morphologically unanalysable forms like *phansi* 'in front, forward'. Ideophones have been included as adverbs. *Prepositionals* are words that incorporate the Dokean "adverbials" *na-* 'with', *nga-* 'by means of', *njenga-* 'like', *kuna-* 'more than', etc., which are better analysed as prepositions. The presentative is Doke's "locative demonstrative copulative" - the briefer name was suggested by van der Spuy (2001). *Copulatives* are all Doke's copulatives, excluding the adjectives mentioned above. *Relatives* are all predicative forms incorporating a relative prefix.

4 The labeling scheme

The labeling scheme has been based on the idea that each morpheme in a word should be labeled, even when words belong to a very restricted class. For example, the demonstratives could have been labeled as composite forms, but instead it is assumed that demonstratives contain between one and three morphemes, e.g. *le<d>si<d7>ya<po3>* 'a demonstrative of the third position referring to class 7' - i.e.. 'that one yonder, class 7'. It should be possible from this detailed labeling to build up an amalgam of the morphological structure of the word. The labels have been chosen to be both as brief as possible and as transparent as possible, though transparency was often sacrificed for brevity. Thus indicative subject prefixes are labeled <*i1-15*>, relative prefixes are labeled <*r*>, and noun prefixes are labeled <*n1-15*>; but negative subject prefixes are labeled <*g1-15*> and possessive agreement prefixes are labeled <*z1-15*>. Sometimes a single label was used for several different forms, when these are orthographically distinct, so for example <*asp*> (aspect) is used as a label for the following, among others: the continuative prefix *sa-* and its allomorph *se-*, the exclusive prefix *se-*, and the potential prefix *nga-* and its allomorph *ng-*. A person searching for forms containing the potential aspect would have to search for *'nga<asp> + ng<asp>'*. However, there should be no ambiguity, as the orthographic form would eliminate this. The detailed description of the scheme is provided by Spiegler et al. (2010).

5 Annotation process

The goal of this project was to build a reasonably sized corpus of morphologically annotated words of high quality which could be later used for developing and training automatic morphological analyzers. For this reason, we had gathered a list of the commonest Zulu word types, defined a partial grammar and parsed Zulu words with a logic algorithm which proposes possible parses based on the partial grammar. Compared to a completely manual approach, this framework provided possible annotations to choose from or the option to type in an annotation if none of the suggestions was the correct one. This semi-automatic process speeded up the labeling by an estimated factor of 3-4, compared to a purely manual approach. In Figure 1 we illustrate the annotation process and in the following subsections each step is detailed.

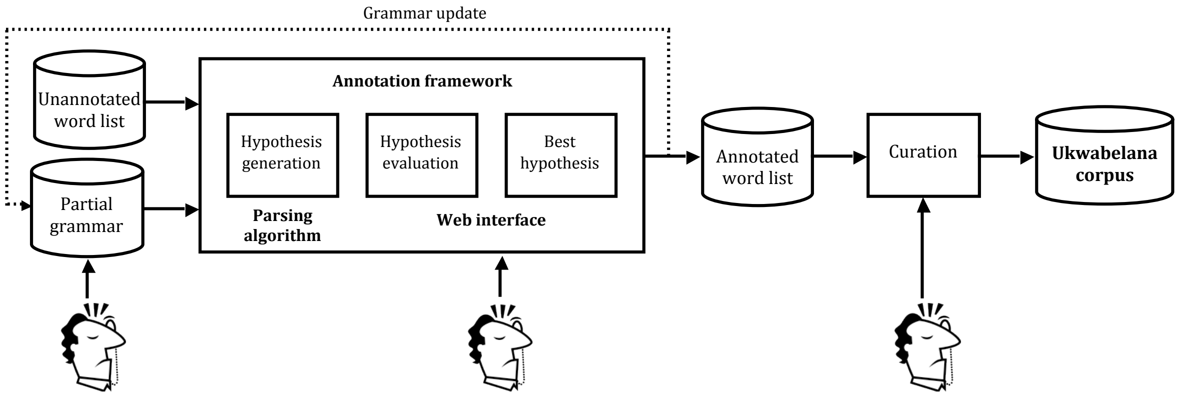

Figure 1: Process view of the annotation.

5.1 Unannotated word list

A list of unannotated Zulu words has been compiled from fictional works and the Zulu Bible. The original list comprises around 100,000 of the commonest Zulu word types. No information, morphological or syntactic, was given along with the words. We selected an initial subset of 10,000 words although our long-term goal is the complete analysis of the entire word list.

5.2 Partial grammar

Our choice for representing the morphological Zulu grammar was the formalism of *Definite Clause Grammars (DCGs)* used in the logic programming language *Prolog*. Although we defined our grammar as a simple context-free grammar, DCGs can also express context-sensitive grammars by associating variables as arguments to non-terminal symbols (Gazdar and Mellish, 1989). When defining our morphological grammar, we assumed that a linguistic expert could enumerate all or at least the most important morphological rules and morphemes of 'closed' morpheme categories, e.g. prefixes and suffixes of nouns and verbs. Morphemes of 'open' categories like noun and verb roots, however, would need to be hypothesized during the semi-automatic analysis and confirmed by the linguistic expert. Our final grammar comprised around 240 morphological rules and almost 300 entries in the morpheme dictionary. Since we did not only want to recognize admissible Zulu words but also obtain their morphological structure, we needed to extend our DCG by adding parse construction arguments as shown in the example below.

Example 3.

```
w((X)) --> n(X).
n((X,Y,Z)) --> iv(X),n2(Y),nr(Z).
iv(iv(a)) --> [a].
n2(n2(ba))--> [ba].
```

A possible parse for the word `abantu` 'people' could be `iv(a),n2(ba),*nr(ntu)` where '$\star$' marks the hypothesized noun root.

With our partial grammar we could not directly use the inbuilt Prolog parser since we had to account for missing dictionary entries: Zulu verb and noun roots. We therefore implemented an algorithm which would generate hypotheses for possible parses according to our grammar. The algorithm will be described in the next subsection.

5.3 Hypothesis generation

For the hypothesis generation we reverted to logic programming and *abductive reasoning*. Abduction is a method of reasoning which is used with incomplete information. It generates possible hypotheses (parses) for an observation (word) and a given theory (grammar). Depending on the implementation, abduction finds the best hypothesis by evaluating all possible explanations. Our abductive algorithm is an extension of the meta-interpreter designed by Flach (1994) which only enumerates possible parses based on the grammar. A linguistic expert would then choose the best hypothesis. The algorithm invokes rules *top-down* starting with the most general until it reaches the last level of syntactic variables. These variables are then matched against their dictionary entries from the left to the right of the word. A possible parse is found if either all syntactic variables can be matched to existing dictionary entries or if an unmatched variable is listed as *abducible*. Abducibles are predefined non-terminal symbols whose dictionary entry can be hypothesized. In our case, abducibles were noun and verb roots.

5.4 Evaluation and best hypothesis

Our annotation framework only enumerated allowable parses for a given word, therefore a linguistic expert needed to evaluate hypotheses. We provided a *web-interface* to the annotation framework, so that multiple users could participate in the annotation process. They would choose either a single or multiple correct parses. If none of the hypotheses were correct, the user would provide the correct analysis. Although our grammar was incomplete it still generated a substantial number of hypotheses per word. These were in no particular order and a result of the inherent ambiguity of Zulu morphology. We therefore experimented with different ways of improving the presentation of parses. The most promising approach was structural sorting. Parses were alphabetically re-ordered according to their morphemes and labels such that similar results were presented next to each other.

5.5 Grammar update

The grammar was defined in an iterative process and extended if the linguistic expert found morphemes of closed categories which had not been listed yet or certain patterns of incomplete or incorrect parses caused by either missing or inaccurate rules. The updated rules and dictionary were considered for newly parsed words.

5.6 Annotated word list and curation process

Although there had been great effort in improving the hypothesis generation of the parsing algorithm, a reasonable number of morphological analyses still had to be provided manually. During the curation process, we therefore had to deal with removing typos and standardizing morpheme labels provided by different experts. In order to guarantee a high quality of the morphological corpus, we also inspected single labels and analyses for their correctness. This was done by examining frequencies of labels and label combinations assuming that infrequent labels and combinations were likely to be incorrect and needed to be manually examined again. The finally curated corpus has an estimated error of 0.4 ± 0.5 incorrect single labels and 2.8 ± 2.1 incorrect complete analyses per 100 parses. Along with each word's analysis we wanted to provide part-of-speech (POS) tags. This was done by using a set of rules which determine the POS tag based on the morphological structure. We developed a prototype of a POS tagger which would assign the part-of-speech to a given morphological analysis based on a set of 34 rules. A summary of morphological analyses and words is given in Table 1. The rules are provided in Spiegler et al. (2010).

Category	**# Analyses**	**# Word types**
Verb	6965	4825
Noun	1437	1420
Relative	1042	988
Prepositional	969	951
Possessive	711	647
Copulative	558	545
Locative	380	379
Adverb	156	155
Modal	113	113
Demonstrative	63	61
Pronoun	38	31
Interjection	24	24
Presentative	15	15
Adjective	14	14
Conjunction	3	3
Total #	12488	10171

Table 1: Categories of labeled words.

5.7 POS tagging of sentences

In addition to the list of morphologically labeled words, we assigned parts-of-speech to a subset of 30,000 Zulu sentences. This task is straightforward if each word of a sentence only belongs to a single grammatical category. This was the case for 2595 sentences. For 431 sentences, however, we needed to disambiguate POS tags. We achieved this by analysing the left and right context of a word form and selecting the most probable part-of-speech from a given list of possible tags.

The overall error is estimated at 3.1±0.3 incorrect POS tags per 100 words for the 3,000 sen-

Dataset	# Sentences	# Word tokens	#Word types	# Words per sentence	Word length
Raw	29,424	288,106	87,154	9.79±6.74	7.49±2.91
Tagged	3,026	21,416	7,858	7.08±3.75	6.81±2.68

Table 2: Statistics of raw and POS-tagged sentences.

tences we tagged. The summary statistics for raw and tagged sentences are shown in Table 2.

6 The Ukwabelana corpus - a resource description

The *Ukwabelana corpus* is three-fold:

1. It contains 10,000 morphologically labeled words and 3,000 POS-tagged sentences.
2. The corpus also comprises around 100,000 common Zulu word types and 30,000 Zulu sentences compiled from fictional works and the Zulu Bible, from which the labeled words and sentences have been sampled.
3. Furthermore, all software and additional data used during the annotation process is provided: the partial grammar in DCG format, the abductive algorithm for parsing with incomplete information and a prototype for a POS tagger which assigns word categories to morphologically analyzed words.

We are making these resources publicly available from `http://www.cs.bris.ac.uk/Research/MachineLearning/Morphology/Resources/` so that they will be of benefit to any person doing research on Zulu or on computer-aided analysis of languages.

7 Conclusions and future work

In this paper, we have given an overview of the morphology of the language Zulu, which is spoken by 23% and understood by more than half of the South African population. As an indigenous language with a written history of 150 years which was only recognised as an official languages in 1994, it is considerably under-resourced. We have spent considerable effort to compile the first open-source corpus of labeled and unlabeled words as well as POS-tagged and untagged sentences to promote research on this Bantu language. We have described the annotation process and the tools for compiling this corpus. We see this work as a first step in an ongoing effort to ultimately label the entire word and sentence corpus.

Our future work includes further automation of the annotation process by extending the described abductive algorithm with a more sophisticated hypothesis evaluation and by combining syntactical and morphological information during the decision process. Our research interest also lies in the field of automatic grammar induction which will help to refine our partial grammar. Another aspect is interactive labeling where a linguistic expert directs the search of an online parsing algorithm by providing additional information. Apart from the benefits to language researchers, we foresee an application of the corpus by machine learners which can develop and train their algorithms for morphological analysis.

Acknowledgements

We would like to thank Etienne Barnard and the Human Language Technologies Research Group from the Meraka Institute for their support during this project. Furthermore, we want to acknowledge Johannes Magwaza, Bruno Golénia, Ksenia Shalonova and Roger Tucker. The research work was sponsored by EPSRC grant EP/E010857/1 *Learning the morphology of complex synthetic languages* and a grant from the NRF (S. Africa).

Abstract

We present a novel *E*valuation *M*etric for *M*orphological *A*nalysis (*EMMA*) that is both linguistically appealing and empirically sound. *EMMA* uses a graph-based assignment algorithm, optimized via integer linear programming, to match morphemes of predicted word analyses to the analyses of a morphologically rich answer key. This is necessary especially for unsupervised morphology analysis systems which do not have access to linguistically motivated morpheme labels. Across 3 languages, *EMMA* scores of 14 systems have a substantially greater positive correlation with mean average precision in an information retrieval (IR) task than do scores from the metric currently used by the Morpho Challenge (MC) competition series. We compute *EMMA* and MC metric scores for 93 separate system-language pairs from the 2007, 2008, and 2009 MC competitions, demonstrating that *EMMA* is not susceptible to two types of gaming that have plagued recent MC competitions: Ambiguity Hijacking and Shared Morpheme Padding. The *EMMA* evaluation script is publicly available from `http://www.cs.bris.ac.uk/Research/MachineLearning/Morphology/Resources/`.

1 Introduction

Words in natural language are constructed from smaller building blocks called *morphemes*. For example, the word *wives* breaks down into an underlying stem, *wife*, together with a *plural* suffix. Analyzing the morphological structure of words is known to benefit a variety of downstream natural language (NL) tasks such as speech recognition (Creutz, 2006; Arısoy et al., 2009), machine translation (Oflazer et al., 2007), and information retrieval (McNamee et al., 2008).

A variety of automatic systems can morphologically analyze words that have been removed from their surrounding context. These systems range from hand-built finite state approaches (Beesley and Karttunen, 2003) to recently proposed algorithms which learn morphological structure in an unsupervised fashion (Kurimo et al., 2007). Since unsupervised systems do not have access to linguistically motivated morpheme labels, they typically produce morphological analyses that are closely related to the written form. Such a system might decompose *wives* as *wiv -es*. Meanwhile, a hand-built system might propose *wife_N +Plural*, or even parse *wives* as a hierarchical feature structure. As morphological analysis systems produce such varied outputs, comparing decompositions from disparate systems is a challenge.

This paper describes *EMMA*, an *E*valuation *M*etric for *M*orphological *A*nalysis that quantitatively measures the quality of a set of morphological analyses in a linguistically adequate, empirically useful, and novel fashion. *EMMA* evaluates analyses that can be represented as a flat set of symbolic features, including hierarchical representations, which can be projected down to a linearized form (Roark and Sproat, 2007).

An automatic metric that discriminates between proposed morphological analyses should

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 1029–1037,
Beijing, August 2010

fulfill certain computational and linguistic criteria. Computationally, the metric should:

1. *Correlate* with the performance of real-world NL processing tasks which embed the morphological analyses.
2. Be *Readily Computable*: The metric will only be useful if it is less time consuming and easier to compute than the larger NL task.
3. Be *Robust*: The metric should be difficult to game and should accurately reflect the distribution of predicted and true morphemes.
4. Be *Readily Interpretable*: When possible, the final numeric score should directly identify the strengths and weaknesses of the underlying morphological analysis system.

While accounting for these computational requirements, a morphology metric should still reward accurate models of linguistic structure. In particular, the metric should account for:

1. *Morphophonology*: Applying a morphological rule may alter the surface form of stem or affix. In the word *wives*, /waivz/, a rule of morphophonology voices the stem-final /f/ of *wife*, /waif/, when the plural suffix is added. A metric should penalize for not placing *wives* and *wife* as forms of the same lexeme.
2. *Allomorphy*: A metric should capture the successful grouping of allomorphs. The German plural has several surface allomorphs including *-en* in *Zeiten* (*times*), *-e* in *Hunde* (*dogs*), and *-s* in *Autos* (*cars*). A metric should reward a morphological analysis system that analyzes the different surface forms of the German plural as underlyingly identical.
3. *Syncretism*: In mirror fashion, a metric should reward analyses that distinguish between surface-identical syncretic morphemes: although *derives* and *derivations* both contain an *-s* morpheme, one marks *3rd person singular* and the other *plural*.
4. *Ambiguity*: Finally, a metric should account for legitimate morphological ambiguity. In Hebrew, the written word *MHGR* has three viable morphological segmentations: *M- H- GR*, "*from the foreigner*", *M- HGR*, "*from Hagar*", and the unsegmented form *MHGR*, meaning "*immigrant*" (Lavie et al., 2004). Absent disambiguating context, a morphological system should be rewarded for calling out all three analyses for *MHGR*.

Morphophonology, allomorphy, syncretism, and ambiguity are all common phenomena in the world's languages. The first three have all received much discussion in theoretical linguistics (Spencer and Zwicky, 2001), while morphological ambiguity has significant practical implications in NL processing, e.g. in machine translation of morphologically complex languages (Lavie et al., 2004; Oflazer et al., 2007).

In Section 2 we propose the metric *EMMA*, which has been specifically designed to evaluate morphological analyses according to our computational and linguistic criteria. Section 3 then describes and qualitatively critiques several well-used alternative metrics. Section 4 empirically compares *EMMA* against the qualitatively-strong metric used in the Morpho Challenge competition series (Kurimo et al., 2009). And we conclude in Section 5.

2 *EMMA*: An *E*valuation *M*etric for *M*orphological *A*nalysis

EMMA, the metric we propose for the evaluation of morphological analyses, like all the metrics that we consider in this paper, compares proposed morphological analyses against an answer key of definitively-analyzed words from a vocabulary. Since a set of proposed analyses is likely to use a different labeling scheme than the answer key, especially true of the output from unsupervised systems, *EMMA* does not perform a direct comparison among proposed and answer analyses. Instead, *EMMA* seeks a one-to-one relabeling of the proposed morphemes that renders them as similar as possible to the answer key. *EMMA*, then, measures the degree to which proposed analyses approximate an isomorphism of the answer key analyses. For exposition, we initially assume that, for each word, a single proposed analysis is scored against a single unambiguous answer analysis. We relax this restriction in Section 2.3, where EMMA scores multiple proposed analyses against a set of legitimately ambiguous morphological analyses.

To find the most appropriate one-to-one morpheme relabeling, *EMMA* turns to a standard algorithm from graph theory: optimal maximum matching in a bipartite graph. A *bipartite graph*, $G = \{X, Y; E\}$, consists of two disjoint sets of vertices, $X = \{x_1, x_2, \ldots, x_n\}$ and $Y = \{y_1, y_2, \ldots, y_m\}$, and a set of edges $e(x_i, y_j) \in E$ such that each edge has one end in X and the other end in Y. In *EMMA*, the set, A, of all unique morphemes in the answer key and the set, P, of all unique morphemes in the proposed analyses serve as the disjoint vertex sets of a bipartite graph.

A *matching* $M \subseteq E$ in a bipartite graph is defined as a set of edges $e(x_i, y_j)$ such that no x_i or y_j is repeated. A *maximum matching* is a matching where no M' with $|M'| > |M|$ exists. Furthermore, a weight $w(x_i, y_j) \in \Re$ may be assigned to each edge $e(x_i, y_j)$ of a bipartite graph. An *optimal assignment* is a maximum matching which also maximizes the sum of the weights of the edges of the matching

$$\sum_{e(x_i,y_j)\in M} w(x_i, y_j) \ .$$

EMMA weights the edge between a particular answer morpheme $a \in A$ and a proposed morpheme $p \in P$ as the number of words, w, in the vocabulary, V, where the answer analysis of w includes morpheme a while the proposed analysis includes p. *EMMA* constructs an optimal assignment maximum matching in this weighted bipartite morpheme graph. The edge weights ensure that the optimal matching will link the answer and proposed morphemes which globally occur in the analyses of the same words most often – restricting each answer morpheme to be represented by at most one proposed morpheme, and each proposed morpheme to represent at most one morpheme in the answer key. On the one hand, the restrictions thus imposed by bipartite matching penalize sets of proposed analyses that do not differentiate between surface-identical *syncretic morphemes*. On the other hand, the same one-to-one matching restrictions penalize proposed analyses that do not conflate *allomorphs* of the same underlying morpheme, whether those allomorphs are phonologically induced or not. Thus, *EMMA* meets our linguistic criteria from Section 1 of modeling syncretism, allomorphy, and morphophonology.

2.1 Maximum Matching by Integer Linear Programming

To construct the maximum matching optimal assignment of answer and proposed morphemes, *EMMA* uses standard integer linear programming techniques as implemented in *lpsolve* (Berkelaar et al., 2004). For the purpose of our integer program, we represent the weight of each potential edge of the optimal bipartite morpheme assignment in a count matrix $C = \{c_{ij}\}$ where c_{ij} is assigned the number of words $w \in V$ which share morpheme a_i in the answer key and p_j in the prediction. We then define a binary matrix $B = \{b_{ij}\}$ of the same dimensions as C. Each b_{ij} will be set to 1 if an edge exists from a_i to p_j in the optimal maximum matching, with $b_{ij} = 0$ otherwise. The integer linear program can then be defined as follows:

$$\operatorname*{argmax}_B \sum_{i,j} (C \cdot B)_{ij} \tag{1}$$

$$s.t. \sum_i b_{ij} \leq 1 \ , \quad \sum_j b_{ij} \quad \leq 1 \ , \quad b_{ij} \geq 0 \ ,$$

where $(C \cdot B)_{ij} = c_{ij} \cdot b_{ij}$ is the element-wise *Hadamard product*.

2.2 Performance Measures

Having settled on a maximum matching optimal assignment of proposed and answer morphemes, *EMMA* derives a final numeric score. Let w_k be the k^{th} word of V; and let A_k and P_k denote, respectively, the sets of morphemes in the answer key analysis of w_k and predicted analysis of w_k. Furthermore, let P_k^* denote the predicted morphemes for w_k where a morpheme p_j is replaced by a_i if $b_{ij} = 1$. Now that A_k and P_k^* contain morpheme labels that are directly comparable, we can define *precision* and *recall* scores for the proposed analysis of the word w_k. Precision is the fraction of correctly relabeled proposed morphemes from among all proposed morphemes of w_k; while *recall* is the number of correctly relabeled morphemes as a fraction of the answer key analysis of w_k. Precision and recall of the full vocabulary are the average word-level precision and recall:

$$precision = \frac{1}{|V|}\sum_{k}^{|V|}\frac{|A_k \bigcap P_k^*|}{|P_k^*|} \quad , \tag{2}$$

$$recall = \frac{1}{|V|}\sum_{k}^{|V|}\frac{|A_k \bigcap P_k^*|}{|A_k|} \quad . \tag{3}$$

Finally, *f-measure* is the harmonic mean of precision and recall:

$$f\text{-}measure = \frac{2 \cdot precision \cdot recall}{precision + recall} \quad . \tag{4}$$

2.3 Morphological Ambiguity in *EMMA*

Thus far we have presented *EMMA* for the scenario where each word has a single morphological analysis. But, as we saw in Section 1 with the Hebrew word *MHGR*, natural language permits surface forms to have multiple legitimate morphological analyses. When a word is truly ambiguous, *EMMA* expects an answer key to contain a set of analyses for that word. Similarly, we permit sets of proposed alternative analyses. To extend *EMMA* with the ability to evaluate alternative analyses we first generalize the optimal maximum matching of morphemes from Section 2.1. We then define a new integer linear program to match answer and proposed *alternative analyses*. Finally, we adjust the performance measures of Section 2.2 to account for alternatives.

2.3.1 Ambiguity and Morpheme Matching

Let $A_{k,r}$ denote the r^{th} alternative answer analysis of the k^{th} word with $1 \leq r \leq m_k$, and let $P_{k,s}$ denote the s^{th} alternative prediction with $1 \leq s \leq n_k$, where m_k is the number of alternative analyses in the answer key and n_k the number of alternative predictions for w_k. We redefine $A_k = \bigcup_r^{m_k} A_{k,r}$ and $P_k = \bigcup_s^{n_k} P_{k,s}$ as the set of all answer or, respectively, predicted morphemes of w_k across all analysis alternatives. Instead of incrementing each c_{ij} entry in the count matrix C by a full count, we now add $\frac{1}{m_k \cdot n_k}$ to c_{ij} for all pairs $(a_i, p_j) \in A_k \times P_k$. This corresponds to counting each combination of an answer key and predicted morpheme normalized by the number of possible pairings between proposed and answer analysis alternatives. When both the answer and proposed analyses consist of just a single alternative, c_{ij} remains unchanged. Generalized morpheme matching still employs the linear program defined in Equation 1.

2.3.2 Matching of Alternative Analyses

After performing a one-to-one morpheme relabelling that accounts for ambiguity, we need to extend *EMMA* with the ability to evaluate alternative analyses. We again turn to optimal maximum matching in a bipartite graph: Where earlier we matched proposed and answer morphemes, now we match full proposed and answer analysis alternatives, maximizing the total number of correctly predicted morphemes across all alternatives. Generalizing on the notation of the unambiguous case, let $P_{k,s}^*$ denote the s^{th} alternative predicted analysis of the k^{th} word where predicted morphemes have been replaced by their assigned answer key morphemes. We introduce a new count matrix $C' = \{c'_{r,s}\}$, where $c'_{r,s}$ is the count of common morphemes of the r^{th} answer key alternative and s^{th} predicted alternative. Based on Equation 1, we calculate the binary matrix $B' = \{b'_{r,s}\}$ which contains the optimal assignment of the alternative answer key and predicted analyses for w_k.

2.3.3 Ambiguity and Performance Scores

We now adjust *EMMA*'s numeric performance measures to account for sets of ambiguous analysis alternatives. *Precision* becomes

$$\frac{1}{|V|}\sum_{k}^{|V|}\frac{1}{n_k}\sum_{r}^{m_k}\sum_{s}^{n_k} b'_{r,s}\frac{|A_{k,r} \bigcap P_{k,s}^*|}{|P_{k,s}^*|} \quad , \tag{5}$$

the ratio of correctly predicted morphemes across all predicted alternatives normalised by the number of predicted alternatives, n_k, and the vocabulary size, $|V|$. The factor $b'_{r,s}$ guarantees that scores are only averaged over pairs of proposed and answer analysis alternatives that have been assigned, that is, where $b'_{r,s} = 1$. *Recall* is measured similarly with

$$\frac{1}{|V|}\sum_{k}^{|V|}\frac{1}{m_k}\sum_{r}^{m_k}\sum_{s}^{n_k} b'_{r,s}\frac{|A_{k,r} \bigcap P_{k,s}^*|}{|A_{k,r}|} \quad . \tag{6}$$

Here, we normalize by m_k, the number of alternative analyses for the k^{th} word that are listed in the answer key. The normalisation factors $\frac{1}{m_k}$ and $\frac{1}{n_k}$ ensure that predicting too few or many alternative analyses is penalised.

3 Other Morphology Metrics

Having presented the *EMMA* metric for evaluating the quality of a set of morphological analyses, we take a step back and examine other metrics that have been proposed. Morphology analysis metrics can be categorized as either: 1. Directly comparing proposed analyses against an answer key, or 2. Indirectly comparing proposed and answer analyses by measuring the strength of an isomorphic-like relationship between the proposed and answer morphemes. The proposed *EMMA* metric belongs to the second category of isomorphism-based metrics.

3.1 Metrics of Direct Inspection

By Segmentation Point. Perhaps the most readily accessible automatic evaluation metric is a direct comparison of the morpheme boundary positions in proposed and answer analyses. As early as 1974, Hafer and Weiss used the direct boundary metric. Although intuitively simple, the segmentation point method implicitly assumes that it is possible to arrive at a valid morphological analysis by merely dividing the characters of a word into letter sequences that can be reconcatenated to form the original word. But, by definition, concatenation cannot describe non-contanative processes like morphophonology and allomorphy. Nor does simple segmentation adequately differentiate between surface-identical syncretic morphemes. Despite these drawbacks, precision and recall of segmentation points is still used in current morphological analysis research (Poon et al. (2009), Snyder and Barzilay (2008), Kurimo et al. (2006)).

Against Full Analyses. To confront the reality of non-concatenative morphological processes, an answer key can hold full morphological analyses (as opposed to merely segmented surface forms). But while a hand-built (Beesley and Karttunen, 2003) or supervised (Wicentowski , 2002) morphology analysis system can directly model the annotation standards of a particular morphological answer key, the label given to specific morphemes is ultimately an arbitrary choice that an unsupervised morphology induction system has no way to discover.

By Hand. On the surface, scoring proposed analyses by hand appears to provide a way to evaluate the output of an unsupervised morphology analysis system. Hand evaluation, however, does not meet our criteria from Section 1 for a robust and readily computable metric. It is time consuming and, as Goldsmith (2001) explains, leaves difficult decisions of what constitutes a morpheme to on-the-fly subjective opinion.

3.2 Metrics of Isomorphic Analysis

Recognizing the drawbacks of direct evaluation, Schone and Jurafsky (2001), Snover et al. (2002), and Kurimo et al. (2007) propose related measures of morphological analysis quality that are based on the idea of an isomorphism. For reasons that will be clear momentarily, we refer to the Schone and Jurafsky, Snover et al., and Kurimo et al. metrics as *soft* isomorphic measures. As discussed in Section 2, metrics of isomorphism measure similarities between the distribution of proposed morphemes and the distribution of answer morphemes, where proposed and answer morphemes may be disjoint symbol sets.

Unlike the *EMMA* metric proposed in Section 2, the soft metrics of isomorphism do not seek to explicitly link proposed morphemes to answer morphemes. Instead, their metrics group sets or pairs of words which share, in *either* the proposed analyses or in the answer analyses, a stem (Schone and Jurafsky, 2001; Snover, 2002), a suffix (Snover et al., 2002), or any arbitrary morpheme (Kurimo et al., 2007). The soft metrics subsequently note whether these same sets or pairs of words share any morpheme in the answer key or, respectively, in the proposed analyses. By foregoing a hard morpheme assignment, the soft metrics do not adequately punish sets of proposed and answer morphemes which fail to model syncretism and/or allomorphy. For example, proposed analyses that annotate *3rd person singular* and *plural* with a single undifferentiated +*s* morpheme will receive recall credit for both nouns and verbs.

3.3 The Morpho Challenge Metric

The Morpho Challenge (MC) competition series for unsupervised morphology analysis algorithms (Kurimo et al., 2009) has used a soft metric of isomorphism in its most recent three years of competition: 2007, 2008, and 2009. According to Kurimo et al. (2009) the Morpho Challenge (MC) measure samples *random word pairs* which share at least one common morpheme. Precision is calculated by generating random word pairs from the set of proposed analyses and then comparing the analyses of the word pairs in the answer key. The fraction of found and expected common morphemes is normalised by the number of words which are evaluated. *Recall* is defined in mirror fashion. The MC metric also normalizes precision and recall scores across sets of alternative analyses for each word in the proposal and answer key. To our knowledge the MC metric is the first isomorphism-based metric to attempt to account for *morphological ambiguity*. As we show in Section 4, however, MC's handling of ambiguity is easily gamed.

The MC metric does meet our criterion of being *readily computable* and, as we will show in the experimental section, the metric also *correlates* to a certain extent with performance on a higher-level natural language processing task. The downside of the MC metric, however, is *robustness*. In addition to MC's crude handling of ambiguity and its over-counting of allomorphs and syncretic morphemes, the random pair sampling method that MC uses is not independent of the set of analyses being evaluated. If two algorithms predict different morpheme distributions, the sampling method will find different numbers of word pairs. We substantiate our claim that the MC metric lacks robustness in Section 4 where we empirically compare it to the *EMMA* metric.

4 Experimental Evaluation

To experimentally evaluate our newly proposed *EMMA* metric, and to quantitatively compare the *EMMA* and MC metrics, we have evaluated results of 93 system-language pairs from Morpho Challenge 2007, 2008, and 2009.[1] The evaluation comprised three algorithms by Bernhard (2007) and Bernhard (2009), one algorithm by Can and Manandhar (2009), the MC baseline algorithm *Morfessor* by Creutz (2006), *UNGRADE* by Golenia et al. (2009), two algorithms by Lavallee and Langlais (2009), one algorithm by Lignos et al. (2009), five *ParaMor* versions by Monson et al. (2008) and Monson et al. (2009), three *Promodes* versions by Spiegler et al. (2009) and one algorithm by Tchoukalov et al. (2009). We ran these algorithms over six data sets available from the MC competition: Arabic (vowelized and non-vowelized), English, Finnish, German, and Turkish. We then scored the system outputs using both *EMMA* and the MC metric against an answer key provided by MC. In Sections 2 and 3.3 we have already commented on the *linguistic characteristics* of both metrics. In this section, we concentrate on their *computational performance*.

Both the *EMMA* and MC metrics are *readily computable*: Both are freely available[2] and they each take less than two minutes to run on the average desktop machines we have used. In terms of *interpretability*, *EMMA* not only returns the performance as precision, recall and f-measure as MC does, but also provides predicted analyses where mapped morphemes are replaced by answer key morphemes. This information is helpful when judging results qualitatively since it exposes tangible algorithmic characteristics. In Table 1 we present the algorithms with the highest MC and *EMMA* scores for each language. For all languages, the *EMMA* and MC metrics place different algorithms highest. One reason for the significantly different rankings that the two metrics provide may be the *sampling of random pairs* that MC uses. Depending on the distribution of predicted morphemes across words, the number of random pairs, which is used for calculating the precision, may vary. For instance, on vowelized Arabic, *Promodes 1* is evaluated over a sample of 100 pairs where MC selected just 47 pairs for *ParaMor Mimic*.

[1] Detailed results can be found in Spiegler (2010).

Table 3: Gaming MC with ambiguity hijacking on Finnish.

Looking at any particular algorithm-language pair, the *EMMA* and MC scores differ considerably and respective raw scores are not directly comparable. More interesting is the extent to which both metrics *correlate* with real NL tasks. Table 2 lists the Spearman rank correlation coefficient for algorithms from MC 2009 on English, Finnish and German comparing rankings of f-measure results returned by either MC or *EMMA* against rankings using the mean average precision (MAP) of an information retrieval (IR) task.[3] All MAP scores are taken from Kurimo et al. (2009). Although both metrics positively correlate with the IR results; *EMMA*'s correlation is clearly stronger across all three languages.

To test the *robustness* of the *EMMA* and MC metrics, we performed two experiments where we intentionally attempt to game the metrics – *ambiguity hijacking* and *shared morpheme padding*. In both experiments, the MC metric showed vulnerability. Ambiguity hijacking results for Finnish appear in Table 3, other languages perform similarly. Using both metrics, we scored the Finnish analyses that were proposed by a) the *Morfessor* algorithm alone, b) *ParaMor* alone, and c) two ways of combining ParaMor and Morfessor: *ParaMorPlusMorfessor* simply lists the ParaMor and Morfessor analyses as alternatives – as if each word were ambiguous between a ParaMor and a Morfessor analysis; *ParaMorMorfessorUnion*, on the other hand, combines the morpheme boundary predictions of *ParaMor* and *Morfessor* into a single analysis. The *ParaMorPlusMorfessor* system games the ambiguity mechanism of the MC metric, achieving an f-measure higher than that of any of the three other algorithms. *EMMA*, however, correctly discovers that the analyses proposed by *ParaMorPlusMorfessor* lie farther from an isomorphism to the the answer key than do the unified analyses of *ParaMorMorfessorUnion*.

In Table 4 we show a second way of gaming the MC metric – *shared morpheme padding*. We add the same unique bogus morpheme to each proposed analysis of every word for all systems.

[3] Detailed results can be found in Spiegler (2010).

Table 4: Gaming MC with shared morpheme padding: Average and standard deviations of the ratio of padded to original scores.

Padding analyses with a shared morpheme significantly increases the recall scores of the MC metric. We summarize our experimental results by calculating, for each language-algorithm pair, the ratio of the score for the padded analyses as compared to that of the original, unpadded analyses. Table 4 reports average and standard deviation of the ratios across all systems for each language. In Arabic (nv. and vw.), the recall increases by 10.83 and 11.17 times, which leads to an inflation of f-measure by 7.20 and 7.13 times – this is a direct result of the soft nature of the MC isomorphism. In contrast, *EMMA*'s recall scores increase much less than MC's do, and *EMMA*'s precision scores decrease proportionately. A small change to the set of proposed analyses does not lead to a huge difference in f-measure – characteristic of a more *robust* metric.

5 Conclusion

This paper has proposed, *EMMA*, a novel evaluation metric for the assessment of the quality of a set of morphological analyses. *EMMA*'s:

1. Coverage of the major morphological phenomena,
2. Correlation with performance on natural language processing tasks, and
3. Computational robustness

all recommend the the metric as a strong and useful measure – particularly when evaluating unsupervised morphology analysis systems which, lacking access to labeled training data, are uninformed of the labeling standard used in the answer key.

	Correlation with IR	
	IR vs. MC	IR vs. *EMMA*
English	0.466	**0.608**
Finnish	0.681	**0.759**
German	0.379	**0.637**

Abstract

In this paper, we describe a novel approach to computational modeling and understanding of social and cultural phenomena in multi-party dialogues. We developed a two-tier approach in which we first detect and classify certain social language uses, including topic control, disagreement, and involvement, that serve as first order models from which presence the higher level social constructs such as leadership, may be inferred.

1. Introduction

We investigate the language dynamics in small group interactions across various settings. Our focus in this paper is on English online chat conversations; however, the models we are developing are more universal and applicable to other conversational situations: informal face-to-face interactions, formal meetings, moderated discussions, as well as interactions conducted in languages other than English, e.g., Urdu and Mandarin.

Multi-party online conversations are particularly interesting because they become a pervasive form of communication within virtual communities, ubiquitous across all age groups. In particular, a great amount of communication online occurs in virtual chat-rooms, typically conducted using a highly informal text dialect. At the same time, the reduced-cue environment of online interaction necessitates more explicit linguistic devices to convey social and cultural nuances than is typical in face-to-face or even voice conversations.

Our objective is to develop computational models of how certain social phenomena such as leadership, power, and conflict are signaled and reflected in language through the choice of lexical, syntactic, semantic and conversational forms by discourse participants. In this paper we report the results of an initial phase of our work during which we constructed a prototype system called DSARMD-1 (Detecting Social Actions and Roles in Multiparty Dialogue). Given a representative segment of multiparty task-oriented dialogue, DSARMD-1 automatically classifies all discourse participants by the degree to which they deploy selected *social language uses*, such as topic control, task control, involvement, and disagreement. These are the mid-level social phenomena, which are deployed by discourse participants in order to achieve or assert higher-level *social constructs*, including leadership. In this work we adopted a two-tier empirical approach where social language uses are modeled through *observable* linguistic features that can be automatically extracted from dialogue. The high-level social constructs are then inferred from a combination of language uses attributed to each discourse participant; for example, a high degree of influence and a high degree of involvement by the same person may indicate a leadership role. In this paper we limit our discussion to the first tier only: how to effectively model and classify social language uses in multi-party dialogue.

2. Related Research

Issues related to linguistic manifestation of social phenomena have not been systematically researched before in computational linguistics; indeed, most of the effort thus far was directed towards the communicative dimension of discourse. While the Speech Acts theory (Austin, 1962; Searle, 1969) provides a generalized framework for multiple levels of discourse analysis (locution, illocution and perlocution), most current approaches to dialogue focus on information content and structural components (Blaylock, 2002; Carberry & Lambert, 1999; Stolcke, et al., 2000) in dialogue; few take into account the effects that speech acts may have upon the social

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 1038–1046,
Beijing, August 2010

roles of discourse participants. Also relevant is research on modeling sequences of dialogue acts – to predict the next one (Samuel et al. 1998; Ji & Bilmes, 2006 inter alia) – or to map them onto subsequences or "dialogue games" (Carlson 1983; Levin et al., 1998), which are attempts to formalize participants' roles in conversation (e.g., Linell, 1990; Poesio & Mikheev, 1998; Field et al., 2008).

There is a body of literature in anthropology, linguistics, sociology, and communication on the relationship between language and power, as well as other social phenomena, e.g., conflict, leadership; however, existing approaches typically look at language use in situations where the social relationships are known, rather than using language predictively. For example, conversational analysis (Sacks et al., 1974) is concerned with the structure of interaction: turn-taking, when interruptions occur, how repairs are signaled, but not what they reveal about the speakers. Research in anthropology and communication has concentrated on how certain social norms and behaviors may be reflected in language (e.g., Scollon and Scollon, 2001; Agar, 1994) with few systematic studies attempting to explore the reverse, i.e., what the linguistic phenomena tell us about social norms and behaviors.

3. Data & Annotation

Our initial focus has been on on-line chat dialogues. While chat data is plentiful on-line, its adaptation for research purposes presents a number of challenges that include users' privacy issues on the one hand, and their complete anonymity on the other. Furthermore, most data that may be obtained from public chat-rooms is of limited value for the type of modeling tasks we are interested in due to its high-level of noise, lack of focus, and rapidly shifting, chaotic nature, which makes any longitudinal studies virtually impossible. To derive complex models of conversational behavior, we need the interaction to be reasonably focused on a task and/or social objectives within a group.

Few data collections exist covering multiparty dialogue, and even fewer with on-line chat. Moreover, the few collections that exist were built primarily for the purpose of training dialogue act tagging and similar linguistic phenomena; few if any of these corpora are suitable for deriving pragmatic models of conversation, including socio-linguistic phenomena. Existing resources include a multi-person meeting corpus ICSI-MRDA and the AMI Meeting Corpus (Carletta, 2007), which contains 100 hours of meetings captured using synchronized recording devices. Still, all of these resources look at spoken language rather than on-line chat. There is a parallel interest in the online chat environment, although the development of useful resources has progressed less. Some corpora exist such as the NPS Internet chat corpus (Forsyth and Martell, 2007), which has been hand-anonymized and labeled with part-of-speech tags and dialogue act labels. The StrikeCom corpus (Twitchell et al., 2007) consists of 32 multi-person chat dialogues between players of a strategic game, where in 50% of the dialogues one participant has been asked to behave 'deceptively'.

It is thus more typical that those interested in the study of Internet chat compile their own corpus on an as needed basis, e.g., Wu et al. (2002), Khan et al. (2002), Kim et al. (2007).

Driven by the need to obtain a suitable dataset we designed a series of experiments in which recruited subjects were invited to participate in a series of on-line chat sessions in a specially designed secure chat-room. The experiments were carefully designed around topics, tasks, and games for the participants to engage in so that appropriate types of behavior, e.g., disagreement, power play, persuasion, etc. may emerge spontaneously. These experiments and the resulting corpus have been described elsewhere (Shaikh et al., 2010b), and we refer the reader to this source. Ultimately a corpus of 50 hours of English chat dialogue was collected comprising more than 20,000 turns and 120,000 words. In addition we also assembled a corpus of 20 hours of Urdu chat.

A subset of English language dataset has been annotated at four levels: communication links, dialogue acts, local topics and meso-topics (which are essentially the most persistent local topics). Although full details of these annotations are impossible to explain within the scope of this article, we briefly describe them below. Annotated datasets were used to develop and train automatic modules that detect and classify social uses of language in discourse. It is important to note that the annotation has been developed to support the objectives of our project and does not necessarily conform to other similar annotation systems used in the past.

- *Communicative links*. In a multi-party dialogue an utterance may be directed towards a specific participant, a subgroup of participants or to everyone.
- *Dialogue Acts*. We developed a hierarchy of 15 dialogue acts for annotating the functional aspect of the utterance in discussion. The tagset we adopted is based on DAMSL (Allen & Core, 1997) and SWBD (Jurafsky et al., 1997), but compressed to 15 tags tuned significantly towards dialogue pragmatics and away from more surface characteristics of utterances (Shaikh et al., 2010a).
- *Local topics*. Local topics are defined as nouns or noun phrases introduced into discourse that are subsequently mentioned again via repetition, synonym, or pronoun.
- *Topic reference polarity*. Some topics, which we call *meso-topics*, persist through a number of turns in conversation. A selection of meso-topics is closely associated with the task in which the discourse participants are engaged. Meso-topics can be distinguished from the local topics because the speakers often make polarized statements about them.

4. Socio-linguistic Phenomena

We are interested in modeling the social phenomena of Leadership and Power in discourse. These high-level phenomena (or Social Roles, *SR*) will be detected and attributed to discourse participants based on their deployment of selected *Language Uses* (LU) in multi-party dialogue. Language Uses are mid-level socio-linguistic devices that link linguistic components deployed in discourse (from lexical to pragmatic) to social constructs obtaining for and between the participants. The language uses that we are currently studying are *Agenda Control*, *Disagreement*, and *Involvement* (Broadwell et al., 2010).

Our research so far is focused on the analysis of English-language synchronous chat, and we are looking for correlations between various metrics that can be used to detect LU in multiparty dialogue. We expect that some of these correlations may be culturally specific or language-specific, as we move into the analysis of Urdu and Mandarin discourse in the next phase of this project.

4.1 Agenda Control in Dialogue

Agenda Control is defined as efforts by a member or members of the group to advance the group's task or goal. This is a complex LU that we will model along two dimensions: (1) *Topic Control* and (2) *Task Control*. Topic Control refers to attempts by any discourse participants to impose the topic of conversation. Task Control, on the other hand, is an effort by some members of the group to define the group's project or goal and/or steer the group towards that goal. We believe that both behaviors can be detected using scalar measures per participant based on certain linguistic features of their utterances.

For example, one hypothesis is that topic control is indicated by the rate of *local topic introductions* (LTI) per participant (Givon, 1983). Local topics may be defined quite simply as noun phrases introduced into discourse, which are subsequently mentioned again via repetition, synonym, pronoun, or other form of co-reference. Thus, one measure of topic control is the number of local topics introduced by each participant as percentage of all local topics in a discourse.

Using an LTI index we can construct assertions about topic control in a discourse. For example, suppose the following information is discovered about the speaker LE in a multi-party discussion *dialogue-1*[1] where 90 local topics are identified:

1. LE introduces 23/90 (25.6%) of local topics in this dialogue.
2. The mean rate of local topic introductions is this dialogue is 14.29%, and standard deviation is 8.01.
3. LE is in the top quintile of participants for introducing new local topics

We can now claim the following, with a degree of confidence (to be determined):

$$TopicControl_{LTI}\,(LE,\ 5,\ dialogue\text{-}1)$$

We read this as follows: *speaker LE exerts the highest degree of topic control in dialogue-1.* Of course, LTI is just one source of evidence and we developed other metrics to complement it. We mention three of them here:

[1] Dialogue-1 refers to an actual dataset of 90-minute chat among 7 participants, covering approximately 700 turns. The task is to select a candidate for a job given a set of resumes.

- *SMT Index*. This is a measure of topic control suggested in (Givon, 1983) and it is based on subsequent mentions of already introduced local topics. Speakers who introduce topics that are discussed at length by the group tend to control the topic of the discussion. The *subsequent mentions of local topics* (SMT) index calculates the percentage of second and subsequent references to the local topics, by repetition, synonym, or pronoun, relative to the speakers who introduced them.
- *Cite Score*. This index measures the extent to which other participants discuss topics introduced by that speaker. The difference between SMT and CiteScore is that the latter reflect to what degree a speaker's efforts to control the topic are assented to by other participants in a conversation.
- *TL Index* (TL). This index stipulates that more influential speakers take longer turns than those who are less influential. The TL index is defined as the average number of words per turn for each speaker. Turn length also reflects the extent to which other participants are willing to 'yield the floor' in conversation.

Like LTI, all the above indices are mapped into a degree of topic control, based on quintiles in normal distribution (Table 1).

	LTI	**SMT**	**CS**	**TL**	AVG
LE	5	5	5	5	5.00
JR	4	4	4	3	3.75
KI	4	3	3	1	2.75
KN	3	5	4	4	4.00
KA	2	2	2	4	2.50
CS	2	2	2	2	2.00
JY	1	1	1	2	1.25

Table 1: Topic Control distribution in dialogue-1. Each row represents a speaker in the group (LE, JR, etc.). Columns show indices used, with degrees per speaker on 5-point scale based on quintiles in normal distribution, and the average value.

Ideally, all the above indices (and others yet to be defined) should predict the same outcome, i.e., for each dialogue participant they should assign the same degree of topic control, relative to other speakers. This is not always the case, and where the indices divert in their predictions, our level of confidence in the generated claims decreases. We are currently working on how these different metrics correlate to each other and how they should be weighted to maximize accuracy of making Topic Control claims. Nonetheless, we can already output a Topic Control map (shown in Table 1) that captures a sense of internal social dynamics within the group.

The other aspect of Agenda Control phenomenon is Task Control. It is defined as an effort to determine the group's goal and/or steer the group towards that goal. Unlike Topic Control, which is imposed by influencing the subject of conversation, Task Control is gained by directing other participants to perform certain tasks or accept certain opinions. Consequently, Task Control is detected by observing the usage of certain dialogue acts, including Action-Directive, Agree-Accept, Disagree-Reject, and related categories. Here again, we define several indices that allow us to compute a degree of Task Control in dialogue for each participant:

- *Directive Index* (DI). The participant who directs others is attempting to control the course of the task that the group is performing. We count the number of directives, i.e., utterances classified as Action-Directive, made by each participant as a percentage of all directives in discourse.
- *Directed Topic Shift Index* (DTSI). When a participant who controls the task offers a directive on the task, then the topic of conversation shifts. In order to detect this condition, we calculate the ratio of coincidence of directive dialogue acts by each participant with topic shifts following them.
- *Process Management index* (PMI). Another measure of Task Control is the proportion of turns each participant has that explicitly address the problem solving process. This includes utterances that involve coordinating the activities of the participants, planning the order of activities, etc. These fall into the category of Task (or Process) Management in most DA tagging systems.
- *Process Management Success Index* (PMSI). This index measures the degree of success by each speaker at controlling the task. A credit is given to the speaker whose suggested curse of action is supported by other speakers for each response that supports the suggestion. Conversely, a credit is taken away for each response that rejects or

qualifies the suggestion. PMSI is computed as distribution of task management credits among the participants over all dialogue utterances classified as Task/Process Management. [2]

As an example, let's consider the following information computed for the PMI index over *dialogue-1*:

1. *Dialogue-1* contains 246 utterances classified as Task/Process Management rather than doing the task.
2. Speaker KI makes 65 of these utterances for a PMI of 26.4%.
3. Mean PMI for participants is 14.3%; 80th percentile is >21.2%. PMI for KI is in the top quintile for all participants.

Based on this evidence we may claim (with yet to be determined confidence) that:

TaskControl$_{PMI}$(*KI, 5, dialogue-1*)

This may be read as follows: *speaker KI exerts the highest degree of Task Control in dialogue-1.* We note that Task Control and Topic Control do not coincide in this discourse, at least based on the PMI index. Other index values for Task Control may be computed and tabulated in a way similar to LTI in Table 1. We omit these here due to space limitations.

4.2 Disagreement in Dialogue

Disagreement is another language use that correlates with speaker's power and leadership. There are two ways in which disagreement is realized: *expressive disagreement* and *topical disagreement* (Stromer-Galley, 2007; Price, 2002). Both can be detected using scalar measures applied to subsets of participants, typically any two participants. In addition, we can also measure for each participant the rate with which he or she generates disagreement (with any and all other speakers). *Expressive Disagreement* is normally understood at the level of dialogue acts, i.e., when discourse participants make explicit utterances of disagreement, disapproval, or rejection in response to a prior speaker's utterance. Here is an example (KI and KA are two speakers in a multiparty dialogue in which participants discuss candidates for a youth counselor job):

KA: *CARLA... women are always better with kids*
KI: *That's not true!*
KI: *Men can be good with kids too*

While such exchanges are vivid examples of expressive disagreement, we are interested in more sustained phenomenon where two speakers repeatedly disagree, thus revealing a social relationship between them. Therefore, one measure of Expressive Disagreement that we consider is the number of Disagree-Reject dialogue acts between any two speakers as a percentage of all utterances exchanged between these two speakers. This becomes a basis for the *Disagree-Reject Index* (DRX). In dialogue-1 we have:

1. Speakers KI and KA have 47 turns between them. Among these there are 8 turns classified as Disagree-Reject, for the DRX of 15.7%.
2. The mean DRX for speakers who make any Disagree-Reject utterances is 9.5%. The pair of speakers KI-KA is in the top quintile (>13.6%).

Based on this evidence we can conclude the following:

ExpDisagreement$_{DRX}$ (*KI,KA, 5, dialogue-1*)

which may be read as follows: *speakers KI and KA have the highest level of expressive disagreement in dialogue-1.* This measure is complemented by a *Cumulative Disagreement Index* (CDX), which is computed for each speaker as a percentage of all Disagree-Reject utterances in the discourse that are made by this speaker. Unlike DRX, which is computed for pairs of speakers, the CDX values are assigned to each group participant and indicate the degree of disagreement that each person generates.

While Expressive Disagreement is based on the use of more overt linguistic devices, *Topical Disagreement* is defined as a difference in referential *valence* in utterances (statements, opinions, questions, etc.) made on a topic. Referential valence of an utterance is determined by the type of statement made about the topic in question, which can be positive (+), negative (–), or neutral (0). A positive statement is one in favor of (*express advocacy*) or in support of (*supporting information*) the topic being discussed. A negative statement is one that is against or negative on

[2] The exact structure of the credit function is still being determined experimentally. For example, more credit may be given to first supporting response and less for subsequent responses; more credit may be given for unprompted suggestions than for those that were responding to questions from others.

the topic being discussed. A neutral statement is one that does not indicate the speaker's position on the topic. Here is an example of opposing polarity statements about the same topic in discourse:

Sp-1: *I like that he mentions "Volunteerism and Leadership"*
Sp-2: *but if they're looking for someone who is experienced then I'd cross him off*

Detecting topical disagreement in discourse is more complicated because its strength may vary from one topic in a conversation to the next. A reasonable approach is thus to measure the degree of disagreement between two speakers on one topic first, and then extrapolate over the entire discourse. Accordingly, our measure of topical disagreement is valuation differential between any two speakers as expressed in their utterances about a topic. Here, the topic (or an "issue") is understood more narrowly than the local topic defined in the previous section (as used in Topic Control, for example), and may be assumed to cover only the most persistent local topics, i.e., topics with the largest number of references in dialogue, or what we call the *meso-topics*. For example, in a discussion of job applicants, each of the applicants becomes a meso-topic, and there may be additional meso-topics present, such as qualifications required, etc.

The resulting *Topical Disagreement Metric* (TDM) captures the degree to which any two speakers advocate the opposite sides of a meso-topic. TDM is computed as an average of *P*-valuation differential for one speaker (advocating *for* a meso-topic) and (–*P*)-valuation differential for the other speaker (advocating *against* the meso-topic).

Using TDM we can construct claims related to disagreement in a given multiparty dialogue of sufficient duration (exactly what constitutes a sufficient duration is still being researched). Below is an example based on a 90-minute chat dialogue-1 about several job candidates for a youth counselor. The discussion involved 7 participants, including KI and KA. Topical disagreement is measured on 5 points scale (corresponding to quintiles in normal distribution):

$TpDisAgree_{TDM}$(*KI,KA,"Carla",4,dialogue-1*)

This may be read as follows: speakers KI and KA *topically disagree to degree 4* on topic [job candidate] "Carla" in dialogue-1. In order to calculate this we compute the value of TDM index between these two speakers. We find that KA makes 30% of all positive utterances made by anyone about Carla (40), while KI makes 45% of all negative utterances against Carla. This places these two speakers in the top quintiles in the "for Carla" polarity distribution and "against Carla" distribution, respectively. Taking into account any opposing polarity statements made by KA against Carla and any statements made by KI for Carla, we calculate the level of topical disagreement between KA and KI to be 4 on the 1-5 scale.

TDM allows us to compute topical disagreement between any two speakers in a discourse, which may also be represented in a 2-dimensional table revealing another interesting aspect of internal group dynamics.

4.3 Involvement in Dialogue

The third type of social language use that we discuss in this paper is Involvement. Involvement is defined as a degree of engagement or participation in the discussion of a group. It is an important element of leadership, although its importance is expected to differ between cultures; in Western cultures, high involvement and influence (topic control) often correlates with group leadership.

In order to measure Involvement we designed several indices based on turn characteristics for each speaker. Four of the indices are briefly explained below:

- The *NP index* (NPI) is a measure of gross informational content contributed by each speaker in discourse. *NPI* counts the ratio of third-person nouns and pronouns used by a speaker to the total number of nouns and pronouns in the discourse.
- The *Turn index* (*TI*) is a measure of *interactional frequency*; it counts the ratio of turns per participant to the total number of turns in the discourse.
- The *Topic Chain Index* (*TCI*) counts the degree to which participants discuss of the most persistent topics. In order to calculate TCI values, we define a *topic chains* for all local topics. We compute frequency of mentions of these longest topics for each participant.
- The *Allotopicality Index* (*ATP*) counts the number of mentions of local topics that were introduced by other participants. An

ATP value is the proportion of a speaker's allotopical mentions, i.e., excluding "self-citations", to all allotopical mentions in a discourse.

As an example, we may consider the following situation in *dialogue-1*:

1. *Dialogue-1* contains 796 third person nouns and pronouns, excluding mentions of participants' names.
2. Speaker JR uses 180 nouns and pronouns for an NPI of 22.6%.
3. The median NPI is 14.3%; JR are in the upper quintile of participants (> 19.9%).

From the above evidence we can draw the following claim:

$Involvement_{NPI}(JR, 5, dialogue\text{-}1)$

This may be read as: *speaker JR is the most involved participant in dialogue-1.*

As with other language uses, multiple indices for Involvement can be combined into a 2-dimensional map capturing the group internal dynamics.

5. Implementation & Evaluation

We developed a prototype automated DSARMD system that comprises a series of modules that create automated annotation of the source dialogue for all the language elements discussed above, including communicative links, dialogue acts, local/meso topics, and polarity. Automatically annotated dialogue is then used to generate language use degree claims. In order to evaluate accuracy of the automated process we conducted a preliminary evaluation comparing the LU claims generated from automatically annotated data to the claims generated from manually coded dialogues. Below we briefly describe the methodology and metrics used.

Each language use is asserted per a participant in a discourse (or per each pair of participants, e.g., for Disagreement) on a 5-point "strength" scale. This can be represented as an ordered sequence $LU_X(d_1, d_2, ... d_n)$, where LU is the language use being asserted, *X* is the index used, d_i is the degree of LU attributed to speaker *i*. This assignment is therefore a 5-way classification of all discourse participants and its correctness is measured by dividing the number of correct assignments by the total number of elements to be classified, which gives the micro-averaged precision. The accuracy metric is computed with several variants as follows:

1. *Strict mapping*: each complete match is counted as 1; all mismatches are counted as 0. For example, the outputs LU_X (5,4,3,2,1) and LU_X (4,5,3,1,1) produce two exact matches (for the third and the last speaker) for a precision of 0.4.
2. *Weighted mapping*: since each degree value d_i in $LU_X(d_1, d_2, ... d_n)$ represents a quintile in normal distribution, we consider the position of the value within the quintile. If two mismatched values are less than ½ quintile apart we assign a partial credit (currently 0.5).
3. *Highest – Rest*: we measure accuracy with which the highest LU degree (but not necessarily the same degree) is assigned to the right speaker vs. any other score. This results in binary classification of scores. The sequences in (1) produce 0.6 match score.
4. *High – Low*: An alternative binary classification where scores 5 and 4 are considered High, while the remaining scores are considered Low. Under this metric, the sequences in (1) match with 100% precision.

The process of automatic assignment of language uses derived from automatically processed dialogues was evaluated against the control set of assignments based on human-annotated data. In order to obtain a reliable "ground truth", each test dialogue was annotated by at least three human coders (linguistics and communication graduate students, trained). Since human annotation was done at the linguistic component level, a strict inter-annotator agreement was not required; instead, we were interested whether in each case a comparable statistical distribution of the corresponding LU index was obtained. Annotations that produced index distributions dissimilar from the majority were eliminated.

Automated dialogue processing involved the following modules:

- *Local topics detection* identifies first mentions by tracking occurrences of noun phrases. Subsequent mentions are identified using fairly simple pronoun resolution (based mostly on lexical features), with Wordnet used to identify synonyms, etc.
- *Meso-topics* are identified as longest-chain local topics. Their *polarity* is assessed at the utterance level by noting presence of positive or negative cue words and phrases.
- *Dialogue acts* are tagged based on presence

of certain cue phrases derived from a training corpus (Webb et al., 2008).

- *Communicative links* are mapped by computing inter-utterance similarity based on n-gram overlap.

Preliminary evaluation results are shown in Tables 3-5 with average performance over 3 chat sessions (approx 4.5 hours) involving three groups of speakers and different tasks (job candidates, political issues). Topic Control and Involvement tables show average accuracy per index. For example, the LTI index, computed over automatically extracted local topics, produces Topic Control assignments with the average precision of 80% when compared to assignments derived from human-annotated data using the strict accuracy metric. However, automated prediction of Involvement based on NPI index is far less reliable, although we can still pick the most involved speaker with 67% accuracy. We omit the indices based on turn length (TL) and turn count (TI) because their values are trivially computed. At this time we do not combine indices into a single LU prediction. Additional experiments are needed to determine how much each of these indices contributes to LU prediction.

Topic Control	**LTI**	**SMT**	**CS**
Strict	0.80	0.40	0.40
Weighted	0.90	0.53	0.53
Highest-Rest	0.90	0.67	0.67
High-Low	1.00	0.84	0.90

Table 3: Topic Control LU assignment performance averages of selected indices over a subset of data covering three dialogues with combined duration of 4.5 hours with total of 19 participants (7, 5, 7 per session).

Involvement	**NPI**	**TCI**	**ATP**
Strict	0.31	0.42	0.39
Weighted	0.46	0.49	0.42
Highest-Rest	0.67	0.77	0.68
High-Low	0.58	0.74	0.48

Table 4: Involvement LU assignment performance averages for selected indices over the same subset of data as in Table 3.

Topical Disagreement performance is shown in Table 5. We calculated precision and recall of assigning a correct degree of disagreement to each pair of speakers who are members of a group. Precision and recall averages are then computed over all meso-topics identified in the test dataset, which consists of three separate 90-minute dialogues involving 7, 5 and 7 speakers, respectively. Our calculation includes the cases where different sets of meso-topics were identified by the system and by the human coder. A strict mapping of levels of disagreement between speakers is hard to compute accurately; however, finding the speakers who disagree the most, or the least, is significantly more robust.

Topical Disagreement	**Prec.**	**Recall**
Strict	0.33	0.32
Weighted	0.54	0.54
Highest-Rest	0.89	0.85
High-Low	0.77	0.73

Table 5: Topical Disagreement LU assignment performance averages over 13 meso-topics discussed in three dialogues with combined duration of 4.5 hours with total of 19 participants (7, 5, and 7 per session).

6. Conclusion

In this paper we presented a preliminary design for modeling certain types of social phenomena in multi-party on-line dialogues. Initial, limited-scale evaluation indicates that the model can be effectively automated. Much work lies ahead, including large scale evaluation, testing index stability and resilience to NL component level error. Current performance of the system is based on only preliminary versions of linguistic modules (topic extraction, polarity assignments, etc.) which perform at only 70-80% accuracy, so these need to be improved as well. Research on Urdu and Chinese dialogues is just starting.

Abstract

We employ Maximum Entropy model to conduct sub-tree alignment between bilingual phrasal structure trees. Various lexical and structural knowledge is explored to measure the syntactic similarity across Chinese-English bilingual tree pairs. In the experiment, we evaluate the sub-tree alignment using both gold standard tree bank and the automatically parsed corpus with manually annotated sub-tree alignment. Compared with a heuristic similarity based method, the proposed method significantly improves the performance with only limited sub-tree aligned data. To examine its effectiveness for multilingual applications, we further attempt different approaches to apply the sub-tree alignment in both phrase and syntax based SMT systems. We then compare the performance with that of the widely used word alignment. Experimental results on benchmark data show that sub-tree alignment benefits both systems by relaxing the constraint of the word alignment.

1 Introduction

Recent research in Statistical Machine Translation (SMT) tends to incorporate more linguistically grammatical information into the translation model known as linguistically motivated syntax-based models. To develop such models, the phrasal structure parse tree is usually adopted as the representation of bilingual sentence pairs either on the source side (Huang et al., 2006; Liu et al., 2006) or on the target side (Galley et al., 2006; Marcu et al., 2006), or even on both sides (Graehl and Knight, 2004; Zhang et al., 2007). Most of the above models either construct a pipeline to transform from/to tree structure, or synchronously generate two trees in parallel (i.e., synchronous parsing). Both cases require syntactically rich translational equivalences to handle non-local reordering. However, most current works obtain the syntactic translational equivalences by initially conducting alignment on the word level. To employ word alignment as a hard constraint for rule extraction has difficulty in capturing such non-local phenomena and will fully propagate the word alignment error to the later stage of rule extraction.

Alternatively, some initial attempts have been made to directly conduct syntactic structure alignment. As mentioned in Tinsley et al. (2007), the early work usually constructs the structure alignment by hand, which is time-consuming. Recent research tries to automatically align the bilingual syntactic sub-trees. However, most of these works suffer from the following problems. Firstly, the alignment is conducted based on heuristic rules, which may lose extensibility and generality in spite of accommodating some common cases (Groves et al., 2004). Secondly, various similarity computation methods are used based merely on lexical translation probabilities (Tinsley et al., 2007; Imamura, 2001) regardless of structural features. We believe the structure information is an important issue to capture the non-local structural divergence of languages by modeling beyond the plain text.

To address the above issues, we present a statistical framework based on Maximum Entropy (MaxEnt) model. Specifically, we consider sub-tree alignment as a binary classification problem and use Maximum Entropy model to classify each instance as *aligned* or *unaligned*. Then, we perform a greedy search within the reduced search space to conduct sub-tree alignment links based on the alignment probabilities obtained from the classifier.

Unlike the previous approaches that can only measure the structural divergence via lexical features, our approach can incorporate both lexical and structural features. Additionally, instead of explicitly describing the instances of sub-tree pairs as factorized sub-structures, we frame most of our features as score based feature functions, which helps solve the problem using limited sub-tree alignment annotated data. To train the model and evaluate the alignment performance, we adopt

Beijing, August 2010

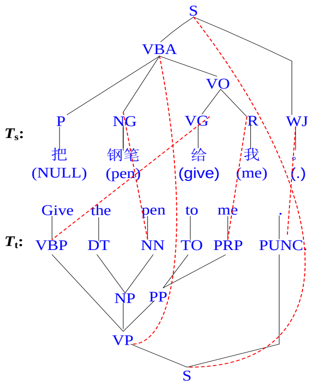

Figure 1: Sub-tree alignment as referred to Node alignment

HIT Chinese-English parallel tree bank for gold standard evaluation. To explore its effectiveness in SMT systems, we also manually annotate sub-tree alignment on automatically parsed tree pairs and perform the noisy data evaluation. Experimental results show that by only using limited sub-tree aligned data of both corpora, the proposed approach significantly outperforms the baseline method (Tinsley et al., 2007). The proposed features are very effective in modeling the bilingual structural similarity. We further apply the sub-tree alignment to relax the constraint of word alignment for both phrase and syntax based SMT systems and gain an improvement in BLEU.

2 Problem definition

A sub-tree alignment process pairs up the sub-trees across bilingual parse trees, whose lexical leaf nodes covered are translational equivalent, i.e., sharing the same semantics. Grammatically, the task conducts links between syntactic constituents with the maximum tree structures generated over their word sequences in bilingual tree pairs.

In general, sub-tree alignment can also be interpreted as conducting multiple links across internal nodes between sentence-aligned tree pairs as shown in Fig. 1. The aligned sub-tree pairs usually maintain a non-isomorphic relation with each other especially for higher layers. We adapt the same criteria as Tinsley et al. (2007) in our study:

(i) a node can only be linked once;

(ii) descendants of a source linked node may only link to descendants of its target linked counterpart;

(iii) ancestors of a source linked node may only link to ancestors of its target linked counterpart.

where the term "node" refers to root of a sub-tree, which can be used to represent the sub-tree.

3 Model

We solve the problem as binary classification and employ MaxEnt model with a greedy search.

Given a bilingual tree pair S^I and T^J, $S^I = \{s_1, \dots, s_i, \dots, s_I\}$ is the source tree consisting of I sub-trees，where I is also the number of nodes in the source tree S^I. $T^J = \{t_1, \dots, t_j, \dots, t_J\}$ is the target tree consisting of J sub-trees, where J is also the number of nodes in the target tree T^J.

For each sub-tree pair (s_i, t_j) in the given bilingual parse trees (S^I, T^J), the sub-tree alignment probability is given by:

$$Pr(a|s_i, t_{j,}\theta) = \frac{\exp[\sum_{m=1}^{M} \lambda_m h_m(a, s_i, t_j, \theta)]}{\sum_{a'} \exp[\sum_{m=1}^{M} \lambda_m h_m(a', s_i, t_j, \theta)]} \quad (1)$$

where

$$a = \begin{cases} 1 & \text{if } (s_i, t_j) \text{ is aligned} \\ 0 & \text{otherwise} \end{cases} \quad (2)$$

Feature functions are defined in a quadruple (a, s_i, t_j, θ). θ is an additional variable to incorporate new dependencies other than the sub-tree pairs. For each feature function $h_m(a, s_i, t_j, \theta)$, a weight λ_m is applied to tailor the distribution.

After classifying the candidate sub-tree pairs as *aligned* or *unaligned*, we perform a greedy search within the reduced search space to conduct *sure* links based on the conditional probability $Pr(a|s_i, t_{j,}\theta)$ obtained from the classifier. The alignment probability is independently normalized for each sub-tree pair and hence suitable as a searching metric.

The greedy search algorithm can be described as an automaton. A state in the search space is a partial alignment with respect to the given bilingual tree pair. A transition is to add one more link of node pairs to the current state. The initial state has no link. The terminal state is a state where no more links can be added according to the definition in Section 2. We use greedy search to generate the best-links at the early stage. There are cases that the correctly-aligned tree pairs have very few links, while we have a bunch of candidates with lower alignment probabilities. However, the sum of the lower probabilities is larger than that of the correct links', since the number of correct links is much fewer. This makes the alignment results biased to be with more links. The greedy search helps avoid this asymmetric problem.

4 Feature Functions

In this section, we introduce a variety of feature functions to capture the semantically equivalent counterparts and structural divergence across languages. For the semantic equivalence, we define lexical and word alignment feature functions. Since those feature functions are directional, we describe most of these functions as conditional feature functions based on the conditional lexical probabilities. We also introduce the tree structural features to deal with the structural divergence of bilingual parse trees. Inspired by Burkett and Klein (2008), we introduce the feature functions in an internal-external manner based on the fact that the feature scores for an aligned sub-tree pair tend to be high inside both sub-trees, while they tend to be low inside one sub-tree and outside the other.

4.1 Internal Lexical Features

We use this feature to measure the degree of semantic equivalence of the sub-tree pair. According to the definition of sub-tree alignment in Section 2, the word sequence covered by the sub-tree pair should be translational equivalence. Therefore, the lexicons within the two corresponding sub-spans should be highly related in semantics. We define the internal lexical features as follows:

$$\phi(s_i|t_j) = \left(\prod_{v\in in(t_j)} \sum_{u\in in(s_i)} P(u|v)\right)^{\frac{1}{|in(t_j)|}}$$

$$\phi(t_j|s_i) = \left(\prod_{u\in in(s_i)} \sum_{v\in in(t_j)} P(v|u)\right)^{\frac{1}{|in(s_i)|}}$$

where $P(v|u)$ refers to the lexical translation probability from the source word u to the target word v within the sub-tree spans, while $P(u|v)$ refers to that from target to source; $in(s_i)$ refers to the word set for the internal span of the source sub-tree s_i, while $in(t_j)$ refers to that of the target sub-tree t_j.

4.2 Internal-External Lexical Features

Intuitively, lexical translation probabilities tend to be high within the translational equivalence, while low within the non-equivalent counterparts. According to this, we define the internal-external lexical feature functions as follows:

$$\varphi(s_i|t_j) = \frac{\sum_{v\in in(t_j)} \max_{u\,\in out(s_i)}\left\{\left(P(u|v)\cdot P(v|u)\right)^{\frac{1}{2}}\right\}}{|in(t_j)|}$$

$$\varphi(t_j|\,s_i) = \frac{\sum_{u\in in(s_i)} \max_{v\,\in out(t_j)}\left\{\left(P(u|v)\cdot P(v|u)\right)^{\frac{1}{2}}\right\}}{|in(s_i)|}$$

where $out(s_i)$ refers to the word set for the external span of the source sub-tree s_i, while $out(t_j)$ refers to that of the target sub-tree t_j. We choose a representation different from the internal lexical feature scores, since for cases with small inner span and large outer span, the sum of internal-external scores may be overestimated. As a result, we change the *sum* operation into *max*, which is easy to be normalized.

4.3 Internal Word Alignment Features

Although the word alignment information within bilingual sentence pairs is to some extent not reliable, the links of word alignment account much for the co-occurrence of the aligned terms. We define the internal word alignment features as follows:

$$\rho(s_i,t_j) = \frac{\sum_{v\in in(t_j)} \sum_{u\in in(s_i)} \delta(u,v)\cdot\left(P(u|v)\cdot P(v|u)\right)^{\frac{1}{2}}}{\left(|in(s_i)|\cdot|in(t_j)|\right)^{\frac{1}{2}}}$$

where

$$\delta(u,v) = \begin{cases} 1 & \text{if } (u,v) \text{ is aligned} \\ 0 & \text{otherwise} \end{cases}$$

The binary function $\delta(u,v)$ is introduced to trigger the computation only when a word aligned link exists for the two words (u,v) within the sub-tree span.

4.4 Internal-External Word Alignment Features

Similar to lexical features, we also introduce internal-external word alignment features as follows:

$$\sigma(s_i|t_j) = \frac{\sum_{v\in in(t_j)} \sum_{u\in out(s_i)} \delta(u,v)\cdot\left(P(u|v)\cdot P(v|u)\right)^{\frac{1}{2}}}{\left(|out(s_i)|\cdot|in(t_j)|\right)^{\frac{1}{2}}}$$

$$\sigma(t_j|s_i) = \frac{\sum_{v\in out(t_j)} \sum_{u\in in(s_i)} \delta(u,v)\cdot\left(P(u|v)\cdot P(v|u)\right)^{\frac{1}{2}}}{\left(|in(s_i)|\cdot|out(t_j)|\right)^{\frac{1}{2}}}$$

where

$$\delta(u,v) = \begin{cases} 1 & \text{if } (u,v) \text{ is aligned} \\ 0 & \text{otherwise} \end{cases}$$

4.5 Tree Structural Features

In addition to the lexical correspondence, we also capture the structural divergence by introducing the tree structural features as follows:

Span difference: Translational equivalent sub-tree pairs tend to share similar length of spans. Thus the model will penalize the candidate sub-tree pairs with largely different length of spans.

$$\xi(s_i,t_j) = \left|\frac{|in(s_i)|}{\max_{1\le k\le I}(|in(s_k)|)} - \frac{|in(t_j)|}{\max_{1\le h\le J}(|in(t_h)|)}\right|$$

Number of Descendants: Similarly, the number of the root's descendants of the aligned sub-trees should also correspond.

$$\tau(s_i,t_j) = \left|\frac{|R(s_i)|}{\max_{1\le k\le I}(|R(s_k)|)} - \frac{|R(t_j)|}{\max_{1\le h\le J}(|R(t_h)|)}\right|$$

where $R(.)$ refers to the descendant set of the root to an individual sub-tree.

Tree Depth difference: Intuitively, translational equivalent sub-tree pairs tend to have similar depth from the root node of the parse tree. We can further allow the model to penalize the candidate sub-tree pairs with different distance from the root node.

$$\omega(s_i, t_j) = \left|\frac{Depth(s_i)}{Height(S^I)} - \frac{Depth(t_j)}{Height(T^J)}\right|$$

4.6 Binary Grammatical Features

In the previous sections, we design some score based feature functions to describe syntactic tree structural similarities, rather than directly using the substructures. This is because for limited annotated tree alignment data, features like tokens and grammar rules are rather sparse. In spite of this, we still have a closed set of grammatical tags which can be covered by a small amount of data. Therefore, we use the combination of root grammar tags of the sub-tree pairs as binary features.

5 Training

We train the sub-tree alignment model in two steps:

Firstly, we learn the various feature functions. On one hand, GIZA++ is offline trained on a large amount of bilingual sentences to compute the lexical and word alignment features. On the other hand, the tree structural features, similar to word and phrase penalty features in phrase based SMT models, are computed online for both training and testing.

Secondly, we train the MaxEnt model in Eq. 1, using the training corpus which consists of the bilingual parse tree pairs with manually annotated sub-tree alignment. We apply the widely used GIS (Generalized Iterative Scaling) algorithm (Darroch and Ratcliff, 1972) to optimize λ_1^M. In practice, we modify Och's implementation YASMET.

Since we consider each sub-tree pair as an individual instance, it is easy to see that the negative samples heavily overwhelm the positive ones. For GIS training, such a skewed distribution easily drives the parameters to facilitate the negative instances. We address this problem by giving more weight to the positive training instances.

6 Experiments on Sub-Tree Alignments

We utilize two different corpora to evaluate the proposed sub-tree alignment method and its capability to plug in the related applications respectively. One is HIT English Chinese parallel tree bank with both tree structure and sub-tree alignment manually annotated. The other is the automatically parsed bilingual tree pairs (allowing minor parsing errors) with manually annotated sub-tree alignment. The latter benefits MT task, since most linguistically motivated syntax SMT systems require a held-out automatic parser to achieve rule induction.

6.1 Data preparation

For the gold standard corpus based experiment, we use HIT[1] Chinese-English parallel tree bank, which is collected from English learning text books in China as well as example sentences in dictionaries. It consists of 16131 gold standard parse tree pairs with manually annotated sub-tree alignments. The annotation strictly preserves the semantic equivalence, i.e., it only conducts *sure* links in the internal node level, while ignoring *possible* links adopted in word alignment. In contrast, in the POS level, n-to-n links are allowed in annotation. In order to be consistent with the definition in Section 2, we delete those n-to-n links in POS level. The word segmentation, tokenization and parse-tree in the corpus are manually constructed or checked. The Chinese parse tree in HIT tree bank adopts a different annotation criterion from the Penn TreeBank annotation, which is designed by the HIT research team. The new criterion can better facilitate the description of some rare structural phenomena in Chinese. The English parse tree still uses Penn TreeBank annotation. The statistics of HIT corpus is shown in Table 1.

	Chinese	English
# of Sentence pair	16131	
Avg. Sentence Length	13.06	13.00
Avg. # of sub-tree	21.60	23.74
Avg. # of alignment	11.71	

Table 1. Statistics for HIT gold standard Tree bank

Since the induction of sub-tree alignment is designed to benefit the machine translation modeling, it is preferable to conduct the sub-tree alignment experiment on the corpus for MT evaluation. However, most syntax based SMT systems use an automatic parser to facilitate training and decoding, which introduces parsing errors. Additionally, the gold standard HIT corpus is not applicable for MT

[1] HIT corpus is designed and constructed by HIT mitlab. http://mitlab.hit.edu.cn/index.php/resources.html . We licensed the corpus from them for research usage.

experiment due to problems of domain divergence, annotation discrepancy (Chinese parse tree adopts a different grammar from Penn Treebank annotations) and degree of tolerance for parsing errors.

Due to the above issues, we annotate a new data set to apply the sub-tree alignment in machine translation. We randomly select 300 bilingual sentence pairs from the Chinese-English FBIS corpus with the length ≤ 30 in both the source and target sides. The selected plain sentence pairs are further parsed by Stanford parser (Klein and Manning, 2003) on both the English and Chinese sides. We manually annotate the sub-tree alignment for the automatically parsed tree pairs according to the definition in Section 2. To be fully consistent with the definition, we strictly preserve the semantic equivalence for the aligned sub-trees to keep a high precision. In other words, we do not conduct any doubtful links. The corpus is further divided into 200 aligned tree pairs for training and 100 for testing. Some initial statistic of the automatically parsed corpus is shown in Table 2.

		Chinese	English
Train	# of Sentence pair	200	
	Avg. Sentence Length	17	20.84
	Avg. # of sub-tree	28.87	34.54
	Avg. # of alignment	17.07	
Test	# of Sentence pair	100	
	Avg. Sentence Length	16.84	20.75
	Avg. # of sub-tree	29.18	34.1
	Avg. # of alignment	17.75	

Table 2. FBIS selected Corpus Statistics

6.2 Baseline approach

We implement the work in Tinsley et al. (2007) as our baseline methodology.

Given a tree pair $< S^I, T^J >$, the baseline approach first takes all the links between the sub-tree pairs as alignment hypotheses, i.e., the Cartesian product of the two sub-tree sets:

$$\{s_1, \ldots, s_i, \ldots, s_I\} \times \{t_1, \ldots, t_j, \ldots, t_J\}$$

By using the lexical translation probabilities, each hypothesis is assigned an alignment score. All hypotheses with zero score are pruned out. Then the algorithm iteratively selects the link of the sub-tree pairs with the maximum score as a *sure* link, and blocks all hypotheses that contradict with this link and itself, until no non-blocked hypotheses remain.

The baseline system uses many heuristics in searching the optimal solutions with alternative score functions. Heuristic *skip1* skips the tied hypotheses with the same score, until it finds the highest-scoring hypothesis with no competitors of the same score. Heuristic *skip2* deals with the same problem. Initially, it skips over the tied hypotheses. When a hypothesis sub-tree pair (s_i, t_j) without any competitor of the same score is found, where neither s_i nor t_j has been skipped over, the hypothesis is chosen as a *sure* link. Heuristic *span1* postpones the selection of the hypotheses on the POS level. Since the highest-scoring hypotheses tend to appear on the leaf nodes, it may introduce ambiguity when conducting the alignment for a POS node whose child word appears twice in a sentence.

The baseline method proposes two score functions based on the lexical translation probability. They also compute the score function by splitting the tree into the internal and external components.

Tinsley et al. (2007) adopt the lexical translation probabilities dumped by GIZA++ (Och and Ney, 2003) to compute the span based scores for each pair of sub-trees. Although all of their heuristics combinations are re-implemented in our study, we only present the best result among them with the highest Recall and F-value as our baseline, denoted as *skip2_s1_span1*[2].

6.3 Experimental settings

• To examine the effectiveness of the proposed features, we

(1) learn the word alignment using the combination of the 14k of HIT tree bank and FBIS (240k) corpus for both our approach and the baseline method, and divide the remaining HIT corpus as 1k for training and 1k for testing.

(2) learn the word alignment on the entire FBIS training corpus (240k) for both our approach and the baseline method. We then train and test on FBIS corpus of 200 and 100 respectively as stated in Table 2.

• In our task, annotating large amount of sub-tree alignment corpus is time consuming and more difficult compared with the tasks like sequence labeling. One of the important issues we are concerned about is whether we can achieve an acceptable performance with limited training data. We

(3) adopt the entire FBIS data (240k) to learn the word alignment and various amount of HIT gold standard corpus to train the MaxEnt model. Then we test the alignment performance on the same HIT test set (1k) as (1).

Baseline [Tinsley 2007]	70.48	78.70	74.36

Table 4. Sub-tree alignment of different feature combination for FBIS test set

- We further test the robustness of our method under different amount of data to learn the lexical and word alignment feature functions. We gradually change the amount of FBIS corpus to train the word alignment. Then we

(4) use the same training (1k) and testing data (1k) with (1);

(5) use FBIS corpus 200 to train MaxEnt model and 100 for testing similar to (2).

6.4 Experimental results

We use Precision, Recall and F-score to measure the alignment performance and obtain the results as follows:

- In Table 3 and 4 for **Exp (1)** and **(2)** respectively, we show that by incrementally adding new features in a certain order, the F-value consistently increases and both outperform the baseline method. From both tables, we find that the **Binary features**, with the combination of root grammar tags of the sub-tree pairs, significantly improve the alignment performance. We also try the different combinations of the parent, child or even siblings to the root nodes. However, all these derivative configurations decrease the performance. We attribute the ineffectiveness to data sparseness. Further exploration suggests that the binary feature in HIT gold standard corpus exhibits a substantially larger improvement against other features than FBIS corpus (Table 3 against Table 4). The reason could be that the grammar tags in the gold standard corpus are accurate, while FBIS corpus suffers from parsing errors. Apart from that, the lexical/word-alignment features in Table 3 do not perform well, since the word alignment is trained mainly on the cross domain FBIS corpus. This is also an important reason why there is a large gap in performance between Table 3 and 4, where the automatic parsed FBIS corpus performs better than HIT gold standard tree bank in all configurations as well as the baseline.
- In Fig. 2(a) for **Exp (3)**, we examine performance under different amount of training data from 1k to 15k. The results change very little with over the amount of 1k. Even with only 0.25k training data, we are able to gain a result close to the best performance. This suggests that by utilizing only a small amount of sub-tree aligned corpus, we can still achieve a satisfactory alignment result. The benefits come from the usage of the score based feature functions by avoiding using substructures as binary features, which suffers from the data sparseness problem.
- In Fig. 2(b-e) for **Exp (4&5)**, we find that increasing the amount of corpus to train GIZA++ does not improve much for the proposed method on both HIT gold standard corpus (Fig. 2: b, c) and the automatic parsed data (Fig. 2: d, e). This is due to the various kinds of features utilized by the MaxEnt model, which does not bet on the lexical and word alignment feature too much. As for the baseline method, we can only detect a relatively large improvement in the initial increment of corpus, while later additions do not help. This result suggests that the baseline method is relatively less extensible since it works completely on the lexical similarities which can be only learned from the word alignment corpus.

7 Experiments on Machine Translation

In addition to the alignment evaluation, we conduct MT evaluation as well. We explore the effectiveness of sub-tree alignment for both phrase and linguistically motivated syntax based systems.

7.1 Experimental configuration

In the experiments, we train the translation model on FBIS corpus (7.2M (Chinese) + 9.2M (English) words in 240,000 sentence pairs) and train a 4-gram language model on the Xinhua portion of the English Gigaword corpus (181M words) using the SRILM Toolkits (Stolcke, 2002). We use these

sentences with less than 50 characters from the NIST MT-2002 test set as the development set (to speed up tuning for syntax based system) and the NIST MT-2005 test set as our test set. We use the Stanford parser (Klein and Manning, 2003) to parse bilingual sentences on the training set and Chinese sentences on the development and test set. The evaluation metric is case-sensitive BLEU-4.

For the phrase based system, we use Moses (Koehn et al, 2007) with its default settings. For the syntax based system, since sub-tree alignment can directly benefit Tree-2-Tree based systems, we apply the sub-tree alignment in an SMT system based on Synchronous Tree Substitution Grammar (STSG) (Zhang et al., 2007). The STSG based decoder uses a pair of *elementary tree* as a basic translation unit. Recent research on tree based systems shows that relaxing the restriction from tree structure to tree sequence structure (Synchronous Tree Sequence Substitution Grammar: STSSG) significantly improves the translation performance (Zhang et al., 2008). We implement the STSG/STSSG based model in Pisces decoder with the same features and settings in Sun et al. (2009). The STSSG based decoder translates each span iteratively in a bottom up manner which guarantees that when translating a source span, any of its sub-spans has already been translated. The STSG based experiment can be easily achieved by restricting the translation rule set in the STSSG decoder to be elementary tree pairs only.

For the alignment setting of the baselines, we use the word alignment trained on the entire FBIS(240k) corpus by GIZA++ with heuristic grow-diag-final for Moses and the syntax systems and perform rule extraction constrained on the word alignment. As for the experiments adopting sub-tree alignment, we use the above word alignment to learn lexical/word alignment features, and train the sub-tree alignment model with FBIS training data (200).

7.2 Experimental results

Utilizing the syntactic rules only has been argued to be ineffective (Koehn et al., 2003). Therefore, instead of using the sub-tree aligned rules only, we try to improve the word alignment constrained rule set by sub-tree alignment as shown in Table 5.

Firstly, we try to *Directly Concatenate* (DirC) the sub-tree alignment constraint rule set[3] to the original syntax/phrase rule set based on word alignment. Then we re-train the MT model based

[3] For syntax based system, it's just the sub-tree pairs deducted from the sub-tree alignment; for phrase based system, it's the phrases with context equivalent to the aligned sub-tree pairs.

on the obtained rule set. Tinsley et al. (2009) attempts different duplication of sub-tree alignment constraint rule set to append to the original phrase rule set and reports positive results. However, as shown in Table 5, we only achieve very minor improvement (in STSSG based model the score even drops) by direct introducing the new rules.

Secondly, we propose a new approach to utilize sub-tree alignment by modifying the rule extraction process. We allow the bilingual phrases which are consistent with *Either* Word alignment *or* Sub-tree alignment (EWoS) instead of to be consistent with word alignment only. The results in Table 5 show that EWoS achieves consistently better performance than the baseline and DirC method. We also find that sub-tree alignment benefits the STSSG based model less compared with other systems. This is probably due to the fact that the STSSG based system relies much on the tree sequence rules.

To benefit intuitive understanding, we provide two alignment snippets in the MT training corpus in Fig. 3, where the red lines across the non-terminal nodes are the sub-tree aligned links conducted by our model, while the purple lines across the terminal nodes are the word alignment links trained by GIZA++. In the first example, the word *Israel* is wrongly aligned to two "以色列"s by GIZA++, where the wrong link is denoted by the dash line. This is common, since in a compound sentence in English, the entities appeared more than once are often replaced by pronouns at its later appearances. Therefore, the syntactic rules constraint by NR^1-NNP^1, IP^2-VP^2 and PP^3-VP^3 respectively cannot be extracted for syntax systems; while for phrase systems, context around the first "以色列" cannot be fully explored. In the second example, the empty word "了" is wrongly aligned, which usually occurs in Chinese-English word alignment. As shown in Fig. 3, both cases can be resolved by sub-tree alignment conducted by our model, indicating that sub-tree alignment is a decent supplement to the word alignment rule set.

BP, STSG, STSSG are baseline rule sets using word alignment to constrain rule extraction.

8 Conclusion

In this paper, we propose a framework for bilingual sub-tree alignment using Maximum Entropy model. We explore various lexical and structural features to improve the alignment performance. We also manually annotated the automatic parsed tree pairs for both alignment evaluation and MT experiment. Experimental results show that our alignment framework significantly outperforms the baseline method and the proposed features are very effective to capture the bilingual structural similarity. Additionally, we find that our approach can perform well using only a small amount of sub-tree aligned training corpus. Further experiment shows that our approach benefits both phrase and syntax based MT systems.

Abstract

Verb classes which integrate a wide range of linguistic properties (Levin, 1993) have proved useful for natural language processing (NLP) applications. However, the real-world use of these classes has been limited because for most languages, no resources similar to VerbNet (Kipper-Schuler, 2005) are available. We apply a verb clustering approach developed for English to French – a language for which no such experiment has been conducted yet. Our investigation shows that not only the general methodology but also the best performing features are transferable between the languages, making it possible to learn useful VerbNet style classes for French automatically without language-specific tuning.

1 Introduction

A number of verb classifications have been built to support natural language processing (NLP) tasks (Grishman et al., 1994; Miller, 1995; Baker et al., 1998; Palmer et al., 2005; Kipper-Schuler, 2005; Hovy et al., 2006). These include both syntactic and semantic classifications, as well as ones which integrate aspects of both. Classifications which integrate a wide range of linguistic properties can be particularly useful for NLP applications suffering from data sparseness. One such classification is VerbNet (Kipper-Schuler, 2005). Building on the taxonomy of Levin (1993), VerbNet groups verbs (e.g. *deliver, post, dispatch*) into classes (e.g. SEND) on the basis of their shared meaning components and syntactic behaviour, identified in terms of meaning preserving diathesis alternations. Such classes can be identified across the entire lexicon, and they may also apply across languages, since their meaning components are said to be cross-linguistically applicable (Jackendoff, 1990).

Offering a powerful tool for generalization, abstraction and prediction, VerbNet classes have been used to support many important NLP tasks, including e.g. computational lexicography, parsing, word sense disambiguation, semantic role labeling, information extraction, question-answering, and machine translation (Swier and Stevenson, 2004; Dang, 2004; Shi and Mihalcea, 2005; Abend et al., 2008). However, to date their exploitation has been limited because for most languages, no Levin style classification is available.

Since manual classification is costly (Kipper et al., 2008) automatic approaches have been proposed recently which could be used to learn novel classifications in a cost-effective manner (Joanis et al., 2008; Li and Brew, 2008; Ó Séaghdha and Copestake, 2008; Vlachos et al., 2009; Sun and Korhonen, 2009). However, most work on Levin type classification has focussed on English. Large-scale research on other languages such as German (Schulte im Walde, 2006) and Japanese (Suzuki and Fukumoto, 2009) has focussed on semantic classification. Although the two classification systems have shared properties, studies comparing the overlap between VerbNet and WordNet (Miller, 1995) have reported that the mapping is only partial and many to many due to fine-grained nature of classes based on synonymy (Shi and Mihalcea, 2005; Abend et al., 2008).

Only few studies have been conducted on Levin style classification for languages other than English. In their experiment involving 59 verbs and three classes, Merlo et al. (2002) applied a supervised approach developed for English to Italian, obtaining high accuracy (86.3%). In another experiment with 60 verbs and three classes,

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 1056–1064,
Beijing, August 2010

they showed that features extracted from Chinese translations of English verbs can improve English classification. These results are promising, but those from a later experiment by Ferrer (2004) are not. Ferrer applied a clustering approach developed for English to Spanish, and evaluated it against the manual classification of Vázquez et al. (2000), constructed using criteria similar (but not identical) to Levin's. This experiment involving 514 verbs and 31 classes produced results only slightly better than the random baseline.

In this paper, we investigate the cross-linguistic potential of Levin style classification further. In past years, verb classification techniques – in particular unsupervised ones – have improved considerably, making investigations for a new language more feasible. We take a recent verb clustering approach developed for English (Sun and Korhonen, 2009) and apply it to French – a major language for which no such experiment has been conducted yet. Basic NLP resources (corpora, taggers, parsers and subcategorization acquisition systems) are now sufficiently developed for this language for the application of a state-of-the-art verb clustering approach to be realistic.

Our investigation reveals similarities between the English and French classifications, supporting the linguistic hypothesis (Jackendoff, 1990) and the earlier result of Merlo et al. (2002) that Levin classes have a strong cross-linguistic basis. Not only the general methodology but also best performing features are transferable between the languages, making it possible to learn useful classes for French automatically without language-specific tuning.

2 French Gold Standard

The development of an automatic verb classification approach requires at least an initial gold standard. Some syntactic (Gross, 1975) and semantic (Vossen, 1998) verb classifications exist for French, along with ones which integrate aspects of both (Saint-Dizier, 1998). Since none of these resources offer classes similar to Levins', we followed the idea of Merlo et al. (2002) and translated a number of Levin classes from English to French. As our aim was to to investigate the cross-linguistic applicability of classes, we took an English gold standard which has been used to evaluate several recent clustering works – that of Sun et al. (2008). This resource includes 17 fine-grained Levin classes. Each class has 12 member verbs whose predominant sense in English (according to WordNet) belongs to that class.

Member verbs were first translated to French. Where several relevant translations were identified, each of them was considered. For each candidate verb, subcategorization frames (SCFs) were identified and diathesis alternations were considered using the criteria of Levin (1993): alternations must result in the same or extended verb sense. Only verbs sharing diathesis alternations were kept in the class.

For example, the gold standard class 31.1 AMUSE includes the following English verbs: *stimulate, threaten, shock, confuse, upset, overwhelm, scare, disappoint, delight, exhaust, intimidate* and *frighten*. Relevant French translations were identified for all of them: *abattre, accabler, briser, déprimer, consterner, anéantir, épuiser, exténuer, écraser, ennuyer, éreinter, inonder*. The majority of these verbs take similar SCFs and diathesis alternations, e.g. *Cette affaire écrase Marie (de chagrin), Marie est écrasée par le chagrin, Le chagrin écrase Marie*. However, *stimuler* (*stimulate*) and *menacer* (*threaten*) do not, and they were therefore removed.

40% of translations were discarded from classes because they did not share the same alernations. The final version of the gold standard (shown in table 1) includes 171 verbs in 16 classes. Each class is named according to the original Levin class. The smallest class (30.3) includes 7 verbs and the largest (37.3) 16. The average number of verbs per class is 10.7.

3 Verb Clustering

We performed an experiment where we

- took a French corpus and a SCF lexicon automatically extracted from that corpus,
- extracted from these resources a range of features (lexical, syntactic and semantic) – a representative sample of those employed in recent English experiments,

Class No	Class	Verbs
9.1	PUT	accrocher, déposer, mettre, placer, répartir, réintégrer, empiler, emporter, enfermer, insérer, installer
10.1	REMOVE	ôter, enlever, retirer, supprimer, retrancher, débarrasser, soustraire, décompter, éliminer
11.1	SEND	envoyer, lancer, transmettre, adresser, porter, expédier, transporter, jeter, renvoyer, livrer
13.5.1	GET	acheter, prendre, saisir, réserver, conserver, garder, préserver, maintenir, retenir, louer, affréter
18.1	HIT	cogner, heurter, battre, frapper, fouetter, taper, rosser, brutaliser, éreinter, maltraiter, corriger,
22.2	AMALGAMATE	incorporer, associer, réunir, mélanger, mêler, unir, assembler, combiner, lier, fusionner
29.2	CHARACTERIZE	appréhender, concevoir, considérer, décrire, définir, dépeindre, désigner, envisager, identifier, montrer, percevoir, représenter, ressentir
30.3	PEER	regarder, écouter, examiner, considérer, voir, scruter, dévisager
31.1	AMUSE	abattre, accabler, briser, déprimer, consterner, anéantir, épuiser, exténuer, écraser, ennuyer, éreinter, inonder,
36.1	CORRESPOND	coopérer, participer, collaborer, concourir, contribuer, prendre part, s’associer, travaille
37.3	MANNER OF SPEAKING	râler, gronder, crier, ronchonner, grogner, bougonner, maugréer, rouspéter, grommeler, larmoyer, gémir, geindre, hurler, gueuler, brailler, chuchoter

47.3	MODES OF BEING	trembler, frémir, osciller, vaciller, vibrer, tressaillir, frissonner, palpiter, grésiller, trembloter, palpiter
51.3.2	RUN	voyager, aller, se promener, errer, circuler, se déplacer, courir, bouger, naviguer, passer

Table 1: A Levin style gold standard for French

- clustered the features using a method which has proved promising in both English and German experiments: spectral clustering,
- evaluated the clusters both quantitatively (using the gold standard) and qualitatively,
- and compared the performance to that recently obtained for English in order to gain a better understanding of the cross-linguistic and language-specific properties of verb classification

This work is described in the subsequent sections.

3.1 Data: the LexSchem Lexicon

We extracted the features for clustering from LexSchem (Messiant et al., 2008). This large subcategorization lexicon provides SCF frequency information for 3,297 French verbs. It was acquired fully automatically from Le Monde newspaper corpus (200M words from years 1991-2000) using ASSCI – a recent subcategorization acquisition system for French (Messiant, 2008). Systems similar to ASSCI have been used in recent verb classification works e.g. (Schulte im Walde, 2006; Li and Brew, 2008; Sun and Korhonen, 2009). Like these other systems, ASSCI takes raw corpus data as input. The data is first tagged and lemmatized using the Tree-Tagger and then parsed using Syntex (Bourigault et al., 2005). Syntex is a shallow parser which employs a combination of statistics and heuristics to identify grammatical relations (GRs) in sentences. ASSCI considers GRs where the target verbs occur and constructs SCFs from nominal, prepositional and adjectival phrases, and infinitival and subordinate clauses. When a verb has no dependency, its SCF is considered as intransitive. ASSCI assumes no predefined list of SCFs but almost any combination of permitted constructions can appear as a candidate SCF. The number of automatically generated SCF types in LexSchem is 336.

Many candidate SCFs are noisy due to processing errors and the difficulty of argument-adjunct distinction. Most SCF systems assume that true arguments occur in argument positions more frequently than adjuncts. Many systems also integrate filters for removing noise from system output. When LexSchem was evaluated after filtering its F-measure was 69 – which is similar to that of other current SCF systems (Messiant et al., 2008) We used the unfiltered version of the lexicon because English experiments have shown that information about adjuncts can help verb clustering (Sun et al., 2008).

4 Features

Lexical entries in LexSchem provide a variety of material for verb clustering. Using this material, we constructed a range of features for experimentation. The first three include basic information about SCFs:

F1: SCFs and their relative frequencies with individual verbs. SCFs abstract over particles and prepositions.

F2: F1, with SCFs parameterized for the tense (the POS tag) of the verb.

F3: F2, with SCFs parameterized for prepositions (PP).

The following six features include information about the lexical context (co-occurrences) of verbs. We adopt the best method of Li and Brew (2008) where collocations (COs) are extracted from the window of words immediately preceding and following a lemmatized verb. Stop words are removed prior to extraction.

F4, F6, F8: COs are extracted from the window of 4, 6 and 8 words, respectively. The relative word position is ignored.

F5, F7, F9: F4, F6 and F8 with the relative word position recorded.

The next four features include information about lexical preferences (LP) of verbs in argument head positions of specific GRs associated with the verb:

F10: LP(PREP): the type and frequency of prepositions in the preposition (PREP) relation.

F11: LP(SUBJ): the type and frequency of nouns in the subject (SUBJ) relation.

F12: LP(IOBJ): the type and frequency of nouns in the object (OBJ) and indirect object (IOBJ) relation.

F13: LP(ALL): the combination of F10-F13.

The final two features refine SCF features with LPs and semantic information about verb selectional preferences (SP):

F14-F16: F1-F3 parameterized for LPs.

F17: F3 refined with SPs.

We adopt a fully unsupervised approach to SP acquisition using the method of Sun and Korhonen (2009), with the difference that we determine the optimal number of SP clusters automatically following Zelnik-Manor and Perona (2004). The method is introduced in the following section. The approach involves (i) taking the GRs (SUBJ, OBJ, IOBJ) associated with verbs, (ii) extracting all the argument heads in these GRs, and (iii) clustering the resulting N most frequent argument heads into M classes. The empirically determined N 200 was used. The method produced 40 SP clusters.

5 Clustering Methods

Spectral clustering (SPEC) has proved promising in previous verb clustering experiments (Brew and Schulte im Walde, 2002; Sun and Korhonen, 2009) and other similar NLP tasks involving high dimensional feature space (Chen et al., 2006). Following Sun and Korhonen (2009) we used the MNCut spectral clustering (Meila and Shi, 2001) which has a wide applicability and a clear probabilistic interpretation (von Luxburg, 2007; Verma and Meila, 2005). However, we extended the method to determine the optimal number of clusters automatically using the technique proposed by (Zelnik-Manor and Perona, 2004).

Clustering groups a given set of verbs $V = \{v_n\}_{n=1}^{N}$ into a disjoint partition of K classes. SPEC takes a similarity matrix as input. All our features can be viewed as probabilistic distributions because the combination of different features is performed via parameterization. Thus we use the Jensen-Shannon divergence (JSD) to construct the similarity matrix. The JSD between two feature vectors v and v' is $d_{jsd}(v, v') = \frac{1}{2}D(v||m) + \frac{1}{2}D(v'||m)$ where D is the Kullback-Leibler divergence, and m is the average of the v and v'.

The similarity matrix W is constructed where $W_{ij} = \exp(-d_{jsd}(v, v'))$. In SPEC, the similarities W_{ij} are viewed as the connection weight ij of a graph G over V. The similarity matrix W is thus the adjacency matrix for G. The degree of a vertex i is $d_i = \sum_{j=1}^{N} w_{ij}$. A cut between two partitions A and A' is defined to be $\text{Cut}(A, A') = \sum_{m \in A, n \in A'} W_{mn}$.

The similarity matrix W is normalized into a stochastic matrix P.

$$P = D^{-1}W \qquad (1)$$

The degree matrix D is a diagonal matrix where $D_{ii} = d_i$.

It was shown by Meila and Shi (2001) that if P has the K leading eigenvectors that are piecewise constant[1] with respect to a partition I^* and their eigenvalues are not zero, then I^* minimizes the multiway normalized cut(MNCut):

$$\text{MNCut}(I) = K - \sum_{k=1}^{K} \frac{\text{Cut}(I_k, I_k)}{\text{Cut}(I_k, I)}$$

P_{mn} can be interpreted as the transition probability between vertices m, n. The criterion can thus be expressed as $\text{MNCut}(I) = \sum_{k=1}^{K}(1 - P(I_k \rightarrow I_k|I_k))$ (Meila, 2001), which is the sum of transition probabilities across different clusters. This criterion finds the partition where the random walks are most likely to happen within the same cluster. In practice, the leading eigenvectors of P are not piecewise constant. But we can extract the partition by finding the approximately equal elements in the eigenvectors using a clustering algorithm like K-Means.

As the value of K is not known beforehand, we use Zelnik-Manor and Perona (2004)'s method to estimate it. This method finds the optimal value by minimizing a cost function based on the eigenvector structure of W.

Like Brew and Schulte im Walde (2002), we compare SPEC against a K-Means baseline. We used the Matlab implementation with euclidean distance as the distance measure.

6 Experimental Evaluation

6.1 Data and Pre-processing

The SCF-based features (F1-F3 and F14-F17) were extracted directly from LexSchem. The CO (F4-F9) and LP features (F10-F13) were extracted from the raw and parsed corpus sentences, respectively, which were used for creating the lexicon. Features that only appeared once were removed. Feature vectors were normalized by the sum of the feature values before clustering. Since our clustering algorithms have an element of randomness, we repeated clustering multiple times. We report the results that minimize the distortion (the distance to cluster centroid).

6.2 Evaluation Measures

We employ the same measures for evaluation as previously employed e.g. by Ó Séaghdha and Copestake (2008) and Sun and Korhonen (2009).

The first measure is modified purity (mPUR) – a global measure which evaluates the mean precision of clusters. Each cluster is associated with its prevalent class. The number of verbs in a cluster K that take this class is denoted by $n_{prevalent}$(K). Verbs that do not take it are considered as errors. Clusters where $n_{prevalent}$(K) = 1 are disregarded as not to introduce a bias towards singletons:

$$\text{mPUR} = \frac{\sum_{n_{prevalent(k_i)}>2} n_{prevalent(k_i)}}{\text{number of verbs}}$$

The second measure is weighted class accuracy (ACC): the proportion of members of dominant clusters DOM-CLUST$_i$ within all classes c_i.

$$\text{ACC} = \frac{\sum_{i=1}^{C} \text{verbs in DOM-CLUST}_i}{\text{number of verbs}}$$

mPUR and ACC can be seen as a measure of precision(P) and recall(R) respectively. We calculate F measure as the harmonic mean of P and R:

$$\text{F} = \frac{2 \cdot \text{mPUR} \cdot \text{ACC}}{\text{mPUR} + \text{ACC}}$$

The random baseline (BL) is calculated as follows: $\text{BL} = 1/\text{number of classes}$

7 Evaluation

7.1 Quantitative Evaluation

In our first experiment, we evaluated 116 verbs – those which appeared in LexSchem the minimum

[1] The eigenvector v is piecewise constant with respect to I if $v(i) = v(j) \forall i, j \in I_k$ and $k \in 1, 2...K$

of 150 times. We did this because English experiments had shown that due to the Zipfian nature of SCF distributions, 150 corpus occurrences are typically needed to obtain a sufficient number of frames for clustering (Sun et al., 2008).

Table 2 shows F-measure results for all the features. The 4th column of the table shows, for comparison, the results of Sun and Korhonen (2009) obtained for English when they used the same features as us, clustered them using SPEC, and evaluated them against the English version of our gold standard, also using F-measure[2].

As expected, SPEC (the 2nd column) outperforms K-Means (the 3rd column). Looking at the basic SCF features F1-F3, we can see that they perform significantly better than the BL method. F3 performs the best among the three features both in French (50.6 F) and in English (63.3 F). We therefore use F3 as the SCF feature in F14-F17 (the same was done for English).

In French, most CO features (F4-F9) outperform SCF features. The best result is obtained with F7: 55.1 F. This is clearly better than the best SCF result 50.6 (F3). This result is interesting since SCFs correspond better than COs with features used in manual Levin classification. Also, SCFs perform considerably better than COs in the English experiment (we only have the result for F4 available, but it is considerably lower than the result for F3). However, earlier English studies have reported contradictory results (e.g. Li and Brew (2008) showed that CO performs better than SCF in supervised verb classification), indicating that the role of CO features in verb classification requires further investigation.

Looking at the LP features, F13 produces the best F (52.7) for French which is slightly better than the best SCF result for the language. Also in English, F13 performs the best in this feature group and yields a higher result than the best SCF-based feature F3.

Parameterizing the best SCF feature F3 with LPs (F14-16) and SPs (F17) yields better performance in French. F15 and F17 have the F of 54.5 and 54.6, respectively. These results are so close to the result of the best CO feature F7 (55.1 – which is the highest result in this experiment) that the differences are not statistically significant. In English, the results of F14-F17 are similarly good; however, only F17 beats the already high performance of F13.

On the basis of this experiment, it is difficult to tell whether shallow CO features or more sophisticated SCF-based features are better for French. In the English experiment sophisticated features performed better (the SCF-SP feature was the best). However, the English experiment employed a much larger dataset. These more sophisticated features may suffer from data sparseness in our French experiment since although we required the minimum of 150 occurrences per verb, verb clustering performance tends to improve when more data is available, and given the fine-grained nature of LexShem SCFs it is likely that more data is required for optimal performance.

We therefore performed another experiment with French on the full set of 147 verbs, using SPEC, where we investigated the effect of instance filtering on the performance of the best features from each feature group: F3, F7, F13 and F17. The results shown in Table 3 reveal that the performance of the features remains fairly similar until the instance threshold of 1000. When 2000 occurrences per verb are used, the differences become clearer, until at the threshold of 4000, it is obvious that the most sophisticated SCF-SP feature F17 is by far the best feature for French (65.4 F) and the SCF feature F3 the second best (60.5 F). The CO-feature F7 and the LP feature F13 are not nearly as good (53.4 and 51.0 F).

Although the results at different thresholds are not comparable due to the different number of verbs and classes (see columns 2-3), the results for features at the same threshold are. Those results suggest that when 2000 or more occurrences per verb are used, most features perform like they performed for English in the experiment of Sun and Korhonen (2009), with CO being the least informative[3] and SCF-SP being the most informa-

[2] Note that the results for the two languages are not mutually comparable due to differences in test sets, data sizes, and feature extraction systems (see Section 8 for discussion). The results for English are included so that we can compare the relative performance of individual features in the two languages in question.

[3] However, it is worth noting that CO is not a useless feature. As table 3 shows, when 150 or fewer occurrences are

		SPEC	K	Eng.
BL		6.7	6.7	6.7

tive feature. The only exception is the LP feature which performed better than CO in English.

7.2 Qualitative Evaluation

We conducted qualitative analysis of the clusters for French: those created using SPEC with F17 and F3. Verbs in the gold standard classes 29.2, 36.1, 37.3, 37.7 and 47.3 (Table 1) performed particularly well, with the majority of member verbs found in the same cluster. These verbs are ideal for clustering because they have distinctive syntactic-semantic characteristics. For example, verbs in 29.2 CHARACTERIZE class (e.g. *concevoir, considérer, dépeindre*) not only have a very specific meaning but they also take high frequency SCFs involving the preposition *comme* (Eng. *as*) which is not typical to many other classes. Interestingly, Levin classes 29.2, 36.1, 37.3, and 37.7 were among the best performing classes also in the supervised verb classification experiment of Sun et al. (2008) because these classes have distinctive characteristics also in English.

The benefit of sophisticated features which integrate also semantic (SP) information (F17) is particularly evident for classes with non-distinctive syntactic characteristics. For example, the intransitive verbs in 43.1 LIGHT EMISSION class (e.g. *briller, étinceler, flamboyer*) are difficult to cluster based on syntax only, but semantic features work because the verbs pose strong SPs on their subjects (entities capable of light emission). In the experiment of Sun et al. (2008), 43.1 was the worst performing class, possibly because no semantic features were used in the experiment.

The most frequent source of error is syntactic idiosyncracy. This is particularly evident for classes 10.1 REMOVE and 45.4 CHANGE OF STATE. Although verbs in these classes can take similar SCFs and alternations, only some of them are frequent in data. For example, the SCF *ôter X à Y* is frequent for verbs in 10.1, but not *ôter X de Y*. Although class 10.1 did not suffer from this problem in the English experiment of Sun et al. (2008), class 45.4 did. Class 45.4 performs particularly bad in French also because its member verbs are low in frequency.

Some errors are due to polysemy, caused partly by the fact that the French version of the gold standard was not controlled for this factor. Some verbs have their predominant senses in classes which are missing in the gold standard, e.g. the most frequent sense of *retenir* is *memorize*, not *keep* as in the gold standard class 13.5.1. GET.

Finally, some errors are not true errors but demonstrate the capability of clustering to learn novel information. For example, the CHANGE OF STATE class 45.4 includes many antonyms (e.g. *weaken* vs. *strenghten*). Clustering (using F17) separates these antonyms, so that verbs *adoucir, atténuer* and *tempérer* appear in one cluster and *consolider* and *renforcer* in another. Although these verbs share the same alternations, their SPs are different. The opposite effect can be observed when clustering maps together classes

available for a verb, CO outperforms all the other features in French, compensating for data sparseness.

which are semantically and syntactically related (e.g. 36.1 CORRESPOND and 37.7 SPEAK). Such classes are distinct in Levin and VerbNet, although should ideally be related. Cases such as these show the potential of clustering in discovering novel valuable information in data.

8 Discussion and Conclusion

When sufficient corpus data is available, there is a strong correlation between the types of features which perform the best in English and French. When the best features are used, many individual Levin classes have similar performance in the two languages. Due to differences in data sets direct comparison of performance figures for English and French is not possible. When considering the general level of performance, our best performance for French (65.4 F) is lower than the best performance for English in the experiment of Sun and Korhonen (2009). However, it does compare favourably to the performance of other state-of-the-art (even supervised) English systems (Joanis et al., 2008; Li and Brew, 2008; Ó Séaghdha and Copestake, 2008; Vlachos et al., 2009). This is impressive considering that we experimented with a fully unsupervised approach originally developed for another language.

When aiming to improve performance further, employing larger data is critical. Most recent experiments on English have employed bigger data sets, and unlike us, some of them have only considered the predominant senses of medium-high frequency verbs. As seen in section 7.1, such differences in data can have significant impact on performance. However, parser and feature extraction performance can also play a big role in overall accuracy, and should therefore be investigated further (Sun and Korhonen, 2009). The relatively low performance of basic LP features in French suggests that at least some of the current errors are due to parsing. Future research should investigate the source of error at different stages of processing. In addition, it would be interesting to investigate whether language-specific tuning (e.g. using language specific features such as auxiliary classes) can further improve performance on French.

Earlier works most closely related to ours are those of Merlo et al. (2002) and Ferrer (2004). Our results contrast with those of Ferrer who showed that a clustering approach does not transfer well from English to Spanish. However, she used basic SCF and named entity features only, and a clustering algorithm less suitable for high dimensional data. Like us, Merlo et al. (2002) created a gold standard by translating Levin classes to another language (Italian). They also applied a method developed for English to Italian, and reported good overall performance using features developed for English. Although the experiment was small (focussing on three classes and a few features only) and involved supervised classification, the results agree with ours.

These experiments support the linguistic hypothesis that Levin style classification can be cross-linguistically applicable. A clustering technique such as the one presented here could be used as a tool for investigating whether classifications are similar across a wider range of more diverse languages. From the NLP perspective, the fact that an unsupervised technique developed for one language can be applied to another language without the need for substantial tuning means that automatic techniques could be used to hypothesise useful Levin style classes for further languages. This, in turn, could facilitate the creation of multilingual VerbNets in the future.

Semi-supervised dependency parsing using generalized tri-training

Anders Søgaard and Christian Rishøj
Center for Language Technology
University of Copenhagen
{soegaard|crjensen}@hum.ku.dk

Abstract

Martins et al. (2008) presented what to the best of our knowledge still ranks as the best overall result on the CONLL-X Shared Task datasets. The paper shows how triads of stacked dependency parsers described in Martins et al. (2008) can label unlabeled data for each other in a way similar to co-training and produce end parsers that are significantly better than any of the stacked input parsers. We evaluate our system on five datasets from the CONLL-X Shared Task and obtain 10–20% error reductions, incl. the best reported results on four of them. We compare our approach to other semi-supervised learning algorithms.

1 Introduction

Semi-supervised learning of structured variables is a difficult problem that has received considerable attention recently, but most results have been negative (Abney, 2008). This paper uses stacked learning (Wolpert, 1992) to reduce structured variables, i.e. dependency graphs, to multinomial variables, i.e. attachment and labeling decisions, which are easier to manage in semi-supervised learning scenarios, and which can later be combined into dependency trees using parsing algorithms for arc-factored dependency parsing. Our approach thus combines ensemble-based methods and semi-supervised learning.

Ensemble-based methods such as stacked learning are used to reduce the instability of classifiers, to average out their errors and to combine the strengths of diverse learning algorithms. Ensemble-based methods have attracted a lot of attention in dependency parsing recently (Sagae and Lavie, 2006; Hall et al., 2007; Nivre and McDonald, 2008; Martins et al., 2008; Fishel and Nivre, 2009; Surdeanu and Manning, 2010). Nivre and McDonald (2008) were first to introduce stacking in the context of dependency parsing.

Semi-supervised learning is typically motivated by data sparseness. For many classification tasks in natural language processing, labeled data can be in short supply but unlabeled data is more readily available. Semi-supervised methods exploit unlabeled data in addition to labeled data to improve performance on classification tasks. If the predictions of a learner l on unlabeled data are used to improve a learner l' in semi-supervised learning, the robustness of learning will depend on the stability of l. Combining ensemble-based and semi-supervised methods may thus lead to more robust semi-supervised learning.

Ensemble-based and semi-supervised methods are some of the areas that receive most attention in machine learning today, but relatively little attention has been given to *combining* these methods (Zhou, 2009). Semi-supervised learning algorithms can be categorized with respect to the number of views, i.e. the number of feature sets, and the number of learners used to inform each other (Hady and Schwenker, 2008). Self-training and expectation maximization are perhaps the best known semi-supervised learning algorithms (Abney, 2008). They are both single-view and single-learner algorithms. Since there is thus only a single perspective on data,

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 1065–1073,
Beijing, August 2010

selecting unlabeled data points with predictions is a difficult task. There is an imminent danger that the learner amplifies its previous mistakes, and while several techniques such as balancing and throttling have been developed to avoid such caveats, using single-view and single-learner algorithms often requires both caution and experience with the modeling task at hand.

Algorithms with multiple views on data are known to be more robust. This insight led to the development of co-training (Blum and Mitchell, 1998), a two-view method where views inform each other, but it also paved the way for the integration of ensemble-based and semi-supervised methods, i.e. for methods with multiple learners. It was mentioned that relatively little work has been devoted to this topic, but there are notable exceptions:

Bennett et al. (2003) generalized boosting to semi-supervised learning in a seminal paper, where the idea of iterative or recursive ensembles was also introduced. Li and Zhou (2005) introduce *tri-training*, a form of co-training that trains an ensemble of three learners on labeled data and runs them on unlabeled data. If two learners agree on their labeling of a data point, the data point is added to the labeled data of the third learner with the prediction of the first two. Didaci and Roli (2006) extend self-training and co-training to multiple learners. Li and Zhou (2007) generalize tri-training to larger ensembles of random trees. The technique is also known as co-forests. Hady and Schwenker (2008) generalize existing ensemble-based methods for semi-supervised learning scenarios; in particular they embed ensembles in a form of co-training that is shown to maintain the diversity of the ensemble over time. Milidiu and Duarte (2009) generalize boosting at start to semi-supervised learning.

This paper applies a generalization of tri-training to two classification problems, attachment and labeling. The attachment classifier's weights are used for arc-factored dependency parsing, and the labeling classifier's weights are then used to label the dependency tree delivered by the parser.

Semi-supervised dependency parsing has attracted a lot of attention recently (Koo et al., 2008; Wang et al., 2008; Suzuki et al., 2009), but there has, to the best of our knowledge, been no previous attempts to apply tri-training or related combinations of ensemble-based and semi-supervised methods to any of these tasks, except for the work of Sagae and Tsujii (2007) discussed in Sect. 2.6. However, tri-training has been applied to Chinese chunking (Chen et al., 2006), question classification (Nguyen et al., 2008) and POS tagging (Søgaard, 2010).

We compare generalized tri-training to other semi-supervised learning algorithms, incl. self-training, the original tri-training algorithm based on bootstrap samples (Li and Zhou, 2005), co-forests (Li and Zhou, 2007) and semi-supervised support vector machines (Sindhwani and Keerthi, 2006).

Sect. 2 introduces dependency parsing and stacked learning. Stacked learning is generalized to dependency parsing, and previous work is briefly surveyed. We then describe how stacked dependency parsers can be further stacked as input for two end classifiers that can be combined to produce dependency structures. These two classifiers will learn multinomial variables (attachment and labeling) from a combination of labeled data and unlabeled data using a generalization of tri-training. Sect. 3 describes our experiments. We describe the data sets, and how the unlabeled data was prepared. Sect. 4 presents our results. Sect. 5 presents an error analysis and discusses the results in light of other results in the literature, and Sect. 6 concludes the paper.

2 Background and related work

2.1 Dependency parsing

Dependency parsing models a sentence as a tree where words are vertices and grammatical functions are directed edges (dependencies). Each word thus has a single incoming edge, except one called the root of the tree. Dependency parsing is thus a structured prediction problem with trees as structured variables. Each sentence has exponentially many possible dependency trees. Our observed variables are sentences with words labeled with part-of-speech tags. The task for each sentence is to find the dependency tree that maximizes an objective function which in our case is learned from a combination of labeled and unlabeled data.

More formally, a dependency tree for a sentence $x = w_1, \ldots, w_n$ is a tree $T = \langle\{0, 1, \ldots, n\}, A\rangle$ with $A \subseteq V \times V$ the set of dependency arcs. Each vertex corresponds to a word in the sentence, except 0 which is the root vertex, i.e. for any $i \leq n$ $\langle i, 0\rangle \notin A$. Since a dependency tree is a tree it is acyclic. A tree is projective if every vertex has a continuous projection, i.e. if and only if for every arc $\langle i, j\rangle \in A$ and node $k \in V$, if $i < k < j$ or $j < k < i$ then there is a subset of arcs $\{\langle i, i_1\rangle, \langle i_1, i_2\rangle, \ldots, \langle i_{k-1}, i_k\rangle\} \in A$ such that $i_k = k$.

In this paper we use a maximum spanning tree algorithm, the so-called Chu-Liu-Edmonds algorithm (CLE) (Edmonds, 1967) to turn the predictions of our semi-supervised classifiers into a dependency tree.

2.2 Stacked learning

Stacked generalization, or simply *stacking*, was first proposed by Wolpert (1992). Stacking is an ensemble-based learning method where multiple weak classifiers are combined in a strong end classifier. The idea is to train the end classifier directly on the predictions of the input classifiers.

Say each input classifier c_i with $1 \leq i \leq n$ receives an input $\mathbf{x}$ and outputs a prediction $c_i(\mathbf{x})$. The end classifier then takes as input $\langle\mathbf{x}, c_1(\mathbf{x}), \ldots, c_n(\mathbf{x})\rangle$ and outputs a final prediction $c_0(\langle\mathbf{x}, c_1(\mathbf{x}), \ldots, c_n(\mathbf{x})\rangle)$. Training is done by cross-validation. In sum, stacking is training a classifier on the output of classifiers.

2.3 Stacked dependency parsing

Stacked learning can be generalized to structured prediction tasks such as dependency parsing. Architectures for stacking dependency parsers typically only use one input parser, but otherwise the intuition is the same: the input parser is used to augment the dependency structures that the end parser is trained and evaluated on.

Nivre and McDonald (2008) first showed how the MSTParser (McDonald et al., 2005) and the MaltParser (Nivre et al., 2007) could be improved by stacking each parser on the predictions of the other. Martins et al. (2008) generalized their work, considering more combinations of parsers, and stacking the end parsers on non-local features from the predictions of the input parser, e.g. siblings and grand-parents. In this work we use three stacked dependency parsers for each language: mst2 (p_1), malt/mst2 (p_2) and malt/mst1 (p_3).

The notation ”malt/mst2” means that the second-order MSTParser has been stacked on the MaltParser. The capital letters refer to feature configurations. Configuration D stacks a level 1 parser on several (non-local) features of the predictions of the level 0 parser (along with the input features): the predicted edge, siblings, grand parents and predicted head of candidate modifier if predicted edge is 0. Configuration E stacks a level 1 parser on the features in configuration D and all the predicted children of the candidate head. The chosen parser configurations are those that performed best in Martins et al. (2008) across the different datasets.

2.4 Stacking stacked dependency parsing

The input features of the input classifiers in stacked learning $\mathbf{x}$ can of course be removed from the input of the end classifier. It is also possible to stack stacked classifiers. This leaves us with four strategies for recursive stacking; namely to constantly augment the feature set, with level n classifiers trained on the predictions of the classifiers at all $n - 1$ lower levels with or without the input features $\mathbf{x}$, or simply to train a level n classifier on the predictions of the level $n - 1$ classifiers with or without $\mathbf{x}$.

In this work we stack stacked dependency parsers by training classifiers on the output of three stacked dependency parsers and POS tags. Consequently, we use one of the features from $\mathbf{x}$. Note that we train classifiers and not parsers on this new level 2.

The reduction is done the following way: First we train a classifier on the relative distance from a word to its head to induce attachments. For example, we may obtain the following features from the predictions of our level 1 parsers:

label	p_1	p_2	p_3	POS
1	1	-1	1	NNP
0	0	0	0	VBD

In the second row all input parsers, p_{1-3} in columnsaa 2–4, agree that the verb is the root of the sentence. Column 1 tells us that this is correct. In the first row, two out of three parsers agree on attaching the noun to the verb, which again is correct. We train level 2 classifiers on feature vectors produced this way. Note that oracle performance of the ensemble is no upper bound on the accuracy of a classifier trained on level 1 predictions this way, since a classifier may learn the right decision from three wrong predictions and a POS tag.

Second we train a classifier to predict dependency relations. Our feature vectors are similar to the ones just described, but now contain dependency label predictions, e.g.:

label	p_1	p_2	p_3	POS
SBJ	SBJ	SBJ	SBJ	NN
ROOT	ROOT	ROOT	COORD	VBN

2.5 Generalized tri-training

Tri-training was originally introduced in Li and Zhou (2005). The method involves three learners that inform each other.

Let L denote the labeled data and U the unlabeled data. Assume that three classifiers c_1, c_2, c_3 have been trained on L. In the original algorithm, the three classifiers are obtained by applying the same learning algorithm to three bootstrap samples of the labeled data; but in generalized algorithms, three different learning algorithms are used. An unlabeled datapoint in U is labeled for a classifier, say c_1, if the other two classifiers agree on its label, i.e. c_2 and c_3. Two classifiers inform the third. If the two classifiers agree on a labeling, we assume there is a good chance that they are right. In the original algorithm, learning stops when the classifiers no longer change; in generalized tri-training, a fixed stopping criterion is used. The three classifiers are combined by voting. Li and Zhou (2005) show that under certain conditions the increase in classification noise rate is compensated by the amount of newly labeled data points.

The most important condition is that the three classifiers are diverse. If the three classifiers are identical, tri-training degenerates to *self-training*. As already mentioned, Li and Zhou (2005) obtain this diversity by training classifiers on bootstrap samples. In their experiments, they consider classifiers based on decision trees, BP neural networks and naïve Bayes inference.

```
for $i \in \{1..3\}$ do
    $c_i \leftarrow train\_classifier(l_i, L)$
end for
repeat
    for $i \in \{1..3\}$ do
        for $x \in U$ do
            $L_i \leftarrow \emptyset$
            if $c_j(x) = c_k(x) (j, k \neq i)$ then
                $L_i \leftarrow L_i \cup \{(x, c_j(x))\}$
            end if
        end for
        $c_i \leftarrow train\_classifier(l_i, L \cup L_i)$
    end for
until stopping criterion is met
apply $c_1$
```

Figure 1: Generalized tri-training.

In this paper we generalize the tri-training algorithm and use three different learning algorithms rather than bootstrap samples to create diversity: a naïve Bayes algorithm (no smoothing), random forests (Breiman, 2001) (with 100 unpruned decision trees) and an algorithm that induces unpruned decision trees. The overall algorithm is sketched in Figure 1 with l_i a learning algorithm.

Our weights are those of the random forest classifier after a fixed number of rounds. The attachment classifier iterates once over the unlabeled data, while the dependency relations classifier uses three iterations. The optimal number of iterations could of course be estimated on development data instead. Given the weights for an input sentence we use CLE to find its most likely dependency tree.

2.6 Related work

This paper uses stacking rather than voting to construct ensembles, but voting has been more widely used in dependency parsing than stacking. Voting was first introduced in dependency parsing in Zeman and Zabokrtsky (2005). Sagae and Lavie (2006) later used weighted voting and reparsing, i.e. using CLE to find the dependency tree that reflects the maximum number of votes. They also showed that binning the vote over part-of-speech tags led to further improvements. This set-up was adopted by Hall et al. (2007) in the best performing system in the CONLL 2007 Shared Task. Fishel and Nivre (2009) later experimented with binning the vote on other features with modest improvements.

Semi-supervised dependency parsing has only recently been explored, and failures have been more frequent than successes. There are, however, noteable exceptions such as Koo et al. (2008), Wang et al. (2008), Suzuki et al. (2009) and Sagae and Gordon (2009).

The semi-supervised methods employed in these experiments are very different from more traditional scenarios such as self-training and co-training. Two approaches (Koo et al., 2008; Sagae and Gordon, 2009) use clusters obtained from large amounts of unlabeled data to augment their labeled data by introducing new features, and two approaches (Wang et al., 2008; Suzuki et al., 2009) combine probability distributions obtained from labeled data with probability distributions obtained from unlabeled data.

Successes with self-training and co-training are rare, and several authors report negative results, e.g. Spreyer and Kuhn (2009). A notable exception in constituent-based parsing is the work of McClosky et al. (2006) who show that self-training is possible if a reranker is used to inform the underlying parser.

Sagae and Tsujii (2007) participated in (and won) the CONLL 2007 Shared Task on domain adaptation. They first trained a maximum entropy-based transition-based dependency parser on the out-of-domain labeled data and an SVM-based transition-based dependency parser on the *reversed* out-of-domain labeled data. The two parsers parse the in-domain labeled data (reversed, in the case of the SVM-based parser). Identical analyses are added to the original training set. The first parser is retrained and used to parse the test data. In sum, the authors do one round of co-training with the following selection criterion: If the two parsers produce the same dependency structures for a sentence, the dependency structure is added to the labeled data. This criterion is also the selection criterion in tri-training.

3 Experiments

3.1 Data

We use five datasets from the CONLL-X Shared Task (Buchholz and Marsi, 2006).[1] Lemmas and morphological features (FEATS) are ignored, since we only add POS and CPOS tags to unlabeled data. For German and Swedish, we use 100,000 sentences from the Leipzig Corpora Collection (Biemann et al., 2007) as unlabeled data. For Danish, Dutch, and Portuguese we use 100,000 sentences from the Europarl corpus (Koehn, 2005). The data characteristics are provided in Figure 2. The unlabeled data were POS tagged using the freely available SVMTool (Gimenez and Marquez, 2004) (model 4, left-right-left).

3.2 Algorithm

Once our data has been prepared, we train the stacked dependency parsers and use them to label training data for our classifiers (∼4,000 tokens), our test data and our unlabeled data. This gives us three sets of predictions for each of the three data sets. Using the features described in Sect. 2.4 we then construct data for training our two triads of classifiers (for attachment and dependency relations). The entire architecture can be depicted as in Figure 3.

We first stack three dependency parsers as described in Martins et al. (2008). We then stack three classifiers on top of these dependency parsers (and POS tags): a naïve Bayes classifier, a random forest, and a decision tree. Finally,

[1] The CONLL-X Shared Task consists of 12 datasets, but we did not have consistently tokenized unlabeled data for Arabic, Chinese, Japanese, Slovene and Turkish. Martins et al. (2008) ignore Czech. Our experiment with the Spanish dataset crashed unexpectedly. We will post results on the website as soon as possible.

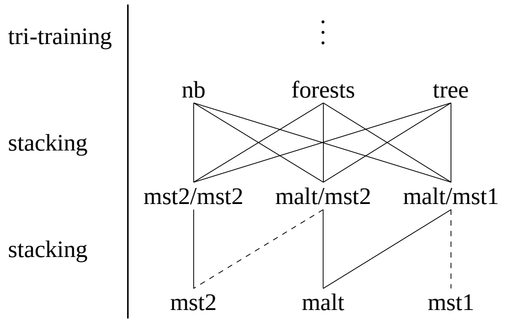

Figure 3: Tri-training stacked classifiers.

we tri-train these three stacked classifiers and for each test sentence output the weights provided by the random forest classifier. These weights are used to find the best possible dependency tree using CLE.

3.3 Baselines

The best of the stacked input parsers is of course our natural baseline.

Since we have generalized tri-training, we also compare generalized tri-training to the original tri-training algorithm based on bootstrap samples. The original tri-training algorithm is run with the same decomposition and the same features as our generalized tri-training algorithm. We use the learning algorithm originally used in Li and Zhou (2005), namely C4.5. We also compare our results to self-training (no pool, no growth rate) and co-forests (Li and Zhou, 2007). Finally, we compare our results to semi-supervised support vector machines (S3VMs) (Sindhwani and Keerthi, 2006). Since S3VMs produce binary classifiers, and one-vs.-many combination would be very time-consuming, we train a binary classifier that produces a probability that any candidate arc is correct and do greedy head selection. We optimized the feature set and included a total of seven features (head POS, dependent POS, dependent left neighbor POS, distance+direction, predictions of the three classifiers).

4 Results

Our results are presented in Figure 4. Labeled (LAS) and unlabeled attachment scores (UAS) and labeling accuracy (LA) are defined as usual and include punctuation signs unless otherwise noted. Difference (Δ) in LAS, error reduction and p-value compare our results to the best input stacked parser (malt/mst2, excerpt for Swedish).

Generalized tri-training (tri-training-CLE), i.e. using CLE to find the best well-formed dependency trees given the weights provided by our tri-trained random forest classifier, leads to highly significant improvements on *all* data sets ($p < 0.001$) with an average error reduction of 14,9%. The results for the other semi-supervised learning algorithms are presented in Figure 5. We only used 10% of the unlabeled data (10k sentences) in this experiment and only did unlabeled parsing, but it is quite evident that these learning strategies seem less promising than gen-

5 Error analysis and discussion

Error reductions are higher with dependencies to the root node and long distance dependencies than with local dependencies. The table below lists the labeled attachment F_1-scores for the five datasets binned on dependency length. The average error reduction is the same for root dependencies and long distance dependencies (length $>$7), but significantly lower for local dependencies. This seems to indicate that large amounts of data are necessary for the parser to recover long distance dependencies.

Our results for Danish, Dutch, German and Portuguese are to the best of our knowledge the best reported results in the literature. Zhang and Chan (2009) obtain a LAS of 87.20 for Swedish with transition-based parsing based on reinforcement learning. They evaluate their system on a subset of the CONLL-X datasets and obtain their (by far) best improvement on the Swedish dataset. They speculate that ”the reason might be that [long distance dependencies] are not popular in Swedish”. Since our parser is particularly good at long distance dependencies, this may also explain why a supervised parser outperforms our system on this dataset. Interestingly, our unlabeled attachment score is a lot better than the one reported by Zhang and Chan (2009), namely 92.45 compared to 91.84.

Generally, our UASs are better than our LASs. Since we separate attachment and labeling out in two independent steps, improvements in UAS and improvements in LA do not necessarily lead to improvements in LAS. While our average error reduction in LAS is 14.9%, our average error reductions in UAS is 23.6%. The average error reduction in LA is 14.0%. In two-stage dependency parsers or dependency parsers with joint models, improvements in UAS are typically followed by comparable improvements in LAS.

6 Conclusion

This paper showed how the stacked dependency parsers introduced in Martins et al. (2008) can be improved by inference from unlabeled data. Briefly put, we stack three diverse classifiers on triads of stacked dependency parsers and let them label unlabeled data for each other in a co-training-like architecture. Our average error reductions in LAS over the best of our stacked input parsers is 14.9%; in UAS, it is 23.6%. The code is available at http://cst.dk/anders/tridep.html.

SemanticRank: Ranking Keywords and Sentences Using Semantic Graphs

George Tsatsaronis [1] and **Iraklis Varlamis** [2] and **Kjetil Nørvåg** [1]
[1]Department of Computer and Information Science,
Norwegian University of Science and Technology

Abstract

The selection of the most descriptive terms or passages from text is crucial for several tasks, such as feature extraction and summarization. In the majority of the cases, research works propose the ranking of all candidate keywords or sentences and then select the top-ranked items as features, or as a text summary respectively. Ranking is usually performed using statistical information from text (i.e., frequency of occurrence, inverse document frequency, co-occurrence information). In this paper we present *SemanticRank*, a graph-based ranking algorithm for keyword and sentence extraction from text. The algorithm constructs a *semantic graph* using implicit links, which are based on semantic relatedness between text nodes and consequently ranks nodes using different ranking algorithms. Comparative evaluation against related state of the art methods for keyword and sentence extraction shows that *SemanticRank* performs favorably in previously used data sets.

1 Introduction

Graph based ranking algorithms can be very helpful when searching for important pages in the World Wide Web, members in a social network, or authors in a publication database. Such algorithms capitalize on the existence of explicit links (e.g., hyperlinks, citations) between the graph vertices. In the case of flat text collections, neither links nor citations exist, so the need to devise implicit edges between text keywords or sentences arises. One feasible solution is to exploit the contextual information of terms and create semantic graphs from text based on content similarity. However, conceptual analysis of text has a strong potential in this direction, since it reveals latent similarities between text segments that discuss the same subject but with different terminology. In this direction, we introduce *SemanticRank*, a new algorithm for ranking text segments. *SemanticRank* comprises two steps: (a) creation of semantic graphs from text using both semantic and statistical information, and (b) application of a graph-based ranking algorithm that exploits the edges' weights.

The key contributions of this work are: (1) a novel method for the construction and weighting of the semantic graph, which contains text segments (terms or sentences) as nodes and weighted edges that capture the semantic relatedness (i.e., relatedness in meaning) between nodes but also consider statistical information, (2) the modular design of the method, which allows any graph-based ranking algorithm to be employed, and (3) thorough experimental evaluation of *SemanticRank* in the keyword extraction and text summarization tasks, and evaluation of several alternatives for the graph-based ranking component.

The paper is organized as follows: Section 2 discusses related work. Section 3 presents the preliminaries of *SemanticRank*: the semantic relatedness measure, the graph creation process and the ranking algorithm alternatives. Section 4 provides the details of our method. Section 5 presents the experimental evaluation of *SemanticRank* in two different tasks: keyword extraction and text summarization. Finally, Section 6 concludes and provides pointers to future work.

2 Related Work

This work addresses the problem of extracting the most representative keywords and sentences from text as a means of text summarization. More specifically, *SemanticRank* capitalizes on the creation of term and sentence graphs from text and on graph-based ranking algorithms in order to support the following tasks: (a) keyword extraction from text, which is performed by selecting the top-ranked terms as the most representative ones, and (b) text summarization, which is done by selecting the top ranked sentences as the most representative ones. For this reason, a survey of research works in keyword extraction and text summarization, with emphasis on graph-based approaches is necessary to understand the requirements for these tasks, to locate benchmark data sets, and state of the art graph-based approaches for the comparative evaluation.

2.1 Keyword Extraction

Keyword extraction is an important task in document indexing, and strongly affects the performance of re-

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 1074–1082,
Beijing, August 2010

trieval, classification clustering, and summarization. Most keyword extraction approaches rely on statistical measures such as term frequency (TF), inverse document frequency (IDF), and variations (Aizawa, 2003). Several works in keyword extraction construct semantic networks from text in order to capture the implicit relations between the individual candidates. Huang et al. (2006) propose the construction of one semantic network per document, and use edges that capture syntactic relations between document terms. Mihalcea and Tarau (2004) suggest a semantic network model where edges express the co-occurrence of terms in the document's sentences. Wang et al. (2007) employ the well known *PageRank* algorithm to perform word sense disambiguation (WSD) and keyword extraction from documents. The graphs that they construct are always subgraphs of the *WordNet* thesaurus[1], which results in low text coverage.

In this work we aim at the design and implementation of a keyword extraction algorithm that takes into account different aspects of text, such as statistical information and the semantic relatedness between keywords. To the best of our knowledge, the current work is the firs to propose a semantic network construction model for keyword extraction based on measures of semantic relatedness between keywords. In Section 3 we discuss the employed measure of semantic relatedness, which utilizes both *WordNet* and *Wikipedia*[2] to increase term coverage.

2.2 Text Summarization

The aim of automatic text summarization is to generate a summary of a pre-specifie length for a given input text. The *Document Understanding Conference* (DUC) [3] series have provided benchmark data sets with documents and manually generated summaries, which can be used for the evaluation of any automatic text summarizer. Research works in this area conduct automatic text summarization by selecting the most important sentences from the input texts (Steinberger and Jezek, 2009). Baseline methods are based on the observation that important sentences inside a text usually occur at its beginning. Thus, a straightforward baseline is to select the firs k sentences as a summary of the text, and setting k in such a way that does not violate the summary length restriction.

Another important class of automated text summarization methods is that of cohesion-based methods. Such methods assume that the important sentences or paragraphs of a given text document are the most connected entities in more or less elaborate semantic structures inside the text. In this direction, the methods construct a graph for each text document, with the vertices being the document sentences, and attempt to determine the most connected vertices in each graph. These methods are further classifie depending on how the graph's edges are constructed, for example using word co-occurrences (Salton et al., 1997), local salience and grammatical relations (Boguarev and Kennedy, 1997), co-reference (Baldwin and Morton, 1998), and combinations of the aforementioned (Mani and Bloedorn, 1998).

More recently, some cohesion-based methods have attempted to capture the semantic similarity of sentences inside a text document, and rank sentences in the constructed semantic graph. For example in the method of Mihalcea and Tarau (2004), the graph contains a vertex for each sentence of the given text document, and weighted edges between sentence. The weights represent the semantic similarity between sentences and are actually the contextual overlap between the sentences' terms. The *PageRank* algorithm is then applied to rank sentences in each of the constructed semantic graphs. In the method of Litvak and Last (2008), the vertices are again the sentences of the given text document and the edges represent the syntactic relations between them. Finally, the *HITS* algorithm is applied on the graph for ranking the sentences.

The conclusion from the literature review is that modern trends in graph-based approaches focus on novel methodologies for weighting edges and constructing semantic graphs, and employ standard techniques for ranking vertices, such as *PageRank*, *HITS*, or variations. Another important findin is that the potentiality of creating the edges between the vertices based on measures of semantic relatedness among the respective nodes is unexploited so far, and this is the core of the current work. Thus, the main difference between *SemanticRank* and the aforementioned approaches is that our edge weighting method employs a measure of semantic relatedness between sentences, that is based on *WordNet* and *Wikipedia*. The motivation behind such a perspective is that such semantic graphs would capture the similarity in meaning among the graph vertices, which was neglected by previous approaches. Finally, regarding the data sets used for evaluation, most works in text summarization use past *DUC* data, whereas in the case of keyword extraction a subset from the *Inspec* bibliographic database has been used in several cases in the past (Mihalcea and Tarau, 2004; Hulth, 2003).

3 Terminology and Preliminaries

A graph-based method for ranking keywords or sentences by constructing semantic graphs comprises two steps: (a) the creation of the semantic graph, with keywords or sentences as vertices, and edges constructed based on a semantic similarity measure between vertices (c.f. Section 3.2), and (b) the adaptation of a new or existent ranking algorithm which analyzes the graph structure and ranks the nodes. Section 3.1 introduces the used terminology. In Section 3.2 we explain how the firs step is done by *SemanticRank*, and in Section 3.3 we present several alternatives for the second step.

3.1 Terminology

In the following we denote with $T(t_i, t_j)$ a pair of terms that occur in text document T. We also assume that T is a member of a document collection D given as input to our method. O represents the used knowledge-base (e.g., thesaurus, dictionary); in our case we are using two such knowledge-bases, namely *WordNet* and *Wikipedia*. With $\mathit{SR}_O(t_i, t_j)$ we denote the semantic relatedness between terms t_i and t_j using O for its computation, and $\mathit{SRS}(A, B)$ represents the semantic relatedness between text segments A and B (e.g., documents, sentences).

Concerning *WordNet*, S_i (S_j) represents the set of the different meanings (senses) with which t_i (t_j) may appear in O. P_{ij} denotes the set of paths connecting senses in S_i with senses in S_j, as these may be found using O. P_{ij}^k represents one such path in the set of paths P_{ij}, namely the k_{th} path. S_{ij} stands for the set of all possible sense pairs between the set of senses S_i and the set of senses S_j. Thus, $|S_{ij}| = |S_i| * |S_j|$. Respectively, S_{ij}^m stands for one such combination, namely the m_{th} combination.

With regards to Wikipedia, W refers to all the *Wikipedia* articles. With a_i we denote the *Wikipedia* article for term t_i. $\mathit{In}(a_i)$ is the set of *Wikipedia* articles that contain at least one link to a_i.

Finally, if d_i is the i_{th} document of D and t_a a term in d_i, then we denote with $\mathit{TF\text{-}IDF}(t_a, d_i) = \frac{\mathit{Count}(t_a,d_i)}{|d_i|} \cdot \log_2 \frac{\mathit{Count}(t_a,D)+1}{|D|}$ the *TF-IDF* weight of t_a in d_i, where $|d_i|$ is the number of term occurrences in d_i, $|D|$ is the number of documents in D, $\mathit{Count}(t_a, d_i)$ the number of occurrences of t_a in d_i, and $\mathit{Count}(t_a, D)$ the number of documents in D that contain t_a.

3.2 Creating Semantic Graphs from Text

A huge volume of literature has been created on how to construct semantic graphs addressing various applications, such as word sense disambiguation (Agirre and Soroa, 2009), keyword and sentence extraction (Mihalcea and Tarau, 2004; Litvak and Last, 2008; Yeh et al., 2008), and computation of semantic relatedness or similarity between terms (Gabrilovich and Markovitch, 2007; Budanitsky and Hirst, 2006; Milne and Witten, 2008).

In this work we adopt a semantic graph construction method which is able to capture the semantic relatedness between terms, as well as text segments. For our purposes we adopt *Omiotis*, the measure proposed by Tsatsaronis et al. (2010) in order to construct and weigh the edges of the semantic graph. *Omiotis* is a knowledge-based measure of semantic relatedness that may capture the semantic relatedness between both keywords and text segments (e.g., sentences, documents), allowing us to construct both semantic keyword graphs for keyword extraction, and semantic sentence graphs for sentence extraction and summarization. Our selection also lies in the fact that *Omiotis* has been shown to perform very well compared to other known measure of semantic relatedness or similarity in tasks such as term-to-term similarity (Tsatsaronis et al., 2010; Budanitsky and Hirst, 2006). However, since *Omiotis* relies solely in *WordNet*, we enhance the coverage of *SemanticRank* by complementing the edge weighting with an additional *Wikipedia*-based measure, namely the measure proposed by Milne and Witten (*MLN*) (2008). In Section 3.2.1 we explain how these two measures are combined in order to compute the semantic relatedness between terms, and in Section 3.2.2 we explain how semantic relatedness is captured between sentences.

3.2.1 Semantic Relatedness Between Terms

The measure presented in (Tsatsaronis et al., 2010) define the semantic relatedness between a pair of terms as shown in Equation 1, where the knowledge-base *O* is *WordNet* (*WN*).

$$\mathit{SR}_{\mathit{WN}}(t_i,t_j)=\max_m\{\max_k\{\mathit{SCM}(S_{ij}^m,P_{ij}^k)\cdot\mathit{SPE}(S_{ij}^m,P_{ij}^k)\}\} \quad (1)$$

where *SCM* and *SPE* are called *Semantic Compactness* and *Semantic Path Elaboration* respectively. Their product measures the weight of the path connecting the two senses in S_{ij}^m, taking into account: the path length, the type of the semantic edges comprising it, and the depth of the intermediate nodes in the *WN* senses hierarchy. The semantic relatedness between two terms t_i, t_j, when $t_i \in \mathit{WN}$ and $t_j \notin \mathit{WN}$, or vice versa, is considered 0. The intuition behind Equation 1 is that the semantic relatedness between two terms should be computed based on the *highest value* path connecting any pair of senses of the two terms. The computation of the *value* takes into account in tandem all of the aforementioned factors.

In order to enhance the coverage of the measure in Equation 1, we combine it with the *WLM Wikipedia*-

based measure of Milne and Witten (2008), which is a low-cost solution for measuring relatedness between terms using the *Wikipedia* articles and link structure as a knowledge base. The semantic relatedness between two terms t_i and t_j according to *WLM* is defined as shown in Equation 2. The intuition behind this formula is that the semantic similarity between two terms becomes higher, as the number of articles pointing to both respective *Wikipedia* articles increases (i.e., as the percentage of the articles linking to both pages compared to the number of articles linking to either of them increases).

$$SR_{Wiki}(t_i,t_j)=\frac{log(\max\{|In(a_i)|,|In(a_j)|\})-log(|In(a_i)\cap In(a_j)|)}{log(|W|)-log(\min\{|In(a_i)|,|In(a_j)|\})} \tag{2}$$

We combine the two measures in a single measure $SRT(t_i, t_j)$, as shown in Equation 3. The reason we prioritize $SR_{WN}(t_i, t_j)$ from $SR_{Wiki}(t_i, t_j)$, when both terms exist in *WN*, is because the former measure has shown much better performance in capturing the semantic relatedness between terms.

$$SRT(t_i, t_j) = \begin{cases} 1, & t_i = t_j \\ SR_{WN}(t_i, t_j), & \text{if } t_i, t_j \in \textit{WordNet} \\ SR_{Wiki}(t_i, t_j), & \text{if } t_i, t_j \in \textit{Wikipedia} \\ 0, & \text{otherwise} \end{cases} \tag{3}$$

3.2.2 Semantic Relatedness Between Texts

To quantify the semantic relatedness for a pair of text segments, we build upon the *SRT* measure, but also take into account the statistical importance of the terms occurring in the respective texts. Given two text segments A and B, and two terms $t_a \in A$ and $t_b \in B$, a measure that combines the statistical importance of t_a and t_b, according to (Tsatsaronis et al., 2010), is the harmonic mean of their *TF-IDF* weights. We denote this quantity as λ_{t_a,t_b}. Then for each term $t_a \in A$, we search for the corresponding term $t_b \in B$, which we symbolize with b_*, that maximizes the product of their combined statistical importance and semantic similarity. In our case, b_* is found by Equation 4. Similarly we can find for each $t_b \in B$ the corresponding a_*.

$$b_* = \arg\max_{t_b \in B}\{\lambda_{t_a,t_b} \cdot SRT(t_a, t_b)\} \tag{4}$$

After finding the set of all b_* and a_* terms, the semantic relatedness between the two texts A and B is computed as shown in Equation 5.

$$SRS(A, B) = \frac{\theta(A, B) + \theta(B, A)}{2} \tag{5}$$

where $\theta(A, B) = \frac{1}{|A|}\sum_{t_a \in A} \lambda_{t_a,b_*} \cdot SRT(t_a, b_*)$, and $\theta(B, A)$ can be computed respectively. The measure in Equation 5 is the measure used by *SemanticRank* to construct the edges between sentence vertices in the case of the semantic sentence graphs for text summarization. Regarding which sense of each term is used for the computation of its semantic relatedness with any other term, the senses that maximize the measure in Equation 3 are picked in each case.

3.3 Ranking Nodes in Semantic Graphs

For the purposes of our experimentation we will be evaluating *SemanticRank* with variations of the known *PageRank* and *HITS* algorithms. Some of those variations are applied for the first time in the framework of ranking nodes in semantic graphs. However, as will be explained in Section 4, in *SemanticRank*, any available vertex ranking methodology can be used instead.

The original versions of *PageRank* and *HITS* rely on the *"rich get richer"* model, which is based on explicit links and ignores edges weights. More specifically, HITS prioritizes good hubs and authorities, whereas PageRank uses a dampening factor (β) in order to avoid clique attacks and promote the centrality of nodes. However, in the case of graphs with implicitly devised links, like in semantic graphs, the edges carry weights, which must be taken into account. In this direction, we employ a modified version of the original *PageRank* algorithm, first introduced by Mihalcea and Tarau (2004). The modified *PageRank* is shown in Equation 6.

$$WPR(i) = (1 - \beta) + \beta \cdot \sum_{j \in IN(i)} \frac{w_{ij} \cdot WPR(j)}{\sum_{k \in OUT(j)} w_{jk}} \tag{6}$$

where i, j, k represent vertices, $IN(i)$ and $OUT(j)$ are the sets of *inlink* nodes of i and *outlink* nodes of j respectively, and w_{ij} is the weight of the edge between nodes i and j. In the case of semantic graphs constructed for keyword extraction, nodes are terms, and, thus, $w_{ij} = SRT(t_i, t_j)$. In the case of semantic graphs constructed for text summarization, i and j are sentences, and, thus, $w_{ij} = SRS(i, j)$.

Similarly to the modification shown in Equation 6 for *PageRank*, we can define a weighted version of *HITS*. The respective *authority* and *hub* scores are shown in Equations 7 and 8.

$$authority(i) = \sum_{j \in In(i)} w_{i,j} \cdot hub(j) \tag{7}$$

$$hub(i) = \sum_{j \in Out(i)} w_{i,j} \cdot authority(j) \tag{8}$$

The aforementioned modifications have been already applied in the past in the case of semantic graphs, with application to keyword extraction and text summarization (Mihalcea and Tarau, 2004; Mihalcea, 2004), although using different semantic graphs. For the extraction of the most important nodes, the modified *PageRank* version is used to rank the nodes according to their final *PageRank* values, and the modified *HITS* to rank nodes according to their final *authority* values. In this work, we also consider and evaluate two additional modifications of *PageRank* in order to rank vertices in the case of the semantic keyword graphs. The first modification that we call *Averaged PageRank Weighting* (*APW*) is presented in Equation 9, and is used after the weighted *PageRank* of Equation 6 has executed. The intuition behind *APW* is that each vertex t_i in the case of the keyword semantic graphs, has a known importance based on its frequency of occurrence (*TF-IDF* weight) inside the given document collection D. Thus, *APW* considers both the importance of vertex t_i inside its semantic graph, and inside its document collection.

$$APW(t_i) = \frac{1}{2}\left(\frac{WPR(t_i)}{WPR_{max}} + \frac{TF\text{-}IDF(t_i, d_j)}{TF\text{-}IDF_{max}}\right) \quad (9)$$

where d_j the specific document from which the semantic keyword graph is created, WPR_{max} is the maximum *PageRank* score found in this graph, and $TF\text{-}IDF_{max}$ is the maximum *TF-IDF* weight found in document d_j.

The second *PageRank* modification that is employed for the first time in the case of semantic keyword graphs is the *priors biased PageRank* (*P-PR*) discussed in (White and Smyth, 2003). The idea is very similar to the works in (Haveliwala, 2002) and (Agirre and Soroa, 2009), and pertain to ranking the nodes in the graph, with regards to a given set of nodes called *priors*. In short, while *PageRank* provides a global ranking of the nodes in the graph, *P-PR* provides a ranking of the nodes with regards to the set of the given *prior* nodes. This is expressed in Equation 10. The only difference with equation 6 is that each node i has its own "*random jump*" probability to the *prior* nodes. Thus, for each node i, *P-PR* has a β_i, which expresses how often we may jump back to the set of the *prior* nodes from node i. The intuition behind *priors* is that certain nodes in the graph are favored against other. In a keyword extraction task the *priors* set may contain the keywords appearing in the document's title.

$$P\text{-}PR(i) = (1-\beta_i)+\beta_i \cdot \sum_{j \in IN(i)} \frac{w_{ij} \cdot P\text{-}PR(j)}{\sum_{k \in OUT(j)} w_{jk}} \quad (10)$$

4 SemanticRank

In this section we present *SemanticRank* (illustrated in Algorithm 1), our algorithm for ranking terms and sentences based on their semantic relatedness. The first step of *SemanticRank* is the semantic graph creation. In the case of semantic keyword graphs, and given a document d_j which belongs in a document collection D, as a preprocessing step, the algorithm detects all $n-$grams of size up to 5 words using a dictionary look-up (i.e., both *WordNet* and *Wikipedia*), and a sliding window, in order to identify candidate keywords, which may be essentially composite terms. The resulting set of terms (i.e., can be terms of 1 to 5 words), which we denote as K_{d_j}, is used for the creation of a graph G with the vertices being all the distinct terms $t_i \in K_{d_j}$. As edge weights w_{ij} *SemanticRank* uses $SRT(t_i, t_j)$ which captures the semantic relatedness between terms t_i and t_j. However, ideally we would also like to incorporate in w_{ij} the statistical information of terms t_i, t_j that we have from

Algorithm 1 SemanticRank(D,*Mode*)

```
INPUT: A text document collection $D$, and a Mode flag
OUTPUT: A ranking $R$ of the semantic graph nodes for every document $d_j \in D$.
Execute(D,Mode)
if Mode is Keywords then
    Identify composite terms of length up to 5 words
end if
Compute and index TF-IDF values for all terms
for all $d_j \in D$ do
    $G$: An initially empty graph
    $G$ = Construct_Semantic_Graph($d_j$,Mode)
    $R$ = Rank_Nodes($G$)
end for
Construct_Semantic_Graph($d_j$,Mode)
$G$: an initially empty graph
if Mode is Keywords then
    Initialize $G$ with $K_{d_j}$
else
    Initialize $G$ with $Sen_{d_j}$
end if
for all pairs of vertices $(v_i, v_j)$ do
    if Mode is Keywords then
        $w_{i,j} = w_{j,i} = \lambda_{v_i,v_j} \cdot SRT(v_i, v_j)$
    else
        $w_{i,j} = w_{j,i} = SRS(v_i, v_j)$
    end if
end for
RETURN $G$
Rank_Nodes(G)
Execute Weighted PageRank in $G$
$R$ = Rank vertices of $G$ in descending order of PageRank values
RETURN $R$ with their PageRank values
```

their frequency of occurrence inside d_j and D. Thus, Equation 11 shows this combination, and it is the formula according to which *SemanticRank* computes the edge weights w_{ij} in the case of the semantic keyword graphs. In the case of semantic sentence graphs creation, *SemanticRank* initializes G with all the distinct sentences Sen_i in d_j as vertices, and it uses Equation 5 to compute the weights between every pair of vertices (i.e., between every pair of sentences). In Algorithm 1 we denote the set of distinct sentences in d_j with Sen_{d_j}.

$$w_{ij} = \lambda_{t_i,t_j} \cdot \mathit{SRT}(t_i, t_j) \tag{11}$$

In both cases, for the given document d_j, and after the creation of the semantic graph, nodes may be ranked according to the values produced by applying either Equation 6, or Equations 7 and 8. For the case of semantic keyword graphs, the top-k ranked nodes are selected as the most important keywords of d_j. For the case of semantic sentence graphs, the top-k ranked nodes are selected as the set of sentences, put together to constitute the automatically generated summary of d_j. In Algorithm 1 we may substitute line 26 with any of the ranking options discussed in Section 3.3. An analogy can be also drawn with PageRank's *random surfer model*, where a user browses the Web by following links from any given Web page. In the context of text modelling, *SemanticRank* implements what we refer to as *text surfing*, which relates to the concept of text cohesion (Halliday and Hasan, 1976), i.e., from a certain concept in a text, we are likely to *follow* ”links” to related concepts, meaning concepts that have lexical or semantic relation to the current concept.

5 Experimental Evaluation

The experimental evaluation is performed in two tasks: (a) keyword extraction, and (b) text summarization. In both cases we create a semantic graph for each document and we rank the nodes accordingly, using Algorithm 1. For our evaluation we use all the ranking algorithm alternatives described in Section 3.3, and compare results with state of the art approaches that use the same ranking algorithms but different graph creation and edge weighting approaches. The various tested ranking alternatives are: weighted *SemanticRank* (*Sem*) using *PageRank* (*WPR*), and *HITS* (*WHITS*), and unweighted *SemanticRank* (*USem*) using the original versions of *PageRank* (*UPR*) and *HITS* (*UHITS*). In the case of keyword extraction we evaluate additionally the *Averaged PageRank Weighting* (*APW*) and *PageRank Priors* (*PPR*), where the *prior* nodes were set to the terms occurring in each abstract's title.

Table 1: Results of the keyword extraction task in the Inspec database.

5.1 Keyword Extraction

We applied *SemanticRank* in an automated keyword extraction task on the Inspec database[4]. The Inspec database stores abstracts of journal papers from computer science and information technology and the keyword extraction task aims in selecting the most descriptive keywords for each abstract. Each abstract has been already assigned keywords by professional indexers, which constitute the gold standards for systems' comparison. The mean number of assigned terms per abstract from the experts is 7.63. The goal is to extract as many of the keywords suggested by the professional indexers as possible for each abstract. In this data set our results are directly comparable to the works in (Mihalcea and Tarau, 2004) and (Hulth, 2003).

We evaluate *SemanticRank* (*Sem*) using varying k values $(5, 10, 15$, and $20)$, where k stands for the number of keywords to be extracted from each abstract. In Table 1 we report the results of macro-averaged pre-

Baseline		0.4779

Table 3: Results (F-Measure) of the single-document summarization task, (DUC 2002).

cision (P), recall (R), and F-Measure (F) over all abstracts. Precision for each abstract is the number of correctly extracted keywords, divided by the number of extracted keywords, and recall differs only in the denominator (number of keywords suggested by the indexers). We also present the best reported results for the algorithms in (Mihalcea and Tarau, 2004), and (Hulth, 2003).

Results show that *SemanticRank* with weighted *PageRank* gives better F-Measure from the approaches in (Mihalcea and Tarau, 2004) and (Hulth, 2003) for $k = 15$ and $k = 20$ and always better from weighted *HITS*. *APW* and *P-PR* have higher F-Measure than *WPR*, achieving top performance (bold values), with *APW* producing the best F-Measure for $k = 20$. In this case, the difference between *APW* and *TextRank*, both in precision and recall, was found statistically significant at the 0.95 confidence level, using Fisher's exact test. In addition, we can observe that the unweighted versions of *PageRank* and *HITS* produce very poor results. This shows that our method benefits greatly from the suggested edges' weighing scheme.

5.2 Text Summarization

We evaluated *SemanticRank* in two different text summarization tasks: single-document, and multi-document summarization. As in the keyword extraction task, we evaluate both the weighted and the unweighted versions of *SemanticRank* (*Sem* and *USem*) using *WPR*, *WHITS*, *UPR*, and *UHITS* respectively. We also compare against state of the art results in the used data sets, and we report on results from related methods (i.e., *TextRank*) when possible.

5.2.1 Single Document Summarization

In the single-document summarization task we have used the data sets of the *Document Understanding Conference* (*DUC*) from the 2001 and 2002 competitions. The two data sets comprise 308 and 567 news articles respectively. For both data sets, two reference summaries per document were provided. The task for the participating systems in both competitions was to provide for each document a summary of at most 100 words. Thus, we apply *SemanticRank* by first ranking sentences following Algorithm 1, and then by merging them, starting from the top ranked sentences, until the 100 words limit is reached. For the evaluation against the reference summaries, we are using the *ROUGE* toolkit, which is based on $N-$grams, and has been the standard evaluation methodology for the summarization task (Lin and Hovy, 2003) in all the recent DUC competitions. Since in *DUC* 2001 and *DUC* 2002 the *ROUGE* system was not the standard evaluation toolkit, we implemented the evaluation of the two tasks in *ROUGE*. The setup we adopted for ROUGE was (*Ngram(1,1)*, stemmed words and no stopwords), identical to the one adopted in (Mihalcea and Tarau, 2004).

In Table 2 we present the F-Measure values produced from *ROUGE* for *SemanticRank*, and the top 5 performing systems (participating systems *T*, *P*, *O*, *V*, and *Q*), for the 2001 data set. Similarly, Table 3 presents the results for the 2002 data set. In both cases we report the performance of a simple baseline method, that takes the first sentences from each article, until the limit of 100 words is reached. When available, we also present the results from (Mihalcea and Tarau, 2004), and also the 0.95 confidence intervals for the F-Measure values, as these were generated by *ROUGE*. The results in the two tables show that *SemanticRank*, when the weighted version of PageRank is used, produces very high F-Measure score. In both cases, our system ranks among the top 2 systems in the task.

System		F (R-2)	F (R-SU4)
Sem	WPR	0.093	0.133
	WHITS	0.078	0.115
USem	UPR	0.031	0.069
	UHITS	0.028	0.062
S40		0.111	0.143
S55		0.098	0.135
S45		0.096	0.132
S44		0.093	0.136
S47		0.093	0.130
Baseline		0.085	0.122

Table 4: Results of the multi-document summarization task (DUC 2007 update task).

5.2.2 Multi Document Summarization

For the multi document summarization task we used the data from the *DUC 2007 update task*. The data set consists of 250 documents organized in topics, and each topic is further divided into three clusters, for each of which gold standard summaries are provided by evaluators. In this case, the average of *ROUGE-2* and *ROUGE-SU4* scores are used for evaluation. Table 4 presents the average F-Measure values for both scores. We also report the top-5 performing systems in the respective task, as well as the performance of the generic baseline that was used in this case. As Table 4 shows, the combination of *SemanticRank* with the weighted *PageRank* produces better results than weighted *HITS* and the unweighted versions. This drop in performance compared to the results in the single-document summarization task can be partly explained by the fact that in this case the *DUC 2007 update task* allows for the system to assume previous knowledge for the document clusters B and C of each topic. In our case, we have not embedded any methodology that takes advantage of this knowledge.

Regarding the top system in Table 4, system *S40*, is the system called *GISTEXTER* (Hickl et al., 2007). *GISTEXTER* uses textual inference and textual contradiction to construct representations of knowledge encoded in a document collection. The system comprises four components: question processing, sentence retrieval, sentence ranking, and summary generation. However, for the summary generation component, a set of heuristics is used to generate the summary. In a similar approach (Amini and Usunier, 2007), where coherent text fragments are sought with regards to the initial question, the authors show that query expansion using a contextual approach may lead to find important terms for the summary, among different related documents. Their system ranked among the top in the main task of *DUC 2007*, leading to the conclusion that for a multi-document summarization system, a contextual approach might be more efficient than *SemanticRank*.

However, from the results presented in Tables 2, 3 and 4, we experienced a very good performance of *SemanticRank* in ranking sentences for the text summarization task, with the weighted ranking variations producing always better results than the unweighted.

6 Conclusions and Future Work

In this paper we introduced *SemanticRank*, a new algorithm for ranking keywords and text segments using measures of semantic relatedness. The novelty of the algorithm is its semantic graph creation step, which is based on a measure of semantic relatedness that combines *WordNet* and *Wikipedia*. We evaluated *SemanticRank* using several alternatives for its ranking step, all based on weighted and unweighted variations of *PageRank* and *HITS*. Results in keyword extraction and text summarization experiments show that it performs favorably over state of the art related methods, and that the selected edges' weighting boosts its performance. In our future work we will examine the potentiality of more graph-based ranking methods, and it is on our next plans to embed *SemanticRank* on more linguistic tasks, such as sentiment analysis and opinion mining.

Chinese CCGbank:
extracting CCG derivations from the Penn Chinese Treebank

Daniel Tse and **James R. Curran**
School of Information Technologies
University of Sydney
{dtse6695,james}@it.usyd.edu.au

Abstract

Automated conversion has allowed the development of wide-coverage corpora for a variety of grammar formalisms without the expense of manual annotation. Analysing new languages also tests formalisms, exposing their strengths and weaknesses.

We present Chinese CCGbank, a 760,000 word corpus annotated with Combinatory Categorial Grammar (CCG) derivations, induced automatically from the Penn Chinese Treebank (PCTB). We design parsimonious CCG analyses for a range of Chinese syntactic constructions, and transform the PCTB trees to produce them. Our process yields a corpus of 27,759 derivations, covering 98.1% of the PCTB.

1 Introduction

An annotated corpus is typically used to develop statistical parsers for a given formalism and language. An alternative to the enormous cost of hand-annotating a corpus for a specific formalism is to convert from an existing corpus.

The Penn Treebank (PTB; Marcus et al., 1994) has been converted to HPSG (Miyao et al., 2004), LFG (Cahill et al., 2002), LTAG (Xia, 1999), and CCG (Hockenmaier, 2003). Dependency corpora, e.g. the German Tiger corpus, have also been converted (Hockenmaier, 2006). The Penn Chinese Treebank (PCTB; Xue et al., 2005) provides analyses for 770,000 words of Chinese. Existing PCTB conversions have targeted TAG (Chen et al., 2005) and LFG (Burke and Lam, 2004; Guo et al., 2007).

We present Chinese CCGbank, a Chinese corpus of CCG derivations automatically induced from the PCTB. Combinatory Categorial Grammar (CCG; Steedman, 2000) is a lexicalised grammar formalism offering a unified account of local and non-local dependencies. We harness the facilities of CCG to provide analyses of Chinese syntax including topicalisation, pro-drop, zero copula, extraction, and the 把 *ba-* and 被 *bei*-constructions.

Pushing the boundaries of formalisms by subjecting them to unfamiliar syntax also tests their universality claims. The freer word order of Turkish (Hoffman, 1996) and the complex morphology of Korean (Cha et al., 2002) led to the development of extensions to the CCG formalism.

We present our analysis of Chinese syntax under CCG, and provide an algorithm, modelled after Hockenmaier and Steedman (2007), to incrementally transform PCTB trees into CCG derivations. The algorithm assigns CCG categories which directly encode head and subcategorisation information. Instances of Chinese syntax demanding special analysis, such as extraction, pro-drop or topicalisation, are pin-pointed and given elegant analyses which exploit the expressivity of CCG.

Our conversion yields CCG analyses for 27,759 PCTB trees (98.1%). Coverage on lexical items, evaluated by 10-fold cross-validation, is 94.46% (by token) and 73.38% (by type).

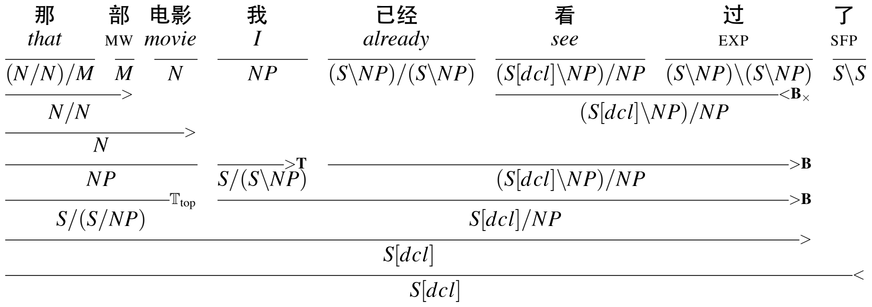
We present the first CCG analysis of Chinese syntax and obtain a wide-coverage CCG corpus of Chinese. Highly efficient statistical parsing using a CCGbank has recently been demonstrated for English (Clark and Curran, 2007). Our Chinese CCGbank will enable the development of similarly efficient wide-coverage CCG parsers for Chinese.

2 Combinatory Categorial Grammar

CCG (Steedman, 2000) is a lexicalised grammar formalism, with a transparent syntax-semantics interface, a flexible view of constituency enabling concise accounts of various phenomena, and a consistent account of local/non-local dependencies.

It consists of *categories*, which encode the type and number of arguments taken by lexical items, and *combinators*, which govern the possible interactions between categories.

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 1083–1091,
Beijing, August 2010



那 部 电影 我 已经 看 过 了

S/(S/NP) S[dcl]/NP
S[dcl]
S[dcl]

Figure 1: Chinese CCG derivation: "That movie, I've already seen."

A CCG grammar defines *atomic categories*, e.g. *NP* and *S*, which may be recursively constructed into *complex categories*, e.g. N/N and $S\backslash NP$.[1] Figure 1 shows how combinators govern the interaction of categories for lexical items, while slashes specify argument directionality.

The combinators allow us to reduce lexical ambiguity, by preserving a word's canonical category even when displaced from its canonical position. This facility is a strength of CCG, but elevates its generative power to mild context-sensitivity.

Some combinators may be disabled in a given language – the *multi-modal* CCG (Baldridge, 2002) allows these distinctions to be lexically specified.

Introducing non-CCG rules decrease categorial ambiguity at the expense of deviating from the formalism. Hockenmaier and Steedman (2002) show that these greatly improve lexical coverage. Their analysis of English employs non-CCG rules to coerce a verb phrase headed by a participle (category $S[ng]\backslash NP$) to a post-nominal modifier:

$$S[ng]\backslash NP \longrightarrow NP\backslash NP \qquad (1)$$

This frees verbs from having to possess a distinct category in each position, thus trading off lexical ambiguity for derivational ambiguity. Honnibal and Curran (2009) extended CCG with *hat categories*, enabling the lexical specification of these unary type-change rules.

Hockenmaier and Steedman (2002, 2007) developed CCGbank, the first wide-coverage English CCG corpus, by converting 1.2 million words from the Wall Street Journal section of the PTB. CCGbank has made possible the development of wide-coverage statistical parsers for CCG in English, notably C&C (Clark and Curran, 2007).

3 Penn Chinese Treebank

Xue et al. (2005) developed the Penn Chinese Treebank (PCTB), the first syntactically annotated corpus for Chinese. The corpus includes newswire text, magazine articles, and transcribed speech.[2]

Xue et al. establishes several principles for a more disciplined and consistent style of annotation compared to the original PTB. These principles include *complement/adjunct marking:* allowing the recovery of predicate-argument structure; *limited semantic role marking:* the annotation of modifier phrases with semantic roles; *covert argument marking:* the retention of traces of arguments deleted through pro-drop; and *NP internal structure:* bracketing of NP structure where the intended interpretation is clear.

The *one relation per bracketing* principle unambiguously encodes a grammatical relation (chiefly, predication, adjunction, or complementation) through the configuration of a node and its children. Xue et al. developed this principle to assist conversions from the PTB, e.g. Hockenmaier (2003), in resolving argument/adjunct distinctions.

PCTB derivations are pre-segmented, pre-tokenised, and POS tagged. Owing to the dearth of morphology in Chinese, the concept of *part of speech* is more fluid than that of English – the word 比较 *bijiao* 'compare' might be glossed as a verb, adjective, adverb, or noun depending on its context. Noun/verb mis-taggings are a frequent error case for PCFG parsing on PCTB data, compounded in Chinese by the lack of function words and morphology (Levy and Manning, 2003). This ambiguity is better handled by the adaptive multitagging approach used by Clark and Curran (2007) for CCG supertagging, in which each lexical item is tagged with a set of CCG categories.

We present our CCG analysis of Chinese syntax below, followed by our conversion algorithm.

[1] *Abbreviations in this paper:* The directionless slash | stands for one of $\{/, \backslash\}$. We also use the verbal category abbreviations $VP \equiv S\backslash NP$ and $TV \equiv (S\backslash NP)/NP$.

[2] We use the Penn Chinese Treebank 6.0 (LDC2007T36).

4 The syntax of Chinese

4.1 Basic clause structure

Chinese is typologically SVO, with some OV elements (relative clauses, adjunct PPs and noun modifiers precede their heads). Numbers and determiners may not modify nouns directly; a *measure word* must intervene.

The category structure of the grammar may be inferred directly from headedness information. Heads subcategorise for the type, number and directionality of their arguments, while adjuncts receive modifier categories of the form $X \mid X$.

(2)	我	在	超市	买
	I	at	supermarket	buy
	NP	$(VP/VP)/NP$	NP	VP/NP
	了	一	盒	鸡蛋
	PERF	one	box:MW	eggs
	$VP\backslash VP$	$(N/N)/M$	M	N

I bought a box of eggs at the supermarket.

4.2 Topicalisation

In topic-prominent languages, the *topic* refers to information which the speaker assumes is known by the listener. In Mandarin, topicalisation manifests as left-dislocation of the topic phrase (Li and Thompson, 1989). We distinguish *gap* and *non-gap* topicalisation depending on whether the topic is co-referent with a gap in the sentence.[3]

For gapped topicalisation (cf. Figure 1), we adopt the Steedman (1987) topicalisation analysis:

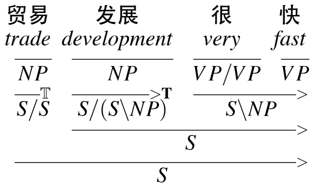
$$T \rightarrow S/(S/T) \text{ for parametrically licensed } T \quad (3)$$

For non-gap topicalisation (Example 5), we use a variation of the analysis described in Hockenmaier and Steedman (2005), which treats the topicalised constituent as a sentential modifier. Under this analysis, the determiner in a topicalised NP receives $(S/S)/N$ instead of its canonical category NP/N. Instead, we propose a unary rule:

$$T \rightarrow S/S \text{ for topicalisation candidate } T \quad (4)$$

This delays the coercion to sentential modifier type (i.e. $NP \rightarrow S/S$) until after the NP has been consolidated, allowing the words under the topicalised NP to preserve their canonical categories.

(5) (As for) trade, it has developed rapidly.



Topicalisation is far less marked in Chinese than in English, and the structure of topicalised constituents is potentially quite complex. The additional categorial ambiguity in Hockenmaier and Steedman (2005) compounds the data sparsity problem, leading us to prefer the unary rule.

4.3 Pro-drop

Since Chinese exhibits *radical pro-drop* (Neeleman and Szendrői, 2007), in which the viability of the pro-drop is not conditioned on the verb, the categorial ambiguity resulting from providing an additional argument-dropped category for every verb is prohibitive.

Rather than engendering sparsity on verbal categories, we prefer derivational ambiguity by choosing the unary rule analysis $S[dcl] \mid NP \rightarrow S[dcl]$ to capture Chinese pro-drop.

4.4 Zero copula

Although the Chinese copula 是 *shi* is obligatory when equating NPs, it may be omitted when equating an NP and a QP or PP (Tiee and Lance, 1986).[4]

(6)	她	今年	十八	岁
	NP	VP/VP	$(S\backslash NP)/M$	M
	3SG	this-year	18	years-old

She is 18 this year.

A solution involving a binary rule $NP\ QP \rightarrow S[dcl]$ is not properly headed, and thus violates the Principle of Lexical Head Government (Steedman, 2000). Conversely, a solution where, for example, 十八 '18' would have to receive the category $(S[dcl]\backslash NP)/M$ instead of its canonical category QP/M would lead to both data sparsity and over-generation, with VP modifiers becoming able to modify the QP directly. Tentatively, we ignore the data sparsity consequences, and have 十八 '18' receive the category $(S[dcl]\backslash NP)/M$ in this context.

[3] Non-gap topicalisation is also known as the *double subject construction* (Li and Thompson, 1989).

[4] The copula is ungrammatical in predication on an adjectival verb, such as 高兴 'happy'. However, we analyse such words as verbs proper, with category $S[dcl]\backslash NP$.

4.5 把 *ba*- and 被 *bei*-constructions

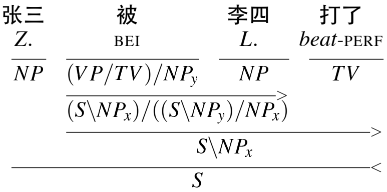
被 *bei* and 把 *ba* introduce a family of passive-like constructions in Chinese. Although superficially similar, the resulting constructions exhibit distinct syntax, as our CCG analysis reflects and clarifies.

In the 被 *bei*-construction, the patient argument of a verb moves to subject position, while the agent either becomes the complement of a particle 被 *bei* (the *long passive*), or disappears (the *short passive*; Yip and Rimmington, 1997). Although the two constructions are superficially similar (apparently differing only by the deletion of the agent NP), they behave differently in more complex contexts (Huang et al., 2008).

The long passive occurs with or without an object gap (deleted by identity with the subject of the matrix verb). We analyse this construction by assigning 被 *bei* a category which permutes the surface positions of the agent and patient. Co-indexation of heads allows us to express long-distance dependencies.

Bei receives $((S\backslash NP_y)/((S\backslash NP_x)/NP_y))/NP_x$ in the gapped case (cf. Example 7) and $((S\backslash NP)/(S\backslash NP_x))/NP_x$ in the non-gapped case.

(7) Zhangsan was beaten by Lisi.



Short passives also occur with or without an object gap, receiving $(S\backslash NP_x)/((S\backslash NP)/NP_x)$ in the gapped case and $(S\backslash NP)\backslash(S\backslash NP)$ in the non-gapped case. Our analysis agrees with Huang et al. (2008)'s observation that short-*bei* is isomorphic to English *tough*-movement: our short-*bei* category is the same as Hockenmaier and Steedman (2005)'s category for English *tough*-adjectives.

In the 把 *ba* construction, a direct object becomes the complement of the morpheme 把 *ba*, and gains semantics related to "being affected, dealt with, or disposed of" (Huang et al., 2008). As for 被 *bei*, we distinguish two variants depending on whether the object is deleted under coreference with the complement of 把 *ba*.

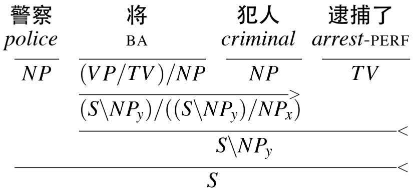
Ba receives $((S\backslash NP_y)/((S\backslash NP_y)/NP_x))/NP_x$ in the gapped case (cf. Example 8), and $((S\backslash NP_y)/(S\backslash NP_y))/NP$ in the non-gapped case.

As Levy and Manning (2003) suggest, we reshape the PCTB analysis of the *ba*-construction so that *ba* subcategorises for its NP and VP, rather than subcategorising for an IP sibling, which allows the NP to undergo extraction.

Tag	*Headedness*	*Example*
VSB	head-final	规划 建设 'plan [then] build'
VRD	right-adjunction	煮 熟 'cook done'
VCP	head-initial	确认 为 'confirm as'
VCD	appositive	投资 设厂 'invest [&] build-factory'
VNV	special	去 不 去 'go [or] not go'
VPT	special	离 得 开 'leave able away'

Table 1: Verb compounds in PCTB

(8) The criminals were arrested by the police.



4.6 Verbal compounding

Verbs resulting from compounding strategies are tagged and internally bracketed. Table 1 lists the types distinguished by the PCTB, and the headedness we assign to compounds of each type.

Modifier-head compounds (PCTB tag VSB) exhibit clear head-final semantics, with the first verb V_1 causally or temporally preceding V_2. Verb coordination compounds (VCD) project multiple heads, like ordinary lexical coordination.

In a resultative compound (VRD), the result or direction of V_1 is indicated by V_2, which we treat as a post-verbal modifier. The *V-not-V* construction (VNV) forms a yes/no question where $V_1 = V_2$. In the *V-bu/de-V* or potential verb construction (VPT), a disyllabic verb $V = V_1V_2$ receives the infix 得 *de* or 不 *bu* with the meaning *can/cannot V*. In both these cases, it is the infixed particle 得 *de* or 不 *bu* which collects its arguments on either side.

4.7 Extraction

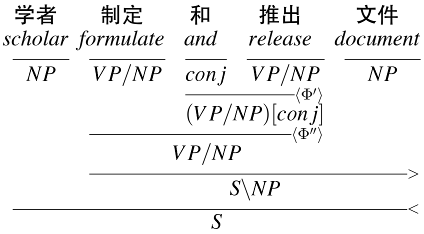
In the Chinese relative clause construction, the particle 的 *de* links a sentence with a subject or object gap with a NP to which that gap co-refers, in an analysis similar to the English construction described by Hockenmaier and Steedman (2005), mediated by the relative pronoun *that*.

As in the English object extraction case, forward type-raising on the subject argument, and forward composition into the verbal category allows us to obtain the correct object gap category S/NP.

4.8 Right node raising

Two coordinated verbs may share one or more contiguous arguments under right node raising. This analysis follows directly from the CCG definition of coordination, requiring no new lexical categories.

(9) Scholars have formulated and are releasing the documents.



4.9 Apposition

Apposition is the juxtaposition of two phrases referring to the same entity. Unlike noun modification, no clear modification relationship holds between the two phrases. The direct juxtaposition rules out Hockenmaier's (2003) analysis where a delimiting comma mediates the apposition. Chinese also allows full sentence/NP apposition:

(10) (用户 浪费 水)$_S$ 事件$_{NP}$
(users waste water)$_S$ incident$_{NP}$
incidents of users wasting water

This gives rise to the Chinese apposition binary rules $NP\ NP \rightarrow NP$ and $S[dcl]\ NP \rightarrow NP$.

5 The translation pipeline

5.1 Tagging

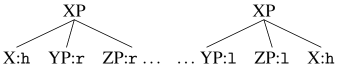
Each PCTB internal node structurally encodes a *configuration*, which lets us distinguish head-initial and head-final complementation from adjunction and predication (Xue et al., 2000).

The tagging mechanism annotates the PCTB tag of each internal node with a *marker*, which preserves this headedness information, even after the nodes are re-structured in the binarisation phase.

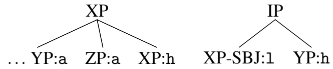
Hockenmaier's (2003) conversion algorithm uses the Magerman (1994) head-finding heuristics, a potential source of noise. Fortunately, the PCTB encodes gold standard headedness data.

The tagging algorithm is straightforward: if a node and its children unify with one of the schemata below, then the markers (e.g. `:l` or `:n`) are attached to its children. The markers `l` and `r` indicate complements *left*, or *right* of the *head* `h`; adjuncts are marked with `a`.

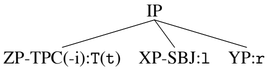
Head-initial, -final complementation



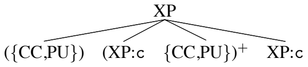
Adjunction, predication



Topicalisation (gap and non-gap)



Coordination



Others identify nodes with special syntax, such as topicalisation (`t/T`), apposition (`A`) or coordination (`c`), for special treatment in following phases.

NP internal structure

To speed annotation, NP internal structure is often left underspecified in PCTB (Xue et al., 2005), as in the Penn Treebank. As a result, 68% of non-trace `NP`s in PCTB have only a flat bracketing.

We assume that the internal structure of flat NPs is right-branching and head-final (Li and Thompson, 1989), following Hockenmaier and Steedman (2005), who assume this structure for English. A re-analysis of PCTB, like Vadas and Curran (2007) for the PTB, could restore this structure, and allow our conversion algorithm to yield the correct CCG analysis with no further modifications.

To obtain this default analysis, each node under NP internal structure receives the marker `n`, except the the final node, the head, which receives `N`.

5.2 Binarisation

CCG combinators take at most two categories, inducing binary derivation trees. As such, PCTB trees must be re-shaped to accommodate a CCG analysis.

Our markers control the shape of the binarised structure: head-initial complementation yields a left-branching tree, while head-final complementation, adjunction, predication, coordination, and NP internal structure all yield right-branching trees. Following Hockenmaier (2003), sentence-final punctuation is attached high.

Although the distinction between word-level tags (such as `NN`, `VA`) and phrasal tags (such as `NP`, `VP`, `LCP`) enables the configurational encoding of grammatical relations, it leaves a large number of

VP	←	VV,VE,VA,VRD	ADJP	←	JJ
ADVP	←	AD, CS	CLP	←	M
LCP	←	LC	DP	←	DT, OD
LST	←	OD	INTJ	←	IJ
FLR	←	*any node*	PP	←	P

Figure 2: Pruned unary projections

LCP	Localiser phrase	PP	Prepositional phrase
M	Measure word	QP	Quantifier phrase
N	Bare noun	S	Sentence
NP	Noun phrase	conj	Conjunction word

Table 2: Chinese CCGbank atomic category set

unary projections. While an intransitive verb (e.g. 睡觉 'sleep') would carry the verbal PCTB tag VV, and a transitive verb combined with its object (e.g. 吃了晚饭 'ate dinner') is annotated as VP, under CCG's freer concept of constituency, both receive the category *S\NP*.

Pruning the unary projections in Fig. 2 prevents spurious category labellings in the next phase.

5.3 Labelling

We label each node of the binarised tree with CCG categories, respecting the headedness information encoded in the markers.

Atomic categories

The chosen mapping from PCTB tags to categories defines the *atomic category set* for the grammar. The richer representation in CCG categories permits some constituents to be expressed using a smaller set of atoms (e.g. an adjective is simply a noun modifier – *N/N*). Despite their critical importance in controlling the degree of under-/over-generation in the corpus, little guidance exists as to the selection of atomic categories in a CCG grammar. We observed the following principles:

Modifier proliferation: when two classes of words can be modified by the same class of modifiers, they should receive a single category;

Over-generation: the atom set should not overgeneralise to accept ungrammatical examples;

Efficiency: the representation may be motivated by the needs of applications such as parsers.

Table 2 shows the eight atomic categories chosen for our corpus. Two of these categories: *LCP* (localisers) and *M* (measure words) have variously been argued to be special sub-classes of nouns (Huang et al., 2008). However, based on our overgeneration criterion, we decided to represent these as atomic categories.

We adopt the bare/non-bare noun distinction from Hockenmaier and Steedman (2007) on parsing efficiency grounds. Although they roughly correspond to English *PP*s, the distributional differences between *PP*s, *LCP*s and *QP*s justify their inclusion as atoms in Chinese. Future work in training a wide-coverage parser on Chinese CCGbank will evaluate the impact of these choices.

Labelling algorithm

We developed a recursive algorithm which applies one of several labelling functions based on the markers on a node and its children.

The algorithm proceeds top-down and assigns a CCG category to every node. The markers on a node's children are matched against the schema of Table 3, applying the categories of the matching schema to the children. The algorithm is then called recursively on each child. If the algorithm is called on an unlabelled node, the mapping from PCTB tags is used to assign a CCG category.

Predication		Left absorption	Adjunction		Right absorption	Right adjunction		Coordination	Head-initial		Partial coordination	Head-final		Apposition	
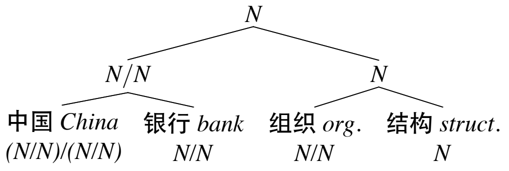
Table 3: Category labelling schemata

Left- and right-absorption are non-CCG rules which functionally ignore punctuation, assuming that they project no dependencies and combine to yield the same category as their non-punctuation sibling (Hockenmaier and Steedman, 2007). In the schema, *p* represents a PCTB punctuation POS tag.

NPs receive a head-final bracketing (by our right-branching assumption), respecting NP internal structure where provided by PCTB:



6 Post-processing

A number of cases remain which are either not covered by the general translation algorithm, or otherwise could be improved in a post-processing step. The primary disharmony at this stage is the presence of *traces*, the empty categories which the PCTB annotation style uses to mark the canonical position of extraposed or deleted constituents. 19,781 PCTB derivations (69.9%) contain a trace. Since CCG aims to provide a transparent interface between surface string syntax and semantics, traces are expressly disallowed (Steedman, 2000). Hence, we eliminate traces from the annotation, by devising alternate analyses in terms of categories and combinatory rules.

Subject/object extraction

8966 PCTB derivations (31.7%) contain a subject extraction, while 3237 (11.4%) contain an object extraction. Figure 3 shows the canonical representation of subject extraction in the PCTB annotation style. The PCTB annotation follows the X' analysis of the relative clause construction as described by Wu (2004), which we transform into an equivalent, trace-free CCG analysis.

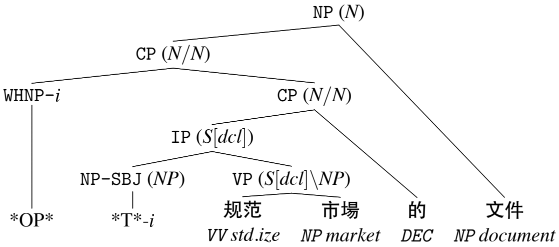


Figure 3: ‘*the document which standardises the market*’

First, the *Spec* trace, WHNP-*i*, coindexed with the extracted argument(s), is deleted. Next, the extracted argument(s) with matching indices are deleted, and category structure is adjusted to generate the correct gap category.

Modifier categories

Under our analysis, aspect particles such as 了 *le* (perfective) and 过 *guo* (experiential) are verbal post-modifiers, corresponding to *right adjunction* in Table 3. Accordingly, an aspect particle following a transitive verb VP/NP will receive the modifier category $(VP/NP)\backslash(VP/NP)$. Under this analysis, every verbal category gives rise to one possible modifier category for each aspect particle, leading to detrimental categorial ambiguity.

However, the generalised backward crossed composition combinator (Steedman, 2000) lets aspect particles retain their canonical category $(S\backslash NP)\backslash(S\backslash NP)$ regardless of the arity of the verb they modify.

Transformations

The PCTB annotation style posits traces to account for gapping, control/raising, argument sharing, pro-drop and topicalisation. To effect the parsimonious CCG analyses of Section 4, structural transformations on the original PCTB trees are necessary to accommodate the new analyses.

We developed a `tgrep`-like language which identifies instances of Chinese constructions, such as right node raising and pro-drop, whose PCTB annotation posits traces. The local trees are then reshaped to accommodate trace-free CCG analyses.

7 Evaluation

This section explores the coverage characteristics of Chinese CCGbank, in comparison with the English and German CCGbanks generated by Hockenmaier. Our analysis follows Hockenmaier (2006) in establishing *coverage* as the metric reflecting how well the target corpus has accounted for constructions in the source corpus.

7.1 Corpus coverage

The Chinese CCGbank conversion algorithm completes for 28,227 of the 28,295 (99.76%) PCTB trees. Annotation noise, and rare but legitimate syntax, such as ellipsis, account for the coverage lost in this phase. Following Hockenmaier and Steedman (2005), we adjust the PCTB annotation only for systematic tagging errors that lead to category mis-assignments, maintaining as far as possible the PCTB bracketing.

269 derivations (0.95%) contain unresolved traces, resulting from annotation noise and rare constructions (such as ellipsis) not currently handled by our translation algorithm. In 468 (1.66%) derivations, residues of PCTB tags not eliminated by the translation algorithm generate malformed categories outside the allowed set (Table 2). Excluding these cases, our conversion algorithm results in a corpus of 27,759 (98.1%) valid derivations.

7.2 Category set

The Chinese CCGbank category set is compared against existing CCG corpora derived from similar automatic corpus conversions, to determine how well we have generalised over syntactic phenomena in the source corpus.

A total of 1197 categories appear in the final corpus, of which 329 occur at least ten times, and 478 are attested only once. By comparison, English CCGbank, contains 1286 categories, 425 of which occur at least ten times, and 440 only once, while German CCGbank has a category inventory of 2506 categories, with 1018 attested only once.[5]

7.3 Lexicon coverage

Lexical item coverage establishes the extent to which data sparsity due to unseen words is problematic in the source corpus, and hence in any corpus derived from it. Hockenmaier and Steedman (2001) showed that formalisms with rich tagsets, such as CCG, are particularly sensitive to this sparsity – while a lexical item may be attested in the training data, it may lack the necessary category.

We divided the 27,759 valid derivations into ten contiguous sections, performing ten-fold cross-validation to determine the coverage of lexical items and CCG categories in the resulting corpus.

Average coverage on lexical items is 73.38%, while average coverage on categories is 88.13%. 94.46% of token types from the held-out set are found in the training set. These figures compare to 86.7% lexical coverage (by type) and 92% (by token) in German CCGbank (Hockenmaier, 2006). Although lexical coverage by token is comparable to the German corpus, we observe a marked difference in coverage by type.

To explain this, we examine the most frequent POS tags among the missing tokens. These are NN (common nouns; 16,552 tokens), NR (proper noun; 8458), VV (verb; 6879), CD (numeral; 1814) and JJ (adjective; 1257). The 100 most frequent missing tokens across the ten folds comprise 48 NR tokens, 46 NR, 3 NT (temporal nouns), 2 JJ (adjectives) and one VA (verbal adjective). Personal names are also not tokenised into surnames and forenames in the PCTB, increasing unseen NR tokens.

The missing VVs (verbs) include 1342 *four-character compounds*, fossilised idiomatic expressions which are considered atomic verbs in the PCTB annotation. Another source of verb sparsity stems from the PCTB analysis of verbal infixation. Given a polysyllabic verb (e.g. 离开 *leave-away* “leave”), we can add the adverbial infix 不 *not* to form a potential verb 离不开 *leave-not-away* “unable to leave”. In the PCTB annotation, however, this results in lexical items for the two cleaved parts, even though 离 *leave* can no longer stand alone as a verb in modern Chinese. In this case, a morphologically decomposed representation which does not split the lexical item could mitigate against this sparsity. Alternatively, candidate verbs for this construction could have the first verb fragment subcategorise for the second.

8 Conclusion

We have developed the first analysis of Chinese with Combinatory Categorial Grammar, crafting novel CCG analyses for a range of constructions including topicalisation, pro-drop, zero copula, verb compounding, and the long-range dependencies resulting from the 把 *ba*- and 被 *bei*-constructions.

We have presented an elegant and economical account of Chinese syntax that exploits the power of CCG combinatory rules, supporting Steedman’s claim to its language-independence.

We have designed a conversion algorithm to extract this analysis from an existing treebank, avoiding the massive cost of hand re-annotation, creating a corpus of 27,759 CCG derivations, covering 98.1% of the PCTB. The corpus will be publicly released, together with the converter, providing the tools to create CCGbanks in new languages.

At release, Chinese CCGbank will include gold-standard head co-indexation data, as required for the training and evaluation of head-driven dependency parsers. Co-indexation analyses, like those provided for the 把 *ba*- and 被 *bei*-constructions, will be extended to all categories.

Future refinements which could be brought to bear on Chinese CCGbank include the integration of PropBank data into CCGbank (Honnibal and Curran, 2007; Boxwell and White, 2008) using Chinese PropBank (Xue, 2008). The *hat categories* of Honnibal and Curran (2009) may better handle form/function discrepancies such as the Chinese zero copula construction, leading to cleaner, more general analyses.

We have presented a wide-coverage Chinese corpus which exploits the strengths of CCG to analyse a range of challenging Chinese constructions. We are now ready to develop rich NLP tools, including efficient, wide-coverage CCG parsers, to address the ever-increasing volumes of Chinese text now available.

[5] All German verbs having at least two categories to account for German verbal syntax contributes to the greater size of the category set (Hockenmaier, 2006).

Abstract

We propose a structure called *dependency forest* for statistical machine translation. A dependency forest compactly represents multiple dependency trees. We develop new algorithms for extracting string-to-dependency rules and training dependency language models. Our forest-based string-to-dependency system obtains significant improvements ranging from 1.36 to 1.46 BLEU points over the tree-based baseline on the NIST 2004/2005/2006 Chinese-English test sets.

1 Introduction

Dependency grammars have become increasingly popular in syntax-based statistical machine translation (SMT). One important advantage of dependency grammars is that they directly capture the dependencies between words, which are key to resolving most parsing ambiguities. As a result, incorporating dependency trees proves to be effective in improving statistical machine translation (Quirk et al., 2005; Ding and Palmer, 2005; Shen et al., 2008).

However, most dependency-based translation systems suffer from a major drawback: they only use 1-best dependency trees for rule extraction, dependency language model training, and decoding, which potentially introduces translation mistakes due to the propagation of parsing errors (Quirk and Corston-Oliver, 2006). While the treelet system (Quirk et al., 2005) takes a dependency tree as input, the string-to-dependency system (Shen et al., 2008) decodes on a source-language string. However, as we will show, the string-to-dependency system still commits to using degenerate rules and dependency language models learned from noisy 1-best trees.

To alleviate this problem, an obvious solution is to offer more alternatives. Recent studies have shown that SMT systems can benefit from widening the annotation pipeline: using packed forests instead of 1-best trees (Mi and Huang, 2008), word lattices instead of 1-best segmentations (Dyer et al., 2008), and weighted alignment matrices instead of 1-best alignments (Liu et al., 2009).

Along the same direction, we propose a structure called *dependency forest*, which encodes exponentially many dependency trees compactly, for dependency-based translation systems. In this paper, we develop two new algorithms for extracting string-to-dependency rules and for training dependency language models, respectively. We show that using the rules and dependency language models learned from dependency forests leads to consistent and significant improvements over that of using 1-best trees on the NIST 2004/2005/2006 Chinese-English test sets.

2 Background

Figure 1 shows a dependency tree of an English sentence *he saw a boy with a telescope*. Arrows point from the child to the parent, which is often referred to as the head of the child. For example, in Figure 1, *saw* is the head of *he*. A dependency tree is more compact than its constituent counterpart because there is no need to build a large superstructure over a sentence.

Shen et al. (2008) propose a novel string-to-dependency translation model that features two important advantages. First, they define that a string-to-dependency rule must have a *well-formed* dependency structure on the target side, which makes efficient dynamic programming possible and manages to retain most useful non-constituent rules. A well-formed structure can be either *fixed* or *floating* . A fixed structure is a

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 1092–1100,
Beijing, August 2010

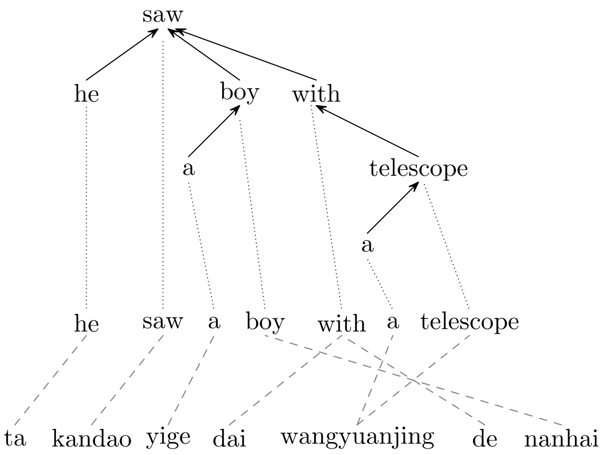

Figure 1: A training example for tree-based rule extraction.

dependency tree with all the children complete. Floating structures consist of sibling nodes of a common head, but the head itself is unspecified or floating. For example, Figure 2(a) and Figure 2(b) are two fixed structures while Figure 2(c) is a floating one.

Formally, for a given sentence $w_{1:l} = w_1 \dots w_l$, $d_1 \dots d_l$ represent the parent word IDs for each word. If w_i is a root, we define $d_i = 0$.

Definition 1. *A dependency structure $d_{i..j}$ is* **fixed on head** *h, where h $\notin [i,j]$, or* **fixed** *for short, if and only if it meets the following conditions*

- $d_h \notin [i,j]$
- $\forall k \in [i,j]$ and $k \neq h, d_k \in [i,j]$
- $\forall k \notin [i,j]$, $d_k = h$ or $d_k \notin [i,j]$

Definition 2. *A dependency structure $d_{i..j}$ is* **floating with children** *C, for a non-empty set C* $\subseteq \{i, ..., j\}$*, or* **floating** *for short, if and only if it meets the following conditions*

- $\exists h \notin [i,j], s.t. \forall k \in C, d_k = h$
- $\forall k \in [i,j]$ and $k \notin C, d_k \in [i,j]$
- $\forall k \notin [i,j]$, $d_k \notin [i,j]$

A dependency structure is **well-formed** if and only if it is either **fixed** or **floating**.

2.1 Tree-based Rule Extraction

Figure 1 shows a training example consisting of an English dependency tree, its Chinese translation, and the word alignments between them. To facilitate identifying the correspondence between the English and Chinese words, we also gives the English sentence. Extracting string-to-dependency rules from aligned string-dependency pairs is similar to extracting SCFG (Chiang, 2007) except that the target side of a rule is a well-formed structure. For example, we can first extract a string-to-dependency rule that is consistent with the word alignment (Och and Ney, 2004):

with ((*a*) *telescope*) $\rightarrow$ *dai wangyuanjing de*

Then a smaller rule

(*a*) *telescope* $\rightarrow$ *wangyuanjing*

can be subtracted to obtain a rule with one non-terminal:

with (X_1) $\rightarrow$ *dai* X_1 *de*

where X is a non-terminal and the subscript indicates the correspondence between non-terminals on the source and target sides.

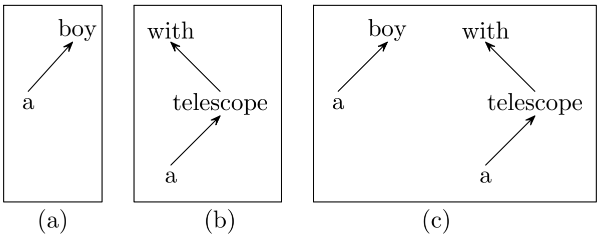

Figure 2: Well-formed dependency structures corresponding to Figure 1. (a) and (b) are fixed and (c) is floating.

2.2 Tree-based Dependency Language Model

As dependency relations directly model the semantics structure of a sentence, Shen et al. (2008) introduce *dependency language model* to better account for the generation of target sentences. Compared with the conventional n-gram language models, dependency language model excels at capturing non-local dependencies between words (e.g., *saw ... with* in Figure 1). Given a dependency tree, its dependency language model probability is a product of three sub-models defined between headwords and their dependants. For example, the probability of the tree in Figure 1 can

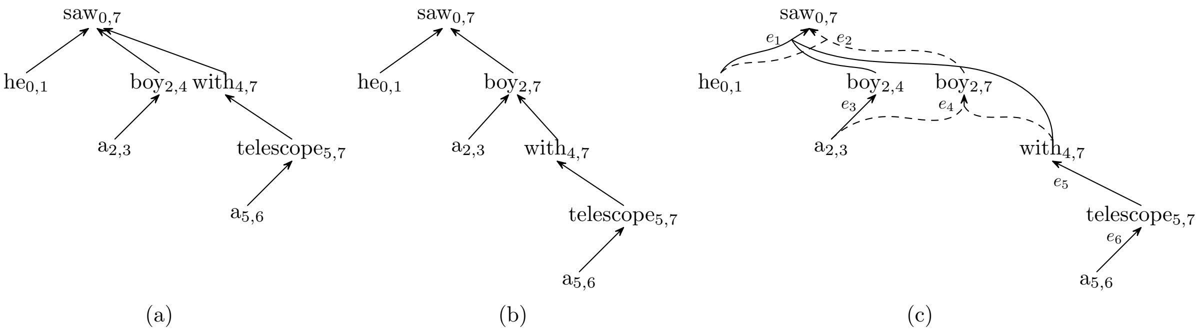

Figure 3: (a) the dependency tree in Figure 1, (b) another dependency tree for the same sentence, and (c) a dependency forest compactly represents the two trees.

be calculated as:

$$\begin{aligned} Prob &= P_T(saw) \\ &\quad \times P_L(he|saw\text{-as-head}) \\ &\quad \times P_R(boy|saw\text{-as-head}) \\ &\quad \times P_R(with|boy, saw\text{-as-head}) \\ &\quad \times P_L(a|boy\text{-as-head}) \\ &\quad \times P_R(telescope|with\text{-as-head}) \\ &\quad \times P_L(a|telescope\text{-as-head}) \end{aligned}$$

where $P_T(x)$ is the probability of word x being the root of a dependency tree. P_L and P_R are the generative probabilities of left and right sides respectively.

As the string-to-tree system relies on 1-best trees for parameter estimation, the quality of rule table and dependency language model might be affected by parsing errors and therefore ultimately results in translation mistakes.

3 Dependency Forest

We propose to encode multiple dependency trees in a compact representation called dependency forest, which offers an elegant solution to the problem of parsing error propagation.

Figures 3(a) and 3(b) show two dependency trees for the example English sentence in Figure 1. The prepositional phrase *with a telescope* could either depend on *saw* or *boy*. Figure 3(c) is a dependency forest compactly represents the two trees by sharing common nodes and edges.

Each **node** in a dependency forest is a word. To distinguish among nodes, we attach a **span** to each node. For example, in Figure 1, the span of the first *a* is $(2, 3)$ because it is the third word in the sentence. As the fourth word *boy* dominates the node $a_{2,3}$, it can be referred to as $boy_{2,4}$. Note that the position of *boy* itself is taken into consideration. Similarly, the word *boy* in Figure 3(b) can be represented as $boy_{2,7}$.

The nodes in a dependency forest are connected by **hyperedges**. While an edge in a dependency tree only points from a dependent to its head, a hyperedge groups all the dependants that have a common head. For example, in Figure 3(c), the hyperedge

$$e_1\text{: } \langle (he_{0,1}, boy_{2,4}, with_{4,7}), saw_{0,7} \rangle$$

denotes that $he_{0,1}$, $boy_{2,4}$, and $with_{4,7}$ are dependants (from left to right) of $saw_{0,7}$.

More formally, a *dependency forest* is a pair $\langle V, E \rangle$, where V is a set of nodes, and E is a set of hyperedges. For a given sentence $w_{1:l} = w_1 \ldots w_l$, each node $v \in V$ is in the form of $w_{i,j}$, which denotes that w dominates the substring from positions i through j (i.e., $w_{i+1} \ldots w_j$). Each hyperedge $e \in E$ is a pair $\langle tails(e), head(e) \rangle$, where $head(e) \in V$ is the head and $tails(e) \in V$ are its dependants.

A dependency forest has a structure of a *hypergraph* such as packed forest (Klein and Manning, 2001; Huang and Chiang, 2005). However, while each hyperedge in a packed forest naturally treats the corresponding PCFG rule probability as its weight, it is challenging to make dependency forest to be a weighted hypergraph because dependency parsers usually only output a score, which can be either positive or negative, for each edge in a dependency tree rather than a hyperedge in a

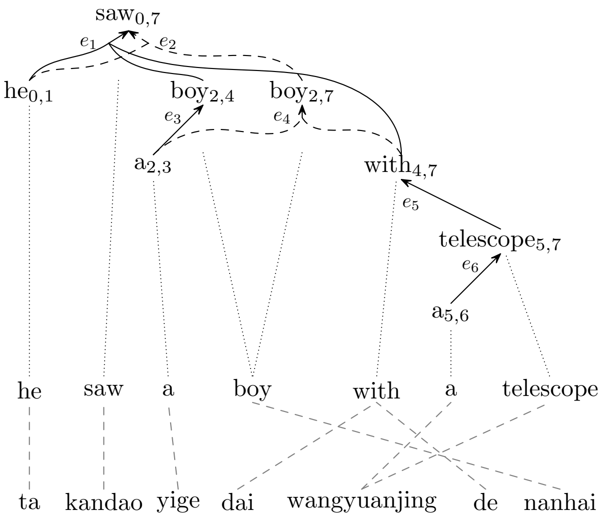

Figure 4: A training example for forest-based rule extraction.

dependency forest. For example, in Figure 3(a), the scores for the edges *he* → *saw*, *boy* → *saw*, and *with* → *saw* could be 13, 22, and -12, respectively.

To assign a probability to each hyperedge, we can first obtain a positive number for a hyperedge using the scores of the corresponding edges:[1]

$$c(e) = exp\left(\frac{\sum_{v \in tails(e)} s\big(v, head(e)\big)}{|tails(e)|}\right) \qquad (1)$$

where $c(e)$ is the count of a hyperedge e, $head(e)$ is a head, $tails(e)$ is a set of dependants of the head, v is one dependant, and $s(v, head(e))$ is the score of an edge from v to $head(e)$. For example, the count of the hyperedge e_1 in Figure 3(c) is

$$c(e_1) = exp\left(\frac{13 + 22 - 12}{3}\right) \qquad (2)$$

Then, the probability of a hyperedge can be obtained by normalizing the count among all hyperedges with the same head collected from a training corpus:

$$p(e) = \frac{c(e)}{\sum_{e':head(e')=head(e)} c(e')} \qquad (3)$$

Therefore, we obtain a weighted dependency forest in which each hyperedge has a probability.

Algorithm 1 Forest-based Initial Phrase Extraction

```
Input: a source sentence $\psi$, a forest $F$, an alignment $a$, and $k$
Output: minimal initial phrase set $\mathcal{R}$
for each node $v \in V$ in a bottom-up order do
    for each hyperedge $e \in E$ and $head(e) = v$ do
        $W \leftarrow \emptyset$
        fixs $\leftarrow$ EnumFixed($v, modifiers(e)$)
        floatings $\leftarrow$ EnumFloating($modifiers(e)$)
        add structures fixs, floatings to $W$
        for each $\omega \in W$ do
            if $\omega$ is consistent with $a$ then
                generate a rule $r$
                $\mathcal{R}$.append($r$)
    keep $k$-best dependency structures for $v$
```

4 Forest-based Rule Extraction

In tree-based rule extraction, one just needs to first enumerate all bilingual phrases that are consistent with word alignment and then check whether the dependency structures over the target phrases are well-formed. However, this algorithm fails to work in the forest scenario because there are usually exponentially many well-formed structures over a target phrase.

The GHKM algorithm (Galley et al., 2004), which is originally developed for extracting tree-to-string rules from 1-best trees, has been successfully extended to packed forests recently (Mi and Huang, 2008). The algorithm distinguishes between minimal and composed rules. Although there are exponentially many composed rules, the number of minimal rules extracted from each node is rather limited (e.g., one or zero). Therefore, one can obtain promising composed rules by combining minimal rules.

Unfortunately, the GHKM algorithm cannot be applied to extracting string-to-dependency rules from dependency forests. This is because the GHKM algorithm requires a complete subtree to exist in a rule while neither fixed nor floating dependency structures ensure that all dependants of a head are included. For example, the floating structure shown in Figure 2(c) actually contains two trees.

Alternatively, our algorithm searches for well-formed structures for each node in a bottom-up style. Algorithm 1 shows the algorithm for extracting initial phrases, that is, rules without non-

[1] It is difficult to assign a probability to each hyperedge. The current method is arbitrary, and we will improve it in the future.

terminals from dependency forests. The algorithm maintains k-best well-formed structures for each node (line 11). The well-formed structures of a head can be constructed from those of its dependants. For example, in Figure 4, as the fixed structure rooted at *telescope*$_{5,7}$ is

$$(a)\ \textit{telescope}$$

we can obtain a fixed structure rooted for the node *with*$_{4,7}$ by attaching the fixed structure of its dependant to the node (*EnumFixed* in line 4). Figure 2(b) shows the resulting fixed structure.

Similarly, the floating structure for the node *saw*$_{0,7}$ can be obtained by concatenating the fixed structures of its dependants *boy*$_{2,4}$ and *with*$_{4,7}$ (*EnumFloating* in line 5). Figure 2(c) shows the resulting fixed structure. The algorithm is similar to Wang et al. (2007), which binarize each constituent node to create some intermediate nodes that correspond to the floating structures.

Therefore, we can find k-best fixed and floating structures for a node in a dependency forest by manipulating the fixed structures of its dependants. Then we can extract string-to-dependency rules if the dependency structures are consistent with the word alignment.

How to judge a well-formed structure extracted from a node is better than others? We follow Mi and Huang (2008) to assign a **fractional count** to each well-formed structure. Given a tree fragment t, we use the inside-outside algorithm to compute its posterior probability:

$$\begin{aligned} \alpha\beta(t) &= \alpha(root(t)) \times \prod_{e \in t} p(e) \\ &\quad \times \prod_{v \in leaves(t)} \beta(v) \end{aligned} \tag{4}$$

where $root(t)$ is the root of the tree, e is an edge, $leaves(t)$ is a set of leaves of the tree, $\alpha(\cdot)$ is outside probability, and $\beta(\cdot)$ is inside probability.

For example, the subtree rooted at *boy*$_{2,7}$ in Figure 4 has the following posterior probability:

$$\begin{aligned} &\alpha(\textit{boy}_{2,7}) \times p(e_4) \times p(e_5) \\ &\times p(e_6) \times \beta(\textit{a}_{2,3}) \times \beta(\textit{a}_{5,6}) \end{aligned} \tag{5}$$

Now the fractional count of the subtree t is

$$c(t) = \frac{\alpha\beta(t)}{\alpha\beta(TOP)} \tag{6}$$

where TOP denotes the root node of the forest.

As a well-formed structure might be non-constituent, we approximate the fractional count by taking that of the minimal constituent tree fragment that contains the well-formed structure. Finally, the fractional counts of well-formed structures can be used to compute the relative frequencies of the rules having them on the target side (Mi and Huang, 2008):

$$\phi(r|lhs(r)) = \frac{c(r)}{\sum_{r':lhs(r')=lhs(r)} c(r')} \tag{7}$$

$$\phi(r|rhs(r)) = \frac{c(r)}{\sum_{r':rhs(r')=rhs(r)} c(r')} \tag{8}$$

Often, our approach extracts a large amount of rules from training corpus as we usually retain exponentially many well-formed structures over a target phrase. To maintain a reasonable rule table size, we discard any rule that has a fractional count lower that a threshold t.

5 Forest-based Dependency Language Model Training

Dependency language model plays an important role in string-to-dependency system. Shen et al. (2008) show that string-to-dependency system achieves 1.48 point improvement in BLEU along with dependency language model, while no improvement without it. However, the string-to-dependency system still commits to using dependency language model from noisy 1-best trees. We now turn to dependency forest for it encodes multiple dependency trees.

To train a dependency language model from a dependency forest, we need to collect all heads and their dependants. This can be easily done by enumerating all hyperedges. Similarly, we use the inside-outside algorithm to compute the posterior probability of each hyperedge e,

$$\begin{aligned} \alpha\beta(e) &= \alpha(head(e)) \times p(e) \\ &\quad \times \prod_{v \in tailes(e)} \beta(v) \end{aligned} \tag{9}$$

For example, the posterior probability of the hyperedge e_2 in Figure 4 is calculated as

$$\begin{aligned} \alpha\beta(e_2) &= \alpha(\textit{saw}_{0,7}) \times p(e_2) \\ &\quad \times \beta(\textit{he}_{0,1}) \times \beta(\textit{boy}_{2,7}) \end{aligned} \tag{10}$$

Rule	DepLM	NIST 2004	NIST 2005	NIST 2006	time
tree	tree	33.97	30.21	30.73	19.6
tree	forest	34.42*	31.06*	31.37*	24.1
forest	tree	34.60*	31.16*	31.45*	21.7
forest	forest	**35.33****	**31.57****	**32.19****	28.5

Table 1: BLEU scores and average decoding time (second/sentence) on the Chinese-English test sets. The baseline system (row 2) used the rule table and dependency language model learned both from 1-best dependency trees. We use " *" and "**" to denote a result is better than baseline significantly at $p < 0.05$ and $p < 0.01$, respectively.

Then, we can obtain the fractional count of a hyperedge e,

$$c(e) = \frac{\alpha\beta(e)}{\alpha\beta(TOP)} \tag{11}$$

Each n-gram (e.g., "boy-as-head a") is assigned the same fractional count of the hyperedge it belongs to.

We also tried training dependency language model as in (Shen et al., 2008), which means all hyperedges were on equal footing without regarding probabilities. However, the performance is about 0.8 point lower in BLEU. One possbile reason is that hyperedges with probabilities could distinguish high quality structures better.

6 Experiments

6.1 Results on the Chinese-English Task

We used the FBIS corpus (6.9M Chinese words + 8.9M English words) as our bilingual training corpus. We ran GIZA++ (Och and Ney, 2000) to obtain word alignments. We trained a 4-gram language model on the Xinhua portion of GIGAWORD corpus using the SRI Language Modeling Toolkit (Stolcke, 2002) with modified Kneser-Ney smoothing (Kneser and Ney, 1995). We optimized feature weights using the minimum error rate training algorithm (Och and Ney, 2002) on the NIST 2002 test set. We evaluated the translation quality using case-insensitive BLEU metric (Papineni et al., 2002) on the NIST 2004/2005/2006 test sets.

To obtain dependency trees and forests, we parsed the English sentences of the FBIS corpus using a shift-reduce dependency parser that enables beam search (Huang et al., 2009). We only retained the best well-formed structure for each node when extracting string-to-tree rules from dependency forests (i.e., $k = 1$). We trained two 3-gram depLMs (one from trees and another from forests) on English side of FBIS corpus plus 2M sentence pairs from other LDC corpus.

Rules	Size	New Rules
tree	7.2M	-
forest	7.6M	16.86%

Table 2: Statistics of rules. The last column shows the ratio of rules extracted from non 1-best parses being used in 1-best derivations.

After extracting rules and training depLMs, we ran our replication of string-to-dependency system (Shen et al., 2008) to translate the development and test sets.

Table 1 shows the BLEU scores on the test sets. The first column "Rule" indicates where the string-to-dependency rules are learned from: 1-best dependency trees or dependency forests. Similarly, the second column "DepLM" also distinguish between the two sources for training dependency language models. The baseline system used the rule table and dependency language model both learned from 1-best dependency trees. We find that adding the rule table and dependency language models obtained from dependency forests improves string-to-dependency translation consistently and significantly, ranging from +1.3 to +1.4 BLEU points. In addition, using the rule table and dependency language model trained from forest only increases decoding time insignificantly.

How many rules extracted from non 1-best

Rule	DepLM	BLEU
tree	tree	22.31
tree	forest	22.73*
forest	tree	22.80*
forest	forest	**23.12****

Table 3: BLEU scores on the Korean-Chinese test set.

parses are used by the decoder? Table 2 shows the number of rules filtered on the test set. We observe that the rule table size hardly increases. One possible reason is that we only keep the best dependency structure for each node. The last row shows that 16.86% of the rules used in 1-best derivations are extracted from non 1-best parses in the forests, indicating that some useful rules cannot be extracted from 1-best parses.

6.2 Results on the Korean-Chinese Task

To examine the efficacy of our approach on different language pairs, we carried out an experiment on Korean-Chinese translation. The training corpus contains about 8.2M Korean words and 7.3M Chinese words. The Chinese sentences were used to train a 5-gram language model as well as a 3-gram dependency language model. Both the development and test sets consist of 1,006 sentences with single reference. Table 3 shows the BLEU scores on the test set. Again, our forest-based approach achieves significant improvement over the baseline ($p < 0.01$).

6.3 Effect of K-best

We investigated the effect of different k-best structures for each node on translation quality (BLEU scores on the NIST 2005 set) and the rule table size (filtered for the tuning and test sets), as shown in Figure 5. To save time, we extracted rules just from the first 30K sentence pairs of the FBIS corpus. We trained a language model and depLMs on the English sentences. We used 10 different k: 1, 2, 3, 4, 5, 6, 7, 8, 9 and 10. Obviously, the higher the k is, the more rules are extracted. When k=10, the number of rules used on the tuning and test sets was 1,299,290 and the BLEU score was 20.88. Generally, both the number of rules and the BLEU score went up with the increase of k. However, this trend did not hold within the range [4,10]. We conjecture that when retaining more dependency structures for each node, low quality structures would be introduced, resulting in much rules of low quality.

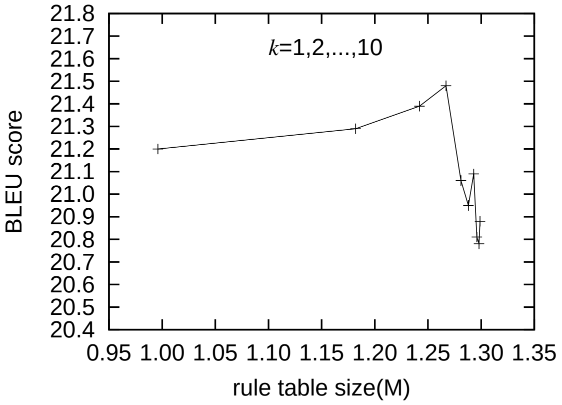

Figure 5: Effect of k-best on rule table size and translation quality.

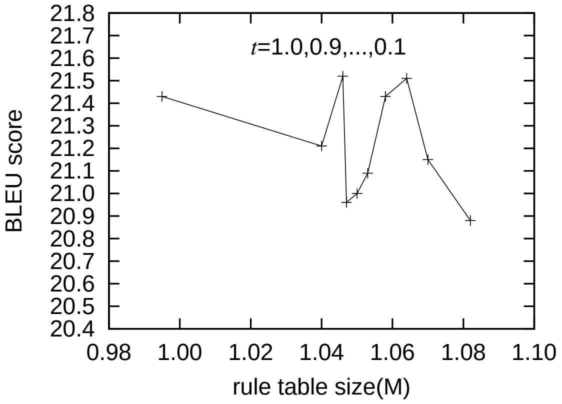

Figure 6: Effect of pruning threshold on rule table size and translation quality.

An interesting finding is that the rule table grew rapidly when k is in range [1,4], while gradually within the range [4,10]. One possible reason is that there are limited different dependency structures in the spans with a maximal length of 10, which the target side of rules cover.

6.4 Effect of Pruning Threshold

Figure 6 shows the effect of pruning threshold on translation quality and the rule table size. We retained 10-best dependency structures for each node in dependency forests. We used 10 different pruning thresholds: 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9 and 1.0. Intuitively, the higher the pruning threshold is, the less rules are extracted. When t=0.1, the number of rules used on the tuning and test sets was 1,081,841 and the BLEU score was 20.68.

Lots of rules are pruned when the pruning threshold increases from 0.0 to 0.3 (around 20%). After pruning away these rules, we achieved 0.6 point improvement in BLEU. However, when we filtered more rules, the BLEU score went down.

Figures 5 and 6 show that using two parameters that have to be hand-tuned achieves a small improvement at the expense of an additional complexity. To simplify the approach, we only keep the best dependency structure for each node without pruning any rule.

7 Related Works

While Mi and Huang (2008) and we both use forests for rule extraction, there remain two major differences. Firstly, Mi and Huang (2008) use a packed forest, while we use a dependency forest. Packed forest is a natural weighted hypergraph (Klein and Manning, 2001; Huang and Chiang, 2005), for each hyperedge treats the corresponding PCFG rule probability as its weight. However, it is challenging to make dependency forest to be a weighted hypergraph because dependency parsers usually only output a score for each edge in a dependency tree rather than a hyperedge in a dependency forest. Secondly, The GHKM algorithm (Galley et al., 2004), which is originally developed for extracting tree-to-string rules from 1-best trees, has been successfully extended to packed forests recently (Mi and Huang, 2008). Unfortunately, the GHKM algorithm cannot be applied to extracting string-to-dependency rules from dependency forests, because the GHKM algorithm requires a complete subtree to exist in a rule while neither fixed nor floating dependency structures ensure that all dependants of a head are included.

8 Conclusion and Future Work

In this paper, we have proposed to use dependency forests instead of 1-best parses to extract string-to-dependency tree rules and train dependency language models. Our experiments show that our approach improves translation quality significantly over a state-of-the-art string-to-dependency system on various language pairs and test sets. We believe that dependency forest can also be used to improve the dependency treelet system (Quirk et al., 2005) that takes 1-best trees as input.

Large Scale Parallel Document Mining for Machine Translation

Jakob Uszkoreit Jay M. Ponte Ashok C. Popat Moshe Dubiner

Google, Inc.
{uszkoreit,ponte,popat,moshe}@google.com

Abstract

A distributed system is described that reliably mines parallel text from large corpora. The approach can be regarded as cross-language near-duplicate detection, enabled by an initial, low-quality batch translation. In contrast to other approaches which require specialized metadata, the system uses only the textual content of the documents. Results are presented for a corpus of over two billion web pages and for a large collection of digitized public-domain books.

1 Introduction

While the World Wide Web provides an abundance of readily available monolingual text, parallel data is still a comparatively scarce resource, yet plays a crucially important role in training statistical machine translation systems.

We describe an approach to mining document-aligned parallel text to be used as training data for a statistical machine translation system. Previous approaches have focused on rather homogeneous corpora and relied on metadata such as publication dates (Munteanu and Marcu, 2005; Munteanu and Marcu, 2006; Udupa et al., 2009; Do et al., 2009; Abdul-Rauf and Schwenk, 2009) or information about document structure (Resnik and Smith, 2003; Chen and Nie, 2000). In large and unstructured collections of documents such as the Web, however, metadata is often sparse or unreliable. Our approach, in contrast, scales computationally to very large and diverse collections of documents and does not require metadata. It is based solely on the textual contents of the input documents.

Casting the problem as one of cross-language near duplicate detection, we use a baseline machine translation system to translate all input documents into a single language. However, the words and phrases that are most discriminatory for the purposes of information retrieval and duplicate detection are the relatively rare ones, precisely those that are less likely to be translated well by the baseline translation system.

Our approach to circumvent this problem and to avoid the prohibitive quadratic computational complexity of the naive approach of performing a comparison of every possible pair of input documents is similar to previous work in near duplicate detection (Broder, 2000; Henzinger, 2006; Manber, 1994) and noisy data retrieval (Harding et al., 1997).

We use shingles consisting of word n-grams to construct relatively rare features from more common, in-vocabulary words. For each input document, we identify a comparatively small set of candidate pairings with documents sharing at least a certain number of such features. We then perform a more expensive comparison between each document and all documents in its candidate set using lower order n-gram features that would typically be too frequent to be used efficiently in forming candidate pairings, but provide a higher coverage of the scored document pairs. Another important aspect of our approach is that it can be implemented in a highly parallel way, as we describe in the following section.

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 1101–1109,
Beijing, August 2010

2 System Description

The input is a set of documents from diverse sources such as web pages and digitized books. In a first stage, all documents are independently translated into English using a baseline statistical machine translation system.

We then extract two different sets of n-grams from the translated documents: matching n-grams that are used to construct the candidate sets as well as scoring n-grams used only in the computation of a score for a given pair of documents. This stage generates two indexes: a *forward index* listing all extracted scoring n-grams, indexed by document; and an *inverted index* referencing all documents from which we extracted a given matching n-gram, indexed by n-grams. The inverted index is also used to accumulate global information about scoring n-grams, such as their document frequency, yet for scoring n-grams we do not accumulate a posting list of all documents in which they occur.

Per-document n-best lists
Discard non-symmetric pairs
Evaluate on reference document
alignments
Join with original input data

Figure 1: Architecture of the Parallel Text Mining System.

In the next step, the system generates all possible pairs of documents for each matching n-gram posting list in the inverted index. Since we keep only those pairs of documents that originated in different languages, we can discard posting lists from the inverted index that contain only a single document, i.e. those of singleton n-grams, or only documents in a single language.

Crucially, we further discard posting lists for matching n-grams whose frequency exceeds a certain threshold. When choosing a sufficiently large order for the matching n-grams, their long-tailed distribution causes only a small fraction of matching n-grams to be filtered out due to frequency, as we show empirically in Section 5. It is this filtering step that causes the overall runtime of the system to be linear in the size of the input data and allows the system to scale to very large document collections.

In parallel, global information about scoring n-grams accumulated in the inverted index that is required for pairwise scoring, such as their document frequency, is folded into the forward index by iterating over all forward index entries, requesting the respective per-feature quantities from the inverted index and storing them with each occurrence of a scoring n-gram in an updated forward index.

In the next stage, we compute pairwise scores for all candidate document pairs, accessing the forward index entry of each of the two scored documents to obtain the respective scoring n-grams. Document pairs with a score below a given threshold are discarded. For each input document, this results in one n-best list per language. In the last step we retain only those document pairs where each document is contained in the n-best list of the other document for its original language. Finally we perform a *join* of our identified translation pairs with the original text by making another pass over the original, untranslated input data where the contents of document pairs with sufficiently high scores are then aggregated and output. Document pairings involving all languages are identified simultaneously. Each stage of the system fits well into the MapReduce programming model (Dean and Ghemawat, 2004). The general architecture is shown in Figure 1.

2.1 Pairwise Scoring

For scoring a pair of documents d and d', the forward index is queried for the entries for both documents. Let $F_d = \{f_1, f_2, ...f_n\}$ and $F_{d'} = \{f'_1, f'_2, ...f'_{n'}\}$ be the sets of scoring n-grams in the forward index entries of d and d', respectively. Let $\text{idf}(f) = \log \frac{|D|}{df(f)}$ be the inverse document frequency of a scoring n-gram f, where $|D|$ is the number of documents in the input corpus and $df(f)$ is the number documents from which we extracted the feature f. Interpreting F_d and $F_{d'}$ as incidence vectors in the vector space of n-grams and replacing each non-zero component f with $\text{idf}(f)$, we compute the score of the document pair as the inverse document frequency weighted cosine similarity of F_d and $F_{d'}$

$$\text{score}(d, d') = \frac{F_d \cdot F_{d'}}{||F_d|| \cdot ||F_{d'}||} \tag{1}$$

The per-document n-best lists are sorted according to this score and document pairs for which the score is below a threshold are discarded completely.

We do not use term frequency in the scoring metric. In preliminary experiments, incorporating the term frequency to yield basic *tf/idf* as well as using other information retrieval ranking functions incorporating term frequencies such as *BM25* (Robertson et al., 1995) resulted in a degradation of performance compared to the simpler scoring function described above. We believe this is due to the fact that, in contrast to the standard information retrieval setting, the overall length of our queries is on par with that of the documents in the collection.

The scoring is completely agnostic regarding the scoring n-grams' positions in the documents. Since especially for long documents such as books this may produce spurious matches, we apply an additional filter to remove document pairs for which the relative ordering of the matching scoring n-grams is very different. Together with each scoring n-gram we also extract its relative position in each document and store it in the forward index. When scoring a document pair, we compute the normalized permutation edit distance (Cormode et al., 2001) between the two sequences of overlapping n-grams sorted by their position in the respective document. If this distance exceeds a certain threshold, we discard the document pair.

2.2 Computational Complexity

By limiting the frequency of matching n-grams, the complexity becomes linear. Let the tunable parameter c be the maximum occurrence count for matching n-grams to be kept in the inverted index. Let m be the average number of matching n-grams extracted from a single document whose count is below c and D be the set of documents in the input corpus. Then the system generates up to $|D| \cdot m \cdot c$ candidate pairings. Scoring a given candidate document pair according to cosine similarity involves computing three dot-products between sparse vectors with one non-zero component per scoring n-gram extracted and not filtered from the respective document. Let s be the average number of such scoring n-grams per document, which is bounded by the average document length. Then the time complexity of the entire document alignment is in

$$O(|D| \cdot m \cdot c \cdot s) \tag{2}$$

and therefore linear in the number of input documents in the corpus and the average document size.

The space complexity is dominated by the size of the inverted and forward indexes, both of which are linear in the size of the input corpus.

2.3 Sentence-Level Alignment

Further filtering is performed on a per-sentence basis during per-document-pair sentence alignment of the mined text with a standard dynamic programming sentence alignment algorithm using sentence length and multilingual probabilistic dictionaries as features. Afterwards we crudely align words within each pair of aligned source and target sentences. This crude alignment is used only to filter nonparallel sentences. Let S be the set of source words, T the set of target words and $S \times T$ the set of ordered pairs. Let the source sentence contain words $S_0 \subset S$ and the target sentence contain words $T_0 \subset T$. An alignment $A_0 \subset S_0 \times T_0$ will be scored by

$$\mathrm{score}(A_0) = \sum_{(s,t) \in A_0} \ln \frac{p(s,t)}{p(s)\, p(t)} \tag{3}$$

where the joint probabilities $p(s,t)$ and marginal probabilities $p(s)$, $p(t)$ are taken to be the respective empirical distributions (without smoothing) in an existing word aligned corpus. This is greedily maximized and the result is divided by its approximate expected value

$$\sum_{(s,t) \in S_0 \times T} \frac{p(s,t)}{p(s)} \ln \frac{p(s,t)}{p(s)\, p(t)} \tag{4}$$

We discard sentence pairs for which the ratio between the actual and the expected score is less than $1/3$. We also drop sentence pairs for which both sides are identical, or a language detector declares them to be in the wrong language.

2.4 Baseline Translation System

To translate the input documents into English we use phrase-based statistical machine translation systems based on the log-linear formulation of the problem (Och and Ney, 2002).

We train the systems on the Europarl Corpus (Koehn, 2002), the DGT Multilingual Translation Memory (European Commission Directorate-General for Translation, 2007) and the United Nations ODS corpus (United Nations, 2006). Minimum error rate training (Macherey et al., 2008) under the BLEU criterion is used to optimize the feature function weights on development data consisting of the *nv-dev2007* and *news-dev2009* data sets provided by the organizers of the 2007 and 2009 WMT shared translation tasks[1]. We use a 4-gram language model trained on a variety of large monolingual corpora. The BLEU scores of our baseline translation system on the test sets from various WMT shared translation tasks are listed in Table 5. An empirical analysis of the impact of the baseline translation system quality on the data mining system is given in Section 6.3.

3 Input Document Collections

We evaluate the parallel text mining system on two input data sets:

web A collection of 2.5 Billion general pages crawled from the Web, containing only pages in Czech, English, French, German, Hungarian and Spanish

books A collection of 1.5 Million public domain books digitized using an optical character recognition system. The collection consists primarily of English, French and fewer Spanish volumes

3.1 Reference Sets

We created reference sets of groups of documents in multiple languages which are true translations of one another for both the *web* and the *books* data set. Due to the presence of duplicates, each reference pairing can contain more than a single alternative translation per language. The *web* reference set was constructed by exploiting the systematic hyperlink structure of the web-site `http://america.gov/`, that links pages in one language to their respective translations into one or more other languages. The resulting reference set contains documents in Arabic, Chinese, English, French, Russian and Spanish, however, for most English pages there is only one translation into one of the other languages. Overall, the reference set contains 6,818 documents and 7,286 translation pairs.

The *books* reference set contains 30 manually aligned groups of translations covering a total of 103 volumes in English and French.

4 Evaluation Metrics

The fact that the system outputs pairs of documents and the presence of duplicate documents in the corpus motivate the use of modified versions of *precision* and *recall*.

[1] available at `http://statmt.org`

Let C be a set of candidate parallel document pairs and let R be a possibly incomplete reference set of groups of parallel documents known to exist in the corpus. Consider the following two subsets of C:

- *Matching* pairs which are in some reference cluster.
- *Touching* pairs which are non-matching but have at least one document in some reference cluster.

We define

$$\text{Precision} = \frac{|C_{\text{Matching}}|}{|C_{\text{Matching}}| + |C_{\text{Touching}}|}$$

and

$$\text{Recall} = \frac{|C_{\text{Matching}}|}{|R|} \qquad (5)$$

5 Parameter Selection

We conducted a series of small-scale experiments on only those documents contained in the *web* reference data set to empirically determine good settings for the tunable parameters of the text mining system. Among the most important parameters are the orders of the n-grams used for pairing documents as well as scoring them. Aside from the obvious impact on the quality of the output, these parameters have a very large influence on the overall computational performance of the system. The choice of the order of the extracted matching n-grams is mainly a trade-off between recall and efficiency. If the order is too large the system will miss valid pairs; if too small the the threshold on matching n-gram frequency will need to be increased.

Figure 2 shows the F1-scores obtained running only on the documents contained in the *web* reference set with different orders of matching and scoring n-grams. Figure 3 shows the corresponding number of pairwise comparisons made when using different orders of matching n-grams. While there is a drop of 0.01 in F1 score between using 2-grams and 5-grams as matching n-grams, this drop in quality seems to be well worth the 42-fold reduction in resulting pairwise comparisons.

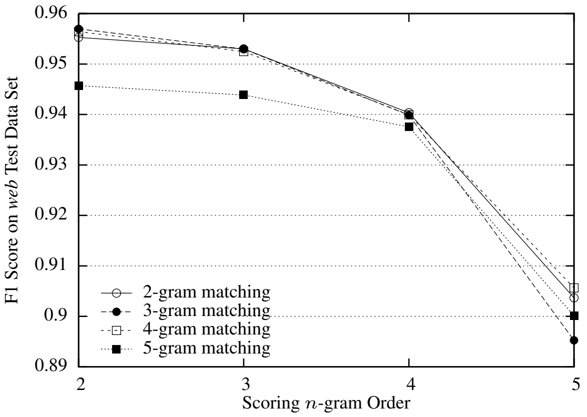

Figure 2: F1 scores on the *web* reference set for different scoring and matching n-gram orders.

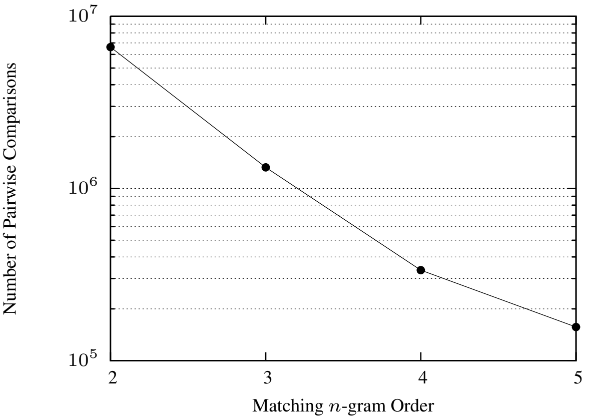

Figure 3: Number of pairwise comparisons made when using matching n-grams of different orders.

The largest portion of the loss in F1 score is incurred when increasing the matching n-gram order from 4 to 5, the reduction in pairwise comparisons, however, is still more than twofold.

Table 1 shows the precision and recall on the *web* reference set when running only on documents in the reference set using 5-grams as matching n-grams and bigrams for scoring for different values of the threshold on the cosine similarity score. In this setting as well as in large-scale experiments on both complete data sets described in section 6.1, a threshold of 0.1 yields the highest F1 score.

score threshold	0.06	0.10	0.12	0.16	0.20
precision	0.92	0.97	0.98	0.99	0.99
recall	0.91	0.91	0.90	0.89	0.83

Table 1: Precision and recall on the *web* reference set when running only on documents contained in the reference set.

6 Evaluation

We run the parallel text mining system on the *web* and *books* data sets using 5-grams for matching and bigrams for scoring. In both cases we discard matching n-grams which occurred in more than 50 documents and output only the highest scoring candidate for each document.

In case of the *web* data set, we extract every 5-gram as potential matching feature. For the *books* data set, however, we downsample the number of candidate matching 5-grams by extracting only those whose integer fingerprints under some hash function have four specific bits set, thus keeping on average only $1/16$ of the matching n-grams. Here, we also restrict the total number of matching n-grams extracted from any given document to 20,000. Scoring bigrams are dropped from the forward index if their document frequency exceeds 100,000, at which point their influence on the pairwise score would be negligible.

Running on the *web* data set, the system on average extracts 250 matching 5-grams per document, extracting a total of approximately 430 Billion distinct 5-grams. Of those, 78% are singletons and 21% only occur in a single language. Only approximately 0.8% of all matching n-grams are filtered due to having a document frequency higher than 50. The forward index initially contains more than 500 Billion bigram occurrences; after pruning out singletons and bigrams with a document frequency larger than 100,000, the number of indexed scoring feature occurrences is reduced to 40%. During scoring, approximately 50 Billion pairwise comparisons are performed.

In total the n-gram extraction, document scoring and subsequent filtering takes less than 24 hours on a cluster of 2,000 state-of-the-art CPUs.

The number of words after sentence-level filtering and alignment that the parallel text mining system extracted for the different languages from each dataset are listed in Table 2.

	baseline	*books*	*web*
Czech	27.5 M	0	271.9 M
French	479.8 M	228.5 M	4,914.3 M
German	54.2 M	0	3,787.6 M
Hungarian	26.9 M	0	198.9 M
Spanish	441.0 M	15.0 M	4,846.8 M

Table 2: The number of words per language in the baseline training corpora and extracted from the two different data sets.

score threshold	0.06	0.10	0.12	0.16	0.20
precision	0.88	0.93	0.95	0.97	0.97
recall	0.68	0.65	0.63	0.52	0.38

Table 3: Precision and recall on the reference set when running on the complete *web* data set with different score thresholds.

score threshold	0.06	0.10	0.12	0.16	0.20
precision	0.95	1.00	1.00	1.00	1.00
recall	0.71	0.71	0.71	0.48	0.38

Table 4: Precision and recall on the reference set when running on the complete *books* data set with different score thresholds.

6.1 Precision and Recall

Tables 3 and 4 show precision and recall on the respective reference sets for the *web* and the *books* input data sets. While the text mining system maintains a very high precision, recall drops significantly compared to running only on the documents in the reference set. One reason for this behavior is that the number of n-grams in the test data set which are sufficiently rare to be used as queries drops with increasing amounts of input data and in particular short documents which only share a small number of matching n-grams anyway, may happen to only share matching n-grams with a too high document frequency. Further analysis shows that another, more significant factor is the existence of multiple, possibly partial translations and near-duplicate documents which cause symmetrization to discard valid document pairs because each document in the pair is determined by the document pair score to be more similar to a different translation of a near-duplicate or sub-

Language Pair	Training Data	WMT 2007 news commentary	WMT 2008 news	WMT 2009 news

set of the document. This problem seems to affect news articles in particular where there are often multiple different translations of large subsets of the same or slightly changed versions of the article.

6.2 Translation Quality

Arabic English	NIST 2006	NIST 2008
Baseline (UN ODS)	44.31	42.79
Munteanu and Marcu	45.13	43.86
Present work	44.72	43.64

Chinese English	NIST 2006	NIST 2008
Baseline (UN ODS)	25.71	19.79
Munteanu and Marcu	28.11	21.69
Present work	28.08	22.02

Table 6: BLEU scores of the Chinese and Arabic to English translation systems trained on the baseline UN ODS corpus and after adding either the Munteanu and Marcu corpora or the training data mined using the presented approach.

We trained a phrase-based translation system on the mined parallel data sets and evaluated it on translation tasks for the language pairs Czech, French, German, Hungarian and Spanish to and from English, measuring translation quality with the BLEU score (Papineni et al., 2002). The translation tasks evaluated are the WMT 2007 news commentary test set as well the WMT 2008 and 2009 news test sets.

The parallel data for this experiment was mined using the general settings described in the previous section and a threshold of 0.1 on the pairwise score. We ensure that the test data is not included in the training data by filtering out all sentences from the training data that share more than 30% of their 6-grams with any sentence from one of the test corpora.

Table 5 shows the BLEU scores of the different translation systems. The consistent and significant improvements in BLEU score demonstrate the usefulness of the mined document pairs in training a translation system.

Even though the presented approach works on a less granular level than the sentence-level approach of Munteanu and Marcu (2005), we compare results on the same input data[2] used by those authors to automatically generate the

Table 7: BLEU scores of the degraded Czech to English baseline systems used for translating Czech documents from the *web* data set as well as those of Czech to and from English systems trained on data mined using translations of varying quality created by sampling from the training data.

Arabic English and Chinese English sentence-aligned parallel LDC corpora LDC2007T08 and LDC2007T09. We trained Arabic and Chinese English baseline systems on the United Nations ODS corpus (United Nations, 2006); we also use these to translate the non-English portions of the input data to English. We then evaluate the effects of also training on either the LDC2007T08 and LDC2007T09 corpora or the parallel documents mined by our approach in addition to the United Nations ODS corpus on the NIST 2006 and 2008 MT evaluation test sets. The results are presented in Table 6.

The approach proposed in (Munteanu and Marcu, 2005) relies critically on the existence of publication dates in order to be computationally feasible, yet it still scales superlinearly in the amount of input data. It could therefore not easily be applied to much larger and less structured input data collections. While our approach neither uses metadata nor operates on the sentence level, in all but one of the tasks, the system trained on the data mined using our approach performs similarly or slightly better.

6.3 Impact of Baseline Translation Quality

In order to evaluate the impact of the translation quality of the baseline system on the quality of the mined document pairs, we trained artificially degraded Czech to English translation systems by sampling from the baseline training data at decreasing rates. We translate the Czech subset of the *web* document collection into English with each of the degraded systems and apply the parallel data mining system in the same configuration.

Table 7 shows the BLEU scores of the degraded baseline systems and those resulting from adding the different mined data sets to the non-degraded Czech English and English Czech systems. Degrading the input data translation quality by up to 8.9% BLEU results in a consistent but only comparatively small decrease of less than 0.6% BLEU in the scores obtained when training on the mined document pairs. This does not only show that the impact of variations of the baseline system quality on the data mining system is limited, but also that the data mining system will already work with a rather low quality baseline system.

7 Conclusion

We presented a scalable approach to mining parallel text from collections of billions of documents with high precision. The system makes few assumptions about the input documents. We demonstrated that it works well on different types of data: a large collection of web pages and a collection of digitized books. We further showed that the produced parallel corpora can significantly improve the quality of a state-of-the-art statistical machine translation system.

Abstract

The precise identification of light verb constructions is crucial for the successful functioning of several NLP applications. In order to facilitate the development of an algorithm that is capable of recognizing them, a manually annotated corpus of light verb constructions has been built for Hungarian. Basic annotation guidelines and statistical data on the corpus are also presented in the paper. It is also shown how applications in the fields of machine translation and information extraction can make use of such a corpus and an algorithm.

1 Introduction

In this paper, we report a corpus containing light verb constructions in Hungarian. These expressions are neither productive nor idiomatic and their meaning is not totally compositional (the noun is usually taken in one of its literal senses but the verb usually loses its original sense to some extent), as it can be seen in the examples from different languages shown below. Since their meaning is the same, only literal translations are provided:

- English: *to give a lecture*, *to come into bloom*, *the problem lies (in)*
- German: *halten eine Vorlesung* to hold a presentation, *in Blüte stehen* in bloom to stand, *das Problem liegt (in)* the problem lies (in)
- French: *faire une présentation* to make a presentation, *être en fleur* to be in bloom, *le problème réside (dans)* the problem resides (in)
- Hungarian: *előadást tart* presentation-ACC holds, *virágba borul* bloom-ILL falls, *probléma rejlik (vmiben)* problem hides (in sg)

Several terms like *complex verb structures*, *support verb constructions* or *light verb constructions* have been used[1] for these constructions in the literature (Langer, 2004). In this paper, the term *light verb constructions* will be employed.

The structure of the paper is as follows. First, the importance of the special NLP treatment of light verb constructions is emphasized in section 2. The precise identification of such constructions is crucial for the successful functioning of NLP applications, thus, it is argued that an algorithm is needed to automatically recognize them (section 4). In order to facilitate the development of such an algorithm, a corpus of light verb constructions has been built for Hungarian, which is presented together with statistical data in section 5. Finally, it is shown how NLP applications in the fields of machine translation and information extraction can profit from the implementation of an algorithm capable of identifying light verb constructions (section 6).

2 Light verb constructions in NLP

In natural language processing, one of the most challenging tasks is the proper treatment of col-

[1] There might be slight theoretical differences in the usage of these terms – e.g. semantically empty support verbs are called *light verbs* in e.g. Meyers et al. (2004a), that is, the term *support verb* is a hypernym of *light verb*. However, these differences are not analyzed in detail in this paper.

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 1110–1118,
Beijing, August 2010

locations, which term comprises light verb constructions as well. Every multiword expression is considered to be a collocation if its members often co-occur and its form is fixed to some extent (Siepmann, 2005; Siepmann, 2006; Sag et al., 2001; Oravecz et al., 2004; Váradi, 2006). Collocations are frequent in language use and they usually exhibit unique behaviour, thus, they often pose a problem to NLP systems.

Light verb constructions deserve special attention in NLP applications for several reasons. First, their meaning is not totally compositional, that is, it cannot be computed on the basis of the meanings of the parts of the collocation and the way they are related to each other. Thus, the result of translating the parts of the collocation can hardly be considered as the proper translation of the original expression. Second, light verb constructions (e.g. *make a mistake*) often share their syntactic pattern with other constructions such as literal verb + noun combinations (e.g. *make a cake*) or idioms (e.g. *make a meal*), thus, their identification cannot be based on solely syntactic patterns. Third, since the syntactic and the semantic head of the construction are not the same – the syntactic head being the verb and the semantic head being the noun –, they require special treatment when parsing. It can be argued that they form a complex verb similarly to phrasal or prepositional verbs (as reflected in the term complex verb structures). Thus, it is advisable to indicate their special syntacto-semantic relationship: in dependency grammars, the new role QUASI-ARGUMENT might be proposed for this purpose.

3 Related work

Light verb constructions – as a subtype of multiword expressions – have been paid special attention in NLP literature. Sag et al. (2001) classify them as a subtype of lexicalized phrases and flexible expressions. They are usually distinguished from productive or literal verb + noun constructions on the one hand and idiomatic verb + noun expressions on the other hand: e.g. Fazly and Stevenson (2007) use statistical measures in order to classify subtypes of verb + noun combinations and Diab and Bhutada (2009) developed a chunking method for classifying multiword expressions.

Identifying multiword expressions in general and light verb constructions in particular is not unequivocal since constructions with similar syntactic structure (e.g. verb + noun combinations) can belong to different subclasses on the productivity scale (i.e. productive combinations, light verb constructions and idioms). That is why well-designed and tagged corpora of multiword expressions are invaluable resources for training and testing algorithms that are able to identify multiword expressions. For instance, Grégoire (2007) describes the design and implementation of a lexicon of Dutch multiword expressions. Focusing on multiword verbs, Kaalep and Muischnek (2006; 2008) present an Estonian database and a corpus and Krenn (2008) describes a database of German PP-verb combinations. The Prague Dependency Treebank also contains annotation for light verb constructions (Cinková and Kolářová, 2005) and NomBank (Meyers et al., 2004b) provides the argument structure of common nouns, paying attention to those occurring in support verb constructions as well. On the other hand, Zarrieß and Kuhn (2009) make use of translational correspondences when identifying multiword expressions (among them, light verb constructions). A further example of corpus-based identification of light verb constructions in English is described in Tan et al. (2006).

Light verb constructions are considered to be semi-productive, that is, certain verbs tend to co-occur with nouns belonging to a given semantic class. A statistical method is applied to measure the acceptability of possible light verb constructions in Stevenson et al. (2004), which correlates reasonably well with human judgments.

4 Identifying light verb constructions

A database of light verb constructions and an annotated corpus might be of great help in the automatic recognition of light verb constructions. They can serve as a training database when implementing an algorithm for identifying those constructions.

The recognition of light verb constructions cannot be solely based on syntactic patterns for other (productive or idiomatic) combinations may exhibit the same verb + noun scheme (see section

2). However, in agglutinative languages such as Hungarian, nouns can have several grammatical cases, some of which typically occur in a light verb construction when paired with a certain verb. For instance, the verb *hoz* 'bring' is a transitive verb, that is, it usually occurs with a noun in the accusative case. On the other hand, when it is preceded or followed by a noun in the sublative or illative case (the typical position of the noun in Hungarian light verb constructions being right before or after the verb[2]), it is most likely a light verb construction. To illustrate this, we offer some examples:

> *vizet hoz*
>
> water-ACC bring
>
> 'to bring some water'

> *zavarba hoz*
>
> trouble-ILL bring
>
> 'to embarrass'

The first one is a productive combination (with the noun being in the accusative form) while the second one is a light verb construction. Note that the light verb construction also has got an argument in the accusative case (syntactically speaking, a direct object complement) as in:

> *Ez a megjegyzés mindenkit zavarba hozott.*
>
> this the remark everyone-ACC trouble-ILL bring-PAST-3SG
>
> 'This remark embarrassed everybody.'

Thus, the presence of an argument in the accusative does not imply that the noun + verb combination is a light verb construction. On the other hand, the presence of a noun in the illative or sublative case immediately preceding or following the verb strongly suggests that a light verb instance of *hoz* is under investigation.

Most light verb constructions have a verbal counterpart derived from the same stem as the noun, which entails that it is mostly deverbal nouns that occur in light verb constructions (as in *make/take a **decision*** compared to ***decide*** or ***döntést** hoz* vs. ***dönt*** in Hungarian). The identification of such nouns is possible with the help of a morphosyntactic parser that is able to treat derivation as well (e.g. hunmorph for Hungarian (Trón et al., 2005)), and the combination of a possible light verb and a deverbal noun typically results in a light verb construction.

Thus, an algorithm that makes use of morphosyntactic and derivational information and previously given lists can be constructed to identify light verb constructions in texts. It is important that the identification of light verb constructions precedes syntactic parsing, for the noun and the verb in the construction form one complex predicate, which has its effects on parsing: other arguments belong not solely to the verb but to the complex predicate.

To the best of our knowledge, there are no corpora of light verb constructions available for Hungarian. That is why we decided to build such a corpus. The corpus is described in detail in section 5. On the basis of the corpus developed, we plan to design an algorithm to automatically identify light verb constructions in Hungarian.

5 The corpus

In order to facilitate the extraction and the NLP treatment of Hungarian light verb constructions, we decided to build a corpus in which light verb constructions are annotated. The Szeged Treebank (Csendes et al., 2005) – a database in which words are morphosyntactically tagged and sentences are syntactically parsed – constitutes the basis for the annotation. We first selected the subcorpora containing business news, newspaper texts and legal texts for annotation since light verb constructions are considered to frequently occur in these domains (see B. Kovács (1999)). However, we plan to extend the annotation to other subcorpora as well (e.g. literary texts) in a later phase. Statistical data on the annotated subcorpora can be seen in Table 1.

5.1 Types of light verb constructions

As Hungarian is an agglutinative language, light verb constructions may occur in various forms.

[2] In a neutral sentence, the noun is right before the verb, in a sentence containing focus, it is right after the verb.

	sentences	words
business news	9574	186030
newspapers	10210	182172
legal texts	9278	220069
total	29062	582871

Table 1: Number of sentences and words in the annotated subcorpora

For instance, the verbal component may be inflected for tense, mood, person, number, etc. However, these inflectional differences can be easily resolved by a lemmatizer. On the other hand, besides the prototypical noun + verb combination, light verb constructions may be present in different syntactic structures, that is, in participles and infinitives and they can also undergo nominalization. These types are all annotated in the corpus texts since they also occur relatively frequently (see statistical data in 5.3). All annotated types are illustrated below.

- **Noun + verb combination <verb>**

  bejelentést tesz

  announcement-ACC makes

  'to make an announcement'

- **Participles <part>**

  – Present participle
    életbe lépő (intézkedés)
    life-ILL stepping (instruction)
    '(an instruction) taking effect'

  – Past participle
    csődbe ment (cég)
    bankrupt-ILL gone (firm)
    '(a firm) that went bankrupt'

  – Future participle
    fontolóra veendő (ajánlat)
    consideration-SUB to be taken (offer)
    '(an offer) that is to be taken into consideration'

  – Infinitive
    forgalomba hozni
    circulation-ILL bring-INF
    'to put into circulation'

- **Nominalization <nom>**

  bérbe vétel

  rent-ILL taking

  'hiring'

Split light verb constructions, where the noun and the verb are not adjacent, are also annotated and tagged. In this way, their identification becomes possible and the database can be used for training an algorithm that automatically recognizes (split) light verb constructions.

5.2 Annotation principles

Corpus texts contain single annotation, i.e. one annotator worked on each text. Light verb constructions can be found in between XML tags <FX> </FX>. In order to decide whether a noun + verb combination is a light verb construction or not, annotators were suggested to make use of a test battery developed for identifying Hungarian light verb constructions (Vincze, 2008).

The annotation process was carried out manually on the syntactically annotated version of the Szeged Treebank, thus, phrase boundaries were also taken into consideration when marking light verb constructions. Since the outmost boundary of the nominal component was considered to be part of the light verb construction, in several cases adjectives and other modifiers of the nominal head are also included in the construction, e.g.:

> *<FX>**nyilvános** ajánlatot tesz</FX>*
>
> public offer-ACC make
>
> 'to make a public offer'

In the case of participles, NP arguments may be also included (although in English, the same argument is expressed by a PP):

> *<FX>**Nyíregyházán** tartott ülésén</FX>*
>
> Nyíregyháza-SUP hold-PPT session-3SGPOSS-SUP
>
> 'at its session held in Nyíregyháza'

Constructions with a nominal component in the accusative case can be nominalized in two ways in Hungarian, as in:

szerződést köt

contract-ACC bind

’to make a contract’

<FX>szerződéskötés</FX>

contract+bind-GERUND

’making a contract’

<FX>adásvételi szerződések megkötése</FX>

sale contract-PL PREVERB-bind-GERUND-3SGPOSS

’making of sales contracts’

Both types are annotated in the corpus.

Besides the prototypical occurrences of light verb constructions (i.e. a bare common noun + verb[3]), other instances were also annotated in the corpus. For instance, the noun might be accompanied by an article or a modifier (recall that phrase boundaries were considered during annotation) or – for word order requirements – the noun follows the verb as in:

Ő hozta a jó döntést.

he bring-PAST-3SG-OBJ the good decision-ACC

’It was him who made the good decision.’

For the above reasons, a single light verb construction manifests in several different forms in the corpus. However, each occurrence is manually paired with its prototypical (i.e. bare noun + verb) form in a separate list, which is available at the corpus website.

5.3 Statistics on corpus data

The database contains 3826 occurrences of 658 light verb constructions altogether in 29062 sentences. Thus, a specific light verb construction occurs 5.8 times in the corpus on average. However, the participle form *irányadó* occurs in 607 instances (e.g. in *irányadó kamat* ’prime rate’) due to the topic of the business news subcorpus, which may distort the percentage rates. For this reason, statistical data in Table 2 are shown the occurrences of *irányadó* excluded.

	verb	part	nom	split	total
business news	565 58.6%	270 28%	90 9.3%	40 4.1%	965 25.2%
news- papers	458 59.3%	192 24.9%	55 7.1%	67 8.7%	772 20.2%
legal texts	640 30.7%	504 24.1%	709 33.9%	236 11.3%	2089 54.6%
total	1663 43.5%	966 25.2%	854 22.3%	236 9%	3826 100%

Table 2: Subtypes of light verb constructions in the corpus

It is revealed that although it is verbal occurrences that are most frequent, the percentage rate of participles is also relatively high. The number of nominalized or split constructions is considerably lower (except for the law subcorpus, where their number is quite high), however, those together with participles are responsible for about 55% of the data, which indicates the importance of their being annotated as well.

As for the general frequency of light verb constructions in texts, we compared the number of verb + argument relations found in the Szeged Dependency Treebank (Vincze et al., 2010) where the argument was a common noun to that of light verb constructions. It has turned out that about 13% of verb + argument relations consist of light verb constructions. This again emphasizes that they should be paid attention to, especially in the legal domain (where this rate is as high as 36.8%). Statistical data are shown in Table 3.

	V + argument	LVC
business news	9524	624 (6.6%)
newspapers	3637	539 (14.8%)
legal texts	2143	889 (36.8%)
total	15574	2052 (13.2%)

Table 3: Verb + argument relations and light verb constructions

The corpus is publicly available for re-

[3] As opposed to other languages where prototypical light verb constructions consist of a verb + a noun in accusative or a verb + a prepositional phrase (see e.g. Krenn (2008)), in Hungarian, postpositional phrases rarely occur within a light verb construction. However, annotators were told to annotate such cases as well.

6 The usability of the corpus

As emphasized earlier, the proper treatment of light verb constructions is of primary importance in NLP applications. In order to achieve this, their identification is essential. The corpus created can function as the training database for the implementation of an algorithm capable of recognizing light verb constructions, which we plan to develop in the near future. In the following, the ways machine translation and information extraction can profit from such a corpus and algorithm are shortly presented.

6.1 Light verb constructions and machine translation

When translating collocations, translation programs face two main problems. On the one hand, parts of the collocation do not always occur next to each other in the sentence (split collocations). In this case, the computer must first recognize that the parts of the collocation form one unit (Oravecz et al., 2004), for which the multiword context of the given word must be considered. On the other hand, the lack (or lower degree) of compositionality blocks the possibility of word-by-word translation (Siepmann, 2005; Siepmann, 2006). However, a (more or less) compositional account of light verb constructions is required for successful translation (Dura and Gawrońska, 2005).

To overcome these problems, a reliable method is needed to assure that the nominal and verbal parts of the construction be matched. This requires an algorithm that can identify light verb constructions. In our corpus, split light verb constructions are also annotated, thus, it is possible to train the algorithm to recognize them as well: the problem of split collocations can be eliminated in this way.

A comprehensive list of light verb constructions can enhance the quality of machine translation – if such lists are available for both the source and the target language. Annotated corpora (especially and most desirably, parallel corpora) and explanatory-combinatorial dictionaries[4] are possible sources of such lists. Since in foreign language equivalents of light verb constructions, the nominal components are usually literal translations of each other (Vincze, 2009), by collating the corresponding noun entries in these lists the foreign language variant of the given light verb construction can easily be found. On the other hand, in order to improve the building of such lists, we plan to annotate light verb constructions in a subcorpus of SzegedParalell, a Hungarian-English manually aligned parallel corpus (Tóth et al., 2008).

6.2 Light verb constructions and information extraction

Information extraction (IE) seeks to process large amounts of unstructured text, in other words, to collect relevant items of information and to classify them. Even though humans usually overperform computers in complex information processing tasks, computers also have some obvious advantages due to their capacity of processing and their precision in performing well-defined tasks.

For several IE applications (e.g. relationship extraction) it is essential to identify phrases in a clause and to determine their grammatical role (subject, object, verb) as well. This can be carried out by a syntactic parser and is a relatively simple task. However, the identification of the syntactic status of the nominal component is more complex in the case of light verb constructions for it is a quasi-argument of the verb not to be confused with other arguments (Alonso Ramos, 1998). Thus, the parser should recognize the special status of the quasi-argument and treat it in a specific way as in the following sentences, one of which contains a light verb construction while the other one a verbal counterpart of the construction:

Pete ***made a decision*** *on his future.*

Pete ***decided*** *on his future.*

[4] Explanatory combinatorial dictionaries are essential for relation descriptions (up to the present, only fractions of the dictionary have been completed for Russian (Mel'čuk and Žolkovskij, 1984) and for French (see Mel'čuk et al. (1984 1999)), besides, trial entries have been written in Polish, English and German that contain the relations of a certain lexical unit to other lexemes given by means of lexical functions (see e.g. Mel'čuk et al. (1995)). These dictionaries indicate light verb constructions within the entry of the nominal component.

In the sentence with the verbal counterpart, the event of deciding involves two arguments: *he* and *his future*. In the sentence with the light verb construction, the same arguments can be found, however, it is unresolved whether they are the arguments of the verb (*made*) or the nominal component (*decision*). If a precise syntactic analysis is needed, it is crucial to know which argument belongs to which governor. Nevertheless, it is still debated if syntactic arguments should be divided between the nominal component and the verb (see Meyers et al. (2004a) on argument sharing) and if yes, how (Alonso Ramos, 2007).

For the purpose of information extraction, such a detailed analysis is unnecessary and in general terms, the nominal component can be seen as part of the verb, that is, they form a complex verb similarly to phrasal or prepositional verbs and this complex verb is considered to be the governor of arguments. Thus, the following data can be yielded by the IE algorithm: there is an event of **decision-making**, **Pete** is its subject and it is about **his future** (and not an event of **making** with the arguments **decision**, **Pete** and **his future**). Again, the precise identification of light verb constructions can highly improve the performance of parsers in recognizing relations between the complex verb and its arguments.

7 Conclusion

In this paper, we have presented the development of a corpus of Hungarian light verb constructions. Basic annotation guidelines and statistical data have also been included. The annotated corpus can serve as a training database for implementing an algorithm that aims at identifying light verb constructions. Several NLP applications in the fields of e.g. machine translation and information extraction may profit from the successful integration of such an algorithm into the system, which we plan to develop in the near future.

Abstract

Syntax based reordering has been shown to be an effective way of handling word order differences between source and target languages in Statistical Machine Translation (SMT) systems. We present a simple, automatic method to learn rules that reorder source sentences to more closely match the target language word order using only a source side parse tree and automatically generated alignments. The resulting rules are applied to source language inputs as a pre-processing step and demonstrate significant improvements in SMT systems across a variety of languages pairs including English to Hindi, English to Spanish and English to French as measured on a variety of internal test sets as well as a public test set.

1 Introduction

Different languages arrange words in different orders, whether due to grammatical constraints or other conventions. Dealing with these word order permutations is one of the fundamental challenges of machine translation. Given an exceptionally large training corpus, a phrase-based system can learn these reordering on a case by case basis. But, if our systems are to generalize to phrases not seen in the training data, they must explicitly capture and model these reorderings. However, permutations are difficult to model and impractical to search.

Presently, approaches that handle reorderings typically model word and phrase movements via a *distortion model* and rely on the target language model to produce words in the right order. Early distortion models simply penalized longer jumps more than shorter jumps (Koehn et al., 2003) independent of the source or target phrases in question. Other models (Tillman, 2004), (Al-Onaizan and Papineni, 2006) generalize this to include lexical dependencies on the source.

Another approach is to incorporate features, based on the target syntax, during modeling and decoding, and this is shown to be effective for various language pairs (Yamada and Knight, 2001), (Zollmann and Venugopal, 2006). Hierarchical phrase-based decoding (Chiang, 2005) also allows for long range reordering without explicitly modeling syntax. While these approaches have been shown to improve machine translation performance (Zollmann et al., 2008) they usually combine chart parsing with the decoding process, and are significantly more computationally intensive than phrase-based systems.

A third approach, one that has proved to be useful for phrase-based SMT systems, is to reorder each source-side sentence using a set of rules applied to a parse tree of the source sentence. The goal of these rules is to make the word order of the source sentence more similar to the expected target sentence word order. With this approach, the reordering rules are applied before training and testing with an SMT system. The efficacy of these methods has been shown on various language pairs including: French to English (Xia and McCord, 2004), German to English (Collins et al., 2005), English to

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 1119–1127,
Beijing, August 2010

Chinese, (Wang et al., 2007) and Hindi to English (Ramanathan et al., 2008).

In this paper, we propose a simple model for reordering conditioned on the source side parse tree. The model is learned using a parallel corpus of source-target sentence pairs, machine generated word alignments, and source side parses. We apply the reordering model to both training and test data, for four different language pairs: English → Spanish, English → French, English → Hindi, and English → German. We show improvements in machine translation performance for all of the language pairs we consider except for English → German. We use this negative result to propose extensions to our reordering model. We note that the syntax based reordering we propose can be combined with other approaches to handling reordering and does not have to be followed by an assumption of monotonicity. In fact, our phrase-based model, trained upon reordered data, retains its reordering models and search, but we expect that these facilities are employed much more sparingly with reordered inputs.

2 Related work

There is a significant quantity of work in syntax based reordering employed to improve machine translation systems. We summarize our contributions to be:

- Learning the reordering rules based on training data (without relying on linguistic knowledge of the language pair)
- Requiring only source side parse trees
- Experimental results showing the efficacy for multiple language pairs
- Using a lexicalized distortion model for our baseline decoder

There have been several studies that have demonstrated improvements with syntax based reordering based upon hand-written rules. There have also been studies investigating the sources of these improvements (Zwarts and Dras, 2007). Hand-written rules depend upon expert knowledge of the linguistic properties of the particular language pair. Initial efforts (Niessen and Ney, 2001) were made at improving German-English translation by handling two phenomena: question inversion and detachable verb prefixes in German. In (Collins et al., 2005), (Wang et al., 2007), (Ramanathan et al., 2008), (Badr et al., 2009) rules are developed for translation from German to English, Chinese to English, English to Hindi, and English to Arabic respectively. (Xu et al., 2009) develop reordering rules based upon a linguistic analysis of English and Korean sentences and then apply those rules to translation from English into Korean and four other languages: Japanese, Hindi, Urdu and Turkish. Unlike this body of work, we automatically learn the rules from the training data and show efficacy on multiple language pairs.

There have been some studies that try to learn rules from the data. (Habash, 2007) learns reordering rules based on a dependency parse and they report a negative result for Arabic to English translation. (Zhang et al., 2007) learn reordering rules on chunks and part of speech tags, but the rules they learn are not hierarchical and would require large amounts of training data to learn rules for long sentences. Additionally, we only keep a single best reordering (instead of a lattice with possible reorderings) which makes the decoding significantly more efficient. (Xia and McCord, 2004) uses source and target side parse trees to automatically learn rules to reorder French sentences to match English order. The requirement to have both source and target side parse trees makes this method inapplicable to any language that does not have adequate tree bank resources. In addition, this work reports results using monotone decoding, since their experiments using non-monotone decoding without a distortion model were actually worse.

3 Reordering issues in specific languages

In this section we discuss the reordering issues typical of translating between English and Hindi, French, Spanish and German which are the four language pairs we experiment on in this paper.

3.1 Spanish and French

Typical word ordering patterns common to these two European languages relate to noun phrases including groups of nouns and adjectives. In contrast to English, French and Spanish adjectives and adjunct nouns follow the main noun, i.e. we typically observe a reversal of word order in noun phrases, e.g., *"A beautiful red car"* translates into French as *"Une voiture rouge beau"*, and as *"Un coche rojo bonito"* into Spanish. Phrase-based MT systems are capable of capturing these patterns provided they occur with sufficient frequency for each example in the training data. For rare noun phrases, however, the MT may produce erroneous word order that can lead to serious distortions in the meaning. Particularly difficult are nominal phrases from specialized domains that involve challenging terminology, for example: "*group reference attribute*" and "*validation checking code*". In both instances, the baseline MT system generated translations with an incorrect word order and, consequently, possibly a different meaning. We will return to these two examples in Section 5.1 to compare the output of a MT system with and without reordering.

3.2 German

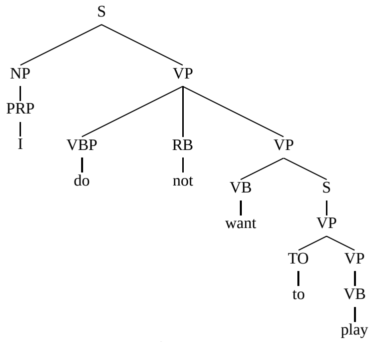
Unlike French and Spanish, German poses a considerably different challenge with respect to word ordering. The most frequent reordering in German relates to verbs, particularly verb groups consisting of auxiliary and main verbs, as well as verbs in relative clauses. Moreover, reordering patterns between German and English tend to span large portions of the sentence. We included German in our investigations to determine whether our automated rule extraction procedure can capture such long distance patterns.

3.3 Hindi

Hindi word order is significantly different than English word order; the typical order followed is Subject Object Verb (although Object Subject Verb order can be used if nouns are followed by appropriate case markers). This is in contrast to English which has a Subject Verb Object order. This can result in words that are close in English moving arbitrarily far apart in Hindi depending on the length of the noun phrase representing the object and the length of the verb phrase. These long range reorderings are generally hard for a phrase based system to capture. Another way Hindi and English differ is that prepositions in English become postpositions in Hindi and appear after the noun phrase. Again, this reordering can lead to long distance movements of words. We include Hindi in our investigation since it has significantly different structure as compared to English.

4 Learning reordering rules

In this section we describe how we learn rules that transform source parse trees so the leaf word order is more like the target language. We restrict ourselves to reorderings that can be obtained by permuting child nodes at various interior nodes in a parse tree. With many reordering phenomena discussed in Section 3 this is a fairly strong assumption about pairs of languages, and there are examples in English→Hindi where such an assumption will not allow us to generate the right reordering. As an example consider the English sentence "*I do not want to play*". The sentence has a parse:



The correct word order of the translation in Hindi is "*I to play not want*" In this case, the word *not* breaks up the verb phrase *want to play* and hence the right Hindi word order cannot be obtained by the reordering allowed by our model. We found such examples to be rare in English→Hindi, and we impose this restriction for the simplicity of the model. Experimental results on several languages show benefits of reordering in spite of this simplifying assumption.

Consider a source sentence s and its corresponding constituency parse tree S[1]. We set up the problem in a probabilistic framework, i.e. we would like to build a probabilistic model $P(T|S)$ that assigns probabilities to trees such that the

[1] In this paper we work with constituency parse trees. Initial experiments, applying similar techniques to dependency parse trees did not yield improvements.

word order in trees T which are assigned higher probability match the order of words in the target language. A parse tree, S is a set of nodes. Interior nodes have an ordered list of children. Leaf nodes in the tree are the words in the sentence s, and interior nodes are labeled by the linguistic constituent that they represent. Each word has a parent node (with only one child) labeled by the part-of-speech tag of the word.

Our model assigns non-zero probabilities to trees that can be obtained by permuting the child nodes at various interior nodes of the tree S. We assume that children of a node are ordered independently of all other nodes in the tree. Thus

$$P(T|S) = \prod_{n \in I(S)} P(\pi(c_n)|S, n, c_n),$$

where $I(S)$ is the set of interior nodes in the tree S, c_n is the list of children of node n and π is a permutation. We further assume that the reordering at a particular node is dependent only on the labels of its children:

$$P(T|S) = \prod_{n \in I(S)} P(\pi(c_n)|c_n).$$

We parameterize our model using a log-linear model:

$$P(\pi(c_n)|c_n) = \frac{1}{Z(c_n)} \exp(\lambda^T f(\pi, c_n)). \quad (1)$$

We choose the simplest possible set of feature functions: for each observed sequence of non-terminals we have one boolean feature per permutation of the sequence of non-terminals, with the feature firing iff that particular sequence is observed. Assuming, we have a training corpus C of (T, S) tree pairs, we could optimize the parameters of our model to maximize : $\prod_{S \in C} P(T|S)$. With the simple choice of feature functions described above, this amounts to:

$$P(\pi(c_n)|c_n) = \frac{\mathrm{count}(\pi(c_n))}{\mathrm{count}(c_n)},$$

where $\mathrm{count}(c_n)$ is the number of times the sequences of nodes c_n is observed in the training data and $\mathrm{count}(\pi(c_n))$ is the number of times that c_n in S is permuted to $\pi(c_n)$ in T. In Section 6, we show considering more general feature functions and relaxing some of the independence might yield improvements on certain language pairs.

For each source sentence s with parse S we find the tree T that makes the given alignment for that sentence pair most monotone. For each node n in the source tree S let D_n be the set of words that are descendants of n. Let us denote by $tpos(n)$ the average position of words in the target sentence that are aligned to words in D_n. Then

$$tpos(n) = \frac{1}{|D_n|} \sum_{w \in D_n} a(w),$$

where $a(w)$ is the index of the word on the target side that w is aligned with. If a word w is not aligned to any target word, we leave it out from the mean position calculation above. If a word w is aligned to many words we let $a(w)$ be the mean position of the words that w is aligned to. For each node n in the tree we transform the tree by sorting the list of children of n according to $tpos$. The pairs of parse trees that we obtain (S, T) in this manner form our training corpus to estimate our parameters.

In using our model, we once again go for the simplest choice, we simply reorder the source side sentences by choosing $\arg\max_T P(T|S)$ both in training and in testing; this amounts to reordering each interior node based on the most frequent reordering of the constituents seen in training. To reduce the effect of noise in training alignments we apply the reordering, only if we have seen the constituent sequence often enough in our training data (a *count threshold* parameter) and if the most frequent reordering is sufficiently more frequent than the next most frequent reordering (a *significance threshold*).

5 Experiments

5.1 Results for French, Spanish, and German

In each language, the rule extraction was performed using approximately 1.2M sentence pairs aligned using a maxent aligner (Ittycheriah and Roukos, 2005) trained using a variety of domains (Europarl, computer manuals) and a maximum entropy parser for English (Ratnaparkhi, 1999). With a significance threshold of 1.2, we obtain about 1000 rules in the eventual reordering process.

Phrase-based systems were trained for each language pair using 11M sentence pairs spanning a variety of publicly available (e.g. Europarl, UN speeches) and internal corpora (IT technical and news domains). The system phrase blocks were extracted based on a union of HMM and max-ent alignments with corpus-selective count pruning. The lexicalized distortion model was used as described in (Al-Onaizan and Papineni, 2006) with a window width of up to 5 and a maximum number of skipped (not covered) words during decoding of 2. The distortion model assigns a probability to a particular word to be observed with a specific jump. The decoder uses a 5-gram interpolated language model spanning the various domains mentioned above. The baseline system without reordering and a system with reordering was trained and evaluated in contrastive experiments. The evaluation was performed utilizing the following (single-reference) test sets:

- *News*: 541 sentences from the news domain.
- *TechA:* 600 sentences from a computer-related technical domain, this has been used as a dev set.
- *TechB:* 1038 sentences from a similar domain as *TechA* used as a blind test.
- *Dev09:* 1026 sentences defined as the *news-dev2009b* development set of the Workshop on Statistical Machine Translation 2009 [2]. This set provides a reference measurement using a public data set. Previously published results on this set can be found, for example, in (Popovic et al., 2009).

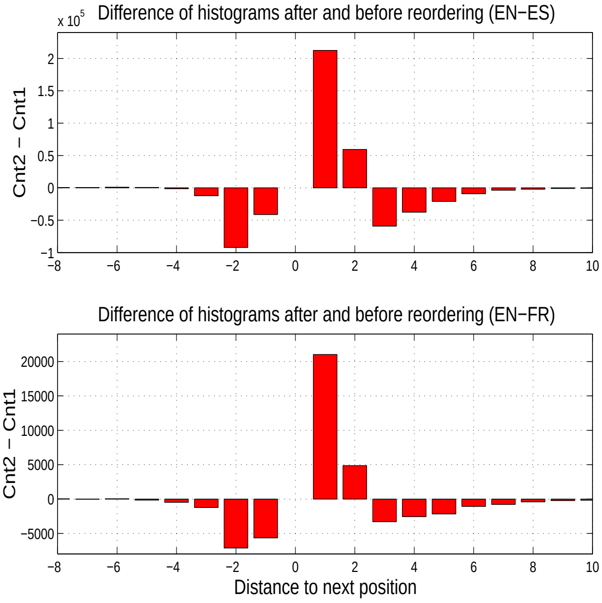


Figure 1: Difference-histogram of word order distortions for English→Spanish (upper), and English→French (lower).

In order to assess changes in word ordering patterns prior to and after an application of the reordering, we created histograms of word jumps in the alignments obtained in the baseline as well as in the reordered system. Given a source word s_i at index i and the target word t_j it is aligned to at index j, a jump of 1 would correspond to s_{i+1} aligning to target word t_{j+1}, while an alignment to t_{j-1} corresponds to a jump of -1, etc. A histogram over the jump values gives us a summary of word order distortion. If all of the jumps were one, then there is no reordering between the two languages. To gain insight into changes introduced by our reordering we look at differences of the two histograms i.e., counts after reordering minus counts before reordering. We would hope that after reordering most of the jumps are small and concentrated around one. Figure 1 shows such *difference*-histograms for the language pairs English→Spanish and English→French, respectively, on a sample of about 15k sentence pairs held out of the system training data. Here, a positive difference value indicates an increased number *after* reordering. In both cases a consistent trend toward monotonicity is observed, i.e more jumps of size one and two, and fewer large jumps. This confirms the intended reordering effect and indicates that the reordering rules extracted generalize well.

Table 1 shows the resulting uncased BLEU scores for English-Spanish and English-French.

In both cases the reordering has a consistent positive effect on the BLEU scores across test sets. In examining the sources of improvement, we noticed that word order in several noun phrases that

[2] http://statmt.org/wmt09/

	System	News	TechA	TechB	Dev09
Spanish	Baseline	0.3849	0.3371	0.3483	0.2244
	Reordered	0.4031	0.3582	0.3605	0.2320
French	Baseline	0.5140	0.2971	0.3035	0.2014
	Reordered	0.5242	0.3152	0.3154	0.2092
German	Baseline	0.2580	0.1582	0.1697	0.1281
	Reordered	0.2544	0.1606	0.1682	0.1271
Hindi	Baseline	20.0			
	Reordered	21.7			

Table 1: Uncased BLEU scores for phrase-based machine translation.

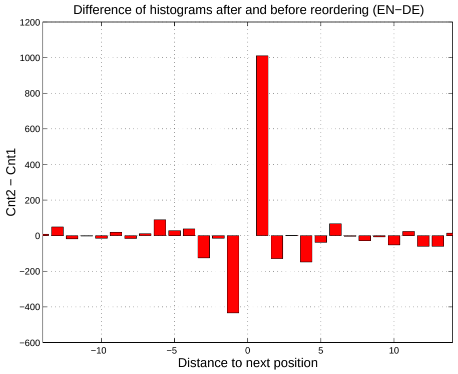

Figure 2: Difference-histogram of word order distortions for English→German.

were not common in the training data were fixed by use of the reordering rules.

Table 1 shows the BLEU scores for the English→German language pair, for which a mixed result is observed. The difference-histogram for English→German, shown in Figure 2, differs from those of the other languages with several increases in jumps of large magnitude, indicating failure of the extracted rules to generalize.

The failure of our simple method to gain consistent improvements comparable to Spanish and French, along with our preliminary finding that a relatively few manually crafted reordering rules (we describe these in Section 6.4) tend to outperform our method, leads us to believe that a more refined approach is needed in this case and will be subject of further discussion below.

5.2 Results for Hindi

Our Hindi-English experiments were run with an internal parallel corpus of roughly 250k sentence pairs (5.5M words) consisting of various domains (including news). To learn reordering rules we used HMM alignments and a maxent parser (Ratnaparkhi, 1999), with a count threshold of 100, and a significance threshold of 1.7 (these settings gave us roughly 200 rules). We also experimented with other values of these thresholds and found that the performance of our systems were not very sensitive to these thresholds. We trained Direct Translation Model 2 (DTM) systems (Ittycheriah and Roukos, 2007) with and without source reordering and evaluated on a test set of 357 sentences from the News domain. We note that the DTM baseline includes features (functions of target words and jump size) that allow it to model lexicalized reordering phenomena. The reordering window size was set to +/- 8 words for the baseline and system with reordered inputs. Table 1 shows the uncased BLEU scores for English-Hindi, showing a gain from using the reordering rules. For the reordered case, the HMM alignments are rederived, but the accuracy of these were no better than those of the unreordered input and experiments showed that the gains in performance were not due to the effect on the alignments.

Figure 3 shows *difference*-histograms for the language pair English→Hindi, on a sample of about 10k sentence pairs held out of the system training data. The histogram indicates that our reordering rules generalize and that the reordered English is far more monotonic with respect to the Hindi.

6 Analysis of errors and future directions

In this section, we analyze some of the sources of errors in reordering rules learned via our model, to better understand directions for further improvement.

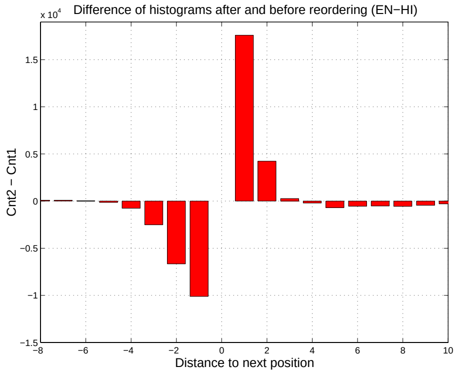

Figure 3: Difference-histogram of word order distortions for English→Hindi.

6.1 Model weakness

In our initial experiments, we noticed that for the most frequent reordering rules in English→Hindi (e.g that IN NP or NP PP flips in Hindi) the probability of a reordering was roughly 65%. This was concerning since it meant that on 35% of the data we would be making wrong reordering decisions by choosing the most likely reordering. To get a better feel for whether we needed a stronger model (e.g by lexicalization or by looking at larger context in the tree rather than just the children), we analyzed some of the cases in our training data where (IN,NP), (NP, PP) pairs were left unaltered in Hindi. In doing that analysis, we noticed examples involving negatives that our model does not currently handle. The first issue was mentioned in Section 4, where the assumption that we can achieve the right word order by reordering constituent phrases, is incorrect. The second issue is illustrated by the following sentences: *I have some/no books*, which have similar parse structures, the only difference being the determiner *some* vs the determiner *no*. In Hindi, the order of the fragments *some books* and the fragment *no books* are different (in the first case the words stay in order, in the second the flip). Handling this example would need our model to be lexicalized. These issue of negatives requiring special handling also came up in our analysis of German (Section 6.4). Other than the negatives (which require a lexicalized model), the major reason for the lack of sharpness of the reordering rule probability was alignment errors and parser issues. We look at these topics next.

Aligner	Number of Sentences	fMeasure	BLEU score
HMM	250k	62.4	21.7
MaxEnt	250k	76.6	21.4
Manual	5k	-	21.3

Table 2: Using different alignments

6.2 Alignment accuracy

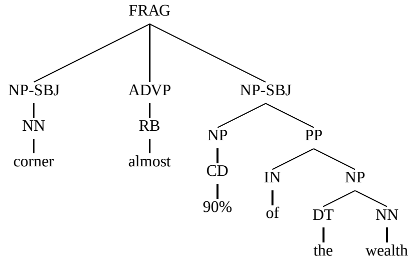
Since we rely on automatically generated alignments to learn the rules, low accuracy of the alignments could impact the quality of the rules learned. This is especially a concern for English→Hindi since the quality of HMM alignments are fairly low. To quantify this effect, we learn reordering rules using three sets of alignments: HMM alignments, alignments from a supervised MaxEnt aligner (Ittycheriah and Roukos, 2005), and hand alignments. Table 2 summarizes our results using aligners with differing alignment qualities for our English→Hindi task and shows that quality of alignments in learning the rules is not the driving factor in affecting rule quality.

6.3 Parser accuracy

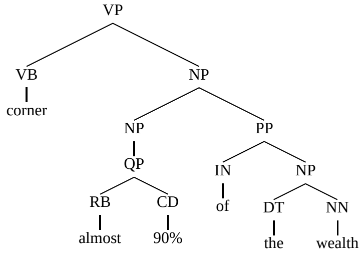
Accuracy of the parser in the source language is a key requirement for our reordering method, because we choose the single best reordering based on the most likely parse of the source sentence. This would especially be an issue in translating *from* languages other than English, where the parser would not be of quality comparable to the English parser.

In examining some of the errors in reordering we did observe a fair fraction attributable to issues in parsing, as seen in the example sentence: *The rich of this country , corner almost 90% of the wealth .*

The second half of the sentence is parsed by the Berkeley parser (Petrov et al., 2006) as:



and by IBM's maximum entropy parser parser (Ratnaparkhi, 1999) as:



With the first parse, we get the right Hindi order for the second part of the sentence which is: *the wealth of almost 90% corner* . To investigate the effect of choice of parser we compared using the Berkeley parser and the IBM parser for reordering, and we found the BLEU score essentially unchanged: 21.6 for the Berkeley parser and 21.7 for the IBM parser. A potential source of improvements might be to use alternative parses (via different parsers or n-best parses) to generate n-best reorderings both in training and at test.

6.4 Remarks on German reordering

Despite a common heritage, German word order is distinct from English, particularly regarding verb placement. This difference can be dramatic, if an auxiliary (e.g. modal) verb is used in conjunction with a full verb, or the sentence contains a subordinate clause. In addition to our experiments with automatically learned rules, a small set of handcrafted reordering rules was created and evaluated. Our preliminary results indicate that the latter rules tend to outperform the automatically derived ones by 0.5-1.0 BLEU points on average. These rules are summarized as follows:

1. In a VP immediately following an NP, move the negation particle to main verb.
2. Move a verb group away from a modal verb; to the end the of a VP. Negation also moves along with verb.
3. Move verb group to end of an embedded/relative clause.
4. In a VP following a subject, move negation to the end of VP (handling residual cases)

The above hand written rules show several weaknesses of our automatically learned rules for reordering. Since our model is not lexicalized, negations are not handled properly as they are tagged RB (along with other adverbs). Another limitation apparent from the first rule above (the movement of verbs in a verb phrase depends on the previous phrase being a noun phrase) is that the automatic reordering rule for a node's children depends only on the children of that node and not a larger context. For instance, a full verb following a modal verb is typically parsed as a VP child node of the modal VP node, hence the automatic rule, as currently considered, will not take the modal verb (being a sibling of the full-verb VP node) into account. We are currently investigating extensions of the automatic rule extraction alorithm to address these shortcomings.

6.5 Future directions

Based on our analysis of the errors and on the hand designed German rules we would like to extend our model with more general feature functions in Equation 1 by allowing features: that are dependent on the constituent words (or headwords), that examine a large context than just a nodes children (see the first German rule above) and that fire for all permutations when the constituent X is moved to the end (or start). This would allow us to generalize more easily to learn rules of the type "move X to the end of the phrase". Another direction that we feel should be explored, is the use of multiple parses to obtain multiple reorderings and combine these at a later stage.

7 Conclusions

In this paper we presented a simple method to automatically derive rules for reordering source sentences to make it look more like target language sentences. Experiments (on internal and public test sets) indicate performance gains for English→French, English→Spanish, and English→Hindi. For English→German we did not see improvements with automatically learned rules while a few hand designed rules did give improvements, which motivated a few directions to explore.

benno.stein@uni-weimar.de

Abstract

Strategic business decision making involves the analysis of market forecasts. Today, the identification and aggregation of relevant market statements is done by human experts, often by analyzing documents from the World Wide Web. We present an efficient information extraction chain to automate this complex natural language processing task and show results for the identification part. Based on time and money extraction, we identify sentences that represent statements on revenue using support vector classification. We provide a corpus with German online news articles, in which more than 2,000 such sentences are annotated by domain experts from the industry. On the test data, our statement identification algorithm achieves an overall precision and recall of 0.86 and 0.87 respectively.

1 Introduction

Touch screen market to hit $9B by 2015. 50 suppliers provide multi-touch screens, and that number is likely to rise.[1]

Strategic business decision making is a highly complex process that requires experience as well as an overall view of economics, politics, and technological developments. Clearly, for the time being this process cannot be done by a computer at the level of a human expert. However, important tasks may be automated such as market forecasting, which relies on identifying and aggregating relevant information from the World Wide Web (Berekoven et. al., 2001). An analyst who interprets the respective data can get a reasonable idea about the future market volume, for example. The problem is that a manually conducted Web search is time-consuming and usually far from being exhaustive. With our research we seek to develop an efficient system that finds and analyzes market forecast information with retrieval, extraction and natural language processing (NLP) techniques.

We contribute to the following situation. For a given product, technology, or industry sector we identify and aggregate statements on its market development found on relevant websites. In particular, we extract time information (“by 2015”) and money information (“$9B”) and use support vector classification to identify sentences that represent market statements. The statements’ subjects (“touch screen”) are found by relating recognized named entities to the time and money information, which we then normalize and aggregate. In this paper we report on results for the statement identification. To the best of our knowledge no data for the investigation of such market analysis tasks has been made publicly available until now. We provide such a corpus with statements on revenue annotated in news articles from the Web; the corpus was created in close collaboration with our industry partner *Resolto Informatik GmbH*.

We pursue two objectives, namely, to support human experts with respect to the effectiveness and completeness of their analysis, and to establish a technological basis upon which more intricate analysis tasks can be automated. To summarize, the main contributions of this paper are:

1. We show how to decompose the identification and aggregation of forecasts into retrieval, extraction, and normalization tasks.

2. We introduce a manually annotated German corpus for computational linguistics research on market information.

3. We offer empirical evidence that classification and extraction techniques can be com-

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 1128–1136,
Beijing, August 2010

bined to precisely identify statements on revenue.

1.1 Related Work

Stein et. al. (2005) were among the first to consider information extraction for automatic market forecasting. Unlike us, the authors put much emphasis on retrieval aspects and applied dependency grammar parsing to identify market statements. As a consequence their approach suffers from the limitation to a small number of predefined sentence structures.

While we obtain market forecasts by extracting expert statements from the Web, related approaches derive them from past market behavior and quantitative news data. Koppel and Shtrimberg (2004) studied the effect of news on financial markets. Lavrenko et al. (2000) used time-series analysis and language models to predict stock market prices and, similarly, Lerman et al. (2008) proposed a system for forecasting public opinion based on concurrent modeling of news articles and market history. Another related field is opinion mining in the sense that it relies on the aggregation of individual statements. Glance et al. (2005) inferred marketing intelligence from opinions in online discussions. Liu et al. (2007) examined the effect of Weblogs on box office revenues and combined time-series with sentiment analysis to predict the sales performance of movies.

The mentioned approaches are intended to reflect or to predict present developments and, therefore, primarily help for *operative* decision making. In contrast, we aim at predicting long-term market developments, which are essential for *strategic* decision making.

2 The Problem

Market forecasts depend on two parameters, the *topic* of interest and the *criterion* to look at. A topic is either an organization or a market. Under a market we unite branches, products, and technologies, because the distinction between these is not clear in general (e.g., for semiconductors). In contrast, we define a criterion to be a metric attribute that can be measured over time. Here we are interested in financial criteria such as revenue, profit, and the like. The ambitious overall task that we want to solve is as follows:

Task description: Given a topic τ and a financial criterion χ, find information for τ on the development of χ. Aggregate the found values on χ with respect to time.

We omit the limitation to forecasts because we could miss useful information otherwise:

(1) *In 2008*, the Egyptian automobile industry achieved *US$ 9.96bn* in sales.

(2) Egypt's automotive sales will rise *by 97% from 2008 to 2013*.

Both sentences have the same topic. In Particular, the 2008 amount of money from example (1) can be aggregated with the forecast in (2) to infer the predicted amount in 2013.

As in these examples, market information can often only be found in running text; the major source for this is the Web. Thus, we seek to find web pages with sentences that represent *statements on a financial criterion* χ and to make these statements processable. Conceptually, such a statement is a 5-tuple $\mathcal{S}_\chi = (S, g, T, M, t_d)$, where S is the topical subject, which may have a geographic scope g, T is a period of time, M consists of a growth rate and/or an amount of money to be achieved during T with respect to χ, and t_d is the statement time, i.e., the point in time when the statement was made.

3 Approach

Our goal is to find and aggregate statements on a criterion χ for a topic τ. In close collaboration with two companies from the semantic technology field, we identified eight high-level subtasks in the overall process as explained in the following. An overview is given in Table 1.

3.1 Find Candidate Documents

To find web pages that are likely to contain statements on χ and τ, we propose to perform a meta-search by starting from a set of characteristic terms of the domain and then using query expansion techniques such as local context analysis (Xu and Croft, 2000). As Stein et. al. (2005) describe,

Subtask	Applied technologies
1 Find candidate documents	meta-search, query expansion, genre analysis
2 Preprocess content	content extraction, sentence splitting, tokenization, POS tagging and chunking
3 Extract entities	time and money extraction, named entity recognition of organizations and markets
4 Identify statements	statistical classification based on lexical and distance features
5 Determine statement type	relation extraction based on dependency parse trees, matching of word lists
6 Fill statement templates	template filling, anaphora resolution, matching of word lists
7 Normalize values	time and money normalization, coreference resolution
8 Aggregate information	chronological merging and averaging, inference from subtopic to topic

Table 1: Subtasks of the identification and aggregation of market statements for a specified topic. Experiments in this paper cover the subtasks written in black.

a genre analysis, which classifies a document with respect to its form, style, and targeted audience, may be deployed afterwards to further improve the quality of the result list efficiently. In this way, we only maintain candidate documents that look promising on the surface.

3.2 Preprocess Content

Preprocessing is needed for accurate access to the document text. Our overall task incorporates relating information from different document areas, so mixing up a web page's main frame and sidebars should be avoided. We choose Document Slope Curve (DSC) for content detection, which looks for plateaus in the HTML tag distribution. Gottron (2007) has offered evidence that DSC is currently the best algorithm in terms of precision. Afterwards, the sentences are split with rules that consider the specific characteristics of reports, press releases and the like, such as headlines between short paragraphs. In succeeding subtasks, tokens as well as their Part-of-Speech and chunk tags are also used, but we see no point in not relying on standard algorithms here.

3.3 Extract Entities

The key to identify a statement $\mathcal{S}_\chi$ on a financial criterion χ is the extraction of temporal and monetary entities. Recent works report that statistical approaches to this task can compete with hand-crafted rules (Ahn et. al., 2005; Cramer et. al., 2007). In the financial domain, however, the focus is only on dates and periods as time information, along with currency numbers, currency terms, or fractions as money information. We found that with regular expressions, which represent the complex but finite structures of such phrases, we can achieve nearly perfect recall in recognition (see Section 5).

We apply named entity recognition (NER) of organizations and markets in this stage, too, so we can relate statements to the appropriate subjects, later on. Note that market names do not follow a unique naming scheme, but we observed that they often involve similar phrase patterns that can be exploited as features. NER is usually done by sequence labeling, and we use heuristic beam search due to our effort to design a highly efficient overall system. Ratinov and Roth (2009) have shown for the CoNLL-2003 shared task that Greedy decoding (i.e., beam search of width 1) is competitive to the widely used Viterbi algorithm while being over 100 times faster at the same time.

3.4 Identify Statements

Based on time and money information, sentences that represent a statement $\mathcal{S}_\chi$ can be identified. Such a sentence gives us valuable hints on which temporal and monetary entity stick together and how to interpret them in relation. Additionally, it serves as evidence for the statement's correctness (or incorrectness). Every sentence with at least one temporal and one monetary entity is a candidate. Criteria such as revenue usually imply small core vocabularies $\mathcal{L}_{pos}$, which indicate that a sentence is on that criterion or which often appear close to it. On the contrary, there are sets of words $\mathcal{L}_{neg}$ that suggest a different criterion. For a given text collection with known statements on χ, both $\mathcal{L}_{pos}$ and $\mathcal{L}_{neg}$ can be found by computing the most discriminant terms with respect to χ. A reasonable first approach is then to filter sentences that contain terms from $\mathcal{L}_{pos}$ and lack terms from $\mathcal{L}_{neg}$, but problems arise when terms from different vocabularies co-occur or statements on different criteria are attached to one another.

Instead, we propose a statistical learning approach. Support Vector Machines (SVMs) have been proven to yield very good performance in both general classification and sentence extraction while being immune to overfitting (Steinwart and Christmann, 2008; Hirao et. al., 2001). For our candidates, we compute lexical and distance features based on $\mathcal{L}_{pos}$, $\mathcal{L}_{neg}$, and the time and money information. Then we let an SVM use these features to distinguish between sentences with statements on χ and others. At least for online news articles, this works reasonably well as we demonstrate in Section 5. Note that classification is not used to match the right entities, but to filter the small set of sentences on χ.

3.5 Determine Statement Type

The statement type implies what information we can process. If a sentence contains more than one temporal or monetary entity, we need to relate the correct T and M to each $\mathcal{S}_\chi$, now. The type of $\mathcal{S}_\chi$ then depends on the available money information, its *trend* and the *time direction*.

We consider four types of money information. χ refers to a period of time that results in a *new amount* A of money in contrast to its *preceding amount* A_p. The difference between A and A_p may be specified as an *incremental amount* Δ_A or as a *relative growth rate* r. M can span any combination of A, A_p, Δ_A and r, and at least A and r constitute a reasonable entity on their own. Sometimes the trend of r (i.e. decreasing or increasing) cannot be derived from the given values. However, this information can mostly be obtained from a nearby indicator word (e.g. “plus” or “decreased”) and, therefore, we address this problem with appropriate word lists. Once the trend is known, any two types imply the others.

Though we are predominantly interested in *forecasts*, statements also often represent a *declaration* on achieved results. This distinction is essential and can be based on time-directional indicators (e.g. “next”) and the tense of leading verbs. For this, we test both feature and kernel methods on dependency parse trees, thereby determining T and M at the same time. We only parse the identified sentences, though. Hence, we avoid running into efficiency problems.

3.6 Fill Statement Templates

The remaining subtasks are ongoing work, so we only present basic concepts here.

Besides T and M, the subject S and the statement time t_d have to be determined. S may be found within the previously extracted named entities using the dependency parse tree from Section 3.5 or by anaphora resolution. Possible limitations to a geographic scope g can be recognized with word lists. In market analysis, the approximate t_d suffices, and for most news articles t_d is similar to their release date. Thus, if no date is in the parse tree, we search the extracted temporal entities for the release date, which is often mentioned at the beginning or end of the document’s content. We fill one template (S, g, T, M, t_d) for each $\mathcal{S}_\chi$ where we have at least S, T, and M.

3.7 Normalize Values

Since we base the extraction on regular expressions, we can normalize most monetary entities with a predefined set of rules. Section 3.5 implies that $M^* = (A^*, r^*)$ is a reasonable normalized form where A^* is A specified in million US-$ and r^* is r as percentage with a fixed number of decimals.[2] Time normalization is more complex. Any period should be transformed to $T^* = (t_s^*, t_e^*)$ consisting of the start date t_s^* and end date t_e^*. Following Ahn et. al. (2005), we consider fully qualified, deictic and anaphoric periods. While normalization of fully qualified periods like “from Apr to Jun 1999” is straightforward, deictic (e.g. “since 2005”, “next year”) and anaphoric mentions (e.g. “in the reported time”) require a reference time. Approaches to resolve such references rely on dates or fully qualified periods in the preceding text (Saquete et. al., 2003; Mani and Wilson, 2000).[3]

[2] Translating the currency requires exchange rates at statement time. We need access to such information or omit the translation if only one currency is relevant.

[3] References to fiscal years even involve a whole search problem if no look-up table on such data is available.

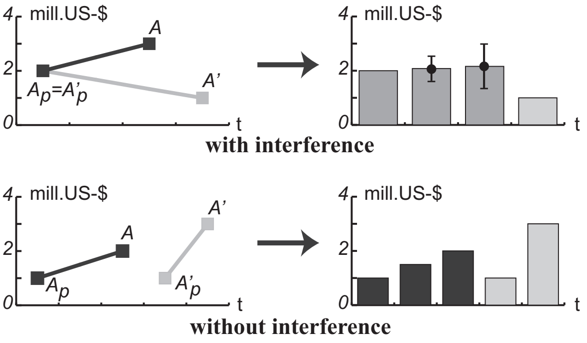

Figure 1: Example for merging monetary values.

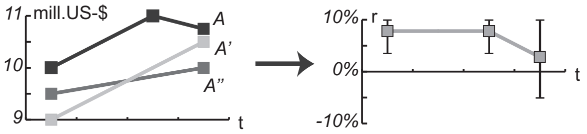

Figure 2: Example for the inference of relative information from absolute values.

If we cannot normalize M or T, we discard the corresponding statement templates. For the others, we have to resolve synonymous co-references (e.g. “Loewe AG” and “Loewe”) before we can proceed to the last step.

3.8 Aggregate Information

We can aggregate the normalized values in either two or three dimensions depending on whether to separate statements with respect to t_d. Aggregation then incorporates two challenges, namely, how to merge values and how to infer information on a topic from values of a subtopic.

We say that two statements on the same topic τ and criterion χ *interfere* if the contained periods of time intersect and the according monetary values do not coincide. In case of declarations, this means that we extracted incorrect values or extracted values incorrectly. For forecasts, on the contrary, we are exactly onto such information. In both cases, an intuitive solution is to compute the average (or median) and deviations. Figure 1 graphically illustrates such merging. The subtopic challenge is based on the assumption that a meaningful number of statements on a certain subtopic of τ implies relative information on τ, as shown in Figure 2. One of the most interesting relations are organizations as subtopics of markets they produce for, because it is quite usual to search for information on a market, but only receive statements on companies. Approaches to this relation may rely e.g. on the web page co-occurrence and term frequencies of the markets and companies.

Statements	Total	Forecasts	Declarations
Complete corpus	2075	523 (25.2%)	1552 (74.8%)
Training set	1366	306 (22.4%)	1060 (77.6%)
Validation set	362	113 (31.2%)	249 (68.8%)
Test set	347	104 (30.0%)	243 (70.0%)

Table 2: Statements on revenue in the corpus.

Altogether, we return the aggregated values linked to the sentences in which we found them. In this way, we make the results verifiable and, thereby, compensate for possible inaccuracies.

4 Corpus

To evaluate the given and related tasks, we built a manually annotated corpus with online news articles on the revenues of organizations and markets. The compilation aims at being representative for target documents, a search engine returns to queries on revenue. The purpose of the corpus is to investigate both the structure of sentences on financial criteria and the distribution of associated information over the text.

The corpus consists of 1,128 German news articles from the years 2003 to 2009, which were taken from 29 news websites like *www.spiegel.de* or *www.capital.de*. The content of each document comes as unicode plain text with appended URL for access to the HTML source code. Annotations are given in a standard XMI file preformatted for the *Unstructured Information Management Architecture* (Ferrucci and Lally, 2004). We created a split, in which 2/3 of the documents constitute the training set and each 1/6 refers to the validation and test set. To simulate real conditions, the training documents were randomly chosen from only the seven most represented websites, while the validation and test data both cover all 29 sources. Table 2 shows some corpus statistics, which give a hint that the validation and test set differ significantly from the training set. The corpus is free for scientific use and can be downloaded at http://infexba.upb.de.

Loewe AG: Vorläufige Neun-Monats-Zahlen
Kronach, [6. November 2007]$_{REF}$ — Das Ergebnis vor Zinsen und Steuern (EBIT) des Loewe Konzerns konnte in den ersten 9 Monaten 2007 um 41% gesteigert werden. Vor diesem Hintergrund hebt die [Loewe AG]$_{ORG}$ ihre EBIT-Prognose für das laufende Geschäftsjahr auf 20 Mio. Euro an. ***Beim Umsatz strebt Konzernchef [Rainer Hecker]$_{AUTH}$ [für das Gesamtjahr]$_{TIME}$ ein höher als ursprünglich geplantes [Wachstum]$_{TREND}$ [von 10% auf ca. 380 Mio. Euro]$_{MONEY}$ an.*** *(...)*

Figure 3: An annotated document in the corpus. The text is taken from *www.boerse-online.de*, but has been modified for clarification.

4.1 Annotations

In each document, every sentence that includes a temporal entity T and a monetary entity M and that represents a *forecast* or *declaration* on the revenue of an organization or market is marked as such. T and M are annotated themselves and linked to the sentence. Accordingly, the *subject* is tagged (and linked) within the sentence boundaries if available, otherwise its last mention in the preceding text. The same holds for optional entities, namely a *reference time*, a *trend indicator* and the *author* of a statement. Altogether, 2,075 statements are tagged in this way. As in Figure 3, only information that refers to a statement on revenue (typed in bold face) is annotated. These annotations may be spread across the text.

The source documents were manually selected and prepared by our industrial partners, and two of their employees annotated the plain document text. With respect to the statement annotations, a preceding pilot study yielded substantial inter-annotator agreement, as indicated by the value $\kappa = 0.79$ of the conservative measure *Cohen's Kappa* (Carletta, 1996). Additionally, we performed a manual correction process for each annotated document to improve consistency.

5 Experiments

We now present experiments for the statement identification, which were conducted on our corpus. The goal was to evaluate whether our combined extraction and classification approach succeeds in the precise identification of sentences that comprise a statement on revenue, while keeping recall high. Only exact matches of the annotated text spans were considered to be correct identifications. Unlike in Section 3, we only worked on plain text, though.

5.1 Experimental Setup

To find candidate sentences, we implemented a sentence splitter that can handle article elements such as subheadings, URLs, or bracketed sentences. We then constructed sophisticated, but efficient regular expressions for time and money. They do not represent correct language, in general, but model the structure of temporal and monetary entities, and use word lists provided by domain experts on the lowest level.[4] For feature computation, we assumed that the closest pair of temporal and monetary entity refers to the enclosing candidate sentence.[5] Since only positive instances I_P of statements on revenue are annotated in our corpus, we declared all candidates, which have no counterpart in the annotated data, to constitute the negative class I_N, and balanced I_P and I_N by "randomly" (seed 42) removing instances from I_N.[6]

For the vocabularies $\mathcal{L}_{pos} = \{P_1, P_2\}$ we first counted the frequencies of all words in the unbalanced sets I_P and I_N. From these, we deleted named entities, numbers and adjectives. If the prefix (e.g. "Umsatz") of a word ("Umsatzplus") occurred, we only kept the prefix. We then filtered all terms that appeared in at least 1.25% of the instances in I_P and more than 3.5 times as much in I_P as in I_N. The remaining words were manually partitioned into two lists:

P_1 = {umgesetzt, Umsatz, Umsätze, setzte} (all of these are terms for revenue)

P_2 = {Billionen, meldet, Mitarbeiter, Verband} (trillions, announce, employee, association)

$\mathcal{L}_{neg} = \{N_1, N_2\}$ was built accordingly. In addition, we set up a list G_1 with genitive pronouns

[4] More details are given at http://infexba.upb.de.

[5] 55% of the candidate sentences in the training set contain more than one temporal and/or monetary entity, so this assumption may lead to errors.

[6] We both tested undersampling and oversampling techniques but saw no effective differences in the results.

and determiners. Based on $\mathcal{L}_{pos}$, $\mathcal{L}_{neg}$ and G_1, we computed the following 43 features for every candidate sentence s:

- **1-8:** Number of terms from P_1 (N_1) in s as well as in the two preceding sentences and in the following sentence.
- **9-10:** Number of terms from P_2 (N_2) in s.
- **11:** Occurrence of term from G_1 next to the monetary entity.
- **12-19:** Forward (backward) distance in tokens between the monetary (temporal) entity in s and a term from P_1 (N_1).
- **20-27:** Forward (backward) distance in number of symbols from $O_1 = \{$'.','?','!'$\}$ between the monetary (temporal) entity in s and a term from P_1 (N_1).
- **28-43:** Same as 20-27 for $O_2 = \{$':',';'$\}$ and $O_3 = \{$','$\}$, respectively.

We trained a linear SVM with cost parameter $C = 0.3$ (selected during validation) on these features using the *Weka* integration of *LibSVM* (Hall et. al., 2009; Fan et. al., 2001). Further features were evaluated, e.g. occurrences of contrapositions or comparisons, but they did not improve the classifier. Instead, we noticed that we can avoid some complex cases when we apply two rules after entity extraction:

R_1: Delete temporal and monetary entities that are directly surrounded by brackets.

R_2: Delete temporal entities that contain the word "Vorjahr" ("preceding year").

Now, we evaluated the following five statement identification algorithms:

- **Naïve:** Simply return all candidate sentences (to estimate the relative frequency of statements on revenue in the corpus).
- **Baseline:** Return all candidate sentences that contain a term from the list P_1.
- **NEG:** Use the results from Baseline. Return all sentences that lack terms from N_1.
- **RB:** Filter candidates using R_1 and R_2. Then apply NEG.
- **SVM:** Filter candidates using R_1 and R_2. Then classify sentences with the SVM.

Recall	**Training**	**Validation**	**Test**
Sentences	0.98	0.98	0.96
Temporal entities	0.97 (0.95)	0.97 (0.94)	0.98 (0.96)
Monetary entities	0.96 (0.96)	0.96 (0.96)	0.95 (0.94)

Table 3: Recall of sentence and entity extraction. In brackets: Recall after applying R_1 and R_2.

5.2 Results

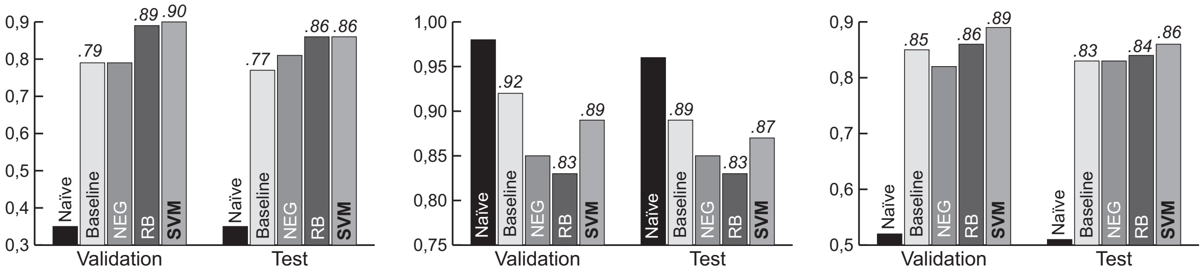
Table 3 shows that we found at least 95% of the sentences, time and money information, which refer to a statement on revenue, in all datasets.[7] We could not measure precision for these since not all sentences and entities are annotated in the corpus, as mentioned in Section 4.

Results for the statement identification are given in Figure 4. Generally, the test values are somewhat lower than the validation values, but analog in distribution. Nearly all statements were recognized by the Naïve algorithm, but only with a precision of 0.35. In contrast, both for Baseline and NEG already around 80% of the found statements were correct. The latter paid a small gain in precision with a significant loss in recall. While RB and SVM both achieved 86% precision on the test set, SVM tends to be a little more precise as suggested by the validation results. In terms of recall, SVM clearly outperformed RB with values of 89% and 87% and was only a little worse than the Baseline. Altogether, the F_1-Measure values show that SVM was the best performing algorithm in our evaluation.

5.3 Error Analysis

To assess the influence of the sentence, time and money extraction, we compared precision and recall of the classifier on the manually annotated and the extracted data, respectively. Table 4 shows

[7] We intentionally did not search for unusual entities like "am 1. Handelstag nach dem Erntedankfest" ("the 1st trading day after Thanksgiving") in order not to develop techniques that are tailored to individual cases. Also, money amounts that lack a currency term were not recognized.



Precision **Recall** **F$_1$-Measure**

Figure 4: Precision, recall and F_1-Measure of the five evaluated statement identification algorithms. SVM is best in precision both on validation and test data and outperforms RB in recall significantly.

that only recall differs significantly. We found that false statement identifications referred to the following noteworthy error cases.

False match: Most false positives result from matchings of temporal and monetary entities that actually do not refer to the same statement.

Missing criterion: Some texts describe the development of revenue without ever mentioning revenue. Surrogate words like "market" may be used, but they are not discriminative enough.

Multiple criteria: Though we aimed at discarding sentences, in which revenue is mentioned without comprising a statement on it, in some cases our features did not work out, mainly due to intricate sentence structure.

Traps: Some sentences contain numeric values on revenue, but not the ones looked for, as in "10% of the revenue". We tackled these cases, but had still some false classifications left.

Hidden boundaries: Finally, we did not find all correct sentence boundaries, which can lead to both false positives and false negatives. The predominant problem was to separate headlines from paragraph beginnings and is partly caused by the missing access to markup tags.

5.4 Efficiency

We ran the identification algorithm on the whole corpus using a *2 GHz Intel Core 2 Duo MacBook* with *4 GB RAM*. The 1,128 corpus documents contain 33,370 sentences as counted by our algorithm itself. Tokenization, sentence splitting, time and money extraction took only 55.2 seconds, i.e., more than 20 documents or 600 sentences each second. Since our feature computation is not optimized yet, the complete identification process is a little less efficient with 7.35 documents or 218 sentences per second. However, it is fast enough to be used in online applications, which was our goal in the end.

Candidates	Data	Precision	Recall
Annotated	validation data	0.91	0.94
	test data	0.87	0.93
Extracted	validation data	0.90	0.89
	test data	0.86	0.87

Table 4: Precision and recall of the statement identification on manually annotated data and on automatically extracted data, respectively.

6 Conclusion

We presented a multi-stage approach for the automatic identification and aggregation of market statements and introduced a manually annotated German corpus for related tasks. The approach has been influenced by industry and is oriented towards practical applications, but is, in general, not specific to the German language. It relies on efficient retrieval, extraction and NLP techniques. By now, we can precisely identify most sentences that represent statements on revenue. This already allows for the support of strategists, e.g. by highlighting such sentences in web pages, which we currently implement as a Firefox extension. The overall problem is complex, though, and we are aware that human experts can do better at present. Nevertheless, time-consuming tasks can be automated and, in this respect, the results on our corpus are very promising.

Towards a Unified Approach to Simultaneous Single-Document and Multi-Document Summarizations

Xiaojun Wan

Peking University
wanxiaojun@icst.pku.edu.cn

Abstract

Single-document summarization and multi-document summarization are very closely related tasks and they have been widely investigated independently. This paper examines the mutual influences between the two tasks and proposes a novel unified approach to simultaneous single-document and multi-document summarizations. The mutual influences between the two tasks are incorporated into a graph model and the ranking scores of a sentence for the two tasks can be obtained in a unified ranking process. Experimental results on the benchmark DUC datasets demonstrate the effectiveness of the proposed approach for both single-document and multi-document summarizations.

1 Introduction

Single-document summarization aims to produce a concise and fluent summary for a single document, and multi-document summarization aims to produce a concise and fluent summary for a document set consisting of multiple related documents. The two tasks are very closely related in both task definition and solution method. Moreover, both of them are very important in many information systems and applications. For example, given a cluster of news articles, a multi-document summary can be used to help users to understand the whole cluster, and a single summary for each article can be used to help users to know the content of the specified article.

To date, single-document and multi-document summarizations have been investigated extensively and independently in the NLP and IR fields. A series of special conferences or workshops on automatic text summarization (e.g. SUMMAC, DUC, NTCIR and TAC) have advanced the technology and produced a couple of experimental online systems. However, the two summarization tasks have not yet been simultaneously investigated in a unified framework.

Inspired by the fact that the two tasks are very closely related and they can be used simultaneously in many applications, we believe that the two tasks may have mutual influences on each other. In this study, we propose a unified approach to simultaneous single-document and multi-document summarizations. The mutual influences between the two tasks are incorporated into a graph-based model. The ranking scores of sentences for single-document summarization and the ranking scores of sentences for multi-document summarization can boost each other, and they can be obtained simultaneously in a unified graph-based ranking process. To the best of our knowledge, this study is the first attempt for simultaneously addressing the two summarization tasks in a unified graph-based framework. Moreover, the proposed approach can be easily adapted for topic-focused summarizations.

Experiments have been performed on both the single-document and multi-document summarization tasks of DUC2001 and DUC2002. The results demonstrate that the proposed approach can outperform baseline independent methods for both the two summarization tasks. The two tasks are validated to have mutual influences on each other.

The rest of this paper is organized as follows: Section 2 introduces related work. The details of the proposed approach are described in Section 3. Section 4 presents and discusses the evaluation results. Lastly we conclude our paper in Section 5.

2 Related Work

Document summarization methods can be either extraction-based or abstraction-based. In this section, we focus on extraction-based methods.

Extraction-based methods for single-document summarization usually assign a saliency score to each sentence in a document and then rank and select the sentences. The score is usually computed based on a combination of statistical and linguistic features, such as term frequency, sentence position, cue words and stigma words (Luhn, 1969; Edmundson, 1969; Hovy and Lin, 1997). Machine learning techniques have also been used for sentence extraction (Kupiec et al., 1995; Conroy and O'Leary, 2001; Shen et al., 2007; Li et al., 2009). The mutual reinforcement principle has been exploited to iteratively extract key phrases and sentences from a document (Zha, 2002; Wan et al, 2007a). Wan et al. (2007b) propose the CollabSum algorithm to use additional knowledge in a cluster of documents to improve single document summarization in the cluster.

In recent years, graph-based ranking methods have been investigated for document summarization, such as TextRank (Mihalcea and Tarau, 2004; Mihalcea and Tarau, 2005) and LexPageRank (ErKan and Radev, 2004). Similar to PageRank (Page et al., 1998), these methods first build a graph based on the similarity relationships between the sentences in a document and then the saliency of a sentence is determined by making use of the global information on the graph recursively. The basic idea underlying the graph-based ranking algorithm is that of "voting" or "recommendation" between sentences.

Similar methods have been used for generic multi-document summarization. A typical method is the centroid-based method (Radev et al., 2004). For each sentence, the method computes a score based on each single feature (e.g. cluster centroids, position and TFIDF) and then linearly combines all the scores into an overall sentence score. Topic signature is used as a novel feature for selecting important content in NeATS (Lin and Hovy, 2002). Various sentence features have been combined by using machine learning techniques (Wong et al., 2008). A popular way for removing redundancy between summary sentences is the MMR algorithm (Carbonell and Goldstein, 1998). Themes (or topics, clusters) in documents have been discovered and used for sentence selection (Harabagiu and Lacatusu, 2005). Hachey (2009) investigates the effect of various source document representations on the accuracy of the sentence extraction phase of a multi-document summarization task. Graph-based methods have also been used to rank sentences in a document set. The methods first construct a graph to reflect sentence relationships at different granularities, and then compute sentence scores based on graph-based learning algorithms. For example, Wan (2008) proposes to use only cross-document relationships for graph building and sentence ranking. Cluster-level information has been incorporated in the graph model to better evaluate sentences (Wan and Yang, 2008).

For topic-focused multi-document summarization, many methods are extensions of generic summarization methods by incorporating the information of the given topic or query into generic summarizers. In recent years, a few novel methods have been proposed for topic-focused summarization (Daumé and Marcu, 2006; Wan et al., 2007c; Nastase 2008; Li et al., 2008; Schilder and Kondadadi, 2008; Wei et al., 2008).

The above previous graph-based summarization methods aim to address either single-document summarization or multi-document summarization, and the two summarization tasks have not yet been addressed in a unified graph-based framework.

3 The Unified Summarization Approach

3.1 Overview

Given a document set, in which the whole document set and each single document in the set are required to be summarized, we use *local saliency* to indicate the importance of a sentence in a particular document, and use *global saliency* to indicate the importance of a sentence in the whole document set.

In previous work, the following two assumptions are widely made for graph-based summarization models:

Assumption 1: A sentence is locally important in a particular document if it is heavily linked with many locally important sentences in the same document.

Assumption 2: A sentence is globally important in the document set if it is heavily linked with many globally important sentences in the document set.

The above assumptions are the basis for PageRank-like algorithms for single document summarization and multi-document summarization, respectively. In addition to the above two assumptions, we make the following two assumptions to consider the mutual influences between the two summarization tasks:

Assumption 3: A sentence is locally important in a particular document, if it is heavily linked with many globally important sentences in the document set.

The above assumption is reasonable because the documents in the set are relevant and the globally important information in the document set will be expressed in many single documents. Therefore, if a sentence is salient in the whole document set, the sentence may be salient in a particular document in the set.

Assumption 4: A sentence is globally important in the document set, if it is heavily linked with many locally important sentences.

The above assumption is reasonable because the documents in the set are relevant and the globally important information in the whole set is the aggregation of the locally important information in each single document. Therefore, if a sentence is salient in a particular document, the sentence has the potential to be salient in the whole document set.

In brief, the local saliency and global saliency of a sentence can mutually influence and boost each other: high local saliency will lead to high global saliency, and high global saliency will lead to high local saliency.

Based on the above assumptions, our proposed approach first builds affinity graphs (each graph is represented by an affinity matrix) to reflect the different kinds of relationships between sentences, respectively, and then iteratively computes the local saliency scores and the global saliency scores of the sentences based on the graphs. Finally, the algorithm converges and the local saliency score and global saliency score of each sentence are obtained. The sentences with high local saliency scores in a particular document are chosen into the summary of the single document, and the sentences with high global saliency scores in the set are chosen into the summary of the document set.

Note that for both summarization tasks, after the saliency scores of sentences have been obtained, the greedy algorithm used in (Wan et al., 2007c) is applied to remove redundancy and finally choose both informative and novel sentences into the summary.

3.2 Algorithm Details

Formally, the given document set is denoted as $D=\{d_i|1\leq i\leq m\}$, and the whole sentence set is denoted as $S=\{s_i|1\leq i\leq n\}$. We let $Info_{single}(s_i)$ denote the local saliency score of sentence s_i in a particular document $d(s_i)\in D$, and it is used to select summary sentences for the single document $d(s_i)$. And we let $Info_{multi}(s_i)$ denote the global saliency score of sentence s_i in the whole document set D, and it is used to select summary sentences for the document set D.

The four assumptions in Section 3.1 can be rendered as follows:

$$Info_{\sin gle}(s_i) \propto \sum_j (W_A)_{ji}\, Info_{\sin gle}(s_j) \quad (1)$$

$$Info_{multi}(s_i) \propto \sum_j (W_B)_{ji}\, Info_{multi}(s_j) \quad (2)$$

$$Info_{\sin gle}(s_i) \propto \sum_j (W_C)_{ji}\, Info_{multi}(s_j) \quad (3)$$

$$Info_{multi}(s_i) \propto \sum_j (W_D)_{ji}\, Info_{\sin gle}(s_j) \quad (4)$$

where W_A, W_B, W_C, W_D are $n\times n$ affinity matrices reflecting the different kinds of relationships between sentences in the document set, where n is the number of all sentences in the document set. The detailed derivation of the matrices will be presented later.

After fusing the above equations, we can obtain the following unified forms:

$$\begin{aligned} Info_{\sin gle}(s_i) &= \mu \sum_j (W_A)_{ji}\, Info_{\sin gle}(s_j) \\ &\quad + (1-\mu)\sum_j (W_C)_{ji}\, Info_{multi}(s_j) \end{aligned} \quad (5)$$

$$\begin{aligned} Info_{multi}(s_i) &= \mu \sum_j (W_B)_{ji}\, Info_{multi}(s_j) \\ &\quad + (1-\mu)\sum_j (W_D)_{ji}\, Info_{\sin gle}(s_j) \end{aligned} \quad (6)$$

However, the above summarization method ignores the feature of sentence position, which has been validated to be very important for document summarizations. In order to incorporate this important feature, we add one prior score to each computation as follows:

$$\begin{aligned} Info_{\sin gle}(s_i) &= \alpha \sum_j (W_A)_{ji}\, Info_{\sin gle}(s_j) \\ &+ \beta \sum_j (W_C)_{ji}\, Info_{multi}(s_j) + \gamma \cdot prior_{\sin gle}(s_i) \end{aligned} \quad (7)$$

$$Info_{multi}(s_i) = \alpha \sum_j (W_B)_{ji} Info_{multi}(s_j) + \beta \sum_j (W_D)_{ji} Info_{single}(s_j) + \gamma \cdot prior_{multi}(s_i) \quad (8)$$

where *α*, *β*, *γ*∈[0,1] specify the relative contributions to the final saliency scores from the different factors, and we have *α*+*β*+*γ*=1. $prior_{single}(s_i)$ is the prior score for the local saliency of sentence s_i, and here $prior_{single}(s_i)$ is computed based on sentence position of s_i in the particular document $d(s_i)$. $prior_{multi}(s_i)$ is the prior score for the global saliency of sentence s_i, and we also compute $prior_{multi}(s_i)$ based on sentence position of s_i.

We use two column vectors $\vec{\boldsymbol{u}} = [Info_{single}(s_i)]_{n\times 1}$ and $\vec{\boldsymbol{v}} = [Info_{multi}(s_i)]_{n\times 1}$ to denote the local and global saliency scores of all the sentences in the set, respectively. And the matrix forms of the above equations are as follows:

$$\vec{\boldsymbol{u}} = \alpha \boldsymbol{W}_A^T \vec{\boldsymbol{u}} + \beta \boldsymbol{W}_C^T \vec{\boldsymbol{v}} + \gamma \vec{\boldsymbol{p}}_{single} \quad (9)$$

$$\vec{\boldsymbol{v}} = \alpha \boldsymbol{W}_B^T \vec{\boldsymbol{v}} + \beta \boldsymbol{W}_D^T \vec{\boldsymbol{u}} + \gamma \vec{\boldsymbol{p}}_{multi} \quad (10)$$

where $\vec{\boldsymbol{p}}_{single} = [prior_{single}(s_i)]_{n\times 1}$ and $\vec{\boldsymbol{p}}_{multi} = [prior_{multi}(s_i)]_{n\times 1}$ are the prior column vectors.

The above matrices and prior vectors are constructed as follows, respectively:

W_A: This affinity matrix aims to reflect the local relationships between sentences in each single document, which is defined as follows:

$$(W_A)_{ij} = \begin{cases} sim_{cosine}(s_i, s_j), \text{ if } \mathrm{d}(s_i) = \mathrm{d}(s_j) \\ \qquad\qquad\qquad \text{and } \mathrm{i} \neq \mathrm{j} \\ 0, \text{ Otherwise} \end{cases} \quad (11)$$

where $d(s_i)$ refers to the document containing sentence s_i. $sim_{cosine}(s_i,s_j)$ is the cosine similarity between sentences s_i and s_j.

$$sim_{cosine}(s_i, s_j) = \frac{\vec{s}_i \cdot \vec{s}_j}{|\vec{s}_i| \times |\vec{s}_j|} \quad (12)$$

where $\vec{s}_i$ and $\vec{s}_j$ are the corresponding term vectors of s_i and s_j. Note that we have $(W_A)_{ij} = (W_A)_{ji}$, and we have $(W_A)_{ii}$ =0 to avoid self loops.

We can see that the matrix contains only the within-document relationships between sentences.

W_B: This affinity matrix aims to reflect the global relationships between sentences in the document set, which is defined as follows:

$$(W_B)_{ij} = \begin{cases} sim_{cosine}(s_i, s_j), \text{ if } \mathrm{d}(s_i) \neq \mathrm{d}(s_j) \\ 0, \text{ Otherwise} \end{cases} \quad (13)$$

We can see that the matrix contains only the cross-document relationships between sentences. We do not include the within-document sentence relationships in the matrix because it has been shown that the cross-document relationships are more appropriate to reflect the global mutual influences between sentences than the within-document relationships in (Wan, 2008).

W_C: This affinity matrix aims to reflect the cross-document relationships between sentences in the document set. However, the relationships in this matrix are used for carrying the influences of the sentences in other documents on the local saliency of the sentences in a particular document. If we directly use Equation (13) to compute the matrix, the mutual influences would be overly used. Because other documents might not be sampled from the same generative model as the specified document, we probably do not want to trust them so much as the specified document. Thus a confidence value is used to reflect out belief that the document is sampled from the same underlying model as the specified document. Heuristically, we use the cosine similarity between documents as the confidence value. And we use the confidence value as the decay factor in the matrix computation as follows:

$$(W_c)_{ij} = \begin{cases} sim_{cosine}(s_i, s_j) \times sim_{cosine}(d(s_i), d(s_j)), \\ \qquad\qquad\qquad \text{if } \mathrm{d}(s_i) \neq \mathrm{d}(s_j) \\ 0, \text{ Otherwise} \end{cases} \quad (14)$$

W_D: This affinity matrix aims to reflect the within-document relationships between sentences. Thus we have ***W_D***=***W_A***, which means that the global saliency score of a sentence is influenced only by the local saliency scores of the sentences in the same document, without considering the sentences in other documents.

Note that the above four matrices are symmetric and we can replace $\boldsymbol{W}_A^T$, $\boldsymbol{W}_B^T$, $\boldsymbol{W}_C^T$ and $\boldsymbol{W}_D^T$ by ***W_A***, ***W_B***, ***W_C*** and ***W_D*** in Equations (9) and (10), respectively.

prior_single(s_i): It is computed under the assumption that the first sentences in a document are usually more important than other sentences.

$$prior_{single}(s_i) = 0.5 + \frac{1}{position(s_i) + 1} \quad (15)$$

where $position(s_i)$ returns the position number of sentence s_i in its document $d(s_i)$. For example, if

s_i is the first sentence in its document, $position(s_i)$ is 1.

The prior weight is then normalized by:

$$prior_{\sin gle}(s_i) = \frac{prior_{\sin gle}(s_i)}{\sum_i prior_{\sin gle}(s_i)} \qquad (16)$$

prior$_{multi}$(s$_i$): We also let the prior weight reflect the influence of sentence position.

$$prior_{multi}(s_i) = prior_{\sin gle}(s_i) \qquad (17)$$

And then the prior weight is normalized in the same way.

The above definitions are for generic document summarizations and the above algorithm can be easily adapted for topic-focused summarizations. Given a topic q, the only change for the above computation is $prior_{multi}(s_i)$. The topic relevance is incorporated into the prior weight as follows:

$$prior_{multi}(s_i) = sim_{\cos ine}(s_i, q) \qquad (18)$$

$$prior_{multi}(s_i) = \frac{prior_{multi}(s_i)}{\sum_i prior_{multi}(s_i)} \qquad (19)$$

In order to solve the iterative problem defined in Equations (9) and (10), we let $\vec{\boldsymbol{r}} = [\vec{\boldsymbol{u}}^T \ \ \vec{\boldsymbol{v}}^{\mathrm{T}}]^T$, $\vec{\boldsymbol{p}} = [\gamma\vec{\boldsymbol{p}}^{\mathrm{T}}_{\text{single}} \ \ \gamma\vec{\boldsymbol{p}}^{\mathrm{T}}_{\text{multi}}]^T$, $\boldsymbol{W} = \begin{bmatrix} \alpha\boldsymbol{W}_A^T & \beta\boldsymbol{W}_C^T \\ \beta\boldsymbol{W}_D^T & \alpha\boldsymbol{W}_B^T \end{bmatrix}$, and then the iterative equations correspond to the following linear system:

$$\vec{\boldsymbol{r}} = \boldsymbol{W}\vec{\boldsymbol{r}} + \vec{\boldsymbol{p}} \qquad (20)$$

$$(\boldsymbol{I} - \boldsymbol{W})\vec{\boldsymbol{r}} = \vec{\boldsymbol{p}} \qquad (21)$$

To guarantee the solution of the above linear system, ***W*** is normalized by columns. If all the elements of a column are zero, we replace the elements with 1/(2*n*), where 2*n* equals to the element number of the column. We then multiply ***W*** by a decay factor θ ($0<\theta<1$) to scale down each element in ***W***, but remain the meaning of ***W***. Here, θ is empirically set to 0.6[1]. Finally, Equation (21) is rewritten as follows:

$$(\boldsymbol{I} - \theta \cdot \boldsymbol{W})\vec{\boldsymbol{r}} = \vec{\boldsymbol{p}} \qquad (22)$$

Thus, the matrix (*I-θW*) is a strictly diagonally dominant matrix and the solution of the linear system exists and we can apply the Gauss-Seidel method used in (Li et al., 2008) to solve the linear system. The GS method is a well-know method for numeric computation in mathematics and the details of the method is omitted here.

4 Empirical Evaluation

4.1 Dataset and Evaluation Metric

Generic single-document and multi-document summarizations have been the fundamental tasks in DUC 2001 and DUC 2002 (i.e. tasks 1 and 2 in DUC 2001 and tasks 1 and 2 in DUC 2002), and we used the two datasets for evaluation. DUC2001 provided 309 articles, which were grouped into 30 document sets. Generic summary of each article was required to be created for task 1, and generic summary of each document set was required to be created for task 2. The summary length was 100 words or less. DUC 2002 provided 59 document sets consisting of 567 articles (D088 is excluded from the original 60 document sets by NIST) and generic summaries for each article and each document set with a length of approximately 100 words were required to be created. The sentences in each article have been separated and the sentence information has been stored into files. The summary of the two datasets are shown in Table 1.

	DUC 2001	DUC 2002
Task	Tasks 1, 2	Tasks 1, 2
Number of documents	309	567
Number of clusters	30	59
Data source	TREC-9	TREC-9
summary length	100 words	100 words

Table 1. Summary of datasets

We used the ROUGE toolkit[2] (Lin and Hovy, 2003) for evaluation, which has been widely adopted by DUC for automatic summarization evaluation. It measured summary quality by counting overlapping units such as the n-gram, word sequences and word pairs between the candidate summary and the reference summary.

The ROUGE toolkit reported separate recall-oriented scores for 1, 2, 3 and 4-gram, and also for longest common subsequence co-occurrences. We showed three of the ROUGE metrics in the experimental results: ROUGE-1 (unigram-based), ROUGE-2 (bigram-based), and ROUGE-W (based on weighted longest common subsequence, weight=1.2). In order to truncate summaries longer than the length limit,

[1] In our pilot study, we can observe good performance when θ is in a wide range of [0.4, 0.8].

[2] We used ROUGEeval-1.4.2 in this study.

we used the “-l 100” option in ROUGE toolkit. We also used the “-m” option for word stemming.

4.2 Evaluation Results

4.2.1 System Comparison

In the experiments, the combination weight γ for the prior score is fixed at 0.15, as in the PageRank algorithm. Therefore, we have $\alpha+\beta=0.85$. Here, we use $\alpha/(\alpha+\beta)$ to indicate the relative contributions of the first two parts in Equations (9) and (10). We empirically set $\alpha/(\alpha+\beta)=0.4$ in the experiments. The proposed unified approach (i.e. UnifiedRank) is compared with a few baseline approaches and the top three participating systems.

The graph-based baselines for single-document summarization are described as follows:

BasicRank: This baseline approach adopts the basic PageRank algorithm to rank sentences based on all sentence relationships in a single document, similar to previous work (Mihalcea and Tarau, 2004).

PositionRank: This baseline approach improves the basic PageRank algorithm by using the position weight of a sentence as the prior score for the sentence. The position weight of a sentence is computed by using Equation (15).

CollabRank1: This baseline approach is the “UniformLink(Gold)” approach proposed in (Wan et al. 2007b). It uses a cluster of multiple documents to improve single document summarization by constructing a global affinity graph.

CollabRank2: This baseline approach is the “UnionLink(Gold)” approach proposed in (Wan et al. 2007b).

The graph-based baselines for multi-document summarization are described as follows:

BasicRank: This baseline approach adopts the basic PageRank algorithm to rank sentences based on all sentence relationships in document set. Both within-document and cross-document sentence relationships are used for constructing the affinity graph.

PositionRank: Similarly, this baseline approach improves the basic PageRank algorithm by using the position weight of a sentence as the prior score for the sentence.

TwoStageRank: This baseline approach leverages the results of single document summarization for multi-document summarization. It first computes the score of each sentence within each single document by using the PositionRank method, and then computes the final score of each sentence within the document set by considering the document-level sentence score as the prior score in the improved PageRank algorithm.

The top three systems are the systems with highest ROUGE scores, chosen from the participating systems on each task, respectively. Tables 2 and 3 show the comparison results for single-document summarization on DUC2001 and DUC2002, respectively. Tables 4 and 5 show the comparison results for multi-document summarization on DUC2001 and DUC2002, respectively. In the tables, SystemX (e.g. System28, SystemN) represents one of the top performing systems. The systems are sorted by decreasing order of the ROUGE-1 scores.

For single-document summarization, the proposed UnifiedRank approach always outperforms the four graph-based baselines over all three metrics on both two datasets. The performance differences are all statistically significant by using t-test (p-value<0.05). The ROUGE-1 score of UnifiedRank is higher than that of the best participating systems and the ROUGE-2 and ROUGE-W scores of UnifiedRank are comparable to that of the best participating systems.

For multi-document summarization, the proposed UnifiedRank approach outperforms all the three graph-based baselines over all three metrics on the DUC2001 dataset, and it outperforms the three baselines over ROUGE-1 and ROUGE-W on the DUC2002 dataset. In particular, UnifiedRank can significantly outperform BasicRank and TwoStageRank over all three metrics on the DUC2001 dataset (t-test, p-value<0.05). Moreover, the ROUGE-1 and ROUGE-W scores of UnifiedRank are higher than that of the best participating systems and the ROUGE-2 score of UnifiedRank is comparable to that of the best participating systems.

The results demonstrate that the single-document and multi-document summarizations can benefit each other by making use of the mutual influences between the local saliency and global saliency of the sentences. Overall, the proposed unified graph-based approach is effective for both single document summarization and multi-document summarization. However, the performance improvement for single-document summarization is more significant than that for multi-document summarization, which shows that the global information in a document set is very beneficial to summarization of each single document in the document set.

4.2.2 *Influences of Combination Weight*

In the above experiments, the relative contributions from the first two parts in Equations (9) and (10) are empirically set as $\alpha/(\alpha+\beta)$=0.4. In this section, we investigate how the relative contributions influence the summarization performance by varying $\alpha/(\alpha+\beta)$ from 0 to 1. A small value of $\alpha/(\alpha+\beta)$ indicates that the contribution from the same kind of saliency scores of the sentences is less important than the contribution from the different kind of saliency scores of the sentences, and vice versa. Figures 1-8 show the ROUGE-1 and ROUGE-W curves for single-document summarization and multi-document summarization on DUC2001 and DUC2002, respectively.

For single document summarization, very small value or very large value for $\alpha/(\alpha+\beta)$ will lower the summarization performance values on the two datasets. The results demonstrate that both the two kinds of contributions are important to the final performance of single document summarization.

For multi-document summarization, a relatively large value (≥0.4) for $\alpha/(\alpha+\beta)$ will lead to relatively high performance values on the DUC2001 dataset, but a very large value for $\alpha/(\alpha+\beta)$ will decrease the performance values. On the DUC2002 dataset, a relatively small value (≤0.4) will lead to relatively high performance values, but a very small value for $\alpha/(\alpha+\beta)$ will decrease the performance values. Though the trends of the curves on the DUC2001 and DUC2002 datasets are not very consistent with each other, the results show that both the two kinds of contributions are beneficial to the final performance of multi-document summarization.

5 Conclusion and Future Work

In this study, we propose a novel unified approach to simultaneous single-document and multi-document summarization by making using of the mutual influences between the two tasks. Experimental results on the benchmark DUC datasets show the effectiveness of the proposed approach.

In future work, we will perform comprehensive experiments for topic-focused document

[3] The summarization results for participating systems on DUC2001 are incomplete.

summarizations to show the robustness of the proposed approach.

"Got You!": Automatic Vandalism Detection in Wikipedia with Web-based Shallow Syntactic-Semantic Modeling

William Yang Wang and Kathleen R. McKeown
Department of Computer Science
Columbia University

Abstract

Discriminating vandalism edits from non-vandalism edits in Wikipedia is a challenging task, as ill-intentioned edits can include a variety of content and be expressed in many different forms and styles. Previous studies are limited to rule-based methods and learning based on lexical features, lacking in linguistic analysis. In this paper, we propose a novel Web-based shallow syntactic-semantic modeling method, which utilizes Web search results as resource and trains topic-specific n-tag and syntactic n-gram language models to detect vandalism. By combining basic task-specific and lexical features, we have achieved high F-measures using logistic boosting and logistic model trees classifiers, surpassing the results reported by major Wikipedia vandalism detection systems.

1 Introduction

Online open collaboration systems are becoming a major means of information sharing on the Web. With millions of articles from millions of resources edited by millions of people, Wikipedia is a pioneer in the fast growing, online knowledge collaboration era. Anyone who has Internet access can visit, edit and delete Wikipedia articles without authentication.

A primary threat to this convenience, however, is vandalism, which has become one of Wikipedia's biggest concerns (Geiger, 2010). To date, automatic countermeasures mainly involve rule-based approaches and these are not very effective. Therefore, Wikipedia volunteers have to spend a large amount of time identifying vandalized articles manually, rather than spending time contributing content to the articles. Hence, there is a need for more effective approaches to automatic vandalism detection.

In contrast to spam detection tasks, where a full spam message, which is typically 4K Bytes (Rigoutsos and Huynh, 2004), can be sampled and analyzed (Itakura and Clarke, 2009), Wikipedia vandals typically change only a small number of words or sentences in the targeted article. In our preliminary corpus (Potthast et al., 2007), we find the average size of 201 vandalized texts to be only 1K Byte. This leaves very few clues for vandalism modeling. The question we address in this paper is: given such limited information, how can we better understand and model Wikipedia vandalism?

Our proposed approach establishes a novel classification framework, aiming at capturing vandalism through an emphasis on shallow syntactic and semantic modeling. In contrast to previous work, we recognize the significance of natural language modeling techniques for Wikipedia vandalism detection and utilize Web search results to construct our shallow syntactic and semantic models. We first construct a baseline model that captures task-specific clues and lexical features that have been used in earlier work (Potthast et al., 2008; Smets et al., 2008) augmenting these with shallow syntactic and semantic features. Our main contributions are:

- Improvement over previous modeling methods with three novel lexical features
- Using Web search results as training data for syntactic and semantic modeling
- Building topic-specific n-tag syntax models and syntactic n-gram models for shallow syntactic and semantic modeling

2 Related Work

So far, the primary method for automatic vandalism detection in Wikipedia relies on rule-based bots. In recent years, however, with the rise of statistical machine learning, researchers have begun to treat Wikipedia vandalism detection task as a classification task. To the best of our knowledge, we are among the first to consider the shallow syntactic and semantic modeling using Natural Language Processing (NLP) techniques, utilizing the Web as corpus to detect vandalism.

ClueBot (Carter, 2007) is one of the most active bots fighting vandalism in Wikipedia. It keeps track of the IP of blocked users and uses simple regular expressions to keep Wikipedia vandalism free. A distinct advantage of rule-based bots is that they have very high precision. However they suffer from fixed-size knowledge bases and use only rigid rules. Therefore, their average recall is not very high and they can be easily fooled by unseen vandalism patterns. According to Smets et al., (2008) and Potthast et al., (2008), rule-based bots have a perfect precision of 1 and a recall of around 0.3.

The Wikipedia vandalism detection research community began to concentrate on the machine learning approaches in the past two years. Smets et al. (2008) wrapped all the content in *diff* text into a bag of words, disregarding grammar and word order. They used Na ïve Bayes as the classification algorithm. Compared to rule-based methods, they show an average precision of 0.59 but are able to reach a recall of 0.37. Though they are among the first to try machine learning approaches, the features in their study are the most straightforward set of features. Clearly, there is still room for improvement.

More recently, Itakura and Clarke (2009) have proposed a novel method using Dynamic Markov Compression (DMC). They model their approach after the successful use of DMC in Web and Mail Spam detection (Bratko et al., 2006). The reported average precision is 0.75 and average recall is 0.73.

To the best of our knowledge, Potthast et al., (2008) report the best result so far for Wikipedia vandalism detection. They craft a feature set that consists of interesting task-specific features. For example, they monitor the number of previously submitted edits from the same author or IP, which is a good feature to model author contribution. Their other contributions are the use of a logistic regression classifier, as well as the use of lexical features. They successfully demonstrate the use of lexical features like vulgarism frequency. Using all features, they reach an average precision of 0.83 and recall of 0.77.

In addition to previous work on vandalism detection, there is also earlier work using the web for modeling. Biadsy et al. (2008) extract patterns in Wikipedia to generate biographies automatically. In their experiment, they show that when using Wikipedia as the only resource for extracting named entities and corresponding collocational patterns, although the precision is typically high, recall can be very low. For that reason, they choose to use Google to retrieve training data from the Web. In our approach, instead of using Wikipedia edits and historical revisions, we also select the Web as a resource to train our shallow syntactic and semantic models.

3 Analysis of Types of Vandalism

In order to better understand the characteristics of vandalism cases in Wikipedia, we manually analyzed 201 vandalism edits in the training set of our preliminary corpus. In order to concentrate on textual vandalism detection, we did not take into account the cases where vandals hack the image, audio or other multimedia resources contained in the Wikipedia edit.

We found three main types of vandalism, which are shown in Table 1 along with corresponding examples. These examples contain both the title of the edit and a snippet of the *diff*-ed content of vandalism, which is the textual difference between the old revision and the new revision, derived through the standard *diff* algorithm (Heckel, 1978).

- **Lexically ill-formed**
  This is the most common type of vandalism in Wikipedia. Like other online vandalism acts, many vandalism cases in Wikipedia involve ill-intentioned or ill-formed words such as vulgarisms, invalid letter sequences, punctuation misuse and Web slang. An interesting observation is that vandals almost never add emoticons in Wikipedia. For the first example in

Vandalism Types	**Examples**
Lexically ill-formed	**Edit Title**: *IPod* shit!!!!!!!!!!!!!!!!!!!!!!
Syntactically ill-formed	**Edit Title**: *Rock music* DOWN WITH SOCIETY MADDISON STREET RIOT FOREVER.
	Edit Title: *Vietnam War* Crabinarah sucks dont buy it
Lexically + syntactically well-formed, semantically ill-intentioned	**Edit Title**: *Global Warming* Another popular theory involving global warming is the concept that global warming is not caused by greenhouse gases. The theory is that Carlos Boozer is the one preventing the infrared heat from escaping the atmosphere. Therefore, the Golden State Warriors will win next season.
	Edit Title: *Harry Potter* Harry Potter is a teenage boy who likes to smoke crack with his buds. They also run an illegal smuggling business to their headmaster dumbledore. He is dumb!

Table 1: Vandalism Types and Examples

Table 1, vulgarism and punctuation misuse are observed.

- **Syntactically ill-formed**

Most vandalism cases that are lexically ill-intentioned tend to be syntactically ill-formed as well. It is not easy to capture these cases by solely relying on lexical knowledge or rule-based dictionaries and it is also very expensive to update dictionaries and rules manually. Therefore, we think that is crucial to incorporate more syntactic cues in the feature set in order to improve performance. Moreover, there are also some cases where an edit could be lexically well-intentioned, yet syntactically ill-formed. The first example of syntactic ill-formed in Table 1 is of this kind.

Feature Sets	**Features**

Task-specific	Number of Revisions;
	Revisions Size Ratio;

Lexical	Vulgarism; Web Slang;
	Punctuation Misuse;
	Comment Cue Words;

Syntactic	Normalized Topic-specific N-tag Log Likelihood and Perplexity
Semantic	Normalized Topic-specific Syntactic N-gram Log Likelihood and Perplexity

Table 2: Feature Sets and Corresponding Features of Our Vandalism Detection System

- **Lexically and syntactically well formed, but semantically ill-intentioned**

This is the trickiest type of vandalism to identify. Vandals of this kind might have good knowledge of the rule-based vandalism detecting bots. Usually, this type of vandalism involves off-topic comments, inserted biased opinions, unconfirmed information and lobbying using very subjective comments. However, a common characteristic of all vandalism in this category is that it is free of both lexical and syntactic errors. Consider the first example of semantic vandalism in Table 1 with edit title "Global Warming": while the first sentence for that edit seems to be fairly normal (the author tries to claim another explanation of the global warming effect), the second sentence makes a sudden transition from the previous topic to mention a basketball star and makes a ridiculous conclusion in the last sentence.

In this work, we realize the importance of incorporating NLP techniques to tackle all the above types of vandalism, and our focus is on the syntactically ill-formed and semantically ill-intentioned types that could not be detected by rule-based systems and straightforward lexical features.

4 Our System

We propose a shallow syntactic-semantic focused classification approach for vandalism detection (Table 2). In contrast to previous work, our approach concentrates on the aspect of using natural language techniques to model vandalism. Our shallow syntactic and semantic modeling approaches extend the traditional n-gram language modeling method with topic-specific n-tag (Collins et al., 2005) syntax models and topic-specific syntactic n-gram semantic models. Moreover, in the Wikipedia vandalism detection task, since we do not have a sufficient amount of training data to model the topic of each edit, we propose the idea of using the Web as corpus by retrieving search engine results to learn our topic-specific n-tag syntax and syntactic n-gram semantic models. The difference between our syntactic and semantic modeling is that n-tag syntax models only model the order of sentence constituents, disregarding the corresponding words. Conversely, for our syntactic n-gram models, we do keep track of words together with their POS tags and model both the word and syntactic compositions as a sequence. The detail of our shallow syntactic-semantic modeling method will be described in subsection 4.4.

We use our shallow syntactic-semantic model to augment our base model, which builds on early work. For example, when building one of our task-specific features, we extract the name of the author of this revision to query Wikipedia about the historical behavior of this author. This kind of task-specific global feature tends to be very informative and thus forms the basis of our system. For lexical level features, we count vulgarism frequencies and also introduce three new lexical features: Web slang, punctuation misuse and comment cue words, all of which will be described in detail in 4.2 and 4.3.

4.1 Problem Representation

The vandalism detection task can be formulated as the following problem. Let's assume we have a vandalism corpus *C*, which contains a set of Wikipedia edits *S*. A Wikipedia edit is denoted as $\boldsymbol{e_i}$. In our case, we have $S = \{\boldsymbol{e_1}, \boldsymbol{e_2}\ldots,\boldsymbol{e}_n\}$. Each edit ***e*** has two consecutive revisions (an old revision R_{old} and a new revision R_{new}) that are unique in the entire data set. We write that $\boldsymbol{e} = \{R_{old}, R_{new}\}$. With the use of the standard *diff* algorithm, we can produce a text R_{diff}, showing the difference between these two revisions, so that $\boldsymbol{e} = \{R_{old}, R_{new}, R_{diff}\}$. Our task is: given S, to extract features from edit $\boldsymbol{e} \in S$ and train a logistic boosting classifier. On receiving an edit ***e*** from the test set, the classifier needs to decide whether this ***e*** is a vandalism edit or a non-vandalism edit. $\boldsymbol{e} \rightarrow \{1,0\}$.

4.2 Basic Task-specific and Lexical Features

Task-specific features are domain-dependent and are therefore unique in this Wikipedia vandalism detection task. In this work, we pick two task-specific features and one lexical feature that proved effective in previous studies.

- **Number of Revisions**
  This is a very simple but effective feature that is used by many studies (Wilkinson and Huberman, 2007; Adler et al., 2008; Stein and Hess, 2007). By extracting the author name for the new revision R_{new}, we can easily query Wikipedia and count how many revisions the author has modified in the history.

- **Revision Size Ratio**
  Revision size ratio measures the size of the new revision versus the size of the old revision in an edit. This measure is an indication of how much information is gained or lost in the new revision R_{new}, compared to the old revision R_{old}, and can be expressed as:

$$\text{RevRatio}(\boldsymbol{e}) = \frac{\sum_{w \,\epsilon\, R\ new} \text{Count (w)}}{\sum_{w \,\epsilon\, R\ old} \text{Count (w)}}$$

  where W represents any word token of a revision.

- **Vulgarism Frequency**
  Revision size ratio measures the size of the new revision versus the Vulgarism frequency was first introduced by Potthast et al. (2008). However, note that not all vulgarism words should be considered as vandalism and sometime even the Wikipedia edit's title and content themselves contain vulgarism words.

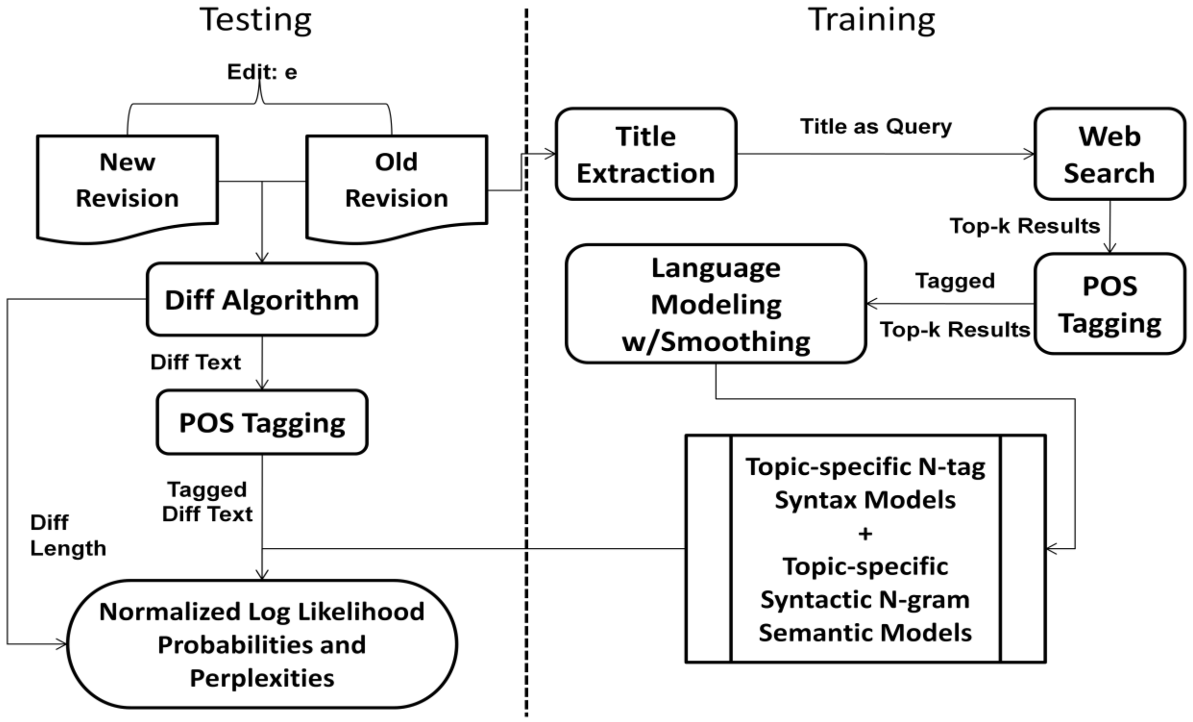

Figure 1. Topic-specific N-tag Syntax Models and Syntactical N-gram for Syntactical and Semantic Modeling

For each *diff* text in an edit ***e***, we count the total number of appearances of vulgarism words v where v is in our vulgarism dictionary[1].

$$\text{VulFreq}(\boldsymbol{e}) = \sum_{v \in \text{Rdiff}} \text{Count}(v)$$

4.3 Novel Lexical Features

In addition to previous lexical features, we propose three novel lexical features in this paper: Web slang frequency, punctuation misuse, and comment cue words frequency.

- **Web Slang and Punctuation Misuse**

  Since Wikipedia is an open Web application, vandalism also contains a fair amount of Web slang, such as, “haha”, “LOL” and “OMG”. We use the same method as above to calculate Web slang frequency, using a Web slang dictionary[2]. In vandalism edits, many vandalism edits also contain punctuation misuse, for example, “!!!” and “???”. However, we have not observed a significant amount of emoticons in the vandalism edits. Based on this, we only keep track of Web slang frequency and the occurrence of punctuation misuse.

- **Comment Cue Words**

  Upon committing each new revision in Wikipedia, the author is required to enter some comments describing the change. Well-intentioned Wikipedia contributors consistently use these comments to explain the motivation for their changes. For example, common non-vandalism edits may contain cue words and phrases like “edit revised, page changed, item cleaned up, link repaired or delinked”. In contrast, vandals almost never take their time to add these kinds of comments. We can measure this phenomenon by counting the frequency of comment cue words.

4.4 Topic-specific N-tag Syntax Models and Syntactic N-grams for Shallow Syntactic and Semantic Modeling

In Figure 1, we present the overview of our approach, which uses Web-trained topic-specific training for both: (1) n-tag syntax models for shallow syntactic modeling and (2) syntactic n-gram models for shallow semantic modeling.

For each Wikipedia edit, we consider its title as an approximate semantic representation, using it as a query to build topic-specific models. In addition, we also use the title information to model the syntax of this topic.

Given R_{diff}, we produce the syntactic version of the *diff*-ed text using a probabilistic POS tagger (Toutanova and Manning, 2000; Toutanova et al., 2003). The edit title is extracted from the corpus (either R_{new} or R_{old}) and is used to query multiple Web search engines in order to collect the n-tag and n-gram training data from the top-*k* results. Before we start training language models, we tag the top-*k* results using the POS tagger. Note that when modeling n-tag syntax models, it is necessary to remove all the words. With the POS-only sequences, we train topic-specific n-tag models to describe the syntax of normal text on the same topic associated with this edit. With the original tagged sequences, we train syntactic n-gram models to represent the semantics of the normal text of this edit.

After completing the training stage, we send the test segment (i.e. the *diff*-ed text sequence) to both the learned n-tag syntax models and the learned syntactic n-gram models. For the n-tag syntax model, we submit the POS tag-only version of the segment. For the syntactic n-gram model, we submit a version of the segment where each original word is associated with its POS-tag. In both cases we compute the log-likelihood and the perplexity of the segment.

Finally, we normalize the log likelihood and perplexity scores by dividing them by the length of R_{diff}, as this length varies substantially from one edit to another. [3] We expect an edit that has low log likelihood probability and perplexity to be vandalism, and it is very likely to be unrelated to the syntax and semantic of the normal text of this Wikipedia edit. In the end, the normalized log probability and perplexity scores will be incorporated into our back-end classifier with all task-specific and lexical features.

Web as Corpus: In this work, we leverage Web search results to train the syntax and semantic models. This is based on the assumption that the Web itself is a large corpus and Web search results can be a good training set to approximate the semantics and syntax of the query.

Topic-specific Modeling: We introduce a topic-specific modeling method that treats every edit in Wikipedia as a unique topic. We think that the title of each Wikipedia edit is an approximation of the topic of the edit, so we extract the title of each edit and use it as keywords to retrieve training data for our shallow syntactic and semantic modeling.

Topic-specific N-tag and Syntactic N-gram: In our novel approach, we tag all the top-*k* query results and *diff* text with a probabilistic POS tagger in both the training and test set of the vandalism corpus. Figure 2(a) is an example of a POS-tagged sequence in a top-*k* query result.

For shallow syntactic modeling, we use an n-tag modeling method (Collins et al., 2005). Given a tagged sequence, we remove all the words and only keep track of its POS tags: tag_{i-2} tag_{i-1}

[3] Although we have experimented with using the length of R_{diff} as a potential feature, it does not appear to be a good indicator of vandalism.

tag_i. This is similar to n-gram language modeling, but instead, we model the syntax using POS tags, rather than its words. In this example, we can use the system in Figure 2 (b) to train an n-tag syntactic model and use the one in Figure 2 (d) to test. As we see, for this test segment, it belongs to the vandalism class and has very different syntax from the n-tag model. Therefore, the normalized log likelihood outcome from the n-tag model is very low.

In order to model semantics, we use an improved version of the n-gram language modeling method. Instead of only counting $word_{i-2}$ $word_{i-1}$ $word_i$, we model composite tag/word feature, e.g. $tag_{i-2}word_{i-2}$ $tag_{i-1}word_{i-1}$ tag_iword_i. This syntactic n-gram modeling method has been successfully applied to the task of automatic speech recognition (Collins et al., 2005). In the example in Figure 2, the vandalism *diff* text will probably score low, because although it shares an overlap bigram "*and roll*" with the phrase "*rock and roll*" in training text, once we apply the shallow syntactic n-gram modeling method, the POS tag bigram "*and/CC roll/VB*" in *diff* text will be distinguished from the "*and/CC roll/NN*" or "*and/CC roll/NNP*" in the training data.

5 Experiments

To evaluate the effectiveness of our approach, we first run experiments on a preliminary corpus that is also used by previous studies and compare the results. Then, we conduct a second experiment on a larger corpus and analyze in detail the features of our system.

5.1 Experiment Setup

In our experiments, we use a Wikipedia vandalism detection corpus (Potthast et al., 2007) as a preliminary corpus. The preliminary corpus contains 940 human-assessed edits from which 301 edits are classified as vandalism. We split the corpus and keep a held-out 100 edits for each class in testing and use the rest for training. In the second experiment, we adopt a larger corpus (Potthast et al., 2010) that contains 15,000 edits with 944 marked as vandalism. The split is 300 edits for each class in held-out testing and the rest used for training. In the description of the second corpus, each edit has been reviewed by at least 3 and up to 15 annotators. If more than 2/3 of the annotators agree on a given edit, then the edit is tagged as one of our target classes. Only 11 cases are reported where annotators fail to form a majority inter-labeler agreement and in those cases, the class is decided by corpus authors arbitrarily.

In our implementation, the Yahoo![4] search engine and Bing[5] search engine are the source for collecting top-*k* results for topic-specific n-gram training data, because Google has a daily query limit. We retrieve top-100 results from Yahoo!, and combine them with the top-50 results from Bing.

For POS tagging, we use the Stanford POS Tagger (Toutanova and Manning, 2000; Toutanova et al., 2003) with its attached wsj3t0-18-bidirectional model trained from the Wall Street Journal corpus. For both shallow syntactic and semantic modeling, we train topic-specific trigram language models on each edit using the SRILM toolkit (Stolcke, 2002).

In this classification task, we used two logistic classification methods that haven't been used before in vandalism detection. Logistic model trees (Landwehr et al., 2005) combine tree induction with linear modeling. The idea is to use the logistic regression to select attributes and build logistic regression at the leaves by incrementally refining those constructed at higher levels in the tree. The second method we used, logistic boosting (Friedman et al., 2000), improves logistic regression with boosting. It works by applying the classification algorithm to reweighted versions of the data and then taking a weighted majority vote of the sequence of classifiers thus produced.

5.2 Preliminary Experiment

In the preliminary experiment, we tried logistic boosting classifiers and logistic model trees as classifiers with 10-fold cross validation. The rule-based method, ClueBot, is our baseline.

We also implemented another baseline system, using the bag of words (BoW) and Naive Bayes method (Smets et al., 2008) and the same toolkit (McCallum, 1996) that Smets et al. used. Then, we compare our result with Potthast et al. (2008), who used the same corpus as us.

[4] http://www.yahoo.com

[5] http://www.bing.com

Systems	**Recall**	**Precision**	**F1**
ClueBot	0.27	**1**	0.43
BoW + Na ïve Bayes	0.75	0.74	0.75
Potthast et. al., 2008	0.77	0.83	0.80
Task-specific +Lexical (LMT)	0.87	0.87	0.87
Task-specific +Lexical (LB)	0.92	0.91	0.91
Our System (LMT)	0.89	0.89	0.89
Our System (LB)	**0.95**	0.95	**0.95**

Table 3: Preliminary Experiment Results; The acronyms: BoW: Bag of Words, LMT: Logistic Model Trees, LB: Logistic Boosting, Task-specific + Lexical: features in section 4.1 and 4.2

As we can see in Table 3, the ClueBot has a F-score (F1) of 0.43. The BoW + Na ïve Bayes approach improved the result and reached an F1 of 0.75. Compared to these results, the system of Potthast et al. (2008) is still better and has a F1 of 0.80.

For the results of our system, LMT gives us a 0.89 F1 and LogitBoost (LB) gives a 0.95 F1. A significant F1 improvement of 15% was achieved in comparison to the previous study (Potthast et al., 2008). Another finding is that we find our shallow syntactic-semantic modeling method improves 2-4% over our task-specific and lexical features.

5.3 Results and Analysis

In the second experiment, a notable difference from the preliminary evaluation is that we have an unbalanced data problem. So, we use random down-sampling method to resample the majority class into balanced classes in the training stage. Then, we also use the two classifiers with 10-fold cross validation.

The F1 result reported by our BoW + Na ïve Bayes baseline is 0.68. Next, we test our task-specific and lexical features that specified in section 4.1 and 4.2. The best result is a F1 of 0.82, using logistic boosting. Finally, with our topic-specific shallow syntactic and semantic modeling features, we have a precision of 0.86, a recall of 0.85 and F1 of 0.85.

Features	**Recall**	**Precision**	**F1**
BoW + Na ïve Bayes	0.68	0.68	0.68
Task-specific (LMT)	0.81	0.80	0.80
Task-specific +Lexical(LMT)	0.81	0.81	0.81
Our System (LMT)	0.84	0.83	0.83
Task-specific (LB)	0.81	0.80	0.80
Task-specific + Lexical (LB)	0.83	0.82	0.82
Our System (LB)	**0.86**	**0.85**	**0.85**

Table 4: Second Experiment Results

Though we are surprised to see the overall F1 for the second experiment are not as high as the first one, we do see that the topic-specific shallow syntactic and semantic modeling methods play an important role in improving the result.

Looking back at the related work we mentioned in section 2, though we use newer data sets, our overall results still seem to surpass major vandalism detection systems.

6 Conclusion and Future Works

We have described a practical classification framework for detecting Wikipedia vandalism using NLP techniques and shown that it outperforms rule-based methods and other major machine learning approaches that are previously applied in the task.

In future work, we would like to investigate deeper syntactic and semantic cues to vandalism. We hope to improve our models using shallow parsing and full parse trees. We may also try lexical chaining to model the internal semantic links within each edit.

Abstract

Question detection serves great purposes in the cQA question retrieval task. While detecting questions in standard language data corpus is relatively easy, it becomes a great challenge for online content. Online questions are usually long and informal, and standard features such as question mark or 5W1H words are likely to be absent. In this paper, we explore question characteristics in cQA services, and propose an automated approach to detect question sentences based on lexical and syntactic features. Our model is capable of handling informal online languages. The empirical evaluation results further demonstrate that our model significantly outperforms traditional methods in detecting online question sentences, and it considerably boosts the question retrieval performance in cQA.

1 Introduction

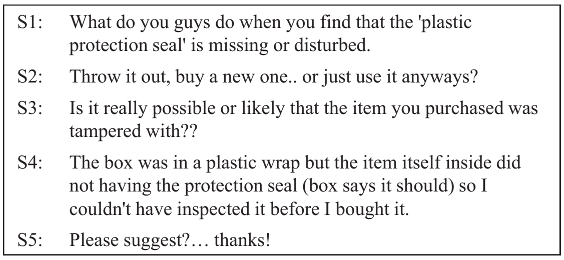
Community-based Question Answering services (cQA) such as Yahoo! Answers have emerged as popular means of information exchange on the web. They not only connect a network of people to freely ask and answer questions, but also allow information seekers to search for relevant historical questions in the cQA archive (Agichtein et al., 2008; Xue et al., 2008; Wang et al., 2009).

Many research works have been proposed to find similar questions in cQA. The state-of-the-art retrieval models include the vector space model (Duan et al., 2008), language model (Duan et al., 2008; Jeon et al., 2005), Okapi model (Jeon et al., 2005), translation model (Jeon et al., 2005; Riezler et al., 2007; Xue et al., 2008), and syntactic tree matching model(Wang et al., 2009). Although experimental studies in these works show that the proposed models are capable of improving question retrieval, they did not give clear explanation on which portion of the question that the user query is actually matched against. A question thread from cQA usually comprises several sub-questions conveying different information needs, and it is highly desirable to identify individual sub-questions and match each of them to the user query. Getting sub-questions clearly identified not only helps the retrieval system to match user query to the most desirable content but also improves the retrieval efficiency.

However, the detection of sub-question is non-trivial. Question sentences in cQA are usually mixed with various description sentences, and they usually employ informal languages, where standard features such as question mark or utterance are likely to be absent. As such, simple heuristics using question mark or 5W1H words (*who, what, where, why, how*) may become inadequate. The demand of special techniques in detecting question sentences online arises due to three particular reasons. First, the question mark could be missing at the end of a question[1], or might be used in cases other than questions such as "*Really bad toothache?*". Second, some questions such as "*I'd like to know the expense of removing wisdom teeth*" are expressed in a declarative form, which neither contains 5W1H words nor is neccessarily ended with "?". Third, some question-like sentences do not carry any actual information need, such as "*Please help me?*". Figure 1 illustrates an example of a question thread

[1] It is reported (Cong et al., 2008) that 30% of online questions do not end with question marks.

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 1155–1163,
Beijing, August 2010



S1: What do you guys do when you find that the 'plastic protection seal' is missing or disturbed.

S2: Throw it out, buy a new one.. or just use it anyways?

S3: Is it really possible or likely that the item you purchased was tampered with??

S4: The box was in a plastic wrap but the item itself inside did not having the protection seal (box says it should) so I couldn't have inspected it before I bought it.

S5: Please suggest?… thanks!

Figure 1: An example of a question thread extracted from Yahoo! Answers

from Yahoo! Answers, where sub-questions S1 and S2 are posted in non-standard forms, and S5 is merely a question-like simple sentence. To the best of our knowledge, none of the existing question retrieval systems are equipped with a comprehensive question detector module to handle various question forms online, and limited effort has been devoted to this direction.

In this paper, we extensively explore characteristics of questions in cQA, and propose a fully automated approach to detecting question sentences. In particular, we complement lexical patterns with syntactic patterns, and use them as features to train a classification model that is capable of handling informal online languages. To save human annotations, we further propose to employ one-class SVM algorithm for model learning, in which only positive examples are used as opposed to requiring both positive and negative examples.

The rest of the paper is organized as follows: Section 2 presents the lexical and syntactic patterns as used for question detection. Section 3 describes the learning algorithm for the classification model. Section 4 shows our experimental results. Section 5 reviews some related work and Section 6 concludes this paper.

2 Pattern Mining for Question Detection

As has been discussed, human generated content on the Web are usually not well formatted, and naive methods such as the use of question mark and 5W1H words are not adequate to correctly detect or capture all online questions. Methods based on hand-crafted rules also fail to cope with various question forms as randomly appeared on the Web. To overcome the shortcomings of these traditional methods, we propose to extract a set of salient patterns from online questions and use them as features to detect question sentences.

In this study, we mainly focus on two kinds of patterns – *sequential pattern* at the lexical level and *syntactic shallow pattern* at the syntactic level. Sequential patterns have been well discussed in many literature, including the identification of comparative sentences (Jindal and Liu, 2006), the detection of erroneous sentences (Sun et al., 2007) and question sentences (Cong et al., 2008) etc. However, works on syntactic patterns have only been partially explored (Zaki and Aggarwal, 2003; Sun et al., 2007; Wang et al., 2009). Grounded on these previous works, we next explain our mining approach of the sequential and syntactic shallow patterns.

2.1 Sequential Pattern Mining

Sequential Pattern is also referred to as *Labeled Sequential Pattern (LSP)* in the literature. It is in the form of $S{\Rightarrow}C$, where S is a sequence $\{t_1, \ldots, t_n\}$, and C is the class label that the sequence S is classified to. In the problem of question detection, a sequence is defined to be a series of tokens from questions, and the class labels are $\{Q, NQ\}$, which stand for question and non-question respectively.

The purpose of sequential pattern mining is to extract a set of frequent subsequence of words that are indicative of questions. For example, the word subsequence "*anyone know what* … *to*" could be a good indication to characterize the question sentence "*anyone know what I can do to make me less tired.*". Note that the mined sequential tokens need not to be contiguous as appeared in the original text.

There is a handful of algorithms available for frequent subsequence extraction. Pei et al. (2001) observed that all occurrences of a frequent pattern can be classified into groups (approximated pattern) and proposed a Prefixspan algorithm. The Prefixspan algorithm quickly finds out all relative frequent subsequences by a pattern growth method, and determines the approximated patterns from those subsequences. We adopt this algorithm in our work due to its high reported efficiency. We impose the following additional constraints for better control over the significance of the mined patterns:

1. Maximum Pattern Length: It limits the maximum number of tokens in a mined sequence.
2. Maximum Token Distance: The two adjacent tokens t_n and t_{n+1} in the pattern need to be within a threshold window in the original text.
3. Minimum Support: The minimum percentage of sentences in Q containing the pattern p.
4. Minimum Confidence: The probability of a pattern $p \Rightarrow Q$ being true in the whole database.

To overcome the word sparseness problem, we generalize each sentence by applying the Part-of-Speech (POS) tags to all tokens except some indicative keywords such as 5W1H words, modal words, stopwords etc. For instance, the question sentence *"How can I quickly tell if my wisdom teeth are coming"* is converted to *"How can I RB VBP if my NN NNS VBP VBG"*, on top of which the pattern mining is conducted. To further capture online language patterns, we mine a set of frequent tokens that are unique to cQA such as *"any1"*, *"im"* and *"whats"*, and keep them from being generalized. The reason to hold back this set of tokens is twofold. First, conventional POS taggers are trained from standard English corpus, and they could mis-tag these non-standard words. Second, the special online tokens are analogue to standard stopwords, and having them properly excluded could help reflect the online users' textual questioning patterns.

It is expected that the converted patterns preserve the most representative features of online questions. Each discovered pattern makes up a binary feature for the classification model that we will introduce in Section 3.

2.2 Syntactic Shallow Pattern Mining

The sequential patterns represent features at the lexical level, but we found that lexical patterns might not always be adequate to categorize questions. For example, the pattern {*when, do*} could presume the non-question "*Levator scapulae is used when you do the traps workout*" to be a question, whereas the question "*know someone with an eating disorder?*" could be overlooked due to the lack of indicative lexical patterns.

These limitations, however, could be alleviated by syntactic features. The syntactic pattern *(SBAR(WHADVP(WRB))(S(NP)(VP)))* extracted from the former example has the order of *NP* and *VP* being switched, which could indicate the sentence to be a non-question, whereas the pattern *(VP(VB)(NP(NP)(PP)))* may be evidence that the latter example is indeed a question, because this pattern is commonly witnessed in the archived questions. Figure 2 shows an example that two questions bear very different wordings but share the same questioning pattern *(S(NP(NN))(VP(VPB)(NP)))* at the syntactic level. In view of the above, we argue that patterns at the syntactic level could complement lexical patterns in identifying question sentences.

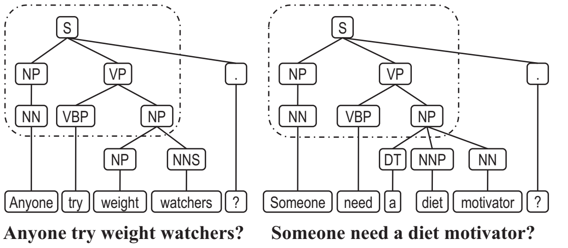


Figure 2: An example of common syntactic patterns observed in two different question sentences

To our knowledge, the mining of salient patterns at the syntactic level was limited to a few tasks. Zaki and Aggarwal (2003) employed tree patterns to classify XML data, Sun et al. (2007) extracted all frequent sub-tree structures for erroneous sentences detection, and Wang et al. (2009) decomposed the parsing tree into fragments and used them to match similar questions. Our work differs from these previous works in that: (1) we also utilize syntactic patterns for the question detection; and (2) we do not blindly extract all possible sub-tree structures, but focus only on certain portions of the parsing tree for better pattern representation and extraction efficiency.

Given a syntactic tree T, we define *syntactic pattern* as a part of sub-structures of T such that the production rule for each non-leaf node in the patterns is intact. For example, the pattern *(S(NP(NN))(VP(VPB)(NP)))* in Figure 2 is considered to be a valid syntactic pattern, whereas *(S(NP(NN))(VP(VPB)))* is not, since the production rule *VP→VPB·NP* is not strictly complied.

We take the following measures to mine salient syntactic patterns: First, we limit the depth of each syntactic pattern to be within a certain range.

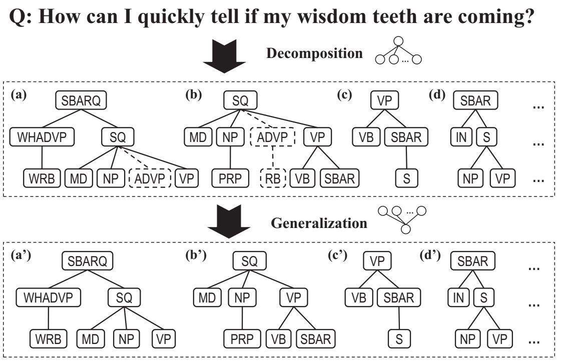

Figure 3: Illustration of syntactic pattern extraction and generalization process

It is believed that the syntax structure will become too specific if it is extended to a deeper level or too general if the depth is too shallow, neither of which produces good representative patterns. We therefore set the depth D of each syntactic pattern to be within a reasonable range ($2 \leq D \leq 4$). Second, we prune away all leaf nodes as well as the production rules at the POS tag level. We believe that nodes at the bottom levels do not carry much useful structural information favored by question detector. For example, the simple grammar rule *NP→DT·NN* does not give any insight to useful question structures. Third, we relax the definition of syntactic pattern by allowing the removal of some nodes denoting modifiers, preposition phrases, conjunctions etc. The reason is that these nodes are not essential in representing the syntactic patterns and are better excluded for generalization purpose. Figure 3 gives an illustration of the process for pattern extraction and generalization. In this example, several syntactic patterns are generated from the question sentence "*How can I quickly tell if my wisdom teeth are coming?*", and the tree patterns (a) and (b) are generalized into (a') and (b'), in which the redundant branch *(ADVP(RB))* that represents the adverb "*quickly*" is detached.

Contents on the Web are prone to noise, and most off-the-shelf parsers are not well-trained to parse online questions. For example, the parsing tree of the question "*whats the matter with it?*" will be very different from that of the question "*what is the matter with it?*". It would certainly be nice to know that "*whats*" is a widely used short form of the phrase "*what is*" on the Web, but we are lack of this kind of thesaurus. Nevertheless, we argue that the parsing errors would not hurt the question detector performance much as long as the mining database is large enough. The reason is that if certain irregular forms frequently occur on the Web, there will be statistical evidences that the syntactic patterns derived from it, though not desired, will commonly occur as well. In other words, we take the wrong patterns and utilize them to detect questions in the irregular forms. Our approach differs from other systems in that we do not intentionally try to rectify the grammatical errors, but leave the errors as they are and use the statistical based approach to capture those informal patterns.

The pattern extraction process is outlined in Algorithm 1. The overall mining strategy is analogous to the mining of sequential patterns, where *support* and *confidence* measures are taken into account to control the significance of the mined patterns. All mined syntactic patterns together with the lexical patterns will be used as features for learning the classification model.

Algorithm 1 *ExtractPattern(S, D)*

```
Input: A set of syntactic trees for sentences ($S$); the depth range ($D$)
Output: A set of sub-tree patterns extracted from $S$
$Patterns$ = {}
for all Syntactic tree $T \in S$ do
    Nodes ← Top-down level order traversal of $T$
    for all node $n \in Nodes$ do
        Extract subtree $p$ rooted under node $n$, with depth within the range $D$
        $p$ ← generalize($p$)
        $Patterns$.add($p$)
    end for
end for
return $Patterns$
```

3 Learning the Classification Model

Although Conditional Random Fields (CRF) is good sequential learning algorithm and has been used in other related work (Cong et al., 2008), here we select Support Vector Machines (SVM) as an alternative learner. The reason is that our task not only deals with sequential patterns but also involves syntactic patterns that possess no sequential criteria. Additionally, SVM has been widely shown to provide superior results compared to other classifiers.

The input to a SVM binary classifier normally consists of both positive and negative examples. While it is easy to discover certain patterns from questions, it is unnatural to identify characteristics for non-questions, as they usually do not share such common lexical and syntactic patterns. The lack of good negative examples leads traditional SVM to perform poorly. To adapt the imbalanced input data, we proposed to employ a one-class SVM method (Manevitz and Yousef, 2002) for learning. The basic idea of one-class SVM is to transform features from only positive examples via a kernel to a hyper-plane and treats the origin as the only member of the second class. It uses relaxation parameters to separate the positive examples from the origin, and finally applies the standard two-class SVM techniques to learn a decision boundary. As a result, anything outside the boundary are considered to be outliers (*i.e.* non-questions in this problem).

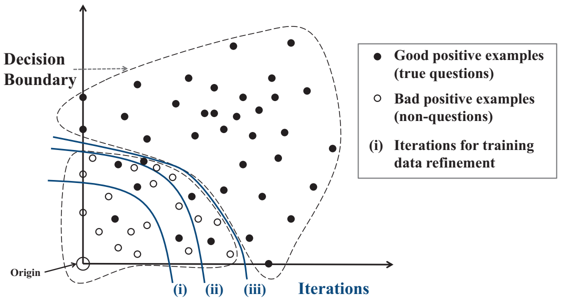
More formally, given n training samples $x_1, \ldots, x_n$ of one class, the hyperplane separating them from the origin is constructed by solving

$$\min \frac{1}{2}\|w\|^2 + \frac{1}{\nu n}\sum_{i=1}^{n}\xi_i - \rho \qquad (1)$$

subject to: $w \cdot \Phi(x_i) \geq \rho - \xi_i$, where Φ is a kernel function, ξ_i is the slack variable, and ν is the parameter controlling the upper bound percentage of outliers. If w and ρ solve this problem, the decision function $f(x) = sign(w \cdot \Phi(x) - \rho)$ will be positive for most examples x_i in the training set.

Supervised learning methods usually require training data to be manually annotated. To save labeling efforts, we take a shortcut by treating all sentences ending with question marks as an initial positive examples. This assumption is acceptable, as Cong et al. (2008) reported that the rule-based method using only question mark achieves a very high precision of over 97% in detecting questions. It in turn indicates that questions ending with "?" are highly reliable to be real questions.

However, the initial training data still contain many sentences ending with "?" but are not true questions. These possible outliers will shift the decision boundary away from the optimal one, and we need to remove them from the training dataset for better classification. Many preprocessing strategies are available for training data refinement, including bootstrapping, condensing, and editing etc. In this work, we employ a SVM-based data editing and classification method proposed by Song et al. (2008), which iteratively sets a small value to the parameter ν of the one-class SVM so as to continuously refine the decision boundary. The algorithm could be better visualized with Figure 4. In each iteration, a new decision boundary will be determined based on the existing set of data points, and a portion of possible outliers will be removed from the training set. It is expected that the learned hyperplane will eventually be very close to the optimal one.



Decision Boundary
● Good positive examples (true questions)
○ Bad positive examples (non-questions)
(i) Iterations for training data refinement
Origin

(ii)
(iii)
Iterations

Figure 4: Illustration of one-class SVM classification with training data refinement (conceptual only). Three iterations (i) (ii) (iii) are presented.

We use the freely available software LIBSVM[2] to conduct the one-class SVM training and testing. A linear kernel is used, as it is shown to be superior in our experiments. In each refinement iteration, the parameter ν is conservatively set to 0.02. The number of iteration is dynamically determined according to the algorithm depicted in (Song et al., 2008). Other parameters are all set to default. The refined decision boundary from the training dataset will be applied to classify questions from non-questions. The question detector model learned will serve as a component for the cQA question retrieval system in our experiments.

4 Experiments

In this section, we present empirical evaluation results to assess the effectiveness of our question detection model. In particular, we first examine the effects of the number of patterns on question detection performance. We further conduct experiments to show that our question de-

Table 2: Question detection performance over different sets of lexical patterns and syntactic patterns

tection model combining both lexical and syntactic features outperforms traditional rule-based or lexical-based methods. We finally demonstrate that our question detection model gives additional performance boosting to question matching.

4.1 Performance Variation over Different Pattern Sets

The performance of the question detection model can be sensitive to the number of features used for learning. To find the optimal number of features used for model training, we examine the performance variation over different amount of lexical and syntactic patterns undertaken for training.

Dataset: We collected a total of around 800k question threads from Yahoo! Answers Healthcare domain. From the collected data, we generated the following three datasets:

- Pattern Mining Set: Comprising around 350k sentences from 60k question threads, where those ending with "?" are treated as questions and others as non-questions.
- Training Set: Positive examples comprising around 130k sentences ending with "?" from another 60k question threads for the one-class SVM learning algorithm.
- Testing Set: Two annotators are asked to tag randomly picked sentences from the remaining set. A total of 2,004 question sentences and 2,039 non-question sentences are annotated.

Methods & Results: We use different combinations of *support* and *confidence* values to generate different set of patterns. The *support* value ranges from 0.40% to 0.55% for lexical patterns with a step size of 0.05%, and ranges from 0.03% to 0.06% for syntactic patterns with a step size of 0.01%. The *confidence* value for both patterns ranges from 60% to 80% with a step size of 5%. These value ranges are empirically determined. Table 1 presents the number of lexical and syntactic patterns mined against different *support* and *confidence* value combinations.

For each set of lexical or syntactic patterns mined, we use them as features for model training. We convert the training sentences into a set of feature vectors and employ the one-class SVM algorithm to train a classifier. The classifier will then be applied to predict the question sentences in the testing set. To evaluate each question detection model, we employ Precision (P), Recall (R), and F_1 as performance metrics, and Table 2 presents the results[3].

We observe from Table 2 that given a fixed support level, the precision generally increases with the confidence level for both lexical and syntactic patterns, but the recall drops. The lexical feature set comprising 1,314 sequential patterns as generated with $\{$*sup=0.45%*, *conf=70%*$\}$ gives the best F_1 score of 88.7%, and the syntactic feature set comprising 580 syntactic patterns generated from $\{$*sup=0.04%*, *conf=65%*$\}$ gives the best F_1 score of 83.7%. It is noted that the sequential patterns give relatively high recall while the syntactic patterns give relatively high precision. Our reading is that the sequential patterns are capable of capturing most questions, but it may also give wrong predictions to non-questions such as "*Lev-*

[3] The results for certain *confidence* levels are not very promising and are not shown in the table due to lack of space.

ator scapulae is used when you do the traps workout" that bears the sequential pattern $\{$*when, do*$\}$. On the other hand, the syntactic patterns could give reliable predictions, but its coverage could suffer due to the limited number of syntactic patterns. We conjecture that a combination of both features could further improve the performance.

4.2 Performance Comparison with Traditional Question Detection Methods

We next conduct experiments to compare the performance of our question detection model to traditional rule-based or lexical-based methods.

Methods & Results: We set up five different systems for meaningful comparisons:

1. 5W1H (baseline1): a rule-based method using 5W1H to determine a question sentence.
2. Question Mark (baseline2): a method using the question mark "?" to judge a question.
3. SeqPattern: Using only the set of 1,314 sequential patterns as features.
4. SynPattern: Using only the set of 580 syntactic patterns as features.
5. SeqPattern+SynPattern: Merging both lexical and syntactic patterns and use them as a set of features for question detection.

We again employ Precision (P), Recall (R), and F_1 as performance metrics to evaluate each question detection system, and tabulate the comparison results in Table 3. From the Table, we observe that 5W1H performs poorly in both precision and recall, and question mark based method gives relatively low recall although the precision is the highest amongst all the methods evaluated. This is in line with the results as observed in (Cong et al., 2008). SeqPattern outperforms the two baseline systems in both R and F_1 scores, and its combination with SynPattern augments the performance in both precision and recall by a lot. It also achieves statistically significant improved results (t-test, p-value<0.05) as compared to other four systems. These results are consistent with our intuition that syntactic patterns can leverage sequential patterns in improving the question detection performance.

It is noted that SeqPattern+SynPattern exhibits the highest recall (R) amongst all the systems. The significance test further suggests that many question sentences miss-detected by 5W1H or Question Mark method could be properly captured by our model. This improvement is meaningful, as the question coverage is also an important factor in the cQA question retrieval task, where high recall implies that more similar questions could be matched and returned, hence improving the question retrieval performance.

System Combination	$P(\%)$	$R(\%)$	$F_1(\%)$
(1) 5W1H	75.37	49.50	59.76
(2) Question Mark	**94.12**	77.50	85.00
(3) SeqPattern	88.92	88.47	88.69
(4) SynPattern	90.06	78.19	83.71
(5) SeqPattern+SynPattern	92.11	**89.67**	**90.87**

Table 3: Performance comparisons for question detection on different system combinations

4.3 Performance Evaluation on Question Retrieval with Question Detection Model

To further demonstrate that our question detection model can improve question retrieval, we incorporate it into different question retrieval systems.

Methods: We select a simple bag-of-word (BoW) system retrieving questions at the lexical level, and a syntactic tree matching (STM) model matching questions at the syntactic level (Wang et al., 2009) as two baselines. For each baseline, we further set up two different combinations:

- Baseline+QM: Using question mark to detect question sentences, and perform question retrieval on top of the detected questions.
- Baseline+QD: Using our proposed model to detect question sentences, and perform question retrieval on top of the detected questions.

This gives rise to additional 4 different system combinations for comparison.

Dataset: We divide the dataset from Yahoo! Answers into a question repository set (750k) and a test set (50k). For the baseline systems, all the repository sentences containing both questions and non-questions are indexed, whereas for systems equipped with QM or QD, only the detected question sentences are indexed for retrieval. We randomly select 250 single-sentence questions from the test set as queries, and for each query, the retrieval system will return a list of top 10 question matches. We combine the retrieved results from different systems and ask two annotators to label each result to be either "relevant" or "irrel-

System Combination	BoW	BoW +QM	BoW +QD	STM	STM +QM	STM +QD
MAP (%)	58.07	59.89	60.68	66.53	68.41	69.85
% improvement of MAP over:						
Baseline	N.A.	+3.13	+4.49	N.A.	+2.83	+4.99
Baseline+QM	N.A.	N.A.	+1.32	N.A.	N.A.	+2.10
P@1 (%)	59.81	61.21	63.55	63.08	64.02	65.42

Table 4: Question retrieval performance on different system combinations measured by MAP and P@1 (Baseline is either BoW or STM)

evant” without telling them which system the result is generated from. By eliminating some query questions that have no relevant matches, the final testing set contains 214 query questions.

Metrics & Results: We evaluate the question retrieval performance using two metrics: Mean Average Precision (MAP) and Top One Precision (P@1). The results are presented in Table 4.

We can see from Table 4 that STM outperforms BoW. Applying QM or QD over BoW and STM boosts the system performance in terms of both MAP and P@1. They also achieve statistical significance as judged by paired t-test (p-value$<$0.05). More specifically, the MAP on QM coupled systems improves by 3.13% and 2.83% respectively over BoW and STM. This is evidence that having question sentences clearly identified could help to retrieve relevant questions more precisely, as without question detection, the user query is likely to be matched to irrelevant description sentences. Our question detection model (QD) further improves the MAP by 1.32% and 2.1% respectively over BoW+QM and STM+QM, and it also yields better top one precision by correctly retrieving questions at the first position on 136 and 140 questions respectively, out of a total of 214 questions. These improvements are in line with our expectation that our model incorporating salient features at both the lexical and syntactic levels is comprehensive enough to capture various forms of questions online, and hence improve the performance of question matching.

5 Related Work

Research on detecting question sentences can generally be classified into two categories. The first category simply employs rule-based methods such as question mark, 5W1H words, or hand-crafted regular expressions to detect questions. As discussed, these conventional methods are not adequate to cope with online questions.

The second category uses machine learning approaches to detect question sentences. Shrestha and McKeown (2004) proposed a supervised rule induction method to detect interrogative questions in email conversations based on part-of-speech features. Yeh and Yuan (2003) used a statistical approach to extract a set of question-related words and derived some syntax and semantic rules to detect mandarin question sentences. Cong et al. (2008) extracted labeled sequential patterns and used them as features to learn a classifier for question detection in online forums.

Question pattern mining is also closely related to the learning of answer patterns. Work on answer patterns includes the web based pattern mining (Zhang and Lee, 2002; Du et al., 2005) and a combination of syntactic and semantic elements (Soubbotin and Soubbotin, 2002) etc.

In contrast to previous work, we do not only focus on standard language corpus, but extensively explore characteristics of online questions. Our approach exploits salient question patterns at both the lexical and syntactic levels for question detection. In particular, we employ the one-class SVM algorithm such that the learning process is weakly supervised and no human annotation is involved.

6 Conclusion

This paper proposed a new approach to detecting question sentences in cQA. We mined both lexical and syntactic question patterns, and used them as features to build classification models. The mining and leaning process is fully automated and requires no human intervention. Empirical evaluation on the cQA archive demonstrated the effectiveness of our model as well as its usefulness in improving question retrieval performance.

We are still investigating other features that are helpful to detect questions. One promising direction for future work is to also employ lexical and syntactic patterns to other related areas such as question type classification etc. It is also interesting to employ a hybrid of CRF and SVM learning methods to boost the accuracy and scalability of the classifier.

Abstract

A range of Natural Language Processing tasks involve making judgments about the semantic relatedness of a pair of sentences, such as Recognizing Textual Entailment (RTE) and answer selection for Question Answering (QA). A key challenge that these tasks face in common is the lack of explicit alignment annotation between a sentence pair. We capture the alignment by using a novel probabilistic model that models tree-edit operations on dependency parse trees. Unlike previous tree-edit models which require a separate alignment-finding phase and resort to ad-hoc distance metrics, our method treats alignments as structured latent variables, and offers a principled framework for incorporating complex linguistic features. We demonstrate the robustness of our model by conducting experiments for RTE and QA, and show that our model performs competitively on both tasks with the same set of general features.

1 Introduction

Many complex Natural Language Processing (NLP) applications can be broken down to a subtask of evaluating the semantic relationship of pairs of sentences (e.g., in Question Answering, answer selection involve comparing each answer candidate against the question). This means that research aiming at analyzing pairs of semantically related natural language sentences is promising because of its reusability: it is not tied to a particular internal representation of meanings, but it nevertheless serves as a first step towards full meaning understanding, which is applicable to a number of applications. At the same time, this paradigm clearly defines the input and output space, facilitating system comparison and standard evaluation. Tasks of this paradigm have drawn much of the focus in recent NLP research, including Recognizing Textual Entailment (RTE), answer selection for Question Answering (QA), Paraphrase Identification (PI), Machine Translation Evaluation (MTE), and many more.

In each of these tasks, inputs to the systems are pairs of sentences that may or may not convey the desired semantic property (e.g., in RTE, whether the hypothesis sentence can be entailed from the premise sentence; in QA, whether the answer candidate sentence correctly answers the question), and the output of the system is a binary classification decision (or a regression score,as in MTE).

Earlier studies in these domains have concluded that simple word overlap measures (e.g., bag of words, n-grams) have a surprising degree of utility (Papineni et al., 2002; Jijkoun and de Rijke, 2005b), but are nevertheless not sufficient for these tasks (Jijkoun and de Rijke, 2005a). A common problem identified in these earlier systems is the lack of understanding of the semantic relation between words and phrases. Later systems that include more linguistic features extracted from resources such as WordNet have enjoyed more success (MacCartney et al., 2006). Studies have also shown that certain prominent syntactic features are often found beneficial (Snow et al., 2006). More recent studies gained further leverage from systematic exploration of the syntactic feature space through analysis of parse trees (Wang et al.,

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 1164–1172,
Beijing, August 2010

2007; Das and Smith, 2009).

There are two key challenges imposed by these tasks. The first challenge has to do with the hidden alignment structures embedded in the sentence pairs. It is straightforward to see that in order to extract word-matching and/or syntax-matching features, inevitably one has to consider the alignment between words and/or syntactic parts. These alignments are not given as inputs, and it is a non-trivial task to decide what the *correct* alignment is. Alignment-based approach have been proven effective by many RTE, QA and MTE systems (Haghighi et al., 2005; Wang et al., 2007; MacCartney et al., 2008; Das and Smith, 2009, *inter alia*). Although alignment is a commonly used approach, it is not the only one. Other studies have successfully applied theorem proving and logical induction techniques, translating both sentences to knowledge representations and then doing inference on these representations (Moldovan et al., 2003; Raina et al., 2005; de Salvo Braz et al., 2005; MacCartney and Manning, 2007, *inter alia*).

A second challenge arises when a system needs to combine various sources of evidence (i.e., surface text features, semantic features, and syntactic features) to make a global classification decision. Quite often these features are heavily overlapping and sometimes contradicting, and thus a robust learning scheme that knows when to activate what feature is desired. Traditional approaches employ a two-stage or multi-stage model where tasks are broken down into alignment finding, feature extraction, and feature learning subtasks (Haghighi et al., 2005; MacCartney et al., 2008). The alignment finding task is typically done by committing to a *one best* alignment, and subsequent features are extracted only according to this alignment. A large body of literature in joint learning has demonstrated that such an approach can suffer from cascaded errors at testing, and does not benefit from the potential for joint learning (Finkel et al., 2006).

In this paper, we present a novel undirected graphical model to address these challenges. A promising approach to these challenges is modeling the alignment as an edit operation sequence over parse tree representation, an approach pioneered by (Punyakanok et al., 2004; Kouylekov and Magnini, 2006; Harmeling, 2007; Mehdad, 2009). We improve upon this earlier work by showing how alignment structures can be inherently learned as structured latent variables in our model. Tree edits are represented internally as state transitions in a Finite-State Machine (FSM), and our model is parameterized as a Conditional Random Field (CRF) (Lafferty et al., 2001), which allows us to incorporate a diverse set of arbitrarily overlapping features.

In comparison to previous work that exploits various ad-hoc or heuristic ways of incorporating tree-edit operations, our model provides an elegant and much more principled way of describing tree-edit operations in a probabilistic setting.

2 Tree-edit CRF for Classification

A training instance consists of a pair of sentences and an associated binary judgment. In RTE, for example, the input sentence pairs is made up of a text sentence (e.g., *Gabriel Garcia Marquez is a novelist and winner of the Nobel prize for literature.*) and a hypothesis sentence (e.g., *Gabriel Garcia Marquez won the Nobel for Literature.*). The pair is judged to be *true* if the hypothesis can be entailed from the text (e.g., the answer is *true* for the example sentence pair).

Formally, we denote the text sentence as *txt* and the hypothesis sentence as *hyp*, and denote their labeled dependency parse trees as $\tau_\mathbf{t}$ and $\tau_\mathbf{h}$, respectively. We use the binary variable $z \in \{0, 1\}$ to denote the judgment.

The generative story behind our model is a parse tree transformation process. $\tau_\mathbf{t}$ is transformed into $\tau_\mathbf{h}$ through a sequence of *tree edits*. Examples of tree edits are *delete child*, *insert parent*, and *substitute current*. An edit sequence $\mathbf{e} = e_1 \ldots e_m$ is *valid* if $\tau_\mathbf{t}$ can be successfully turned into $\tau_\mathbf{h}$ according to $\mathbf{e}$. An example of a trivial valid edit sequence is one that first *deletes* all nodes in $\tau_\mathbf{t}$ then *inserts* all nodes in $\tau_\mathbf{h}$.

Delete, *insert* and *substitute* form the three basic edit operations. Each step in an edit sequence is also linked with current edit positions in both trees, denoted as $\mathbf{e}.\mathbf{p} = e_1.p \ldots e_m.p$. We index the tree nodes using a level-order tree traversal scheme (i.e., root is visited first and assigned index 0, then each one of the first level children of the root is visited in turn, and assigned an index number incremented by 1). It is worth noting that every valid edit sequence has a corresponding alignment mapping. Nodes that are inserted or deleted are aligned to *null*, and nodes that are substituted are aligned. One can find many edit sequence for the same alignment, by altering the order of edit operations.

We extend these basic edit operations into more elaborate edit operations based on the linguistic and syntactic properties of the current tree nodes that they fire on. For example, the following are all possible edit operations: *delete* a noun that is SUB of the root, *delete* a named-entity of type PERSON, *substitute* roots of the tree. In our experiments, we designed a set of 45 edit operations (12 *delete*, 12 *insert* and 21 *substitute*). More details of the edit operations are described in §4. Depending on the specific application domain, more sophisticated and verbose tree edit operations can be designed and easily incorporated into our model. In particular, tree edit operations involving deleting, inserting or substituting entire treelets seem interesting and promising, requiring merely a simple extension to the forward-backward dynamic programming.

Next, we design a Finite-State Machine (FSM) in which each edit operation is mapped to a unique state, and an edit sequence is mapped into a transition sequence among states (denoted as $\mathbf{e}.\mathbf{a} = e_1.a \ldots e_m.a$). In brief, an edit sequence is associated with a sequence of edit positions in the trees ($\mathbf{e}.\mathbf{p} = e_1.p \ldots e_m.p$), as well as a transition sequence among states ($\mathbf{e}.\mathbf{a} = e_1.a \ldots e_m.a$).

The probability of an edit sequence $\mathbf{e}$ given the parse trees is defined as:

$$P(\mathbf{e} \mid \tau_{\mathbf{t}}, \tau_{\mathbf{h}}) = \frac{1}{Z} \prod_{i=1}^{|\mathbf{e}|} \exp \theta \cdot \mathbf{f}(e_{i-1}, e_i, \tau_{\mathbf{t}}, \tau_{\mathbf{h}}) \quad (1)$$

where $\mathbf{f}$ are feature functions, θ are associated feature weights, and Z is the partition function to be defined next.

Recall that our training data is composed of not only positive examples but also negative examples. In order to take advantage of this label information, we adopt an interesting discriminative learning framework first introduced by McCallum et al. (2005). We call the FSM state set described above the *positive* state set ($\mathcal{S}_1$), and duplicate the exact same set of states, and call the new set *negative* state set ($\mathcal{S}_0$). We then add a starting state(S_s), and add non-deterministic transitions from S_s to every state in $\mathcal{S}_1$. We then add the same transitions for $\mathcal{S}_0$. We now arrive at a new FSM structure where upon arriving at the starting state, one makes a non-deterministic decision to enter either the positive set or the negative set and stay in that set until reaching the end of the edit sequence, since no transitions are allowed across the positive and negative set. Each edit operation sequence can now be associated with a sequence of positive states as well as a sequence of negative states. The intuitive idea is that during training, we want to maximize the weights of the positive examples in the positive state set and minimize their weights in the negative state set, and vice versa. In other words, we want the positive state set to attract positive examples but push away negative examples. Figure 1 illustrates two example valid edit sequences in the FSM, one in the positive state set and one in the negative state set.

Formally, the partition function Z in (1) is defined as the sum of weights of all valid edit sequences in both the positive set and negative set. Features extracted from positive states are disjoint from features extracted from negative states.

$$Z = \sum_{\mathbf{e}:\, \mathbf{e}.\mathbf{a} \subseteq S_s + \{\mathcal{S}_0 \bigcup \mathcal{S}_1\}^*} \prod_{i=1}^{|\mathbf{e}|} \exp \theta \cdot \mathbf{f}(e_{i-1}, e_i, \tau_{\mathbf{t}}, \tau_{\mathbf{h}})$$

Recall $z \in \{0,1\}$ is the binary judgment indicator variable. The conditional probability of z is obtained by marginalizing over all edit sequences that have state transitions in the state set corresponding to z:

$$P(z \mid \tau_{\mathbf{t}}, \tau_{\mathbf{h}}) = \sum_{\mathbf{e}:\, \mathbf{e}.\mathbf{a} \subseteq S_s + \mathcal{S}_z^*} P(\mathbf{e} \mid \tau_{\mathbf{t}}, \tau_{\mathbf{h}}) \quad (2)$$

The L_2-norm penalized log-likelihood over n training examples ($\mathcal{L}$) is our training objective function:

$$\mathcal{L} = \sum_{j=1}^{n} \log(P(z^{(j)} \mid \tau_{\mathbf{t}}^{(j)}, \tau_{\mathbf{h}}^{(j)})) - \frac{\|\theta\|^2}{2\sigma^2} \quad (3)$$

At test time, the z with higher probability is taken as our prediction outcome.

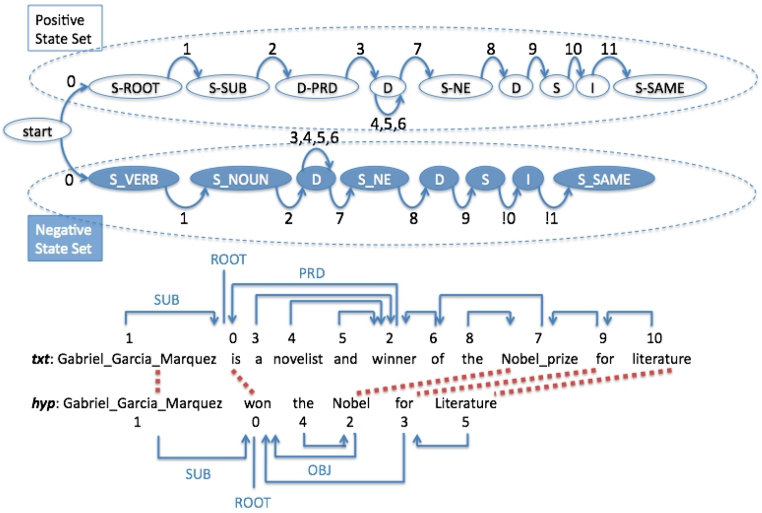

Figure 1: This diagram illustrates the FSM architecture. There is a single start state, and we can transit into either the positive state set (nodes that are not shaded), or the negative state set (shaded nodes). Here we show two examples of valid edit sequences. They result in the same alignment structure as show in the bottom half of the diagram (dotted lines across the two sentences are alignment links). Numbers over the arcs in the state diagram denote the edit sequence index, and numbers under each word in the parse tree diagram denote each node's level-order index number.

3 Parameter Estimation

We used Expectation Maximization method since the objective function given in (3) is non-convex. In the M-step, finding the optimal parameters under the current model expectation involves computing forward-backward style dynamic programming (DP) in a three-dimensional table (two for inputs and one for states) and optimization using L-BFGS method. In practice the resulting DP table can be quite large (for a sentence pair of length 100, and 2 sets of 45 states, we obtain 900,000 entries). We improved efficiency by pruning out partial sequences that do not lead to a complete valid sequence and pre-compute the state-transition table and features.

4 Edit Operations

Table 1 lists the groups of edit operations we designed and their descriptions. Not shown in the table are three default edits (*insert*, *delete* and *substitute*), which fire when none of the more specific edit operations match. Edit operations listed in the the top-left section capture basic matching, deletion and insertion of surface text, part-of-speech tags and named-entity tags. The top-right section capture alignments of semantically related words, based on relational information extracted from various linguistic resources, such as WordNet and NomBank. And the bottom section capture syntactic edits. Note that multiple edit operations can fire at the same edit position if conditions are matched (e.g., we can choose to delete if there are more words to edit in *txt*, or to insert if there are more words to edit in *hyp*).

5 Features

One of the most distinctive advantages of our model compared to previous tree-edit based models is the ability to include a wide range of non-independent, rich linguistic features. The features we employed can be broken down into two categories. The first category is *zero-order* features that model the current edit step. They consist of a conditioning property of the current edit, and the current state in the FSM. The second category is *first-order* features that capture state transitions, by concatenating the current FSM state with the previous FSM state. One simple form of zero-order feature is the current FSM state itself. The FSM states already carry a lot of information about the current edits. Conditioning properties are used to further describe the current edit. They are often more fine-grained and complex (e.g.,

Surface edits		**Semantic edits**	
{I,D,S}-{POS}	insert/delete/substitute words of a POS type, where POS is *noun*, *verb* or *proper noun*	S-SYNONYM	substitute two words that are synonyms
		S-HYPERNYM	substitute two words that are hypernyms
{I,D,S}-NE	insert/delete/substitute named-entity words	S-ANTONYM	substitute two words that are antonyms
{I,D,S}-LIKE	insert/delete/substitute words that expresses likelihood, e.g., *maybe*, *possibly*	S-ACRONYM	substitute two words in which one is an acronym of the other
{I,D,S}-MODAL	insert/delete/substitute modal verbs, e.g., *can*, *could*, *may*	S-NOMBANK	substitute two words that are related according to NomBank
S-{SAME/DIFF}	the words being substituted are the same or different	S-NUM-0,1	substitute two words that are both numerical values, and 1 if they match, 0 if they mismatch
Syntactic edits			
{I,D,S}-ROOT	insert/delete/substitute root of the trees		
{I,D,S}-{REL}	insert/delete/substitute a tree node of grammatical relation type, where REL is either SUB, OBJ, VC or PRD		

Table 1: List of edit operations. I for INSERT, D for DELETE, and S for SUBSTITUTE.

syntactic-matching conditions listed below). To give an example, in Figure 1, the second edit operation in the example sequence is S-NE. A matching condition feature that fires with this state could be *substitute_NE_type_PERSON*, which tells us exactly what type of named-entity is being substituted.

It is notable that in designing edit operations and features, there is a continuum of choice in terms of how much information to be encoded as features versus edit operations. To better illustrate the trade-off, consider the two extreme cases of this continuum. At one extreme, we can design a system where there are only three basic edit operations, and all extra information in our current set of edit operations can be encoded as features. For example, in this case edit operation S-NE would become S with feature *substitute_NE*. The other extreme is to encode every zero-order feature as a separate edit operation. The amount of information encoded in the zero-order features and edit operations is the same in both cases, but the difference lies in first-order features and efficiency. When encoding more information as edit operations (and thus more states in FSM), first-order features become much more expressive; whereas when encoding more information as features, computation becomes cheaper as the number of possible state transition sequences is reduced. In our experiments, we aim to keep a minimal set of edit operations that are meaningful but not overly verbose, and encode additional information as features. Each feature is a binary feature initialized with weight 0.

Due to space limitation, we list the most important zero-order features. Many of these features are inspired by MacCartney et al. (2006) and Snow et al. (2006), but not as sophisticated.

Word matching features. These features detect if a text word and a hypothesis word match the following conditions:

1. have the same lemma
2. one is a phrase and contains the other word
3. are multi-word phrases and parts match
4. have the same/different named-entity type(s) + the named-entity type(s)

Tree structure features. These features try to capture syntactic matching/mismatching information from the labeled dependency parse trees. 1. whether the roots of the two trees are aligned
2. parent-child pair match
3. (2.) and labels also match
4. (2.) and labels mismatch
5. (4.) and detailing the mismatching labels
6. parent+label match, child mismatch
7. child and label match, parents are {hyper/syno/anto}nym
8. looking for specific SUB/OBJ/PRD construct as in Snow et al. (2006).

6 Preprocessing

In all of our experiments, each input pair of text and hypothesis sentence is preprocessed as following: Sentences were first tokenized by the standard Penn TreeBank tokenization script, and then we used MXPOST tagger (Ratnaparkhi, 1996) for part-of-speech (POS) tagging. POS tagged sentences were then parsed by MST-Parser (McDonald et al., 2005) to produce labeled dependency parse trees. The parser was trained on the entire Penn TreeBank. The last step in the pipeline is named-entity tagging using Stanford NER Tagger (Finkel et al., 2005).

7 RTE Experiments

Given an input text sentence and a hypothesis sentence, the task of RTE is to make predictions about whether or not the hypothesis can be entailed from the text sentence. We use standard evaluation datasets RTE1-3 from the Pascal RTE Challenges (Dagan et al., 2006). For each RTE dataset, we train a tree-edit CRF model on the training portion and evaluate on the testing portion. We report accuracy of classification results, and precision and recall for the true entailment class. There is a balanced positive-negative sample distribution in each dataset, so a random baseline gives 50% classification accuracy. We used RTE1 for feature selection and tuning σ in the L_2 regularizer ($\sigma = 5$ was used). RTE2 and RTE3 were reserved for testing.

Our system is compared with four systems on RTE2 and three other systems on the RTE3 dataset.[1] We chose these systems for comparison because they make use of syntactic dependencies and lexical semantic information. Notably other systems that give state-of-the-art performance on RTE use non-comparable techniques such as theorem-proving and logical induction, and often involve significant manual engineering specifically for RTE, thus do not make meaningful comparison to our model.

For RTE2, Kouylekov and Magnini (2006) experimented with various TED cost functions and found a combination scheme to work the best for RTE. Vanderwende et al. (2006) used syntactic heuristic matching rules with a lexical-similarity back-off model. Nielsen et al. (2006) extracted features from dependency path, and combined them with word-alignment features in a mixture of experts classifier. Zanzotto et al. (2006) proposed a syntactic cross-pair similarity measure for RTE.

For RTE3, Harmeling (2007) took a similar classification-based approach with transformation sequence features. Marsi et al. (2007) described a system using dependency-based paraphrasing techniques for RTE. de Marneffe et al. (2006) described a system where best alignments between the sentence pairs were first found, then classification decisions were made based on these alignments.

RTE2	**Acc.%**	**Prec.%**	**Rec.%**
Vanderwende et al., 2006	60.2	59.0	67.0
K&M, 2006	60.5	58.9	70.0
Nielsen et al., 2006	61.1	59.0	73.3
Zanzotto et al., 2006	63.9	60.8	78.0
Tree-edit CRF	63.0	61.7	68.5

Marsi et al., 2007	59.1	-	-
Harmeling, 2007	59.5	-	-
de Marneffe et al., 2006	60.5	61.8	60.2
Tree-edit CRF	61.1	61.3	65.3

Table 2: Results on RTE2 and RTE3 dataset. Results for de Marneffe et al. (2006) were reported by MacCartney and Manning (2008).

Table 2 presents RTE results. Our model performs competitively on both datasets. On RTE2, our model gives second best performance among the methods we compare against, and the difference in accuracy from the best system is quite small (7 out of 800 examples). We observe a larger gap in recall, suggesting our method tends to give higher precision, which is also commonly found in other syntax-based systems (Snow et al., 2006). It is worth noting that Zanzotto et al. (2006) achieved second place in the official RTE2 evaluation. On RTE3, our model outperforms the other syntax-based systems compared. In particular, out system gives the same precision level as the second best system (de Marneffe et al., 2006) without sacrificing as much recall, which is the most common drawback found in syntax-based systems.

8 QA Experiments

A second Tree-edit CRF model was trained for the task of answer selection for Question Answering. In this task, the input pair consists of a short factoid question (e.g., *Who beat Floyd Patterson to take the title away?*) and an answer candidate sentence (e.g., *He saw Ingemar Johansson knock down Floyd Patterson seven times there in winning the heavyweight title.*). The pair is judged positive if the answer candidate sentence correctly answers the question and provides sufficient con-

[1] Different systems are used for comparison because none of these systems reported performance on both datasets.

Table 3: Results on QA task reported in Mean Average Precision (MAP) and Mean Reciprocal Rank (MRR).

textual support (i.e., does not merely contain the answer key, for example, *"Ingemar Johansson was a world heavyweight champion"* would not be a correct answer). We followed the same experimental setup as Wang et al. (2007) and Heilman and Smith (2010). The training portion of the dataset consists of 5919 manually judged Q/A pairs from previous QA tracks at Text REtrieval Conference (TREC 8–12). There are also 1374 Q/A pairs for development and 1866 Q/A pairs for testing, both from the TREC 3 evaluation. The task is framed as a sentence retrieval task, and thus Mean Average Precision (MAP) and Mean Reciprocal Rank (MRR) are reported for the ranked list of most probable answer candidates. We compare out model with four other systems. Wang et al. (2007) proposed a Quasi-synchronous Grammar formulation of the problem which also models alignment as structured latent variables, but in a generative probabilistic model. Their method gives the current state-of-the-art performance on this task. Heilman and Smith (2010) presented a classification-based approach with tree-edit features extracted from a tree kernel. Cui et al. (2005) developed a dependency-tree based information discrepancy measure. Punyakanok et al. (2004) used a generalized Tree-edit Distance method to score mappings between dependency parse trees. All systems were evaluated against the same dataset as the one we used. Results of replicated systems for the last two were reported by Wang et al. (2007), with lexical-semantic augmentation from WordNet.

Results in Table 3 show that our model gives the same level of performance as Wang et al. (2007), with no statistically significant difference ($p > 5$ in sign test). Both systems out-perform the other two earlier systems significantly.

9 Discussion

Our experiments on RTE and QA applications demonstrated that Tree-edit CRF models provide results competitive with previous syntax-based methods. Even though the improvements were quite moderate in some cases, the important point is that our model provides a novel principled framework. It works across different problem domains with minimal domain knowledge and feature engineering, whereas previous methods are only engineered for a particular task and are hard to generalize to new problems.

While the current Tree-edit CRF model can model a large set of linguistic phenomenon and tree-transformations, it has some clear limitations. One of the biggest drawbacks is the lack of support for modeling phrasal re-ordering, which is a very common and important linguistic phenomena. It is not straightforward to implement re-ordering in the current model because it breaks the word-order constraint which admits tractable forward-backward style dynamic programming. However, this shortcoming can be addressed partially by extending the model to deal with constrained re-ordering per Zhang (1996).

10 Related Work

Tree Edit Distance (TED) have been studied extensively in theoretical and algorithmic research (Klein, 1989; Zhang and Shasha, 1989; Bille, 2005). In recent years we have seen many work on applying TED based methods for NLP-related tasks (Punyakanok et al., 2004; Kouylekov and Magnini, 2006; Harmeling, 2007; Mehdad, 2009). Mehdad (2009) proposed a method based on particle swarm optimization technique to automatically learn the TED cost function. Another work that also developed an interesting approach to stochastic tree edit distance is Bernard et al. (2008), but unfortunately experiments in the paper were limited to digit recognition and tasks on small artificial datasets.

Many different approaches to modeling sentence alignment have been proposed before (Haghighi et al., 2005; MacCartney et al., 2008). Haghighi et al. (2005) treated alignment finding in RTE as a graph matching problem between sentence parse trees. MacCartney et al. (2008) described a phrase-based alignment model for MT, trained by the Perceptron learning algorithm. A line of work that offers similar treatment of alignment to our model is the Quasi-synchronous Grammar (QG) (Smith and Eisner, 2006; Wang et al., 2007; Das and Smith, 2009). QG models alignments between two parse trees as structured latent variables. The generative story of QG describes one that builds the parse tree of one sentence, loosely conditioned on the parse tree of the other sentence. This formalism prefers but is not confined to tree isomorphism, therefore possesses more model flexibility than synchronous grammars.

The work of McCallum et al. (2005) inspired the discriminative training framework that we used in our experiments. They presented a String Edit Distance model that also learns alignments as hidden structures for simple tasks such as restaurant name matching.

Our work is also closely related to other recent work on learning probabilistic models involving structural latent variables (Clark and Curran, 2004; Petrov et al., 2007; Blunsom et al., 2008; Chang et al., 2010). The Tree-edit CRF model we present here is a new addition to this family of interesting models for discriminative learning with structural latent variables.

11 Conclusion

We described a Tree-edit CRF model for predicting semantic relatedness of pairs of sentences. Our approach generalizes TED in a principled probabilistic model that embeds alignments as structured latent variables. We demonstrate a wide-range of lexical-semantic and syntactic features can be easily incorporated into the model. Discriminatively trained, the Tree-edit CRF led to competitive performance on the task of Recognizing Textual Entailment and answer selection for Question Answering.

Abstract

The character-based tagging approach is a dominant technique for Chinese word segmentation, and both discriminative and generative models can be adopted in that framework. However, generative and discriminative character-based approaches are significantly different and complement each other. A simple joint model combining the character-based generative model and the discriminative one is thus proposed in this paper to take advantage of both approaches. Experiments on the Second SIGHAN Bakeoff show that this joint approach achieves 21% relative error reduction over the discriminative model and 14% over the generative one. In addition, closed tests also show that the proposed joint model outperforms all the existing approaches reported in the literature and achieves the best F-score in four out of five corpora.

1 Introduction

Chinese word segmentation (CWS) plays an important role in most Chinese NLP applications such as machine translation, information retrieval and question answering. Many statistical methods for CWS have been proposed in the last two decades, which can be classified as either *word-based* or *character-based*. The word-based approach regards the word as the basic unit, and the desired segmentation result is the best word sequence found by the search process. On the other hand, the character-based approach treats the word segmentation task as a character tagging problem. The final segmentation result is thus indirectly generated according to the tag assigned to each associated character. Since the vocabulary size of possible character-tag-pairs is limited, the character-based models can tolerate *out-of-vocabulary* (OOV) words and have become the dominant technique for CWS in recent years.

On the other hand, statistical approaches can also be classified as either adopting a *generative model* or adopting a *discriminative model*. The generative model learns the joint probability of the given input and its associated label sequence, while the discriminative model learns the posterior probability directly. Generative models often do not perform well because they make strong independence assumptions between features and labels. However, (Toutanova, 2006) shows that generative models can also achieve very similar or better performance than the corresponding discriminative models if they have a structure that avoids unrealistic independence assumptions.

In terms of the above dimensions, methods for CWS can be classified as:

1) The word-based generative model (Gao et al., 2003; Zhang et al., 2003), which is a well-known approach and has been used in many successful applications;

2) The word-based discriminative model (Zhang and Clark, 2007), which generates word candidates with both word and character features and is the only word-based model that adopts the discriminative approach；

3) The character-based discriminative model (Xue, 2003; Peng et al., 2004; Tseng et al., 2005; Jiang et al., 2008), which has become the dominant method as it is robust on OOV words and is capable of handling a range of different features, and it has been adopted in many previous works;

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 1173–1181,
Beijing, August 2010

4) The character-based generative model (Wang et al., 2009), which adopts a character-tag-pair-based *n*-gram model and achieves comparable results with the popular character-based discriminative model.

In general, character-based models are much more robust on OOV words than word-based approaches do, as the vocabulary size of characters is a closed set (versus the open set of that of words). Furthermore, among those character-based approaches, the generative model and the discriminative one complement each other in handling *in-vocabulary* (IV) words and OOV words. Therefore, a character-based joint model is proposed to combine them.

This proposed joint approach has achieved good balance between IV word recognition and OOV word identification. The experiments of closed tests on the second SIGHAN Bakeoff (Emerson, 2005) show that the joint model significantly outperforms the baseline models of both generative and discriminative approaches. Moreover, statistical significance tests also show that the joint model is significantly better than all those state-of-the-art systems reported in the literature and achieves the best F-score in four of the five corpora tested.

2 Character-Based Models for CWS

The goal of CWS is to find the corresponding word sequence for a given character sequence. Character-based model is to find out the corresponding tags for given character sequence.

2.1 Character-Based Discriminative Model

The character-based discriminative model (Xue, 2003) treats segmentation as a tagging problem, which assigns a corresponding tag to each character. The model is formulated as:

$$P(t_1^n \mid c_1^n) = \prod_{k=1}^{n} P(t_k \mid t_1^{k-1}, c_1^n) \approx \prod_{k=1}^{n} P(t_k \mid c_{k-2}^{k+2}) \qquad (1)$$

Where t_k is a member of {***B**egin*, ***M**iddle*, ***E**nd*, ***S**ingle*} (abbreviated as B, M, E and S from now on) to indicate the corresponding position of character c_k in its associated word. For example, the word “北京市 (Beijing City)” will be assigned with the corresponding tags as: “北/B (North) 京/M (Capital) 市/E (City)”.

Since this tagging approach treats characters as basic units, the vocabulary size of those possible character-tag-pairs is limited. Therefore, this method is robust to OOV words and could possess a high *recall of OOV words* ($\mathrm{R_{OOV}}$). Although the dependency between adjacent tags/labels can be addressed, the dependency between adjacent characters within a word cannot be directly modeled under this framework. Lower *recall of IV words* ($\mathrm{R_{IV}}$) is thus usually accompanied (Wang et al., 2009).

In this work, the character-based discriminative model is implemented by adopting the feature templates given by (Ng and Low, 2004), but excluding those ones that are forbidden by the closed test regulation of SIGHAN (e.g., $Pu(C_0)$: whether C_0 is a punctuation). Those feature templates adopted are listed below:

$(a)\, C_n\, (n = -2, -1, 0, 1, 2);$

$(b)\, C_n C_{n+1}\, (n = -2, -1, 0, 1);$

$(c)\, C_{-1} C_1$

For example, when we consider the third character “奥” in the sequence “北京奥运会”, template (a) results in the features as following: C_{-2}=北, C_{-1}=京, C_0=奥, C_1=运, C_2=会, and template (b) generates the features as: $C_{-2}C_{-1}$=北京, $C_{-1}C_0$=京奥, C_0C_1=奥运, C_1C_2=运会, and template (c) gives the feature $C_{-1}C_1$=京运.

2.2 Character-Based Generative Model

To incorporate the dependency between adjacent characters in the character-based approach, (Wang et al., 2009) proposes a character-based generative model. In this approach, word w_i is first replaced with its corresponding sequence of [character, tag] (denoted as [*c*, *t*]), where tag is the same as that adopted in the above character-based discriminative model. With this representation, this model can be expressed as:

$$\begin{aligned} P(w_1^m \mid c_1^n) &\equiv P([c,t]_1^n \mid c_1^n) \\ &= P(c_1^n \mid [c,t]_1^n) \times P([c,t]_1^n) \big/ P(c_1^n) \end{aligned} \qquad (2)$$

Since $P(c_1^n \mid [c,t]_1^n) \equiv 1$ and $P(c_1^n)$ is the same for various candidates, only $P([c,t]_1^n)$ should be considered. It can be further simplified with Markov Chain assumption as:

$$P([c,t]_1^n) \approx \prod_{i=1}^{n} P([c,t]_i \mid [c,t]_{i-k}^{i-1}). \qquad (3)$$

Compared with the character-based discriminative model, this generative model keeps the capability to handle OOV words because it also regards the character as basic unit. In addition, the dependency between adjacent

Table 1: The corresponding lambda weight of features for “露宿者” in the sentence “[該] [處] [的] [露宿者] [只] [有] [數] [人]”. In the Feature column and Tag row, the value is the corresponding lambda weight for the feature and tag under ME framework. The meanings of those features are explained in Section 2.1.

characters is now directly modeled. This will give sharper preference when the history of assignment is given. Therefore, this approach not only holds robust IV performance but also achieves comparable results with the discriminative model. However, the OOV performance of this approach is still lower than that of the discriminative model (see in Table 5), which would be discussed in the next section.

3 Problems with the Character-Based Generative Model

The character-based generative model can handle the dependency between adjacent characters and thus performs well on IV words. However, this generative trigram model is derived under the second order Markov Chain assumption. Future character context (i.e., C_1 and C_2) is thus not utilized in the model when the tag of the current character (i.e., t_0) is determined. Nevertheless, the future context would help to select the correct tag when the associated trigram has not been observed in the training-set, which is just the case for those OOV words. In contrast, the discriminative one could get help from the future context in this case. The example given in the next paragraph clearly shows the above situation.

At the sentence “該(that) 處(place) 的(of) 露宿者(street sleeper) 只(only) 有(have) 數(some) 人(person) (There are only some street sleepers in that place)” in the CITYU corpus, “露/B宿/M者/E(street sleeper)” is observed to be an OOV word, while “露/B宿/E(sleep on the street)” is an IV word, where the associated tag of each character is given after the slash symbol. The character-based generative model wrongly splits “露宿者” into two words “露/B宿/E” and “者/S (person)”, as the associated trigram for “露宿者” is not seen in the training set. However, the discriminative model gives the correct result for “宿/M” and the dominant features come from its future context “者” and “只”. Similarly, the future context “只” helps to give the correct tag to “者/E”. Table 1 gives the corresponding lambda feature weights (under the Maximum Entropy (ME) (Ratnaparkhi, 1998) framework) for “露宿者” in the discriminative model. It shows that in the column of “C_1” below “宿”, the lambda value associated with the correct tag “M” is 2.9422, which is the highest value in that column and is far greater than that of the wrong tag “E” (i.e., -1.2696) assigned by the generative model. Which indicates that the future feature “C_1” is the most useful feature for tagging “宿”.

The above example shows the character-based generative model fails to handle some OOV words such as “露宿者” because this approach cannot utilize future context when it is indeed required. However, the future context for the generative model scanning from left to right is just its past context when it scans from right to left. It is thus expected that this kind of errors will be fixed if we let the model scans from both directions, and then combine their results. Unfortunately, it is observed that these two scanning modes share over 90% of their errors. For example, in CITYU corpus, the left-to-right scan generates 1,958 wrong words and the right-to-left scan results 1,947 ones, while 1,795 of them are the same. Similar behavior can also be observed on other corpora.

To find out what are the problems, 10 errors that are similar to “露宿者” are selected to examine. Among those errors, only one of them is fixed, and “露宿者” still cannot be correctly segmented. Having analyzed the scores of the model scanning from both directions, we found that the original scores (from left-to-right scan) at the stages “者” and “宿” indeed get better if the model scans from right-to-left. However, the score at the stage “露” deteriorates because the useful feature “者” (a past non-adjacent character for “露” when scans form right-to-left) still cannot be utilized when the past context “宿者” as a whole is unseen, when the related probabilities are estimated via modified Kneser-Ney smoothing (Chen and Goodman, 1998) technique.

Two scanning modes seem not complementing each other, which is out of our original expectation. However, we found that the character-based generative model and the discriminative one complement each other much more than the two scanning modes do. It is observed that these two approaches share less than 50% of their errors. For example, in CITYU corpus, the generative approach generates 1,958 wrong words and the discriminative one results 2,338 ones, while only 835 of them are the same.

The statistics of the remaining errors resulted from the generative model and the discriminative model is shown in Table 2. As shown in the table, it can be seen that the generative model and the discriminative model complement each other on handling IV words and OOV words (In the “IV Errors” column, the number of “G+D-” is much more than the “G-D+”, while the behavior is reversed in the “OOV Errors” column).

IV Errors			OOV Errors		
G+D-	G-D+	G-D-	G+D-	G-D+	G-D-
12,027	4,723	7,481	2,384	6,139	3,975

Table 2: Statistics for remaining errors of the character-based generative model and the discriminative one on the second SIGHAN Bakeoff (“G+D-” in the “IV Errors” column means that the generative model segments the IV words correctly but the discriminative one gives wrong results. The meanings of other abbreviations are similar with this one.).

4 Proposed Joint Model

Since the performance of both IV words and OOV words are important for real applications, we need to combine the strength from both models. Among various combining methods, log-linear interpolation combination is a simple but effective one (Bishop, 2006). Therefore, the following character-based joint model is proposed, and a parameter α is used to weight the generative model in a cross-validation set.

$$\begin{aligned} Score(t_k) &= \alpha \times \log(P([c,t]_k \,\big|\, [c,t]_{k-2}^{k-1})) \\ &\quad + (1-\alpha) \times \log(P(t_k \,\big|\, c_{k-2}^{k+2})) \end{aligned} \tag{4}$$

Where t_k indicates the corresponding position of character c_k, and α $(0.0 \le \alpha \le 1.0)$ is the weight for the generative model. $Score(t_k)$ will be used during searching the best sequence. It can be seen that these two models are integrated naturally as both are character-based.

Generally speaking, if the “G(or D)+” has a strong preference on the desired candidate, but the “D(or G)-” has a weak preference on its top-1 incorrect candidate, then this combining method would correct most “G+D- (also G-D+)” errors. On the other hand, the advantage of combining two models would vanish if the “G(or D)+” has a weak preference while the “D(or G)-” has a strong preference over their top-1 candidates. In our observation, these two models meet this requirement quite well.

5 Weigh Various Features Differently

For a given observation, intuitively each feature should be trained only once under the ME framework and its associated weight will be automatically learned from the training corpus. However, when we repeat the work of (Jiang et al., 2008), which reports to achieve the state-of-art performance in the data-sets that we adopt, it has been found that some features (e.g., C_0) are unnoticeably trained several times in their model (which are implicitly generated from different feature templates used in the paper). For example, the feature C_0 actually

Corpus	Abbrev.	Encoding	Training Size (Words/Type)	Test Size (Words/Type)	OOV Rate

	PKU(cvt.)	Unicode/CP936	1.1M/55K	104K/13K	0.035

Table 3: Corpus statistics for the second SIGHAN Bakeoff

appears twice, which is generated from two different templates C_n (with n=0, generates C_0) and [C_0C_n] (used in (Jiang et al., 2008), with n=0, generates [C_0C_0]). The meanings of features are illustrated in Section 2.1. Those repetitive features also include [$C_{-1}C_0$] and [C_0C_1], which implicitly appear thrice. And it is surprising to discover that its better performance is mainly due to this implicit feature repetition but the authors do not point out this fact. As all the features adopted in (Jiang et al., 2008) possess binary values, if a binary feature is repeated *n* times, then it should behave like a real-valued feature with its value to be "*n*", at least in principle. Inspired by the above discovery, accordingly, we convert all the binary-value features into their corresponding real-valued features. After having transformed binary features into their corresponding real-valued ones, the original discriminative model is re-trained under the ME framework.

This new implementation, which would be named as the character-based discriminative-plus model, just weights various features differently before conducting ME training. Afterwards, it is further combined with the generative trigram model, and is called the character-based joint-plus model.

6 Experiments

The corpora provided by the second SIGHAN Bakeoff (Emerson, 2005) were used in our experiments. The statistics of those corpora are shown in Table 3.

Note that the PKU corpus is a little different from others. In the training set, Arabic numbers and English characters are in full-width form occupying two bytes. However, in the testing set, these characters are in half-width form occupying only one byte. Most researchers in the SIGHAN Bakeoff competition performed a conversion before segmentation (Xiong et al., 2009). In this work, we conduct the tests on both unconverted (ucvt.) case and converted (cvt.) case. After the conversion, the OOV rate of converted corpus is obviously lower than that of unconverted corpus.

To fairly compare the proposed approach with previous works, we only conduct *closed tests*[1]. The metrics *Precision* (**P**), *Recall* (**R**), *F-score* (**F**) (*F*=2*PR*/(*P*+*R*)), *Recall of OOV* ($\mathbf{R_{OOV}}$) and *Recall of IV* ($\mathbf{R_{IV}}$) are used to evaluate the results.

6.1 Character-Based Generative Model and Discriminative Model

As shown in (Wang et al., 2009), the character-based generative trigram model significantly exceeds its related bigram model and performs the same as its 4-gram model. Therefore, SRI Language Modeling Toolkit[2] (Stolcke, 2002) is used to train the trigram model with modified Kneser-Ney smoothing (Chen and Goodman, 1998). Afterwards, a beam search decoder is applied to find out the best sequence.

For the character-based discriminative model, the ME Package[3] given by Zhang Le is used to conduct the experiments. Training was done with Gaussian prior 1.0 and 300, 150 iterations for AS and other corpora respectively. Table 5 gives the segmentation results of both the character-based generative model and the discriminative model. From the results, it can be seen that the generative model achieves comparable results with the discriminative one and they outperform each other on different corpus. However, the generative model exceeds the discriminative one on R_{IV} (0.973 vs. 0.956) but loses on R_{OOV} (0.511 vs. 0.680). It illustrates that they complement each other.

[1] According to the second Sighan Bakeoff regulation, the closed test could only use the training data directly provided. Any other data or information is forbidden, including the knowledge of characters set, punctuation set, etc.

Table 4: Corpus statistics for Development sets and Testing sets. A "/" separates the OOV number (or OOV rate) with respect to the original training sets and the new training sets.

6.2 Character-Based Joint Model

For the character-based joint model, a development set is required to obtain the weight α for its associated generative model. A small portion of each original training corpus is thus extracted as the development set and the remaining data is regarded as the new training-set, which is used to train two new parameter-sets for both generative and discriminative models associated.

The last 2,000, 600, 400, and 300 sentences for AS, MSR, CITYU, and PKU are extracted from the original training corpora as their corresponding development sets. The statistics for new data sets are shown in Table 4. It can be seen that the variation of the OOV rate could be hardly noticed. The F-scores of the joint model, versus different α, evaluated on four development sets are shown in Figure 1. It can be seen that the curves are not sharp but flat near the top, which indicates that the character-based joint model is not sensitive to the α value selected. From those curves, the best suitable α for AS, CITYU, MSR and PKU are found to be 0.30, 0.60, 0.60 and 0.60, respectively. Those alpha values will then be adopted to conduct the experiments on the testing sets.

Table 5: Segmentation results of various character-based models on the second SIGHAN Bakeoff, the generative trigram model (G), the discriminative model (D), the discriminative-plus model (D-Plus), the joint model (J) and the joint-plus model (J-Plus).

As shown in Table 5, the joint model significantly outperforms both the character-based generative model and the discriminative one in F-score on all the testing corpora. Compared with the generative approach, the joint model increases the overall R_{OOV} from 0.510 to 0.633, with the cost of slightly degrading the overall R_{IV} from 0.973 to 0.971. This shows that the joint model holds the advantage of the generative model on IV words. Compared with the discriminative model, the proposed joint model improves the overall R_{IV} from 0.956 to 0.971, with the cost of degrading the overall R_{OOV} from 0.680 to 0.633. It clearly shows that the joint model achieves a good balance between IV words and OOV words and achieves the best F-scores obtained so far (21% relative error reduction over the discriminative model and 14% over the generative model).

6.3 Weigh Various Features Differently

Inspired by (Jiang et al., 2008), we set the real-value of C_0 to be 2.0, the value of $C_{-1}C_0$ and C_0C_1 to be 3.0, and the values of all other features to be 1.0 for the character-based discriminative-plus model. Although it seems reasonable to weight those closely relevant features more (C_0 should be the most relevant feature for assigning tag t_0), both implementations seem to be equal if their corresponding lambda-values are also updated accordingly. However, Table 5 shows that this new discriminative-plus implementation (D-Plus) significantly outperforms the original one (overall F-score is raised from 0.947 to 0.953) when both of them adopt real-valued features. It is not clear how this change makes the difference.

Similar improvements can be observed with two other ME packages. One anonymous reviewer pointed out that the duplicated features should not make difference if there is no regularization. However, we found that the duplicated features would improve the performance whether we give Gaussian penalty or not.

Afterwards, this new implementation and the generative trigram model are further combined (named as the joint-plus model). Table 5 shows that this joint-plus model also achieves better results compared with the discriminative-plus model, which illustrates that our joint approach is an effective and robust method for CWS. However, compared with the original joint model, the new joint-plus approach does not show much improvement, regardless of the significant improvement made by the discriminative-plus model, as the additional benefit generated by the discriminative-plus model has already covered by the generative approach (Among the 6,965 error words corrected by the discriminative-plus model, 6,292 (90%) of them are covered by the generative model).

7 Statistical Significance Tests

Although Table 5 has shown that the proposed joint (joint-plus) model outperforms all the baselines mentioned above, we want to know if the difference is statistically significant enough to make such a claim. Since there is only one testing set for each training corpus, the bootstrapping technique (Zhang et al., 2004) is adopted to conduct the tests: Giving an testing-set T_0, additional *M-1* new testing-sets $T_0,\ldots,T_{M-1}$ (each with the same size of T_0) will be generated by repeatedly re-sampling data from T_0. Then, we will have a total of M testing-sets (M=2000 in our experiments).

J-Plus	J	~	>	~	>	>

Table 6: Statistical significance test of F-score among various character-based models.

7.1 Comparisons with Baselines

We then follow (Zhang et al., 2004) to measure the 95% confidence interval for the discrepancy between two models. If the confidence interval does not include the origin point, we then claim that system A is significantly different from system B. Table 6 gives the results of significant tests among various models mentioned above. In this table, “>” means that system A is significantly better than B, where as “<” denotes that system A is significantly worse than B, and “~” indicates that these two systems are not significantly different.

As shown in Table 6, the proposed joint model is significantly better than the two baseline models on all corpora. Similarly, the proposed joint-plus model also significantly outperforms the generative model and the discriminative-plus model on all corpora except on the PKU(ucvt.). The comparison shows that the proposed joint (also joint-plus) model indeed exceeds each of its component models.

7.2 Comparisons with Previous Works

The above comparison mainly shows the superiority of the proposed joint model among those approaches that have been implemented. However, it would be interesting to know if the joint (and joint-plus) model also outperforms those previous state-of-the-art systems.

The systems that performed best for at least one corpus in the second SIGHAN Bakeoff are first selected for comparison. This category includes (Asahara et al., 2005) (denoted as

Asahara05) and (Tseng et al., 2005) [4] (**Tseng05**). (Asahara et al., 2005) achieves the best result in the AS corpus, and (Tseng et al., 2005) performs best in the remaining three corpora. Besides, those systems that are reported to exceed the above two systems are also selected. This category includes (Zhang et al., 2006) (**Zhang06**), (Zhang and Clark, 2007) (**Z&C07**) and (Jiang et al., 2008) (**Jiang08**). They are briefly summarized as follows. (Zhang et al., 2006) is based on sub-word tagging and uses a confidence measure method to combine the sub-word CRF (Lafferty et al., 2001) and rule-based models. (Zhang and Clark, 2007) uses perceptron (Collins, 2002) to generate word candidates with both word and character features. Last, (Jiang et al., 2008)[5] adds repeated features implicitly based on (Ng and Low, 2004). All of the above models, except (Zhang and Clark, 2007), adopt the character-based discriminative approach.

All the results of the systems mentioned above are shown in Table 7. Since the systems are not re-implemented, we cannot generate paired samples from those *M* testing-sets. Instead, we calculate the 95% confidence interval of the joint (also joint-plus) model. Afterwards, those systems can be compared with our proposed models. If the F-score of system B does not fall within the 95% confidence interval of system A (joint or joint-plus), then they are statistically significantly different.

Table 8 gives the results of significant tests for those systems mentioned in this section. It shows that both our joint-plus model and joint model exceed (or are comparable to) almost all the state-of-the-art systems across all corpora, except (Zhang and Clark, 2007) at PKU(ucvt.). In that special case, (Zhang and Clark, 2007) outperforms the joint-plus model by 0.3% on F- score (0.4% for the joint model). However, our joint-plus model exceeds it more over AS and CITYU corpora by 1.0% and 0.5%, respectively (1.0% and 0.3% for the joint model). Thus, it is fair to say that both our joint model and joint-plus model are superior to the state-of-the-art systems reported in the literature.

Table 8: Statistical significance test of F-score for previous state-of-the-art systems.

8 Conclusion

From the error analysis of the character-based generative model and the discriminative one, we found that these two models complement each other on handling IV words and OOV words. To take advantage of these two approaches, a joint model is thus proposed to combine them. Experiments on the Second SIGHAN Bakeoff show that the joint model achieves 21% error reduction over the discriminative model (14% over the generative model). Moreover, closed tests on the second SIGHAN Bakeoff corpora show that this joint model significantly outperforms all the state-of-the-art systems reported in the literature.

Last, it is found that weighting various features differently would give better result. However, further study is required to find out the true reason for this strange but interesting phenomenon.

[4] We are not sure whether (Asahara et al., 2005) and (Tseng et al., 2005) performed a conversion before segmentation in PKU corpus. In this paper, we followed previous works, which cited and compared with them.

[5] The data for (Jiang et al., 2008) given at Table 7 are different from what were reported at their paper. In the communication with the authors, it is found that the script for evaluating performance, provided by the SIGHAN Bakeoff, does not work correctly in their platform. After the problem is fixed, the re-evaluated real performances reported here deteriorate from their original version. Please see the announcement in Jiang's homepage (http://mtgroup.ict.ac.cn/~jiangwenbin/papers/error_correction.pdf).

Abstract

We explore the near-synonym lexical choice problem using a novel representation of near-synonyms and their contexts in the latent semantic space. In contrast to traditional latent semantic analysis (LSA), our model is built on the lexical level of co-occurrence, which has been empirically proven to be effective in providing higher dimensional information on the subtle differences among near-synonyms. By employing supervised learning on the latent features, our system achieves an accuracy of 74.5% in a "fill-in-the-blank" task. The improvement over the current state-of-the-art is statistically significant.

We also formalize the notion of *subtlety* through its relation to semantic space dimensionality. Using this formalization and our learning models, several of our intuitions about subtlety, dimensionality, and context are quantified and empirically tested.

1 Introduction

Lexical choice is the process of selecting content words in language generation. Consciously or not, people encounter the task of lexical choice on a daily basis — when speaking, writing, and perhaps even in inner monologues. Its application also extends to various domains of natural language processing, including Natural Language Generation (NLG, Inkpen and Hirst 2006), writers' assistant systems (Inkpen, 2007), and second language (L2) teaching and learning (Ouyang et al., 2009).

In the context of *near-synonymy*, the process of lexical choice becomes profoundly more complicated. This is partly because of the subtle nuances among near-synonyms, which can arguably differ along an infinite number of dimensions. Each dimension of variation carries differences in style, connotation, or even truth conditions into the discourse in question (Cruse, 1986), all making the seemingly intuitive problem of "choosing the right word for the right context" far from trivial even for native speakers of a language. In a widely-adopted "fill-in-the-blank" task, where the goal was to guess missing words (from a set of near-synonyms) in English sentences, two human judges achieved an accuracy of about 80% (Inkpen, 2007). The current state-of-the-art accuracy for an automated system is 69.9% (Islam and Inkpen, 2010).

When the goal is to make plausible or even elegant lexical choices that best suit the *context*, the representation of that context becomes a key issue. We approach this problem in the *latent semantic space*, where transformed local co-occurrence data is capable of implicitly inducing global knowledge (Landauer and Dumais, 1997). A latent semantic space is constructed by reducing the dimensionality of co-occurring linguistic units — typically words and documents as in *Latent Semantic Analysis* (LSA). We refer to this *level of association* (LoA) as *document LoA* hereafter. Although document LoA can benefit topical level classification (e.g., as in document retrieval, Deerwester et al. 1990), it is not necessarily suitable for lexical-level tasks which might require information on a more fine-grained level (Edmonds and Hirst, 2002). Our experimental results show

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 1182–1190,
Beijing, August 2010

noticeable improvement when the co-occurrence matrix is built on a lexical LoA between words within a given context window.

One intuitive explanation for this improvement is that the lexical-level co-occurrence might have helped recover the high-dimensional subtle nuances between near-synonyms. This conjecture is, however, as imprecise as it is intuitive. The notion of *subtlety* has mostly been used qualitatively in the literature to describe the level of difficulty involved in near-synonym lexical choice. Hence, we endeavor to formalize the concept of subtlety computationally by using our observations regarding the relationship between "subtle" concepts and their lexical co-occurrence patterns.

We introduce related work on near-synonymy, lexical choice, and latent semantic space models in the next section. Section 3 elaborates on lexical and contextual representations in latent semantic space. In Section 4, we formulate near-synonym lexical choice as a learning problem and report our system performance. Section 5 formalizes the notion of subtlety and its relation to dimensionality and context. Conclusions and future work are presented in Section 6.

2 Related Work

2.1 Near-Synonymy and Nuances

Near-synonymy is a concept better explained by intuition than by definition — which it does not seem to have in the existing literature. We thus borrow Table 1 from Edmonds and Hirst (2002) to illustrate some basic ideas about near-synonymy. Cruse (1986) compared the notion of *plesionymy* to cognitive synonymy in terms of mutual entailment and semantic traits, which, to the best of our knowledge, is possibly the closest to a textbook account of near-synonymy.

There has been a substantial amount of interest in characterizing the nuances between near-synonyms for a computation-friendly representation of near-synonymy. DiMarco et al. (1993) discovered 38 dimensions for differentiating near-synonyms from dictionary usage notes and categorized them into semantic and stylistic variations. Stede (1993) focused on the latter and further decomposed them into seven scalable subcategories. By organizing near-synonym variations into a tree structure, Inkpen and Hirst (2006) combined stylistic and attitudinal variation into one class parallel to denotational differences. They also incorporated this knowledge of near-synonyms into a knowledge base and demonstrated its application in an NLG system.

Table 1: Examples of near-synonyms and dimension of variations (Edmonds and Hirst, 2002).

Types of variation	***Examples***
Continuous, intermittent	seep:drip
Emphasis	enemy:foe
Denotational, indirect	error:mistake
Denotational, fuzzy	woods:forest
Stylistic, formality	pissed:drunk:inebriated
Stylistic, force	ruin:annihilate
Expressed attitude	skinny:thin:slim:slender
Emotive	daddy:dad:father
Collocational	task:job
Selectional	pass away:die
Sub-categorization	give:donate

2.2 Lexical Choice Evaluation

Due to their symbolic nature, many of the early studies were only able to provide "demo runs" in NLG systems rather than any empirical evaluation. The study of near-synonym lexical choice had remained largely qualitative until a "fill-in-the-blank" (FITB) task was introduced by Edmonds (1997). The task is based on sentences collected from the 1987 *Wall Street Journal* (WSJ) that contain any of a given set of near-synonyms. Each occurrence of the near-synonyms is removed from the sentence to create a "lexical gap", and the goal is to guess which one of the near-synonyms is the missing word. Presuming that the 1987 WSJ authors have made high-quality lexical choices, the FITB test provides a fairly objective benchmark for empirical evaluation for near-synonym lexical choice. The same idea can be applied to virtually any corpus to provide a fair amount of gold-standard data at relatively low cost for lexical choice evaluation.

The FITB task has since been frequently adopted for evaluating the quality of lexical choice systems on a standard dataset of seven near-synonym sets (as shown in Table 2). Edmonds

(1997) constructed a second-order lexical co-occurrence network on a training corpus (the 1989 WSJ). He measured the *word-word distance* using *t-score* inversely weighted by both distance and order of co-occurrence in the network. For a sentence in the test data (generated from the 1987 WSJ), the candidate near-synonym minimizing the sum of its distance from all other words in the sentence (*word-context distance*) was considered the correct answer. Average accuracy on the standard seven near-synonym sets was 55.7%.

Inkpen (2007) modeled word-word distance using *Pointwise Mutual Information* (PMI) approximated by word counts from querying the *Waterloo Multitext System* (Clarke et al., 1998). Word-context distance was the sum of PMI scores between a candidate and its neighboring words within a window-size of 10. An unsupervised model using word-context distance directly achieved an average accuracy of 66.0%, while a supervised method with lexical features added to the word-context distance further increased the accuracy to 69.2%.

Islam and Inkpen (2010) developed a system which completed a test sentence with possible candidates one at a time. The candidate generating the most probable sentence (measured by a 5-gram language model) was proposed as the correct answer. N-gram counts were collected from *Google Web1T Corpus* and smoothed with *missing counts*, yielding an average accuracy of 69.9%.

2.3 Lexical Choice Outside the Near-synonymy Domain

The problem of lexical choice also comes in many flavors outside the near-synonymy domain. Reiter and Sripada (2002) attributed the variation in lexical choice to cognitive and vocabulary differences among individuals. In their meteorology domain data, for example, the term *by evening* was interpreted as *before 00:00* by some forecasters but *before 18:00* by others. They claimed that NLG systems might have to include redundancy in their output to tolerate cognitive differences among individuals.

2.4 Latent Semantic Space Models and LoA

LSA has been widely applied in various fields since its introduction by Landauer and Dumais (1997). In their study, LSA was conducted on *document* LoA on encyclopedic articles and the latent space vectors were used for solving TOEFL synonym questions. Rapp (2008) used LSA on *lexical* LoA for the same task and achieved 92.50% in accuracy in contrast to 64.38% given by Landauer and Dumais (1997). This work confirmed our early postulation that document LoA might not be tailored for lexical level tasks, which might require lower LoAs for more fine-grained co-occurrence knowledge. Note, however, that confounding factors might also have led to the difference in performance, since the two studies used different weighting schemes and different corpora for the co-occurrence model[1]. In Section 3.2 we will compare models on the two LoAs in a more controlled setting to show their difference in the lexical choice task.

3 Representing Words and Contexts in Latent Semantic Space

We first formalize the FITB task to facilitate later discussions. A test sentence $t = \{w_1, \ldots, w_{j-1}, s_i, w_{j+1}, \ldots, w_m\}$ contains a near-synonym s_i which belongs to a set of synonyms $S = \{s_1, \ldots, s_n\}, 1 \leq i \leq n$. A FITB test case is created by removing s_i from t, and the *context* (the incomplete sentence) $c = t - \{s_i\}$ is presented to subjects with a set of possible choices S to guess which of the near-synonyms in S is the missing word.

3.1 Constructing the Latent Space Representation

The first step in LSA is to build a *co-occurrence matrix M* between words and documents, which is further decomposed by *Singular Value Decomposition* (SVD) according to the following equation:

$$M_{v\times d} = U_{v\times k}\Sigma_{k\times k}V^T_{k\times d}$$

[1] The former used *Groliers Academic American Encyclopedia* with weights divided by word entropy, while the latter used the *British National Corpus* with weights multiplied by word entropy.

Here, subscripts denote matrix dimensions, U, Σ, and V together create a decomposition of M, v and d are the number of word types and documents, respectively, and k is the number of dimensions for the latent semantic space. A word w is represented by the row in U corresponding to the row for w in M. For a context c, we construct a vector $\mathbf{c}$ of length v with zeros and ones, each corresponding to the presence or absence of a word w_i with respect to c, i.e.,

$$\mathbf{c}_i = \begin{cases} 1 & \text{if } w_i \in c \\ 0 & \text{otherwise} \end{cases}$$

We then take this *lexical space* vector $\mathbf{c}_{v\times 1}$ as a *pseudo-document* and transform it into a *latent semantic space* vector $\hat{c}$:

$$\hat{\mathbf{c}} = \Sigma^{-1} U^T \mathbf{c} \qquad (1)$$

An important observation is that this representation is equivalent to a *weighted centroid* of the context word vectors: when $\mathbf{c}$ is multiplied by $\Sigma^{-1}U^T$ in Equation (1), the product is essentially a weighted sum of the rows in U corresponding to the context words. Consequently, simple modifications on the weighting can yield other interesting representations of context. Consider, for example, the weighting vector $\mathbf{w}_{k\times 1} = (\sigma_1, \cdots, \sigma_k)^T$ with

$$\sigma_i = \frac{1}{|2(p_{\text{gap}} - i) - 1|}$$

where p_{gap} is the position of the "gap" in the test sentence. Multiplying $\mathbf{w}$ before Σ^{-1} in Equation (1) is equivalent to giving the centroid gradient-decaying weights with respect to the distance between a context word and the near-synonym. This is a form of a *Hyperspace Analogue to Language* (HAL) model, which is sensitive to word order, in contrast to a *bag-of-words* model.

3.2 Dimensionality and Level of Association

The number of dimensions k is an important choice to make in latent semantic space models. Due to the lack of any principled guideline for doing otherwise, we conducted a brute force grid search for a proper k value for each LoA, on the basis of the performance of the unsupervised model (Section 4.1 below).

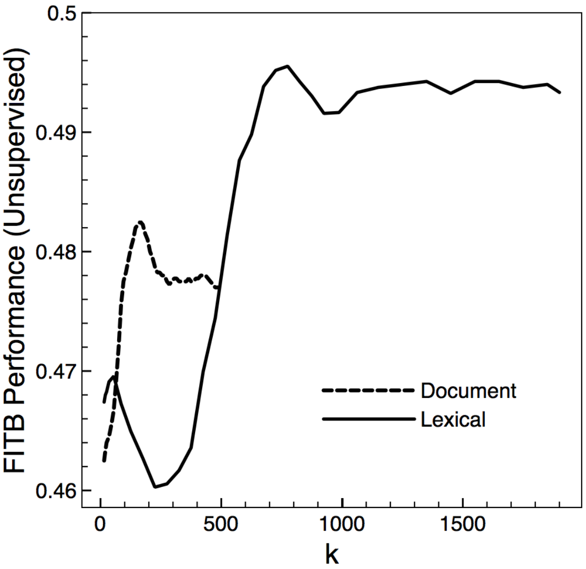

Figure 1: FITB Performance on different LoAs as a function of the latent space dimensionality.

In Figure 1, performance on FITB using this unsupervised model is plotted against k for document and lexical LoAs. Document LoA is very limited in the available number of dimensions[2]; higher dimensional knowledge is simply unavailable from this level of co-occurrence. In contrast, lexical LoA stands out around $k = 550$ and peaks around $k = 700$. Although the advantage of lexical LoA in the unsupervised setting is not significant, later we show that lexical LoA nonetheless makes higher-dimensional information available for other learning methods.

Note that the scale on the y-axis is stretched to magnify the trends. On a zero-to-one scale, the performance of these unsupervised methods is almost indistinguishable, indicating that the unsupervised model is not capable of using the high-dimensional information made available by lexical LoA. We will elaborate on this point in Section 5.2.

[2] The dimensions for document and lexical LoAs on our development corpus are $55,938 \times 500$ and $55,938 \times 55,938$, respectively. The difference is measured between $v \times d$ and $v \times v$ (Section 3.1).

4 Learning in the Latent Semantic Space

4.1 Unsupervised Vector Space Model

When measuring distance between vectors, LSA usually adopts regular vector space model distance functions such as *cosine similarity*. With the context being a centroid of words (Section 3.1), the FITB task then becomes a *k-nearest neighbor* problem in the latent space with $k = 1$ to choose the best near-synonym for the context:

$$s^* = \underset{s_i}{\operatorname{argmax}} \cos(U_{\text{rowId}(\mathbf{v}(s_i),M)}, \hat{\mathbf{c}})$$

where $\mathbf{v}(s_i)$ is the corresponding row for near-synonym s_i in M, and $\text{rowId}(\mathbf{v}, M)$ gives the row number of a vector $\mathbf{v}$ in a matrix M containing $\mathbf{v}$ as a row.

In a model with a cosine similarity distance function, it is detrimental to use Σ^{-1} to weight the context centroid $\hat{\mathbf{c}}$. This is because elements in Σ are the singular values of the co-occurrence matrix along its diagonal, and the amplitude of a singular value (intuitively) corresponds to the significance of a dimension in the latent space; when the inverted matrix is used to weight the centroid, it will "misrepresent" the context by giving more weight to less-significantly co-occurring dimensions and thus sabotage performance. We thus use Σ instead of Σ^{-1} in our experiments. As shown in Figure 1, the best unsupervised performance on the standard FITB dataset is 49.6%, achieved on lexical LoA at $k = 800$.

4.2 Supervised Learning on the Latent Semantic Space Features

In traditional latent space models, the latent space vectors have almost invariantly been used in the unsupervised setting discussed above. Although the number of dimensions has been reduced in the latent semantic space, the inter-relations between the high-dimension data points may still be complex and non-linear; such problems lend themselves naturally to supervised learning.

We therefore formulate the near-synonym lexical choice problem as a supervised classification problem with latent semantic space features. For a test sentence in the FITB task, for example, the context is represented as a latent semantic space vector as discussed in Section 3.1, which is then paired with the correct answer (the near-synonym removed from the sentence) to form one training case.

We choose *Support Vector Machines* (SVMs) as our learning algorithm for their widely acclaimed classification performance on many tasks as well as their noticeably better performance on the lexical choice task in our pilot study. Table 2 lists the supervised model performance on the FITB task together with results reported by other related studies. The model is trained on the 1989 WSJ and tested on the 1987 WSJ to ensure maximal comparability with other results. The optimal k value is 415. Context window size[3] around the gap in a test sentence also affects the model performance. In addition to using the words in the original sentence, we also experiment with enlarging the context window to neighboring sentences and shrinking it to a window frame of n words on each side of the gap. Interestingly, when making the lexical choice, the model tends to favor more-local information — a window frame of size 5 gives the best accuracy of 74.5% on the test. Based on *binomial exact test*[4] with a 95% confidence interval, our result outperforms the current state-of-the-art with statistical significance.

5 Formalizing Subtlety in the Latent Semantic Space

In this section, we formalize the notion of subtlety through its relation to dimensionality, and use the formalization to provide empirical support for some of the common intuitions about subtlety and its complexity with respect to dimensionality and size of context.

5.1 Characterizing Subtlety Using Collocating Differentiator of Subtlety

In language generation, subtlety can be viewed as a subordinate semantic trait in a linguistic realiza-

[3] Note that the *context window* in this paragraph is implemented on FITB test cases, which is different from the context size we compare in Section 5.3 for building co-occurrence matrix.

[4] The binomial nature of the outcome of an FITB test case (right or wrong) makes *binomial exact test* a more suitable significance test than the *t-test* used by Inkpen (2007).

Table 2: Supervised performance on the seven standard near-synonym sets in the FITB task. *95% Confidence* based on *Binomial Exact Test*.

	Co-occur.	SVMs	5-gram	SVMs on
Near-synonyms	network	& PMI	language model	latent vectors
	(Edmonds, 1997)	(Inkpen, 2007)	(Islam and Inkpen, 2010)	(Section 4.2)
difficult, hard, tough	47.9%	57.3%	**63.2**%	61.7%
error, mistake, oversight	48.9%	70.8%	78.7%	**82.5**%
job, task, duty	68.9%	**86.7**%	78.2%	82.4%
responsibility, burden, obligation, commitment	45.3%	66.7%	**72.2**%	63.5%
material, stuff, substance	64.6%	71.0%	70.4%	**78.5**%
give, provide, offer	48.6%	56.1%	55.8%	**75.4**%
settle, resolve	65.9%	75.8%	70.8%	**77.9**%

Data size	29,835	31,116	31,116	30,300
95% confidence	55.1–56.3%	68.7–69.7%	69.3–70.4%	74.0–75.0%

tion of an intention[5]. A key observation regarding subtlety is that it is non-trivial to *characterize* subtle differences between two linguistic units by their collocating linguistic units. More interestingly, the difficulty in such characterization can be approximated by the difficulty in finding a third linguistic unit satisfying the following constraints:

1. The unit must collocate closely with at least one of the two linguistic units under differentiation;

2. The unit must be characteristic of the difference between the pair.

Such approximation is meaningful in that it transforms the abstract *characterization* into a concrete task of finding this third linguistic unit. For example, suppose we want to find out whether the difference between *glass* and *mug* is subtle. The approximation boils the answer down to the difficulty of finding a third word satisfying the two constraints, and we may immediately conclude that the difference between the pair is *not* subtle since it is relatively easy to find *wine* as the qualifying third word, which 1) collocates closely with *glass* and 2) characterizes the difference between the pair by instantiating one of their major differences — the purpose of use. The same reasoning applies to concluding *non-subtlety* for word pairs such as *pen* and *pencil* with *sharpener*, *weather* and *climate* with *forecast*, *watch* and *clock* with *wrist*, etc.

In contrast, for the pair *forest* and *woods*, it might be easy to find words satisfying one but not both constraints. Consequently, the lack of such qualifying words — or at least the relative difficulty for finding one — makes the difference between this pair more subtle than in the previous examples.

We call a linguistic unit satisfying both constraints a *collocating differentiator of subtlety* (CDS). Notably, the second constraint puts an important difference between CDSs and the conventional sense of collocation. On the lexical level, CDSs are not merely words that collocate more with one word in a pair than with the other; they have to be *characteristic of the differences* between the pair. In the example of *forest* and *woods*, one can easily find a word exclusively collocating with one but not the other — such as *national forest* but not **national woods*; however, unlike the CDSs in the previous examples, the word *national* does not characterize any of the differences between the pair in size, primitiveness,

[5] The same principle applies when we replace "generation" with "understanding" and "an intention" with "a cognition".

proximity to civilization, or wildness (Edmonds and Hirst, 2002), and consequently fails to satisfy the second constraint.

5.2 Relating Subtlety to Latent Space Dimensionality[6]

As mentioned in Section 4.1, elements of a latent space vector are in descending order in terms of co-occurrence significance, i.e., the information within the first few dimensions is obtained from more closely collocating linguistic units. From the two constraints in the previous section, it follows that it should be relatively easier to find a CDS for words that can be well distinguished in a lower-dimensional sub-space of the latent semantic space, and the difference among such words should *not* be considered subtle.

We thus claim that co-occurrence-based information capable of characterizing subtle differences must then reside in higher dimensions in the latent space vectors. Furthermore, our intuition on the complexity of subtlety can also be empirically tested by comparing the performance of supervised and unsupervised models at different k values. One of the differences between the two types of models is that supervised models are better at unraveling the convoluted inter-relations between high-dimensional data points. Under this assumption, if we hypothesize that subtlety is a certain form of complex, high-dimensional relation between semantic elements, then the difference in performance between the supervised and unsupervised model should increase as the former recovers subtle information in higher dimensions.

As shown in Figure 2, performance of both models is positively correlated to the number of dimensions in the latent semantic space (with correlation coefficient $\rho = 0.95$ for supervised model and $\rho = 0.81$ for unsupervised model). This suggests that the lexical choice process is indeed “picking up” implicit information about subtlety in the higher dimensions of the latent vectors. Meanwhile, the difference between the performance of the two models correlates strongly to k with $\rho = 0.95$. Significance tests on the “difference of *difference*”[7] between their performances further reveal increasing difference in growth rate of their performance. Significance is witnessed in both the F-test and the paired t-test,[8] indicating that the subtlety-related information in the higher dimensions exhibits complex clustering patterns that are better recognized by SVMs but beyond the capability of the KNN model.

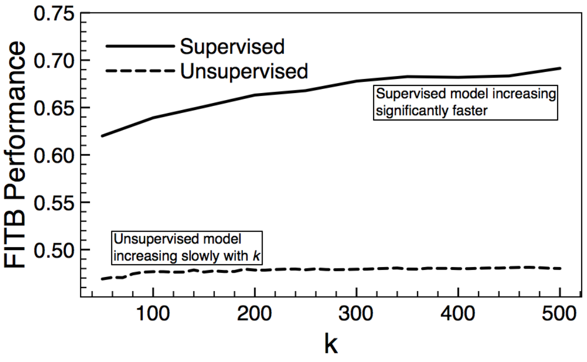

Figure 2: Supervised performance increasing further from unsupervised performance in higher dimensions.

5.3 Subtlety and the Level of Context

Our previous models on lexical LoA associated words within the same sentence to build the co-occurrence matrix. Lexical LoA also allows us to associate words that co-occur in different *levels of context* (LoC) such as paragraphs or documents. This gives an approximate measurement of how much context a lexical LoA model uses for word co-occurrence. Intuitively, by looking at more context, higher LoC models should be better at differentiating more subtle differences.

We compare the performance of models with different LoCs in Figure 3. The sentence LoC model constantly out-performs the paragraph LoC model after $k = 500$, indicating that, by *inter-model comparison*, larger LoC models do not necessarily perform better on higher dimensions. However, there is a noticeable difference in the optimal dimensionality for the model performances. Sentence LoC performance peaks around

[6] In order to keep the test data (1987 *WSJ*) unseen before producing the results in Table 2, models in this section were trained on *The Brown Corpus* and tested on 1988–89 *WSJ*.

[7] The italicized *difference* is used in its mathematical sense as the discrete counterpart of *derivative*.

[8] F-test: $f(1,16) = 9.13, p < 0.01$. Paired t-test: $t(8) = 4.16$ with two-tailed $p = 0.0031$. Both conducted on 10 data points at $k = 50$ to 500 with a step of 50.

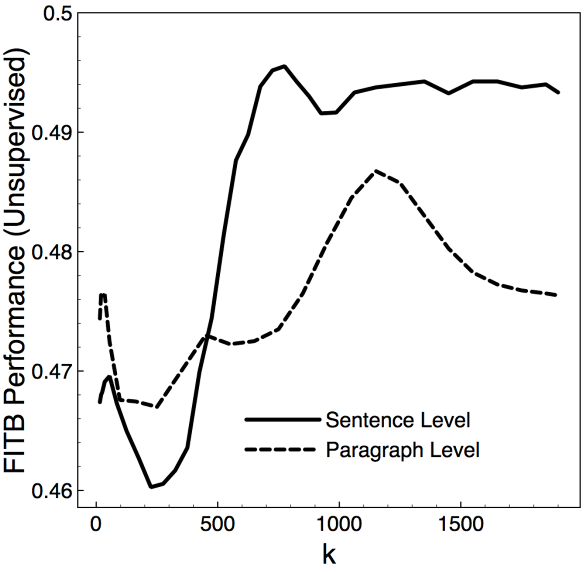

Figure 3: LoC in correlation to latent space dimensionality for optimal model performance.

$k = 700$ — much lower than that of paragraph LoC which is around $k = 1,100$. Such difference may suggest that, by *intra-model comparison*, each model may have its own "comfort zone" for the degree of subtlety it differentiates; models on larger LoC are better at differentiating between more subtle nuances, which is in accordance with our intuition.

One possible explanation for sentence LoC models outperforming paragraph LoC models is that, although the high-dimensional elements are weighed down by Σ due to their insignificance in the latent space, their contribution to the output of distance function is larger in paragraph LoC models because the vectors are much *denser* than that in the sentence LoC model; since the unsupervised method is incapable of recognizing the clustering patterns well in high-dimensional space, the "amplified" subtlety information is eventually taken as noise by the KNN model. An interesting extension to this discussion is to see whether a *supervised* model can consistently perform better on higher LoC in all dimensions.

6 Conclusions and Future Work

We propose a latent semantic space representation of near-synonyms and their contexts, which allows a thorough investigation of several aspects of the near-synonym lexical choice problem. By employing supervised learning on the latent space features, we achieve an accuracy of 74.5% on the "fill-in-the-blank" task, outperforming the current state-of-the-art with statistical significance.

In addition, we formalize the notion of *subtlety* by relating it to the dimensionality of the latent semantic space. Our empirical analysis suggests that subtle differences between near-synonyms reside in higher dimensions in the latent semantic space in complex clustering patterns, and that the degree of subtlety correlates to the level of context for co-occurrence. Both conclusions are consistent with our intuition.

As future work, we will make better use of the easy customization of the context representation to compare HAL and other models with *bag-of-words* models. The correlation between subtlety and dimensionality may lead to many interesting tasks, such as measuring the degree of subtlety for individual near-synonyms or near-synonym sets. With regard to context representation, it is also intriguing to explore other dimensionality reduction methods (such as *Locality Sensitive Hashing* or *Random Indexing*) and to compare them to the SVD-based model.

Abstract

Dynamic sentiment ambiguous adjectives (DSAAs) like "large, small, high, low" pose a challenging task on sentiment analysis. This paper proposes a knowledge-based method to automatically determine the semantic orientation of DSAAs within context. The task is reduced to sentiment classification of target nouns, which we refer to sentiment expectation instead of semantic orientation widely used in previous researches. We mine the Web using lexico-syntactic patterns to infer sentiment expectation of nouns, and then exploit character-sentiment model to reduce noises caused by the Web data. At sentence level, our method achieves promising result with an f-score of 78.52% that is substantially better than baselines. At document level, our method outperforms previous work in sentiment classification of product reviews.

1 Introduction

In recent years, sentiment analysis has attracted considerable attention in the NLP community. It is the task of mining positive and negative opinions from natural language, which can be applied to many research fields. Previous work on this problem falls into three groups: opinion mining of documents, sentiment classification of sentences and polarity prediction of words. Sentiment analysis both at document and sentence level rely heavily on word level.

The most frequently explored task at the word level is to determine the polarity of words, in which most work centers on assigning a prior polarity to words or word senses in the lexicon out of context. However, for some words, the polarity varies strongly with context, making it hard to attach each to a fixed sentiment category in the lexicon. For example, the word "low" has a positive orientation in "low cost" but a negative orientation in "low salary". We call these words like "low" dynamic sentiment ambiguous adjectives (DSAAs). Turney and Littman (2003) claim that DSAAs cannot be avoided in a real-world application. But unfortunately, DSAAs are discarded by most research concerning sentiment analysis.

In this paper, we are devoted to the challenging task of disambiguating DSAAs. The task is to automatically determine the semantic orientation (SO) of DSAAs within context. We limit our work to 14 frequently used adjectives in Chinese, such as "large, small, many, few, high, low", which all have the meaning of measurement. Although the number of such ambiguous adjectives is not large, they are frequently used in real text, especially in the texts expressing opinions and emotions. As demonstrated by the experimental results in this paper, the disambiguation of 14 DSAAs can obviously improve the performance of sentiment classification of product reviews.

The task of disambiguating DSAAs is reduced to sentiment classification of nouns. Previous studies classify nouns into three categories: positive, negative and neutral. In contrast, we propose two categories of sentiment expectation

*Most of the work was performed when the author was a student at Peking University.

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 1191–1199,
Beijing, August 2010

of nouns: positive expectation and negative expectation. This paper presents a novel approach to automatically predict sentiment expectation of nouns. First, we infer the sentiment expectation of a noun by mining the Web with strongly-polar-steering lexico-syntactic patterns. Secondly, we derive the sentiment expectation of a noun from its component characters, which capture the semantic relationship between Chinese words and characters. Finally, a better performance is obtained by combing the two methods. We conduct two types of experiments: the experimental results at the sentence level validate the effectiveness of our approach; the experimental results at the document level confirm the significance of the problem we addressed.

2 Related Work

2.1 Word-level Sentiment Analysis

Recently there has been extensive research in sentiment analysis, for which Pang and Lee (2008) give an in-depth survey of literature. Closer to our study is the large body of work on automatic SO prediction of words (Hatzivassiloglou and McKeown, 1997; Turney and Littman, 2003; Kim and Hovy, 2004; Andreevskaia and Bergler, 2006), but unfortunately they all discard DSAAs in their research. In recent years, some studies go a step further, attaching SO to senses instead of word forms (Esuli and Sebastiani, 2006; Wiebe and Mihalcea, 2006; Su and Markert 2008), but their work is still limited in lexicon out of context.

The most relevant work is Ding et al. (2008), in which DSAAs are named as context dependant opinions. They argue that there is no way to know the SO of DSAAs without prior knowledge, and asking a domain expert to provider such knowledge is scalable. They adopt a holistic lexicon-based approach to solve this problem, which exploits external information and evidences in other sentences and other reviews. On the contrary in this paper, we obtain the prior knowledge of a product by mining the web, and then use such knowledge to determine the SO of DSAAs. The prior knowledge of a product, which is closer to the sentiment expectation of nouns described in this paper, is an important research issue in itself and has many applications in sentiment analysis, as discussed in section 3.2.

2.2 Phrase-level Sentiment Analysis

The disambiguation of DSAAs can also be considered as a problem of phrase-level sentiment analysis. Wilson et al. (2004) present a two-step process to recognize contextual polarity that employs machine learning and a variety of features. Takamura et al. (2006, 2007) propose latent variable model and lexical network to determine SO of phrases, focusing on “noun+adjective” pairs. Their experimental results suggest that the classification of pairs containing ambiguous adjectives is much harder than those with unambiguous adjectives. The above mentioned approaches are all supervised, and need human labeled data for training. In contrast, our method is unsupervised and can overcome the data acquisition bottleneck. Moreover, we focus on the much harder task of disambiguating DSAAs in “noun+adjective” pairs.

2.3 Pattern-based Method

Previous studies have applied pattern-based method to sentiment analysis (Riloff and Wiebe, 2003; Wiebe et al., 2004; Riloff et al., 2005; Wiebe and Mihalcea, 2006; Andreevskaia and Berger; 2006). The differences with our method lie in two aspects: the used resources (corpus versus web) and the research target (subjective expressions versus sentiment expectation).

2.4 Character-based Method

Chinese characters carry semantic information that is indicative of semantic properties of words. Previous studies have exploited the character-based model to predict the semantic categories of Chinese unknown words (Chen, 2004; Lu, 2007). Yuen et al. (2004) presents a method to infer the SO of a Chinese word from its statistical association with strong-polarized characters rather than with strong-polarized words. The work by Ku et al. (2006) is similar to ours because they also define the sentiment score of a word by its composite characters. However, their algorithm is based only on frequency, while we exploit point mutual information that can capture the character-sentiment association.

3 Determining SO of Adjective by Target Noun

3.1 Classification of DSAAs

The frequently used DSAAs are given below. We group them into two categories: positive-like adjectives and negative-like adjectives. These adjectives are neutral out of context, but positive or negative emotion will be evoked when they co-occur with some target nouns, making it hard to assign each to a fixed sentiment category in lexicon.

(1) Positive-like adjectives (*Pa*) = {大 da|large, 多 duo|many, 高 gao|high, 厚 hou|thick, 深 shen|deep, 重 zhong|heavy, 巨大 ju-da|huge, 重大 zhong-da|great}

(2) Negative-like adjectives (*Na*) ={小 xiao|small, 少 shao |few, 低 di|low, 薄 bao|thin, 浅 qian|shallow, 轻 qing|light}

3.2 Sentiment Expectation of Noun

The SO of most DSAAs can be determined by target nouns in noun-adjective phrases, as shown in Table 1. For example, the word "high" has a positive orientation when the target noun is "salary" but a negative orientation when the target noun is "price". Therefore, the task can be reduced to sentiment classification of nouns.

Positive 潜力大|potential is great 工资高|salary is high	Negative 潜力小|potential is small 工资低|salary is low
Negative 压力大|pressure is big 价格高|price is high	Positive 压力小|pressure is small 价格低|price is low

Table 1: The SO of DSAAs in noun-adjective phrases

In previous research, the SO of nouns is classified into three categories: positive, negative and neutral. Accordingly, "压力 ya-li|pressure" will be assigned as negative and "潜力 qian-li|potential" as positive, while "工资 gong-zi|salary" and "价格 jia-ge|price" will be assigned as neutral, as the two terms are objective and cannot evoke positive or negative emotion. Different from the traditional classification scheme, we propose sentiment expectation and classify nouns into two categories: positive expectation and negative expectation. For a positive expectation noun, people usually expect the thing referred to by the noun to be bigger, higher or happen frequently. On the contrary, for a negative expectation noun, people usually expect the thing referred to by the noun to be smaller, lower or don't happen . For example, "价格 jia-ge|price" is a negative expectation noun, as most people in most cases expect that the product prices become low, whereas "工资 gong-zi|salary" is a positive expectation noun, as most people in most cases expect that their salaries become high. The relationship between traditional SO and sentiment expectation can be defined as: positive (negative) terms correspond to positive (negative) expectation terms, but some neutral terms may also carry positive (negative) expectation.

Su and Markert (2008) argue that polarity can also be attached to objective words. The difference with our scheme is that, for example, "价格 jia-ge|price" is attached to negative expectation in our scheme while is still neutral in Su and Markert's method.

The distinction between positive and negative expectation nouns is vital to determine the SO of some phrases. Using it to disambiguate DSAAs is a good example. Another application is the phrase containing verbs with the meaning of status change. For example, "工资上涨了|salary has been raised" will evoke positive emotion, while "价格上涨了 jiage-shangzhang-le|prices have gone up" will evoke negative emotion. As far as we are aware, this is the first sentiment analysis scheme that tries to exploit people's expectation towards nouns.

3.3 Determination of DSAAs

The SO of DSAAs in a given phrase can be calculated by Eq. (1).

$$C(a) = \begin{cases} 1 & \text{if a is positive-like} \\ -1 & \text{if a is negative-like} \end{cases} \qquad (1)$$

$$C(n) = \begin{cases} 1 & \text{if n is positive expectation} \\ -1 & \text{if n is negative expectation} \end{cases}$$

$$SO(a)=C(a)*C(n)$$

If adverb="不 bu|not", $SO(a)= -SO(a)$

Where C(a) denotes the category of DSAAs; C(n) denotes the sentiment expectation of nouns; SO(a) is the SO of DSAAs in a give noun-adjective phrase. When the adverb is the negation term "不 bu|not", the SO is reversed.

4 Predicting Sentiment Expectation of Noun

4.1 Pattern-based Prediction Using a Web Search Engine

In natural language, there are some lexico-syntactic patterns that people frequently use when they express their opinion about something. For example:

(3) 工资*有点*低 | Salary is *a little* low.

(4) 价格*有点*高| Price is *a little* high.

The pattern "<n> 有点 <a>" carries a strong negative association in Chinese language. When a man is saying "工资有点低| Salary is a little low", it indicates that he wishes his "工资 |salary" to be raised. On the contrary, when a man is saying "价格有点高| price is a little high", it indicates that he wishes "价格 |price" to go down. As a result, "工资 |salary" has positive expectation while "价格 |price" has negative expectation.

With the rapid development and expansion of the internet, Web has become an important medium for people to post their ideas. The opinions expressed on the Web reflect the common cognition shared by collection of people in a culture. Therefore, using a Web search engine with the strong-polar-steering lexico-syntactic patterns as queries, we can infer the sentiment expectation of a noun, by calculating its statistical association with positive and negative hits.

As an example, using the search engine Baidu[2] with the pattern "<n> 有点 <a>" as queries, we obtain the following hits:

(5) 工资*有点*低 | Salary is a little low. (2890 hits)
工资*有点*高 | Salary is a little high (67 hits)

(6) 价格*有点*高 | Price is a little high. (19400 hits)
价格*有点*低 | Price is a little low. (1080 hits)

The more than 40 times more numerous hits for "工资有点低 |Salary is a little low" indicate that that "工资|salary" is a positive expectation noun. For the same reason, we can infer that "价格 |price" has negative expectation.

DSAAs are classified into two opposite sets *Pa* and *Na*, as listed in (1) and (2) respectively. Here two-character adjectives ("巨大 |huge" and "重大 |great") are discarded. Four types of lexico-syntactic patterns, which are also classified into two opposite sets in consistent with *Pa* and *Na*, are used in this paper, as listed in Table 2. These patterns were manually designed, inspired by linguistic knowledge and after a deep investigation on the Web.

Pos. expectation patterns	Neg. expectation patterns
1) <n> 有点 *Na* n is a little *Na* 2) <n> 有点儿 *Na* n is a little *Na* 3) <n> *Na*, 怎么办 n is *Na*, what should we do? 4) 嫌 <n> *Na* n is too *Na*	1) <n> 有点 *Pa* n is a little *Pa* 2) <n> 有点儿 *Pa* n is a little *Pa* 3) <n> *Pa*, 怎么办 n is *Pa*, what should we do? 4) 嫌 <n> *Pa* n is too *Pa*

Table 2: The lexico-syntactic patterns

Here the noun (n) in these patterns was instantiated by 9,468 nouns in our collected data. A noun has together 48 patterns, 24 positive and 24 negative ones. For each noun, we obtain the hits of both positive and negative expectation patterns, using the search engine Baidu. The sentiment expectation of a noun is acquired by Eq. (2) and Eq. (3), where the magnitude of $PT\_SO(n)$ can be considered as the strength of sentiment expectation.

$$\begin{aligned} PT\_SO(n) = & \sum_{b\in Na}\sum_{i=1}^{4} PositivePatternHit_i(n,b) \\ & - \sum_{a\in Pa}\sum_{i=1}^{4} NegativePatternHit_i(n,a) \end{aligned} \tag{2}$$

$$\text{n is } \begin{cases} \text{positive expectation} & \text{if } PT\_SO(n)>0 \\ \text{negative expectation} & \text{if } PT\_SO(n)<0 \\ \text{not predicted} & \text{if } PT\_SO(n)=0 \end{cases} \tag{3}$$

Table 3 gives some nouns with sentiment expectation predicted by the pattern-based method, descending (the left column) and ascending (the right column) by the absolute value of $PT\_SO(n)$. Most words (9 out of 10) are correctly predicted, demonstrating that the result of pattern-based method is promising. The only wrong predicted noun is "感觉 |feeling", due to the fact that most instances of it on the Web data are used as verb rather than noun, like "感觉有点大| I think it is large".

[2] http://baidu.com.cn.

Positive expectation	Negative expectation
Noun ($PT\_SO(n)$)	Noun ($PT\_SO(n)$)
钱|money (31349)	温度|temperature(-111576)
工资|wage (26311)	噪音|noise (-45790)
感觉|feeling (20102)	价格|price (-25653)
收入|income(19429)	代价|cost (-22051)
官|officer (10630)	血压|blood pressure (-21788)

Table 3: Examples of nouns with sentiment expectation predicted by the pattern-based method

4.2 Character-based Derivation Using Sentiment Lexicons

But the sentiment expectation of some nouns cannot be predicted with the pattern-based method, mainly due to the reason that these nouns don't occur in the listed patterns in Table 2. An alternate way is to exploit the semantic knowledge of Chinese characters. It is assumed that there is a strong association between the sentiment category of a word and its component characters. For example, the three words "罪恶 zui'e|evil, 罪行 zuixing|crime, 罪过 zuiguo|fault", which all contain the character "罪 zui|sin" that carries negative meaning, are all negative expectation nouns.

First, we compute the character-word sentiment association by the following PMI formula, based on a sentiment lexicon:

$$PMI(c, Positive) = \log \frac{P(c, Positive)}{P(c)P(Positive)}$$

$$PMI(c, Negative) = \log \frac{P(c, Negative)}{P(c)P(Negative)} \quad (4)$$

$$SO(c) = PMI(c, Positive) - PMI(c, Negative)$$

Where $P(c, Positive)$ is the probability of a character c in the positive category; $P(c)$ is the probability of a character c in the sentiment lexicon; $P(Positive)$ is the probability of the positive category in the sentiment lexicon. $PMI(c, Negative)$ has the similar meaning. Probabilities are estimated according to the maximum likelihood principle.

The open language resources for Chinese sentiment analysis are quite limited. We selected the following two sentiment lexicons.

Sentiment HowNet. HowNet has published the Chinese vocabulary for sentiment analysis[3], which was manually constructed. The positive category contains 4,566 words and the negative category contains 4,370 words.

Sentiment BaiduHit. In our collected data, we extracted 9,468 nouns. Using the pattern-based method we acquired sentiment expectation of these nouns, where 2,530 ones were assigned as positive expectation, 1,837 ones as negative expectation and 5,101 ones were not predicted. It is assumed that most nouns are correctly predicted. These nouns with their sentiment expectation constitute the lexicon of Sentiment BaiduHit, which is automatically constructed.

Combining HowNet and BaiduHit. Most sentiment characters derived from HowNet have adjective property, since most words in Sentiment HowNet are adjectives. On the contrary, most sentiment characters derived from BaiduHit have noun property. Therefore, the combination of the two lexicons can cover more characters. As Sentiment HowNet is manually compiled, the sentiment characters derived from it should be more reasonable than those from BaiduHit. When combining the two lexicons in computing character polarity, we assign a high priority to HowNet. Only when a character is out of vocabulary in HowNet, we resort to BaiduHit.

Then, we acquire the sentiment category of a word by computing the following equation. Let a word consist of n characters $w = c_1, c_2, \ ... c_n$, the sentiment category of the word is calculated by the average sentiment value of its component characters:

$$CH\_SO(w) = \frac{1}{n}\sum_{i=1}^{n} SO(c_i) \quad (5)$$

$$\text{w is} \begin{cases} \text{positive expectation if } CH\_SO(w)>0 \\ \text{negative expectation if } CH\_SO(w)<0 \\ \text{neutral} \qquad\qquad\quad \text{if } CH\_SO(w)=0 \end{cases} \quad (6)$$

We acquired *sentiment expectation* of 9,468 nouns in our collected data, based on Sentiment HowNet, Sentiment BaiduHit, and the combination of the two lexicons, respectively.

Table 6 gives examples of nouns with sentiment expectation acquired by the character-based method combining the two lexicons of HowNet and BaiduHit, descending (the left column) and ascending (the right column) by the absolute value of $CH\_SO(w)$.

[3] http://www.keenage.com/html/c_index.html.

Positive expectation	Negative expectation
Noun($CH\_SO(w)$)	Noun($CH\_SO(w)$)
美称|good name (3.23)	灰|ash (-3.22)
健美|health (3.06)	毛|gross (-2.93)
香|fragrance (3.05)	税|tax (-2.89)
美方|U.S.A (2.98)	毛病|fault (-2.84)
职称|title (2.64)	毒|poison (-2.82)

Table 4: Example of nouns with sentiment expectation predicted by the character-based method

4.3 Integrating Pattern-based Prediction and Character-based Derivation

The two methods of pattern-based prediction and character-based derivation have complementary properties. The pattern-based method concentrates on a word's usage on the Web, whereas the character-based method focuses on the internal structure of a word. So the two methods can be integrated to get better performance. The results using pattern-based method are much better than character-based method, as illustrated in Table 3 and Table 4. So in the integrated scheme, we give a high priority to pattern-based method. The pattern-based approach is mainly used, and only when the value of $|PT\_SO(n)|$ is smaller than a threshold r, the character-based method is adopted. Because when the value of $|PT\_SO(n)|$ is very small, it could be caused by random noises on the Web. We set r to 9 according to empirical analysis in the development data.

5 Experiments

5.1 Sentiment Analysis at Sentence Level

5.1.1 Data

We collected data from two sources. The main part was extracted from Xinhua News Agency of Chinese Gigaword (Second Edition) released by LDC. The texts were automatically word-segmented and POS-tagged using the open software ICTCLAS[4]. In order to concentrate on the disambiguation of DSAAs, and reduce the noise introduced by the parser, we extracted sentences containing strings in pattern of (7), where the target noun is modified by the adjective in most cases.

(7) noun+adverb+adjective (adjective $\in$ DSAAs)
e.g. 成本/n 较/d 低/a | the cost is low.

Another small part of data was extracted from the Web. Using the search engine Google[5], we searched the queries as in (8):

(8) 很| very+ adjective (adjective $\in$ DSAAs)
From the returned snippets, we manually picked out some sentences that contain the strings of (7). Also, the sentences were automatically word-segmented and POS-tagged using ICTCLAS.

DSAAs in the data were assigned as positive, negative or neutral, independently by two annotators. Since we focus on the distinction between positive and negative categories, the neutral instances were removed. Table 5 gives statistics of the data, and the inter-annotator agreement is in a high level with a kappa of 0.91. After cases with disagreement were negotiated between the two annotators, a gold standard annotation was agreed upon. In this paper, 3066 instances were divided randomly into three parts, 1/3 of which were used as the development data, and 2/3 were the test data.

Most of the data has been used as the benchmark dataset of SemEval-2010 task 18 "disambiguating sentiment ambiguous adjectives" (Wu and Jin, 2010), and so it can be downloaded freely for research.

	Pos#	Neg#	Total#
Pos#	1280	58	1338
Neg#	72	1666	1738
Total#	1352	1724	3066

Table 5: The statistics of DSAAs data

5.1.2 Baseline

We conducted two types of baseline.

Simple Baseline. Not considering the context, assign all positive-like adjectives as positive, and all negative-like adjectives as negative.

HowNet Baseline. Acquiring SO of nouns from Sentiment HowNet, the polarity of DSAAs is computed by Eq. (1).

5.1.3 Methods

Pattern-based method. Acquiring sentiment expectation of nouns using the pattern-based method, the polarity of DSAAs is computed by Eq.(1).

[4] http://www.ictclas.org/.

[5] http://www.google.com/.

Character-based method. Acquiring sentiment expectation of nouns using the character-based method, based on Sentiment HowNet, Sentiment BaiduHit and the combination of the two lexicons respectively, the polarity of DSAAs is computed by Eq.(1).

Integrated method. Acquiring sentiment expectation of nouns by integrating pattern-based and character-based methods, the polarity of DSAAs is computed by Eq. (1).

5.1.4 Results

Table 6 gives the experimental results at sentence level with different methods.

Methods	Pre.	Rec.	F
Simple Baseline	61.20	61.20	61.20
HowNet Baseline	97.58	9.88	17.94
Pattern-based	75.83	71.67	73.69
Character-based (HowNet)	69.89	69.37	69.63
Character-based (BaiduHit)	68.66	68.59	68.62
Character-based (Combined)	71.01	70.94	70.97
Integrated method	**78.52**	**78.52**	**78.52**

Table 6: The experimental results at sentence level

As for the simple baseline, both the precision and recall are low, suggesting that DSAAs cannot be neglected for sentiment analysis in a real-world application.

The HowNet baseline achieves a quite high precision of 97.58%, but a rather poor recall of 9.88%, suggesting that SO of nouns described in traditional sentiment lexicon, like HowNet, cannot effectively disambiguate DSAAs.

The proposed methods in this paper all yield results that are substantially better than two types of baseline. The pattern-based method, as straightforward as it is, achieves promising result with an f-score of 73.69%, which is 12.49% higher than the simple baseline. The pattern-based method outperforms the character-based method (combined) by 4.82% in precision and 0.73% in recall. The performance of the character-based method based on Sentiment BaiduHit is competitive with that based on Sentiment HowNet, which again proves the effectiveness of the pattern-based method. The character-based method combining the two lexicons outperforms each lexicon with small improvement. The approach integrating pattern-based and character-based methods outperforms each method in isolation, achieving an f-score of 78.52% that is 17.32% higher than the simple baseline and 60.58% higher than HowNet baseline.

5.2 Sentiment Analysis at Document Level

5.2.1 Data

We also investigated the impact of disambiguating DSAAs on the sentiment classification of product reviews. Following the work of Wan (2008), we selected the same dataset. The dataset contains 886 Chinese product reviews, which are manually annotated with polarity labels: positive or negative. Also, the files are automatically word-segmented and POS-tagged using ICTCLAS. We extracted the files that contain the following strings, where the nouns are modified by DSAAs in most cases.

(9) noun+adjective (adjective $\in$ DSAAs)
noun+adverb+adjective
noun+adverb+adverb+adjective.

We obtained 212 files, up to 24% of the overall data, suggesting again that DSAAs are frequently used in product reviews and cannot be avoided in a real-world application.

5.2.2 Methods

Our goal is not to propose a new method, but instead to test the performance gain by adding the disambiguation of DSAAs. We adopted the same algorithm with Wan (2008), and also used Sentiment-HowNet. But in our experiment, *Negation_Dic* contains only one term "不 bu|not", for the sake of repeatable experiments.

The baseline algorithm is illustrated by the non-italic part in Figure 1, where we set the same parameters with Wan's approach: *PosValue*=1, *NegValue*=-2, *q*=2, *ρ*=2.

We added the disambiguation of DSAAs to the algorithm, as illustrated by the italic part in Figure 1. When a word is a DSAA, compute its SO with the proposed integrated method, rather than using its prior polarity specified in HowNet. For *Dy_PosValue* and *Dy_NegValue*, we first set *Dy_PosValue*=1 and *Dy_NegValue*=-2, just the same as *PosValue* and *NegValue.* In the second attempt, in order to further intensify the polarity of DSAAs, we set *Dy_PosValue*=1.5 and *Dy_NegValue*=-2.5. Other parameters were set the same as baseline.

Algorithm Compute_SO:

```
1. Tokenize document d into sentence set S, and each sentence s∈S is tokenized into word set Ws;
2. For any word w in a sentence s∈S, compute its value SO(w) as follows:
    1) if w ∈DSAAs, compute SO(w) with the integrated method.
        If SO(w)=1, SO(w)=Dy_PosValue;
        If SO(w)=-1, SO(w)=Dy_NegValue;
    2) if w∈Positive_Dict, SO(w)=PosValue;
    3) If w∈Negative_Dict, SO(w)=NegValue;
    4) Otherwise, SO(w)=0;
    5) Within the window of q words previous to w, if there is a term w'∈Negation_Dict,
        SO(w)= –SO(w);
    6) Within the window of q words previous to w, if there is a term w' ∈Intensifier_Dict,
        SO(w) =ρ×SO(w);
3. $S(d) = \sum_{s\in S} \sum_{w\in Ws} SO(w)$
```

Figure 1: Algorithm of computing SO of documents

5.2.3 Results

Adding the disambiguation of *DSAAs*, the performance of sentiment classification of 212 product reviews was significantly improved, as shown in Table 7.

		Baseline	DSAAs (1, -2)	DSAAs (1.5,-2.5)
Pos.	Pre.	75.89	77.50	76.61
	Rec.	78.70	86.11	87.96
	F	77.27	81.58	81.90
Neg.	Pre.	87.01	88.46	87.06
	Rec.	64.42	66.35	71.15
	F	74.03	75.82	78.31
Total	MacroF	75.62	78.60	**80.06**
	Accu.	71.70	76.42	**79.72**

Table 7: The experimental results at document level

As an example, the following review, which consists of only one sentence, is correctly classified as positive by DSAAs method, but is classified as negative by the baseline approach.

(10) 体积小，重量轻，携带很方便。
| Small size, light weight, and easy to carry.

According to HowNet, as shown in Table 8, the sentence contains two negative words "小|small" and "轻|light" and one positive word "方便 fangbian|easy", resulting the overall negative prediction. In our approach, "体积 tiji|size" and "重量 zhongliang|weight" are assigned as negative expectation, and consequently both "体积小|small size" and "重量轻|light weight" have positive meaning, resulting the overall positive prediction.

Pos.	大 |large, 高 |high, 厚 |thick, 深 |deep, 重|heavy, 重大|great
Neg.	小 |small, 低 |low, 薄 |thin, 浅 |shallow, 轻|light
OOV	多|many, 少|few, 巨大|huge

Table 8: The SO of DSAAs described in HowNet

Adding the disambiguation of DSAAs, our method obviously outperforms the baseline by 4.44% in f-score and 8.02% in accuracy. The improvement in recall is especially obvious. When intensifying the polarity of DSAAs by setting *Dy_PosValue*=1.5 and *Dy_NegValue*=-2.5, the recall is improved by 9.26% for positive category and 6.73% for negative category.

6 Conclusion and Future Work

This paper presents a knowledge-based unsupervised method to automatically disambiguate dynamic sentiment ambiguous words, focusing on 14 DSAAs. We exploit pattern-based and character-based methods to infer sentiment expectation of nouns, and then determine the polarity of DSAAs based on the nouns. For the sentiment analysis at sentence level, our method achieves promising result that is significantly better than two types of baseline, which validates the effectiveness of our approach. We also apply the disambiguation of 14 DSAAs to the sentiment classification of product reviews, resulting obvious improvement in performance, which proves the significance of the issue.

There leaves room for improvement. Our future work will explore more contextual information in disambiguating DSAAs. In addition, we will find out new methods to reduce noises when mining the Web to infer sentiment expectation of nouns. Discovering the lexico-syntactic patterns for sentiment expectation of nouns automatically or semi-automatically with bootstrapping method is also a challenging direction.

Abstract

As tokenization is usually ambiguous for many natural languages such as Chinese and Korean, tokenization errors might potentially introduce translation mistakes for translation systems that rely on 1-best tokenizations. While using lattices to offer more alternatives to translation systems have elegantly alleviated this problem, we take a further step to tokenize and translate jointly. Taking a sequence of atomic units that can be combined to form words in different ways as input, our joint decoder produces a tokenization on the source side and a translation on the target side simultaneously. By integrating tokenization and translation features in a discriminative framework, our joint decoder outperforms the baseline translation systems using 1-best tokenizations and lattices significantly on both Chinese-English and Korean-Chinese tasks. Interestingly, as a tokenizer, our joint decoder achieves significant improvements over monolingual Chinese tokenizers.

1 Introduction

Tokenization plays an important role in statistical machine translation (SMT) because tokenizing a source-language sentence is always the first step in SMT systems. Based on the type of input, Mi and Huang (2008) distinguish between two categories of SMT systems : *string-based* systems (Koehn et al., 2003; Chiang, 2007; Galley et al., 2006; Shen et al., 2008) that take a string as input and *tree-based* systems (Liu et al., 2006; Mi et al., 2008) that take a tree as input. Note that a tree-based system still needs to first tokenize the input sentence and then obtain a parse tree or forest of the sentence. As shown in Figure 1(a), we refer to this pipeline as **separate** tokenization and translation because they are divided into single steps.

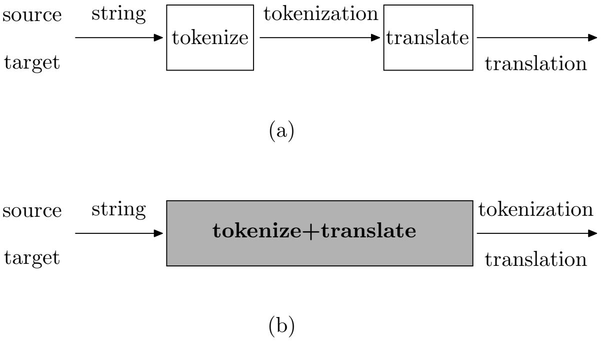

Figure 1: (a) Separate tokenization and translation and (b) joint tokenization and translation.

As tokenization for many languages is usually ambiguous, SMT systems that separate tokenization and translation suffer from a major drawback: tokenization errors potentially introduce translation mistakes. As some languages such as Chinese have no spaces in their writing systems, how to segment sentences into appropriate words has a direct impact on translation performance (Xu et al., 2005; Chang et al., 2008; Zhang et al., 2008). In addition, although agglutinative languages such as Korean incorporate spaces between "words", which consist of multiple morphemes, the granularity is too coarse and makes the training data considerably sparse. Studies reveal that segmenting “words” into morphemes effectively improves translating morphologically rich languages (Oflazer, 2008). More importantly, a tokenization close to a gold standard does not necessarily leads to better translation quality (Chang et al., 2008; Zhang et al., 2008). Therefore, it is necessary to offer more tokenizations to SMT systems to alleviate the tokenization error propagation problem. Recently, many researchers have shown that replacing 1-best tokenizations with lattices improves translation performance significantly (Xu et al., 2005; Dyer et al., 2008; Dyer, 2009).

We take a next step towards the direction of offering more tokenizations to SMT systems by proposing **joint** tokenization and translation. As shown in Figure 1(b), our approach tokenizes and translates jointly to find a tokenization and a translation for a source-language string simultaneously. We integrate translation and tokenization models into a discriminative framework (Och and Ney, 2002), within which tokenization and translation models interact with each other. Experiments show that joint tokenization and translation outperforms its separate counterparts (1-best tokenizations and lattices) significantly on the NIST 2004 and 2005 Chinese-English test sets. Our joint decoder also reports positive results on Korean-Chinese translation. As a tokenizer, our joint decoder achieves significantly better tokenization accuracy than three monolingual Chinese tokenizers.

2 Separate Tokenization and Translation

Tokenization is to split a string of characters into meaningful elements, which are often referred to as words. Typically, machine translation separates tokenization from decoding as a preprocessing step. An input string is first preprocessed by a tokenizer, and then is translated based on the tokenized result. Take the SCFG-based model (Chiang, 2007) as an example. Given the character sequence of Figure 2(a), a tokenizer first splits it into the word sequence as shown in Figure 2(b), then the decoder translates the word sequence using the rules in Table 1.

This approach makes the translation process simple and efficient. However, it may not be optimal for machine translation. Firstly, optimal granularity is unclear for machine translation. We might face severe data sparseness problem by using large granularity, while losing much useful information with small one. Consider the example in Figure 2. It is reasonable to split *duo fen* into two words as *duo* and *fen*, since they have one-to-one alignments to the target side. Nevertheless, while *you* and *wang* also have one-to-one alignments, it is risky to segment them into two words. Because the decoder is prone to translate *wang* as a verb *look* without the context *you*. Secondly, there may be tokenization errors. In Figure2(c), *tao fei ke* is recognized as a Chinese person name with the second name *tao* and the first name *fei-ke*, but the whole string *tao fei ke* should be a name of the Indonesian badminton player.

r_1	*tao-fei-ke* →*Taufik*
r_2	*duo fen* → *gain a point*
r_3	x_1 *you-wang* x_2 → x_1 *will have the chance to* x_2

Table 1: An SCFG derivation given the tokenization of Figure 2(b).

Therefore, it is necessary to offer more tokenizations to SMT systems to alleviate the tokenization error propagation problem. Recently, many researchers have shown that replacing 1-best tokenizations with lattices improves translation performance significantly. In this approach, a lattice compactly encodes many tokenizations and is fixed before decoding.

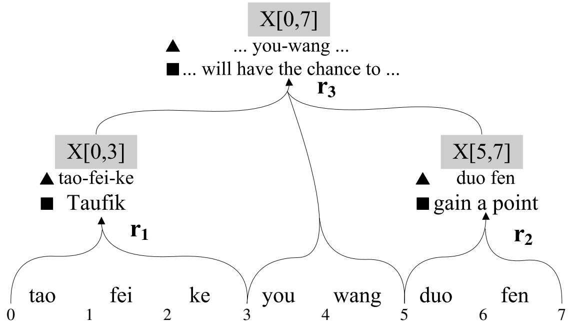

Figure 3: A derivation of the joint model for the tokenization in Figure 2(b) and the translation in Figure 2 by using the rules in Table 1. ▲ means tokenization while ■ represents translation.

3 Joint Tokenization and Translation

3.1 Model

We take a next step towards the direction of offering more tokenizations to SMT systems by proposing **joint** tokenization and translation. As shown in Figure 1(b), the decoder takes an untokenized string as input, and then tokenizes the source side string while building the corresponding translation of the target side. Since the traditional rules like those in Table 1 natively include tokenization information, we can directly apply them for simultaneous construction of tokenization and translation by the source side and target side of rules respectively. In Figure 3, our joint model takes the character sequence in Figure 2(a) as input, and synchronously conducts both translation and tokenization using the rules in Table 1.

As our model conducts tokenization during decoding, we can integrate tokenization models as features together with translation features under the discriminative framework. We expect tokenization and translation could collaborate with each other. Tokenization offers translation with good tokenized results, while translation helps tokenization to eliminate ambiguity. Formally, the probability of a derivation D is represented as

$$P(D) \propto \prod_i \phi_i(D)^{\lambda_i} \tag{1}$$

where ϕ_i are features defined on derivations including translation and tokenization, and λ_i are feature weights. We totally use 16 features:

- 8 traditional translation features (Chiang, 2007): 4 rule scores (direct and reverse translation scores; direct and reverse lexical translation scores); language model of the target side; 3 penalties for word count, extracted rule and glue rule.
- 8 tokenization features: maximum entropy model, language model and word count of the source side (Section 3.2). To handle the Out Of Vocabulary (OOV) problem (Section 3.3), we also introduce 5 OOV features: OOV character count and 4 OOV discount features.

Since our model is still a string-based model, the CKY algorithm and cube pruning are still applicable for our model to find the derivation with max score.

3.2 Adding Tokenization Features

Maximum Entropy model (ME). We first introduce ME model feature for tokenization by casting it as a labeling problem (Xue and Shen, 2003; Ng and Low, 2004). We label a character with the following 4 types:

- **b**: the **b**egin of a word
- **m**: the **m**iddle of a word
- **e**: the **e**nd of a word
- **s**: a **s**ingle-character word

Taking the tokenization *you-wang* of the string *you wang* for example, we first create a label sequence *b e* for the tokenization *you-wang* and then calculate the probability of tokenization by

$$\begin{aligned} & P(\textit{you-wang} \mid \textit{you wang}) \\ & = P(\mathrm{b\ e} \mid \textit{you wang}) \\ & = P(\mathrm{b} \mid \textit{you}, \textit{you wang}) \\ & \quad \times P(\mathrm{e} \mid \textit{wang}, \textit{you wang}) \end{aligned}$$

Given a tokenization w_1^L with L words for a character sequence c_1^n, we firstly create labels l_1^n for every characters and then calculate the probability by

$$P(w_1^L|c_1^n) = P(l_1^n|c_1^n) = \prod_{i=1}^{n} P(l_i|c_i, c_1^n) \tag{2}$$

Under the ME framework, the probability of assigning the character c with the label l is represented as:

$$P(l|c, c_1^n) = \frac{\exp[\sum_i \lambda_i h_i(l, c, c_1^n)]}{\sum_{l'} \exp[\sum_i \lambda_i h_i(l', c, c_1^n)]} \qquad (3)$$

where h_i is feature function, λ_i is the feature weight of h_i. We use the feature templates the same as Jiang et al., (2008) to extract features for ME model. Since we directly construct tokenization when decoding, it is straight to calculate the ME model score of a tokenization according to formula (2) and (3).

Language Model (LM). We also use the n-gram language model to calculate the probability of a tokenization w_1^L:

$$P(w_1^L) = \prod_{i=1}^{L} P(w_i | w_{i-n+1}^{i-1}) \qquad (4)$$

For instance, we compute the probability of the tokenization shown in Figure 2(b) under a 3-gram model by

$$\begin{aligned} & P(\textit{tao-fei-ke}) \\ \times & P(\textit{you-wang} \mid \textit{tao-fei-ke}) \\ \times & P(\textit{duo} \mid \textit{tao-fei-ke}, \textit{you-wang}) \\ \times & P(\textit{fen} \mid \textit{you-wang}, \textit{duo}) \end{aligned}$$

Word Count (WC). This feature counts the number of words in a tokenization. Language model is prone to assign higher probabilities to short sentences in a biased way. This feature can compensate this bias by encouraging long sentences. Furthermore, using this feature, we can optimize the granularity of tokenization for translation. If larger granularity is preferable for translation, then we can use this feature to punish the tokenization containing more words.

3.3 Considering All Tokenizations

Obviously, we can construct the potential tokenizations and translations by only using the extracted rules, in line with traditional translation decoding. However, it may limits the potential tokenization space. Consider a string *you wang*. If *you-wang* is not reachable by the extracted rules, the tokenization *you-wang* will never be considered under this way. However, the decoder may still create a derivation by splitting the string as small as possible with tokenization *you wang* and translating *you* with *a* and *wang* with *look*, which may hurt the translation performance. This case happens frequently for named entity especially. Overall, it is necessary to assure that the decoder can derive all potential tokenizations (Section 4.1.3).

To assure that, when a span is not tokenized into a single word by the extracted rules, we will add an operation, which is considering the entire span as an OOV. That is, we tokenize the entire span into a single word with a translation that is the copy of source side. We can define the set of all potential tokenizations $\tau(c_1^n)$ for the character sequence c_1^n in a recursive way by

$$\tau(c_1^n) = \bigcup_{i}^{n-1} \{\tau(c_1^i) \bigotimes \{w(c_{i+1}^n)\}\} \qquad (5)$$

here $w(c_{i+1}^n)$ means a word contains characters c_{i+1}^n and $\bigotimes$ means the times of two sets. According to this recursive definition, it is easy to prove that all tokenizations is reachable by using the glue rule ($S \Rightarrow SX, SX$) and the added operation. Here, glue rule is used to concatenate the translation and tokenization of the two variables S and X, which acts the role of the operator $\bigotimes$ in equation (5).

Consequently, this introduces a large number of OOVs. In order to control the generation of OOVs, we introduce the following OOV features:

OOV Character Count (OCC). This feature counts the number of characters covered by OOV. We can control the number of OOV characters by this feature. It counts 3 when *tao-fei-ke* is an OOV, since *tao-fei-ke* has 3 characters.

OOV Discount (OD). The chances to be OOVs vary for words with different counts of characters. We can directly attack this problem by adding features OD_i that reward or punish OOV words which contains with i characters, or $OD_{i,j}$ for OOVs contains with i to j characters. 4 OD features are used in this paper: 1, 2, 3 and 4+. For example, OD_3 counts 1 when the word *tao-fei-ke* is an OOV.

Method	Train	#Rule	Test	TFs	MT04	MT05	Speed

	SF	148M			37.02	34.56	17.37
	ME	141M			36.78	34.17	17.23
	All	219M			**37.25****	**34.88****	17.52

Table 2: Comparison of Separate and Joint methods in terms of BLEU and speed (second per sentence). Columns *Train* and *Test* represents the tokenization methods for training and testing respectively. Column *TFs* stands for whether the 8 tokenization features is used (√) or not (×). *ICT*, *SF* and *ME* are segmenter names for preprocessing. *All* means combined corpus processed by the three segmenters. Lattice represent the system implemented as Dyer et al., (2008). ** means significantly (Koehn, 2004) better than Lattice ($p < 0.01$).

4 Experiments

In this section, we try to answer the following questions:

1. Does the joint method outperform conventional methods that separate tokenization from decoding. (Section 4.1)

2. How about the tokenization performance of the joint decoder? (Section 4.2)

4.1 Translation Evaluation

We use the SCFG model (Chiang, 2007) for our experiments. We firstly work on the Chinese-English translation task. The bilingual training data contains 1.5M sentence pairs coming from LDC data.[1] The monolingual data for training English language model includes Xinhua portion of the GIGAWORD corpus, which contains 238M English words. We use the NIST evaluation sets of 2002 (MT02) as our development data set, and sets of 2004(MT04) and 2005(MT05) as test sets. We use the corpus derived from the People's Daily (Renmin Ribao) in Feb. to Jun. 1998 containing 6M words for training LM and ME tokenization models.

Translation Part. We used GIZA++ (Och and Ney, 2003) to perform word alignment in both directions, and grow-diag-final-and (Koehn et al., 2003) to generate symmetric word alignment. We extracted the SCFG rules as describing in Chiang (2007). The language model were trained by the SRILM toolkit (Stolcke, 2002).[2] Case insensitive NIST BLEU (Papineni et al., 2002) was used to measure translation performance.

Tokenization Part. We used the toolkit implemented by Zhang (2004) to train the ME model. Three Chinese word segmenters were used for comparing: ICTCLAS (*ICT*) developed by institute of Computing Technology Chinese Academy of Sciences (Zhang et al., 2003); *SF* developed at Stanford University (Huihsin et al., 2005) and *ME* which exploits the ME model described in section (3.2).

4.1.1 Joint Vs. Separate

We compared our joint tokenization and translation with the conventional separate methods. The input of separate tokenization and translation can either be a single segmentation or a lattice. The lattice combines the 1-best segmentations of segmenters. Same as Dyer et al., (2008), we also extracted rules from a combined bilingual corpus which contains three copies from different segmenters. We refer to this version of rules as *All*.

Table 2 shows the result.[3] Using *all* rule table, our joint method significantly outperforms the best single system *SF* by $+1.96$ and $+1.66$ points on MT04 and MT05 respectively, and also outperforms the lattice-based system by $+1.46$ and $+0.93$ points. However, the 8 tokenization features have small impact on the lattice system, probably because the tokenization space limited

[1] including LDC2002E18, LDC2003E07, LDC2003E14, Hansards portion of LDC2004T07, LDC2004T08 and LDC2005T06

[2] The calculation of LM probabilities for OOVs is done by the SRILM without special treatment by ourself.

[3] The weights are retrained for different test conditions, so do the experiments in other sections.

ME	LM	WC	OCC	OD	MT05
×	×	×	×	×	24.97
√	×	×	×	×	25.30
×	√	×	×	×	24.70
×	×	√	×	×	24.84
×	×	×	√	×	25.51
×	×	×	×	√	25.34
×	√	√	×	×	25.74
√	√	√	√	√	26.37

Table 3: Effect of tokenization features on Chinese-English translation task. "√" denotes using a tokenization feature while "×" denotes that it is inactive.

Method	BLEU	#Word	Grau	#OOV
ICT	33.06	30,602	1.65	644
SF	33.22	30,119	1.68	882
ME	30.91	29,717	1.70	1,614
Lattice	33.95	30,315	1.66	494
Joint$_{ICT}$	34.69	29,723	1.70	996
Joint$_{SF}$	34.56	29,839	1.69	972
Joint$_{ME}$	34.17	29,771	1.70	1,062
Joint$_{All}$	34.88	29,644	1.70	883

Table 4: Granularity (Grau, counts of character per word) and counts of OOV words of different methods on MT05. The subscript of joint means the type of rule table.

by lattice has been created from good tokenization. Not surprisingly, our decoding method is about 2.6 times slower than lattice method with tokenization features, since the joint decoder takes character sequences as input, which is about 1.7 times longer than the corresponding word sequences tokenized by segmenters. (Section 4.1.4).

The number of extracted rules with different segment methods are quite close, while the *All* version contains about 45% more rules than the single systems. With the same rule table, our joint method improves the performance over separate method up to $+3.03$ and $+3.26$ points (*ME*). Interestingly, comparing with the separate method, the tokenization of training data has smaller effect on joint method. The BLEU scores of MT04 and MT05 fluctuate about 0.5 and 0.7 points when applying the joint method, while the difference of separate method is up to 2 and 3 points respectively. It shows that the joint method is more robust to segmentation performance.

4.1.2 Effect of Tokenization Model

We also investigated the effect of tokenization features on translation. In order to reduce the time for tuning weights and decoding, we extracted rules from the FBIS part of the bilingual corpus, and trained a 4-gram English language model on the English side of FBIS.

Table 3 shows the result. Only using the 8 translation features, our system achieves a BLEU score of 24.97. By activating all tokenization features, the joint decoder obtains an absolute improvement by 1.4 BLEU points. When only adding one single tokenization feature, the *LM* and *WC* fail to show improvement, which may result from their bias to short or long tokenizations. However, these two features have complementary advantages and collaborate well when using them together (line 8). The OCC and OD features also contribute improvements which reflects the fact that handling the generation of OOV is important for the joint model.

4.1.3 Considering All Tokenizations?

In order to explain the necessary of considering all potential tokenizations, we compare the performances of whether to tokenize a span as a single word or not as illustrated in section 3.3. When only tokenizing by the extracted rules, we obtain 34.37 BLEU on MT05, which is about 0.5 points lower than considering all tokenizations shown in Table 2. This indicates that spuriously limitation of the tokenization space may degenerate translation performance.

4.1.4 Results Analysis

To better understand why the joint method can improve the translation quality, this section shows some details of the results on the MT05 data set.

Table 4 shows the granularity and OOV word counts of different configurations. The lattice method reduces the OOV words quite a lot which is 23% and 70% comparing with ICT and ME. In contrast, the joint method gain an absolute improvement even thought the OOV count do not decrease. It seems the lattice method prefers to translate more characters (since smaller granularity and less OOVs), while our method is inclined to maintain integrity of words (since larger granularity and more OOVs). This also explains the difficulty of deciding optimal tokenization for translation before decoding.

There are some named entities or idioms that

Method	Type	F_1	Time
Monolingual	ICT	97.47	0.010
	SF	97.48	0.007
	ME	95.53	0.008
Joint	ICT	97.68	9.382
	SF	97.68	10.454
	ME	97.60	10.451
	All	97.70	9.248

Table 5: Comparison of segmentation performance in terms of F_1 score and speed (second per sentence). *Type* column means the segmenter for monolingual method, while represents the rule tables used by joint method.

are split into smaller granularity by the segmenters. For example:"史 东" which is an English name "Stone" or "豆-蔻 年-华" which means "teenage". Although the separate method is possible to translate them using smaller granularity, the translation results are in fact wrong. In contrast, the joint method tokenizes them as entire OOV words, however, it may result a better translation for the whole sentence.

We also count the overlap of the segments used by the $Joint_{All}$ system towards the single segmentation systems. The tokenization result of $Joint_{All}$ contains $29,644$ words, and shares $28,159$, $27,772$ and $27,407$ words with ICT, SF and ME respectively. And 46 unique words appear only in the joint method, where most of them are named entity.

4.2 Chinese Word Segmentation Evaluation

We also test the tokenization performance of our model on Chinese word segmentation task. We randomly selected 3k sentences from the corpus of People's Daily in Jan. 1998. 1k sentences were used for tuning weights, while the other 2k sentences were for testing. We use MERT (Och, 2003) to tune the weights by minimizing the error measured by F_1 score.

As shown in Table 5, with all features activated, our joint decoder achieves an F_1 score of 97.70 which reduces the tokenization error comparing with the best single segmenter *ICT* by 8.7%. Similar to the translation performance evaluation, our joint decoder outperforms the best segmenter with any version of rule tables.

Feature	F_1
TFs	97.37
TFs + RS	97.65
TFs + LM	97.67
TFs + RS + LM	97.62
All	97.70

Table 6: Effect of the target side information on Chinese word segmentation. *TFs* stands for the 8 tokenization features. *All* represents all the 16 features.

4.2.1 Effect of Target Side Information

We compared the effect of the 4 Rule Scores (RS), target side Language Model (LM) on tokenization. Table 6 shows the effect on Chinese word segmentation. When only use tokenization features, our joint decoder achieves an F_1 score of 97.37. Only integrating language model or rule scores, the joint decoder achieves an absolute improvement of 0.3 point in F_1 score, which reduces the error rate by 11.4%. However, when combining them together, the F_1 score deduces slightly, which may result from the weight tuning. Using all feature, the performance comes to 97.70. Overall, our experiment shows that the target side information can improve the source side tokenization under a supervised way, and outperform state-of-the-art systems.

4.2.2 Best Tokenization = Best Translation?

Previous works (Zhang et al., 2008; Chang et al., 2008) have shown that preprocessing the input string for decoder by better segmenters do not always improve the translation quality, we reverify this by testing whether the joint decoder produces good tokenization and good translation at the same time. To answer the question, we used the feature weights optimized by maximizing BLEU for tokenization and used the weights optimized by maximizing F_1 for translation. We test BLEU on MT05 and F_1 score on the test data used in segmentation evaluation experiments. By tuning weights regarding to BLEU (the configuration for Joint$_{All}$ in table 2), our decoder achieves a BLEU score of 34.88 and an F_1 score of 92.49. Similarly, maximizing F_1 (the configuration for the last line in table 6) leads to a much lower BLEU of 27.43, although the F_1 is up to 97.70. This suggests that better tokenization may not always lead to better translations and vice versa

Rule	#Rule	Method	Test	Time
Morph	46M	Separate	21.61	4.12
Refined	55M		21.21	4.63
All	74M	Joint	21.93*	5.10

Table 7: Comparison of Separate and Joint method in terms of BLEU score and decoding speed (second per sentence) on Korean-Chinese translation task.

even by the joint decoding. This also indicates the hard of artificially defining the best tokenization for translation.

4.3 Korean-Chinese Translation

We also test our model on a quite different task: Korean-Chinese. Korean is an agglutinative language, which comes from different language family comparing with Chinese.

We used a newswire corpus containing 256k sentence pairs as training data. The development and test data set contain 1K sentence each with one single reference. We used the target side of training set for language model training. The Korean part of these data were tokenized into morpheme sequence as atomic unit for our experiments.

We compared three methods. First is directly use morpheme sequence (Morph). The second one is refined data (Refined), where we use selective morphological segmentation (Oflazer, 2008) for combining morpheme together on the training data. Since the selective method needs alignment information which is unavailable in the decoding, the test data is still of morpheme sequence. These two methods still used traditional decoding method. The third one extracting rules from combined (All) data of methods 1 and 2, and using joint decoder to exploit the different granularity of rules.

Table 7 shows the result. Since there is no gold standard data for tokenization, we do not use ME and LM tokenization features here. However, our joint method can still significantly ($p < 0.05$) improve the performance by about +0.3 points. This also reflects the importance of optimizing granularity for morphological complex languages.

5 Related Work

Methods have been proposed to optimize tokenization for word alignment. For example, word alignment can be simplified by packing (Ma et al., 2007) several consecutive words together. Word alignment and tokenization can also be optimized by maximizing the likelihood of bilingual corpus (Chung and Gildea, 2009; Xu et al., 2008). In fact, these work are orthogonal to our joint method, since they focus on training step while we are concerned of decoding. We believe we can further the performance by combining these two kinds of work.

Our work also has connections to multilingual tokenization (Snyder and Barzilay, 2008). While they have verified that tokenization can be improved by multilingual learning, our work shows that we can also improve tokenization by collaborating with translation task in a supervised way.

More recently, Liu and Liu (2010) also shows the effect of joint method. They integrate parsing and translation into a single step and improve the performance of translation significantly.

6 Conclusion

We have presented a novel method for joint tokenization and translation which directly combines the tokenization model into the decoding phase. Allowing tokenization and translation to collaborate with each other, tokenization can be optimized for translation, while translation also makes contribution to tokenization performance under a supervised way. We believe that our approach can be applied to other string-based model such as phrase-based model (Koehn et al., 2003), string-to-tree model (Galley et al., 2006) and string-to-dependency model (Shen et al., 2008).

Build Chinese Emotion Lexicons Using A Graph-based Algorithm and Multiple Resources

Ge Xu, Xinfan Meng, Houfeng Wang
Key Laboratory of Computational Linguistics (Peking University), Ministry of Education
Institute of Computational Linguistics, Peking University
{xuge, mxf, wanghf}@pku.edu.cn

Abstract

For sentiment analysis, lexicons play an important role in many related tasks. In this paper, aiming to build Chinese emotion lexicons for public use, we adopted a graph-based algorithm which ranks words according to a few seed emotion words. The ranking algorithm exploits the similarity between words, and uses multiple similarity metrics which can be derived from dictionaries, unlabeled corpora or heuristic rules. To evaluate the adopted algorithm and resources, two independent judges were asked to label the top words of ranking list.

It is observed that noise is almost unavoidable due to imprecise similarity metrics between words. So, to guarantee the quality of emotion lexicons, we use an iterative feedback to combine manual labeling and the automatic ranking algorithm above. We also compared our newly constructed Chinese emotion lexicons (happiness, anger, sadness, fear and surprise) with existing counterparts, and related analysis is offered.

1 Introduction

Emotion lexicons have a great impact on the results of related tasks. With high-quality emotion lexicons, systems using simple methods can achieve competitive performance. However, to manually build an emotion lexicon is time-consuming. Many research works in building lexicons use automatic methods to assist the building procedure. Such works commonly rank words by the similarities to a set of seed words, then those words with high ranking scores are more likely to be added to the final lexicons or used as additional seed words.

For Chinese, emotion lexicons are scarce resources. We can get a small set of emotion words from semantic dictionary (such as CCD, HowNet, synonym dictionaries) or directly from related papers (Xu and Tao, 2003) (Chen et al. , 2009), but it is often not sufficient for practical systems. Xu et al. (2008) constructed a large-scale emotion ontology dictionary, but it is not publicly available yet.

In this paper, we adopted a graph-based algorithm to automatically rank words according to a few seed words. Similarity between words can be utilized and multiple resources are used to boost performance. Combining manual labeling with automatic ranking through an iterative feedback framework, we can produce high-quality emotion lexicons. Our experiments focused on Chinese, but the method is applicable to any other language as long as suitable resources exist.

The remainder of this paper is organized as follows. In Section 2, related works are introduced. In Section 3, we describe a graph-based algorithm and how to incorporate multiple resources. Section 4 gives the details of applying the algorithm on five emotions and shows how to evaluate the results. Section 5 focuses on how to build and evaluate emotion lexicons, linguistic consideration and instruction for identifying emotions are also included. Finally, conclusion is made in Section 6.

2 Related work

Riloff and Shepherd (1997) presented a corpus-based method that can be used to build semantic lexicons for specific categories. The input to the system is a small set of seed words for a category and a representative text corpus. The output is a ranked list of words that are associated with the category. An approach proposed by (Turney, 2002) for the construction of polarity started with a few positive and negative seeds, then used a similarity method (pointwise mutual information) to grow this seed list from web corpus. Our experiments are similar with these works, but we use a different ranking method and incorporate multiple resources. To perform rating inference on reviews, Goldberg and Zhu (2006) created a graph on both labeled and unlabeled reviews, and then solved an optimization problem to obtain a smooth rating function over the whole graph. Rao and Ravichandran (2009) used three semi-supervised methods in polarity lexicon induction based on WordNet, and compared them with corpus-based methods. Encouraging results show methods using similarity between words can improve the performance. Wan and Xiao (2009) presented a method to use two types of similarity between sentences for document summarization, namely similarity within a document and similarity between documents. The ranking method in our paper is similar to the ones used in above three papers, which fully exploit the relationship between any pair of sample points (both labeled and unlabeled). When only limited labeled data are available, such method achieves significantly better predictive accuracy over other methods that ignore the unlabeled examples during training.

Xu et al. (2008) at first formed a taxonomy for emotions, under which an affective lexicon ontology exploiting various resources was constructed. The framework of ontology is filled by the combination of manual classification and automatic methods. To our best knowledge, this affective lexicon ontology is the largest Chinese emotion-oriented dictionary.

3 Our method

3.1 A graph-based algorithm

For our experiments, we chose the graph-based algorithm in (Zhou et al. , 2004) which is transductive learning and formulated as follows:

Given a point set $\chi = \{x_1, ..., x_l, x_{l+1}, ..., x_n\}$, the first l points $x_i (i \leq l)$ are labeled and the remaining points $x_u (l+1 \leq u \leq n)$ unlabeled. The goal is to rank the unlabeled points.

Let F denotes an n-dimensional vector whose elements correspond to ranking scores on the data set χ. Define another n-dimensional vector Y with $Y_i = 1$ if x_i is labeled and $Y_i = 0$ otherwise. Y denotes the initial label assignment.

The iterative algorithm is shown in the following:

Algorithm 1 A graph-based algorithm

```
1. Construct the weight matrix $W$ and set $W_{ii}$ to zero to avoid self-reinforcement. $W$ is domain-dependent.
2. Construct the similarity matrix $S = D^{1/2}WD^{1/2}$ using symmetric normalization. $D$ is a diagonal matrix with $D_{ii} = \Sigma_j W_{ij}$.
3. Iterate $F(t+1) = \alpha SF(t) + (1-\alpha)Y$ until convergence, where $\alpha$ is a parameter in (0, 1), and $F(0) = Y$. We clamp labeled points to 1 after each iteration.
4. Let $F^*$ denote $F(t)$ when the iteration converges.
```

In our experiments, labeled points are seed emotion words, S_{ij} denotes the similarity between *i*th word and *j*th word. In an iteration, each word absorbs label information from other words. More similar two words are, more influence they have on each other. The label information (initially from seed emotion words) will propagate along S. The final output F^* contains ranking scores for all words, and a score indicates how similar the corresponding word is to the seed emotion words.

The implementation of the iterative algorithm is theoretically simple, which only involves basic matrix operation. Compared with methods which do not exploit the relationship between samples, experiments showing advantages of graph-based learning methods can be found in (Rao and Ravichandran, 2009),(Goldberg and Zhu, 2006),(Tong et al. , 2005),(Wan and Xiao, 2009),(Zhu and Ghahramani, 2002) etc. When labeled data are scarce, such graph-based transductive learning methods are especially useful.

3.2 Incorporate multiple resources

For building the emotion lexicons, we are faced with lots of resources, such as semantic dictionaries, labeled or unlabeled corpora, and some linguistic experiences which can be presented as heuristic rules. Naturally we want to use these resources together, thus boosting the final performance. In graph-base setting, such resources can be used to construct the emotion-oriented similarity between words, and similarities will be represented by matrices.

The schemes to fuse similarity matrices are presented in (Sindhwani et al. , 2005), (Zhou and Burges, 2007), (Wan and Xiao, 2009) and (Tong et al. , 2005) etc. In our paper, not aiming at comparing different fusion schemes, we used a linear fusion scheme to fuse different similarities matrices from different resources. The scheme is actually a convex combination of matrices, with weights specified empirically.

The fusion of different similarity matrices falls in the domain of multi-view learning. A well-known multi-view learning method is Co-Training, which uses two views (two resources) to train two interactive classifiers (Blum and Mitchell, 1998). Since we focus on building emotion lexicons using multiple resources (multiple views), those who want to see the advantages of multi-view learning over learning with one view can refer to (Blum and Mitchell, 1998), (Sindhwani et al. , 2005), (Zhou and Burges, 2007), (Wan and Xiao, 2009) and (Tong et al. , 2005) etc.

4 Experiments

We use the method in section 3 to rank for each emotion with a few seed emotion words. Once we implement the ranking algorithm 1, the main work resides in constructing similarity matrices, which are highly domain-dependent.

4.1 Construct similarity matrices

Here, we introduce how to construct four similarity matrices used in building emotion lexicons. Three of them are based on cooccurrence of words; the fourth matrix is from a heuristic rule.

We use ictclas3.0[1] to perform word segmentation and POS tagging.

In our experiments, the number of words involved in ranking is 93506[2], so theoretically, the matrices are 93506 × 93506. If the similarity between any pair of words is considered, the computation becomes impractical in both time and space cost. So we require that each word has at most 500 nearest neighbors.

Four matrices are constructed as follows:

4.1.1 Similarity based on a unlabeled corpus

The unlabeled corpus used is People's Daily[3](人民日报1997∼2004). After word segmentation and POS tagging, we chose three POS's (i,a,l)[4]. The nouns were not included to limit the scale of word space. We set the cooccurrence window to a sentence, and removed the duplicate occurrences of words. Any pair of words in a sentence will contribute a unit weight to the edge which connects the pair of words.

4.1.2 Similarity based on a synonym dictionary

We used the Chinese synonym dictionary (哈工大同义词词林扩展版[5]) for this matrix. In this dictionary, the words in a synonym set are presented in one line and separated by spaces, so there is no need to perform word segmentation and POS tagging. Any pair of words in one line will contribute a unit weight to the edge which connects the pair of words.

4.1.3 Similarity based on a semantic dictionary

We used The Contemporary Chinese Dictionary (现代汉语词典) to construct the third simi-

[1] downloaded from http://www.ictclas.org/

[2] Words are selected after word segmentation and POS tagging, see section 4.1.1∼4.1.3 for selection of words in details.

[3] http://icl.pku.edu.cn/

[4] i=Chinese idiom, a=adjective, l=Chinese phrase

[5] http://ir.hit.edu.cn/

larity matrix. Since word segmentation may segment the entries of the dictionary, we extracted all the entries in the dictionary and store them in a file whose words ictclas3.0 was required not to segment. Furthermore, for an entry in the dictionary, the example sentences or phrases appearing in its gloss may contain many irrelevant words in terms of emotions, so they were removed from the gloss.

After word segmentation and POS tagging[6], we set the cooccurrence window to one line (an entry and its gloss without example sentences or phrases), and removed the duplicate occurrences of words. An entry and any word in the modified gloss will contribute a unit weight to the edge which connects the pair of words. This constructing was a bit different, since we did not consider the similarity between words in modified gloss.

4.1.4 similarity based on a heuristic rule

In Chinese, a word is composed of one or several Chinese characters. A Chinese character is normally by itself an independent semantic unit, so the similarity between two words can be inferred from the character(s) that they share. For example, the Chinese word 欣 (happy) appears in the word 欣然 (readily). Since 欣然 and 欣 share one Chinese character, they are regarded as similar. Naturally, the larger the proportion that two words share, the more similar they are. In this way, the fourth weighted matrix was formed. To avoid incurring noises, we exclude the cases where one Chinese character is shared, with the exception that the Chinese character itself is one of the two Chinese words.

4.1.5 Fusion of four similarity matrices

After processing all the lines (or sentences), the weighted matrices are normalized as in algorithm 1, then four similarity matrices are linearly fused with equal weights (1/4 for each matrix).

4.2 Select seed emotion words

In our experiments, we chose emotions of *happiness, sadness, anger, fear and surprise* which are widely accepted as basic emotions[7]. Empirically, we assigned each emotion with seed words given in Table 1.

Emotion	**Seed words**
喜(happiness)	高兴, 愉快, 欢乐, 喜悦, 兴高采烈, 欢畅, 开心
怒(anger)	愤怒, 不满, 恼火, 生气, 愤恨, 恼怒, 愤懑, 震怒, 悲愤, 窝火, 痛恨, 恨之入骨, 义愤填膺, 怒气冲天
哀(sadness)	悲伤, 沮丧, 痛苦, 伤心, 难过, 悲哀, 难受, 消沉, 灰心丧气, 悲戚, 闷闷不乐, 哀伤, 悲愤, 悲切, 悲痛欲绝, 欲哭无泪
惧(fear)	恐惧, 惧怕, 担心, 提心吊胆, 害怕, 惊恐, 疑惧, 畏惧, 不寒而栗, 望而生畏
惊(surprise)	惊讶, 大吃一惊 ,震惊, 惊恐, 惊异, 惊骇, 惊, 出乎意料, 惊喜, 惊叹

Table 1: Seed emotion words

4.3 Evaluation of our method

We obtained five ranking lists of words using the method in section 3. Following the work of (Riloff and Shepherd, 1997), we adopted the following evaluation setting.

To evaluate the quality of emotion ranking lists, each list was manually rated by two persons independently. For each emotion, we selected the top 200 words of each ranking list and presented them to judges. We presented the words in random order so that the judges had no idea how our system had ranked the words. The judges were asked to rate each word on a scale from 1 to 5 indicating how strongly it was associated with an emotion, 0 indicating no association. We allowed the judges to assign -1 to a word if they did not know what it meant. For the words rated as -1, we manually assigned ratings that we thought were appropriate.

The results of judges are shown in figures 1-5. In these figures, horizontal axes are the number of reviewed words in ranking lists and vertical axes are number of emotion words found (with 5 different strength). The curve labeled as $> x$ means that it counts the number of words which are rated

[6] since we do not segment entries in this dictionary, all POS's are possible

[7] Guidelines for identifying emotions is in section 5, before that, we understand emotions through common sense.

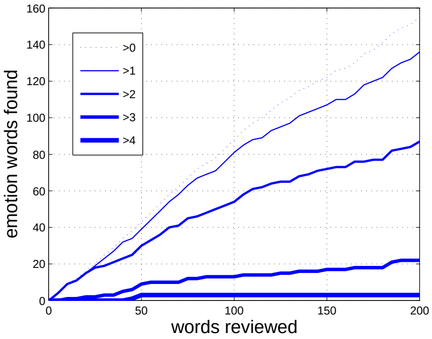

Figure 1: happiness

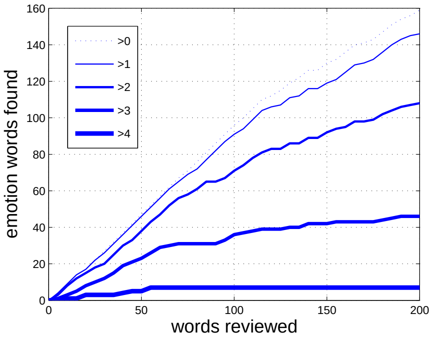

Figure 2: anger

greater than x by either judge.

Curves ($> 0, > 1, > 2$) display positive slopes even at the end of the 200 words, which implies that more emotion words would occur if more than 200 words are reviewed. By comparison, curves ($> 3, > 4$) tend to be flat when they are close to the right side, which means the cost of identifying high-quality emotion words will increase greatly as one checks along the ranking list in descendent order.

It is observed that words which both judges assign 5 are few. In *surprise* emotion, the number is even 0. Such results may reflect that emotion is harder to identify compared with topical categories in (Riloff and Shepherd, 1997).

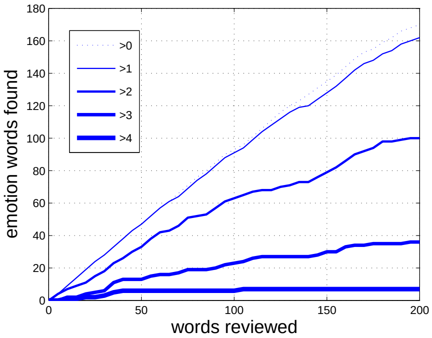

Figure 3: sadness

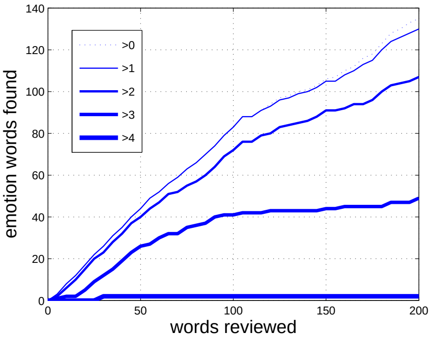

Figure 4: fear

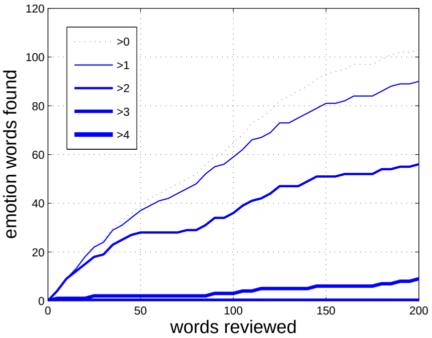

Figure 5: surprise

From the semantic dictionary, our method found many low-frequency emotion words such as 忭 (pleasant, glad), 蘧然 (surprise and happy), 忉怛 (sad), or those used in Chinese dialects such as 毛咕 (fear), 挂气 (angry). Such emotion words are necessary for comprehensive emotion lexicons.

Because more POS's than adjectives and verbs are included in our experiments, some emotion words such as the noun 冷门 (unexpected winner),and the adverb 竟然 (to one's surprise) are also spotted, which to some extent implies the generality of our method.

5 Construct emotion lexicons

The above section introduced a method to rank words with a few seed emotion words. However, to build emotion lexicons requires that we manually remove the noises incurred by the automatic ranking method. Accordingly, guidelines for identifying emotions are needed, and also some linguistic consideration in identifying emoting words should be given.

5.1 An iterative feedback to denoise

In our experiments, we observed that noises incurred by similarity matrices are almost unavoidable. For example, in the unlabeled corpus, 国事访问 (state visits) always co-occurred with 高兴 (happy) or 愉快 (happy), so in happiness emotion, 国事访问 acquired a high ranking position (174th); in terms of the heuristic rule, 意料 (expected) shares two Chinese characters with 出乎意料 (unexpected, surprised), however they have opposite meaning because 出乎 (exceed, beyond) is a negative word. 意料 unfavorably ranked high (88th) in surprise emotion; from the semantic dictionary, the gloss of 年画 (Chinese Spring Festival pictures) contains 欢乐 (happy), thus in happiness emotion, 年画 ranked high (158th).

So after each ranking of an emotion, in the descendent order of ranking scores, we manually revised some scores in about top 500. Several criteria (see 5.2 and 5.3) were given to guide if a word has a specified emotion. For those words surely bearing the specified emotion, we assigned 1 to them ,and left others unchanged. Seeing the words newly revised to be 1 as new seed emotion words, we run the ranking algorithm again. After such feedback was repeated 2∼3 times, we collected all the words labeled with 1 to form the final emotion lexicons. In (Zhou et al. , 2004), the author also suggested such *iterative feedback* to extend the query (seed) set and improve the ranking output. Commonly, the size of an emotion lexicon is small, so we do not have to check too many words.

The human revising procedure is sensitive to annotators' background. To improve the quality of the emotion lexicons, experts with linguistic or psychology background will help.

Furthermore, the ranking algorithm used in our paper is clearly sensitive to the initial seed words, but since we adopt an iterative feedback framework, the words not appearing in the initial set of seed words will show up in next iteration with high ranking scores. We also performed experiments which selected emotion seed words based on the Chinese synonym dictionary and the emotion words in (Chen et al. , 2009), similar results were found.

5.2 Guidelines for identifying emotions

The same as (Chen et al. , 2009), we used the definition that emotion is the felt awareness of bodily reactions to something perceived or thought. Also, we were highly influenced by the structure of the affective lexicon presented by (Ortony et al. , 1987), and used the Affective states and Affective-Behavioral conditions in the structure to identify emotion words in our paper[8].

With such guidelines, 胆小 (cowardice, relates more to external evaluation) is not an emotional word of fear. We also intentionally distinguish between emotions and expression of emotions. For example, 大笑 (laugh), 哈哈 (haw-haw) are seen as expression of happiness and 颤抖 (tremble) as of fear, but not as emotion words. In addition, we try to distinguish between an emotion and the cause of an emotion, see 5.3 for an example.

For each emotion, brief description is given as below[9]:

1. **Happiness**：the emotional reaction to something that is satisfying.
2. **Anger**：do not satisfy the current situation and have a desire to fight or change the situation. Often there exists a target for this emotion.
3. **Sadness**：an emotion characterized by feelings of disadvantage, loss, and helplessness. Sadness often leads to cry.
4. **Fear**：the emotional response to a perceived threat. Fear almost always relates to future events, such as worsening of a situation, or continuation of a situation that is unacceptable.
5. **Surprise**：the emotional reaction to something unexpected.

5.3 Linguistic consideration for identifying emotion words

If a word has multiple senses, we only consider its emotional one(s). For example, 生气 (as a verb, it means *be angry*, but means *vitality or spirits* as a noun) will appear in the emotion lexicon of anger.

[8] According to (Ortony et al. , 1987), *surprise* should not be seen as a basic emotion for it relates more to cognition. However, our paper focuses on the building of emotion lexicons, not the disputable issue of basic emotions

[9] we mainly referred to http://en.wikipedia.org/wiki

If one sense of a word is the combination of emotions, the word will appear in all related emotions.

We mainly consider four POS's, namely nouns, verbs, adjectives and adverb[10]. If a word has multiple POS's, we normally consider its POS with strongest emotion (Empirically, we think the emotion strength ranks in decedent order as following: adjectives, verbs, adverbs, nouns.). So we consider the verb of 恐惧 (fear) when it can be used as a noun and a verb in Chinese. The 生气 example above also applies here.

For each of four POS's, instruction for emotion identification is given as below:

Nouns: For example, 怒火 (rage, anger), 喜气 (joy or jubilation), 冷门 (an unexpected winner) are selected as emotion words. We distinguish between an emotion and the cause of an emotion. For example, calamity often leads to sadness, but does not directly contain the emotion of sadness. 冷门 appears in the surprise lexicon because we believe it contains surprise by itself.

Adverbs: The adverbs selected into emotion lexicons contain the emotions by themselves. For example, 竟然 (unexpectedly), 欣欣然 (cheerily), 气哼哼 (angrily), 蓦地 (unexpectedly), 伤心地 (sadly) etc.

Verbs: As in (Ortony et al. , 1987), Chinese emotion verbs also fall into at least two distinct classes, causatives and noncausatives. Both classes are included in our emotion lexicons. For example, 动肝火 (be angry), 担心 (fear) are noncausative verbs, while 激怒 (enrage), 震惊 (to make someone surprised) are causative ones. Probably due to the abundant usage of 令人/让人/使人 (to make someone) etc., causative emotion verbs are few compared to noncausative ones in Chinese.

Adjective：Quite a lot of emotion words fall in this POS, since adjectives are the natural expression of internal states of humans. For example, 高兴 (happy), 惊讶 (surprised), 愤怒 (angry) etc.

For any word that it is hard to identify at first sight, we used a search tool[11] to retrieve sentences which contain the word, and then identify if the word is emotional or not by its usage in the sentences.

5.4 Comparison with existing Chinese emotion resources

诧、骇、惊、讶、矍、蘧、愕、遽、骇然、赫然、竟然、居然、蘧然、愕然、愕然、矍然、爆冷、爆冷门、不料、不意、不虞、诧异、吃惊、出乎意料、出乎意外、出乎预料、出冷门、出其不意、出人意料、出人意外、触目惊心、错愕、大吃一惊、大惊失色、大惊小怪、怪讶、骇怪、骇然、骇人听闻、骇异、好家伙、赫然、赫然而怒、黑马、惊诧、惊呆、惊服、惊骇、惊慌、惊慌失措、惊惶、惊惶失措、惊魂未定、惊悸、惊惧、惊恐、惊恐万状、惊奇、惊人、惊世骇俗、惊叹、惊悉、惊喜、惊喜交集、惊喜万分、惊吓、惊羡、惊讶、惊疑、惊异、惊厥、惊愕、竟然、竟是、竟至、竟自、居然、冷不丁、冷不防、冷孤丁、冷门、没成想、猛不防、猛孤丁地、纳罕、始料不及、始料未及、受宠若惊、受惊、谁料、谁知、突如其来、未料、闻所未闻、想不到、心惊、心惊胆颤、心惊胆战、讶异、一语惊人、意料之外、意外、意想不到、又惊又喜、震惊、蓦地

Table 2: The emotion lexicon of surprise

Under the guidelines for manually identifying emotion words, we finally constructed five Chinese emotion lexicons using the iterative feedback. The newly constructed emotion lexicons were also reported as resources together with our paper. The emotion lexicon of *surprise* is shown in Table 2. In this part, we compare our lexicons with the following counterparts, see Table 3.

Ours1 in the table is the final emotion lexicons, and Ours2 is the abridged version that excludes the words of single Chinese character and Chinese idioms.

Chinese Concept Dictionary (CCD) is a WordNet-like semantic lexicon(Liu et al. , 2003).

[10] For Chinese idioms, we only considered those used as these four POS's, omitted those used as a statement, such as 哀兵必胜 (an army burning with righteous indignation is bound to win)

[11] provided by Center for Chinese Linguistics of Peking University, http://ccl.pku.edu.cn

	喜	怒	哀	惧	惊
CCD nouns	22	27	38	46	10
(Xu and Tao, 2003)	45	12	28	21	12
(Chen et al. , 2009)	28	34	28	17	11
(Xu et al. , 2008)	609	187	362	182	47
Ours1	95	118	97	106	99
Ours2	52	77	72	57	65

Table 3: Compare various emotion lexicons

We only considered the noun network which is richly developed in CCD, as in other semantic dictionaries. For each emotion, we chose its synset as well as the synsets of its hypernym and hyponym(s). In fact, most of words in the emotion nouns extracted can be used as verbs or adjectives in Chinese. However, since CCD is not designed for emotion analysis, words which are expression of emotions such as 哭泣 (cry) or evaluation such as 胆小 (cowardice) were included.

Selecting nouns and verbs, Xu and Tao (2003) offered an emotion taxonomy of 390 emotion words. The taxonomy contains 24 classes of emotions and excludes Chinese idioms. By our inspection to the offered emotion words in this taxonomy, the authors tried to exclude expression of emotions, evaluation and cause of emotions from emotions, which is similar with our processing[12]. Ours2 is intentionally created to compare with this emotion taxonomy.

Based on (Xu and Tao, 2003), Chen et al. (2009) removed the words of single Chinese character; let two persons to judge if a word is an emotional one and only those agreed by the two persons were seen as emotion words. It is worth noting that Chen et al. (2009) merges 怒 (anger) and 烦 (fidget) in (Xu and Tao, 2003) to form the 怒 (anger) lexicon, thus 讨厌 (dislike) appears in anger lexicon. However, we believe 讨厌 (dislike) is different with 怒 (anger), and should be put into another emotion. Also, we distinguish between 恨 (hate) and 怒 (anger).

Xu et al. (2008) constructed a large-scale affective lexicon ontology. Given the example words in their paper, we found that the authors did not intentionally exclude the expression of emotions such as 面红耳赤 (literally, red face and ear), 笑眯眯 (literally, be smiling). Such criteria of identifying emotion words may partially account for the large size of their emotion resources.

6 Conclusion and future work

In this paper, aiming to build Chinese emotion lexicons, we adopt a graph-based algorithm and incorporate multiple resources to improve the quality of lexicons and save human labor. This is an initial attempt to build Chinese emotion lexicons, the quality of constructed emotion lexicons is far from perfect and is supposed to be improved step by step.

The method in this paper can be further extended to subjectivity/polarity classification and other non-sentimental tasks such as word similarity computing, and can be also adapted to other languages. The more resources we use, the more human cost can be saved and the higher the quality of built emotion lexicons is.

In the future work, we want to construct other emotion lexicons such as 好 (like, love), 恶 (dislike), 欲 (desire) etc. using the same method.

Abstract

Nocuous ambiguity occurs when a linguistic expression is interpreted differently by different readers in a given context. We present an approach to automatically identify nocuous ambiguity that is likely to lead to misunderstandings among readers. Our model is built on a machine learning architecture. It learns from a set of heuristics each of which predicts a factor that may lead a reader to favor a particular interpretation. An ambiguity threshold indicates the extent to which ambiguity can be tolerated in the application domain. Collections of human judgments are used to train heuristics and set ambiguity thresholds, and for evaluation. We report results from applying the methodology to coordination and anaphora ambiguity. Results show that the method can identify nocuous ambiguity in text, and may be widened to cover further types of ambiguity. We discuss approaches to evaluation.

1 Introduction

Traditional accounts of ambiguity have generally assumed that each use of a linguistic expression has a unique intended interpretation in context, and attempted to develop a model to determine it (Nakov and Hearst, 2005; Brill and Resnik, 1994). However, disambiguation is not always appropriate or even desirable (Poesio and Artstein, 2008). Ambiguous text may be interpreted differently by different readers, with no consensus about which reading is the intended one. Attempting to assign a preferred interpretation may therefore be inappropriate. Misunderstandings among readers do occur and may have undesirable consequences. In requirements engineering processes, for example, this results in costly implementation errors (Boyd et al., 2005).

Nonetheless, most text does not lead to significant misinterpretation. Our research aims to establish a model that estimates how likely an ambiguity is to lead to misunderstandings. Our previous work on nocuous ambiguity (Chantree et al., 2006; Willis et al., 2008) cast ambiguity not as a property of a text, but as a property of text in relation to a set of stakeholders. We drew on human judgments - interpretations held by a group of readers of a text – to establish criteria for judging the presence of nocuous ambiguity. An ambiguity is *innocuous* if it is read in the same way by different people, and *nocuous* otherwise. The model was tested on co-ordination ambiguity only.

In this paper, we implement, refine and extend the model. We investigate two typical ambiguity types arising from coordination and anaphora. We extend the previous work (Willis et al., 2008) with additional heuristics, and refine the concept of ambiguity threshold. We experiment with alternative machine learning algorithms to find optimal ways of combining the output of the heuristics. Yang et al. (2010a) describes a complete implementation in a prototype tool running on full text. Here we present our experimental results, to illustrate and evaluate the extended methodology.

The rest of the paper is structured as follows. Section 2 introduces the methodology for automatic detection of nocuous ambiguity. Sections 3 and 4 provide details on how the model is applied to coordination and anaphora ambiguity. Experimental setup and results are reported in Section 5, and discussed in Section 6. Section 7 reports on related work. Conclusions and future work are found in Section 8.

2 Methodology for Nocuous Ambiguity Identification

This section describes the main ideas underpinning our model of ambiguity. We distinguish between structural and interpretative aspects. The former captures the fact that text may have structure (i.e. syntax) which, in principle, permits multiple readings. These are relatively straightforward to identify from the linguistic constructs present in the text. The latter acknowledges that if text is interpreted in the same way by different readers, it has a low risk of being misunderstood. Modelling interpretive aspects requires access to human judgments about texts. Our approach has three elements, which we describe in turn: collection of human judgments; heuristics that model those judgments, and a machine learning component to train the heuristics.

Human judgments. We define an ambiguity as nocuous if it gives rise to diverging interpretations. Wasow et al. (2003) suggests that ambiguity is always a product of the meaning that people assign to language, and thus a subjective phenomenon. We capture individual interpretations of instances of ambiguity by surveying participants, asking them for their interpretation. We use this information to decide whether, given some ambiguity threshold, a particular instance is seen as innocuous or nocuous depending on the degree of dissent between judges.

A key concept in determining when ambiguity is nocuous is the *ambiguity threshold.* Different application areas may need to be more or less tolerant of ambiguity (Poesio and Artstein, 2008). For instance, requirements documents describing safety critical systems should seek to avoid misunderstandings between stakeholders. Other cases, such as cookbooks, could be less sensitive. Willis et al. (2008)'s general concept of ambiguity threshold sought to implement a flexible tolerance level to nocuous ambiguity. Given an instance of ambiguous text, and a set of judgments as to the correct interpretation, the *certainty* of an interpretation is the percentage of readers who assign that interpretation to the text. For example, in Table 1 below (sec. 3.1), the certainty of the two interpretations, HA and LA of expression (a) are 12/17=71% and 1/17=5.9% respectively. Here, an expression shows *nocuous ambiguity* if none of the possible interpretations have a certainty exceeding the chosen threshold. Later in this section, we will describe further experiments with alternative, finer grained approaches to setting and measuring thresholds, that affect the classifier's behaviour.

Heuristics. Heuristics capture factors that may favour specific interpretations. Each heuristic embodies a hypothesis, drawn from the literature, about a linguistic phenomenon signifying a preferred reading. Some use statistical information (e.g., word distribution information obtained from a generic corpus, the BNC [1], using the Sketch Engine[2]). Others flag the presence of surface features in the text, or draw on semantic or world knowledge extracted from linguistic resources like WordNet[3] or VerbNet[4].

Machine learning (ML). Individual heuristics have limited predictive power: their effectiveness lies in their ability to operate in concert. Importantly, the information they encapsulate may be interdependent. We harness this by using ML techniques to combine the outputs of individual heuristics. ML is an established method for recognizing complex patterns automatically, making intelligent decisions based on empirical data, and learning of complex and nonlinear relations between data points. Our model uses supervised learning ML techniques, deducing a function from training data, to classify instances of ambiguity into nocuous or innocuous cases. The classifier training data consists of pairs of input objects (i.e. vectors made up of heuristics scores) and desired outputs (i.e. the class labels determined by the distribution of human judgments as captured by thresholds). To select an appropriate ML algorithm for the nocuity classifier, we tested our datasets (described in later sections) on several algorithms in the WEKA[5] package (e.g., decision tree, J48, Naive Bayes, SVM, Logistic Regression, LogitBoost, etc.)

To train, and validate, a nocuity classifier for a particular form of ambiguity, we build a dataset of judgments, and select heuristics that model

[4] http://verbs.colorado.edu/~mpalmer/projects/verbnet.html

[5] http://www.cs.waikato.ac.nz/~ml/index.html

the information underlying the human judgements about a preferred interpretation.

We validated the approach on two forms of ambiguity. Sections 3 and 4 discuss how the methodology is applied to forms of coordination and anaphoric ambiguity, and evaluate the performance of the final classifiers.

3 Automatic Identification of Nocuous Coordination Ambiguity

Our previous work on nocuous ambiguity has focused on coordination ambiguity: a common kind of structural ambiguity. A coordination structure connects two words, phrases, or clauses together via a coordination conjunction (e.g., '*and*', '*or*', etc) as in the following examples:

(1) *They support a typing system for architectural components and connectors.*

(2) *It might be rejected or flagged for further processing.*

In (1), the coordination construction '*architectural components and connectors*' consists of a **near conjunct** (NC) (i.e. '*components*'), a **far conjunct** (FC) (i.e. '*connectors*'), and the attached **modifier** (M) (i.e. '*architectural*'). This construction allows two bracketings corresponding to high modifier attachment (*[architectural [components and connectors]]*) or low modifier attachement (*[[architectural components] and connector]*). Our aim is to refine Chantree et al (2006) and Willis et al (2008), hence our focus is on the two phenomena they treated: modification in noun phrase coordination (as in (1)) and in verb phrase coordination (as in (2)).

We implemented the heuristics described in the earlier work, and introduced two further ones (local document collocation frequency, and semantic similarity). We used the Chantree et al (2006) dataset of human judgments, but employed the LogitBoost algorithm for implementing the nocuity classifier (rather than the Logistic Regression equation). The following subsections give more detail.

3.1 Building a dataset

Coordination instances. Our dataset was collected and described by Chantree et al. (2006). It contains 138 coordination instances gathered from a set of requirement documents. Noun compound conjunctions account for the majority (85.5%) of cases (118 instances). Nearly half of these arose as a result of noun modifiers, while there are 36 cases with adjective and 18 with preposition modifiers.

Human judgment collection. The coordination instances containing potential ambiguity were presented to a group of 17 computing professionals including academic staff or research students. For each instance, the judges were asked to select one of three options: high modifier attachment (HA), low modifier attachment (LA), or ambiguous (A). Table 1 shows the judgment count for two sample instances. In instance (a) in table 1, the *certainty* of HA is 12/17=71%, and the *certainty* of LA is 1/17=6%. Instance (b) was judged mainly to be ambiguous.

	Judgments		
	HA	LA	A
(a) *security* and *privacy* requirements	12	1	4
(b) electrical *characteristics* and *interface*	4	4	9

Table 1. Judgment count for the sample instances (HA=high attachment; LA=low attachment; and A=Ambiguous)

We set an ambiguity threshold, τ, to determine whether the distribution of interpretations is nocuous or innocuous with respect to that particular τ. If the *certainty* of neither interpretation, HA or LA, exceeds the threshold τ, we say this is an instance of *nocuous* coordination. Otherwise it is *innocuous*. Here, (a) displays nocuous ambiguity for τ>71%.

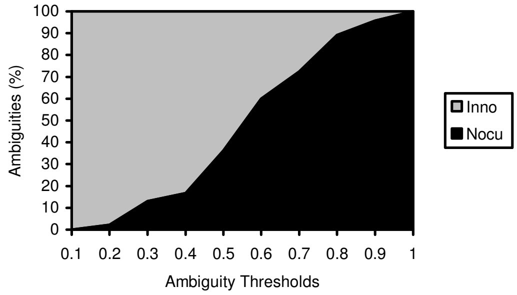

Figure 1. Proportions of interpretations at different ambiguity thresholds in the coordination instances

Figure 1 shows the systematic relationship between ambiguity threshold and the incidence of nocuous ambiguity in the dataset. Low thresholds can be satisfied with a very low certainty scores resulting in few instances being considered nocuous. At high thresholds, almost all instances are classified as nocuous unless the judges report a consensus interpretation.

3.2 Heuristics to predict Nocuity

Each heuristic tests a factor favouring a high or low modifier attachment (HA or LA). We implemented and extended Willis et al. (2008).

Coordination matching favours HA when the head words of near and far conjuncts are frequently found coordinated in a general corpus like BNC, suggesting they may form a single syntactic unit.

Distribution similarity measures how often two words are found in the same contexts. It favours HA where it detects a strong distributional similarity between the headwords of the two conjuncts, suggesting these form a syntactic unit (Kilgariff 2003).

Collocation frequency favours LA when the modifier is collocated much more frequently with the headword of the near conjunct than the far conjunct, in the document, or in the BNC.

Morphology favours HA when the conjunct headwords share a morphological marker (suffix) (Okumura and Muraki 1994).

Semantic similarity favours HA when the conjunct headwords display strong similarity in the taxonomic structure in WordNet[6].

3.3 Nocuity classification

To train, and test, the nocuity classifier, each ambiguity training/test instance is represented as an attribute-value vector, with the values set to the score of a particular heuristic. The class label of each instance (nocuous (Y) or innocuous (N) at a given ambiguity threshold) is determined by the *certainty* measure as discussed earlier. We selected the LogitBoost algorithm for building the classifier, because it outperformed other candidates on our training data than. To determine whether a test instance displays nocuity or not, we presented its feature vector to the classifier, and obtained a predicted class label (Y or N).

4 Automatic Identification of Nocuous Anaphora Ambiguity

An **anaphor** is an expression referring to an **antecedent**, usually a noun phrase (NP) found in the preceding text. A*naphora ambiguity* occurs when there are two or more candidate antecedents, as in example (3).

(3) *The procedure shall convert the 24 bit image to an 8 bit image, then display* ***it*** *in a dynamic window.*

In this case, both of the NPs, '*the 24 bit image*' and '*an 8 bit image*', are considered potential candidate antecedents of the anaphor '*it*'.

Anaphora ambiguity is difficult to handle due to contextual effects spread over several sentences. Our goal is to determine whether a case of anaphora ambiguity is nocuous or innocuous, automatically, by using our methodology.

4.1 The building of the Dataset

Anaphora instances. We collected 200 anaphora instances from requirements documents from RE@UTS website[7]. We are specifically concerned with 3rd person pronouns, which are widespread in requirements texts. The dataset contains different pronoun types. Nearly half the cases (48%) involve subject pronouns, although pronouns also occurred in objective and possessive positions (15% and 33%, respectively). Pronouns in prepositional phrases (e.g., '*under it')* are rarer (4% - only 8 instances).

Human judgment collection. The instances were presented to a group of 38 computing professionals (academic staff, research students, software developers). For each instance, the judges were asked to select the antecedent from the list of NP candidates. Each instance was judged by at least 13 people. Table 2 shows an example of judgment counts, where 12 out of 13 judges committed to '*supervisors*' as the antecedent of *'they'*, whereas 1 chose '*tasks*'.

1. Supervisors may only modify tasks **they** supervise to the agents they supervise.		
	Response Percent	Response Count
(a) supervisors	92.3%	12
(b) tasks	7.7%	1

Table 2. Judgment count for an anaphora ambiguity instance.

Ambiguity threshold. Given an anaphor, the interpretation *certainty* of a particular NP candidate is calculated as the percentage of the judgments for this NP against the total judgments for the instance. For example, consider the example in Table 2. The certainty of the NP '*supervisors*'

[6] Implemented by the NLP tool - Java WordNet Similarity Library. http://nlp.shef.ac.uk/result/software.html

[7] http://research.it.uts.edu.au/re/

is 12/13=92.3% and the certainty of the NP '*tasks*' is 1/13=7.7%. Thus, at an ambiguity threshold of, for instance, *τ* = 0.8, the ambiguity in Table 2 is *innocuous* because the agreement between the judges exceeds the threshold.

Figure 2 shows the relationship between ambiguity threshold and occurrence of nocuous ambiguity. As in Figure 1, the number of nocuous ambiguities increases with threshold τ. For high thresholds (e.g., τ≥0.9), more than 60% of instances are classified as nocuous. Below threshold (τ≤0.4), fewer than 8 cases are judged nocuous. Also, comparing Figures 1 and 2 would appear to suggest that, in technical documents, anaphora ambiguity is less likely to lead to misunderstandings than coordination.

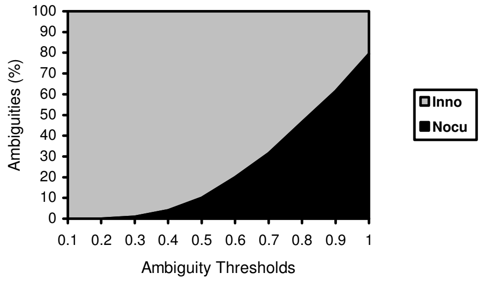

Figure 2. Proportions of interpretations at different ambiguity thresholds in the anaphora instances.

4.2 Antecedent Preference Heuristics

Drawing on the literature on anaphoric reference, we developed 12 heuristics of three types: related to *linguistic properties* of text components, to *context and discourse* information, or to *statistical* information drawn from standard corpora. Yang et al. (2010b) gives more detail. A heuristic marks candidate antecedents which it favours, or disfavours. For instance, heuristics favour definite NPs as antecedents, candidate NPs which agree in number and syntactic role with the anaphor, and those which share a syntactic collocation pattern in the text. They also favour those which respect the semantic constraints (e.g., animacy) propagated from subcategorisation information, and reward proximity to the anaphor. They disfavour candidate antecedents that occur in prepositional phrases, and those occupying a syntactic role distinct from the anaphor. Note: not all NPs are marked by all heuristics, and some heuristics are interdependent.

4.3 Nocuous Ambiguity Identification

Unlike coordination ambiguity, where judges chose for high or low modifier attachment, anaphora have scope over a variable set of potential antecedents, depending on each particular instance. To accommodate this, we developed an *antecedent* classifier which assigns a weighted antecedent tag to each NP candidate associated with an instance. Tag information is used subsequently to predict the whether the instance displays nocuous ambiguity.

The antecedent classifier is built using the Naive Bayes algorithm within the WEKA package and is trained to return three classes of candidate antecedent: *positive (Y)*, *questionable (Q)*, or *negative (N)*. In an *innocuous* case, a candidate NP will be classed as *Y* if its interpretation certainty exceeds the threshold set by τ, and tagged as *N* otherwise; in a *nocuous* case, it will be classed as *N* if its certainty is 0%, and classified as *Q* otherwise.

1. The LPS operational scenarios represent sequences of activities performed by operations personnel as **they** relate to the LPS software.		
	Response	Label
(a) the LPS operational scenarios	33.3%	Q
(b) sequences of activities	66.7%	Q
(c) activities	0%	N
(d) operations personnel	0%	N

Table 3. The determination of antecedent label for the NP candidates in a NOCUOUS ambiguity case (τ =0.8)

2. Testing performed to demonstrate to the acquirer that a CSCI system meets **its** specified requirements.		
	Response Percent	Class Label
(a) Testing	0%	N
(b) the acquirer	16.7%	N
(c) a CSCI system	83.3%	Y

Table 4. The determination of antecedent label for the NP candidates in a INNOCUOUS ambiguity case (τ =0.8)

	Antecedent Class Label		
	Y	Q	N
τ = 0.5	181	54	623
τ = 0.6	160	99	599
τ = 0.7	137	149	572
τ = 0.8	107	209	542
τ = 0.9	77	261	520
τ = 1.0	41	314	503

Table 5. The distribution of three antecedent class label at different ambiguity thresholds

Table 3 and 4 illustrate antecedent labels for NP antecedent candidates in a nocuous and innocuous case. Candidates (a) and (b) in Table 3 are labeled Q because their certainty falls below the threshold (τ = 0.8). For the same threshold, candidate (c) in Table 4 is tagged as *Y*. Table 5 shows the distribution of tags at certainty thresholds $\tau \geq 0.5$ for all (858) candidate antecedents in our sample.

Our intended application is a system to alert experts to risk of misunderstandings. This suggests we should emphasise recall even at the expense of some precision (Berry et al. 2003). We developed two versions of the algorithm that determines whether an instance is nocuous or not, depending on the contribution made by its antecedent candidates tagged *Y*. We relax constraints by introducing two concepts: a weak positive threshold W_Y and a weak negative threshold W_N set at 0.5 and 0.4, respectively[8]. The rationale for weak thresholds is that antecedent preference reflects a spectrum with *Y* (high), *Q* (medium), and *N* (low). Weak positive and negative thresholds act as buffers to the *Q* area. Antecedent NPs that fall in the W_Y or W_N buffer area are treated as possible false negative (FN) for the classification of the label *Q*. An antecedent tag *Y*/*N* is labeled as weak positive or negative depending on these thresholds. The algorithm for identifying nocuous ambiguity is given in Figure 3. It treats as innocuous those cases where the antecedent label list contains one clear *Y* candidate, whose certainty exceeds all others by a margin.

Given an anaphora ambiguity instance with multiple potential NPs, the antecedent classifier returns a label list, $R = \{r_1, r_2, \ldots, r_n\}$, for individual NPs.

Parameters:

1) W_Y - the threshold for the *weak positive* label. The label *Y* is viewed as *weak positive* when the positive prediction score $r_i < W_Y$

2) W_N - the threshold for the *weak negative* label. The label *N* is viewed as *weak negative* when the negative prediction score $r_i < W_N$

Procedure:

```
if the label list R contains
        (one Y, no Q, one or more N )
   or
        (no Y, one Q, one or more N but not weak negative )
   or
       (one Y but not weak positive, any number of Q or N)
then
        the ambiguity is INNOCUOUS
else
        the ambiguity is NOCUOUS
```

Figure 3. The algorithm for nocuous ambiguity identification

5 Experiments and Results

In all experiments, the performance was evaluated using 5-fold cross-validation, using standard measures of Precision (P), Recall (R), F-measure (F), and Accuracy. We use two naive baselines: BL-1 assumes that all ambiguity instances are *innocuous*; BL-2 assumes that they are all *nocuous*. For fair comparison against the baselines, for both forms of ambiguity, we only report the performance of our ML-based models when the incidence of nocuous ambiguities falls between 10% ~ 90% of the set (see Figures 1 and 2). We first report our findings for the identification of nocuous coordination ambiguities and then discuss the effectiveness of our model in distinguishing possible nocuous ambiguities from a set of ambiguity instances.

5.1 Nocuous Coordination Ambiguity Identification

Willis et al (2008) demonstrated the ability of their approach to adapt to different thresholds by plotting results against the two naïve base lines. Since we extended and refined their approach described we plot our experimental results (CM-1), for comparison, using the same measures, against their evaluation data (CM-2), in Figure 4.

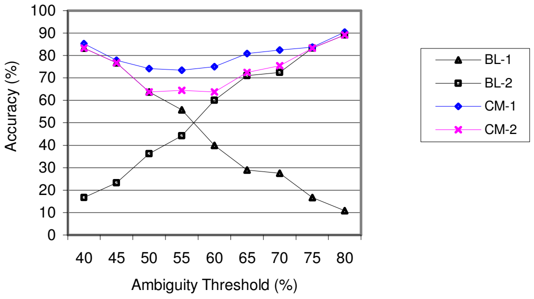

Figure 4. The performance comparison of the ML-based models, CM-1 and CM-2, to the two baseline models, BL-1 and BL-2, in nocuous coordination ambiguity identification.

Our CM-1 model performed well with an accuracy of above 75% on average at all ambiguity threshold levels. As expected, at very high and very low thresholds, we did not improve on the naive baselines (which have perfect recall and hence high accuracy). The CM-1 model displayed its advantage when the ambiguity threshold fell in the range between 0.45 and 0.75 (a significantly wider range than reported for CM-2 Willis et al (2008)). CM-1 maximum improvement was achieved around the 58% crossover point where the two naïve baselines intersect and our model achieved around 21% increased accu-

[8] Weak positive and negative thresholds are set experimentally.

racy. This suggests that the combined heuristics do have strong capability of distinguishing nocuous from innocuous ambiguity at the weakest region of the baseline models.

Figure 4 also shows that, the CM-1 model benefitted from the extended heuristics and the LogitBoost algorithm with an increased accuracy of around 5.54% on average compared with CM-2. This suggests that local context information and semantic relationships between coordinating conjuncts provide useful clues for the identification of nocuous ambiguity. Furthermore, the LogitBoost algorithm is more suitable for dealing with a numeric-attribute feature vector than the previous Logistic Regression algorithm.

5.2 Nocuous Anaphora Ambiguity Identification

We report on two implementations: one with weak thresholds (AM-1) and one without (AM-2). We compare both approaches using the baselines, BL-1 and BL-2 (in Figure 5). It shows that AM-1 and AM-2 achieve consistent improvements on baseline accuracy at high thresholds (τ≥0.75). Here also, the improvement maximises around the 83% threshold point where the two baselines intersect. However, the ML-based models perform worse than BL-1 at the lower thresholds (0.5≤τ≤0.7). One possible explanation is that, at low thresholds, performance is affected by lack of data for training of the *Q* class label, an important indicator for nocuous ambiguity (see Table 5). This is also consistent with the ML models performing well at higher thresholds, when enough nocuous instances are available for training.

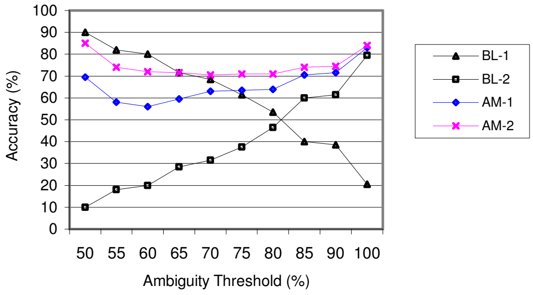

Figure 5. The performance comparison of the ML-based models, AM-1 and AM-2, to the two baseline models, BL-1 and BL-2, in nocuous anaphora ambiguity identification.

Figure 5 further shows that the model with weak thresholds (AM-1) did not perform as well as the model without weak thresholds (AM-2) on accuracy. Although both models perform much better than the baselines on precision (more experimental results are reported in Yang et al. (2010b)), the actual precisions for both models are relatively low, ranging from 0.3 ~ 0.6 at different thresholds. When the AM-1 model attempts to discover more nocuous instances using weak thresholds, it also introduces more false positives (innocuous instances incorrectly classed as nocuous). The side-effect of introducing false positives for AM-1 is to lower accuracy. However, the AM-1 model outperforms both AM-2 and BL-2 models on F-measure (Figure 6), with an average increase of 5.2 and 3.4 percentage points respectively. This reveals that relaxing sensitivity to the ambiguity threshold helps catch more instances of nocuous anaphora ambiguity.

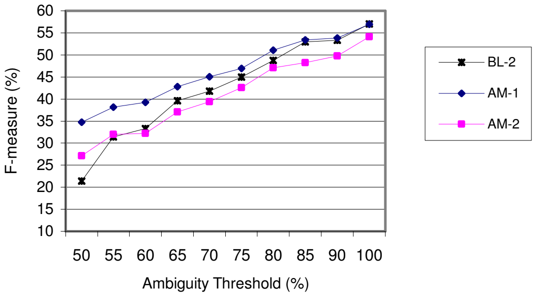

Figure 6. The performance comparison of the ML-based models, AM-1 and AM-2, to the baseline model BL-2 (naïve nocuous)

6 Discussions

We presented judges with sentences containing ambiguities without any surrounding context, even though contextual information (e.g., discourse focus) clearly contributes to interpretation. This is a weakness in our data collection technique. Besides contextual information, van Deemter's Principle of Idiosyncratic Interpretation (1998) suggests that some factors, including the reader's degree of language competence, can affect perceptions of ambiguity. Similarly, familiarity with a domain, including tacit specialist information (Polanyi, 1966), and the extent to which this is shared by a group, will have an effect on the extent to which stakeholders arrive at diverging interpretations.

In our case, we extracted instances from requirements documents covering several technical domains. Judgements are sensitive to the backgrounds of the participants, and the extent to which stakeholder groups share such a background. Also, we used several large, generic NL resources, including the BNC and WordNet. The performance of several heuristics would change if they drew on domain specific resources. Different interpretations may be compatible, and so not necessarily contribute to misunderstanding.

Finally, we used different machine learning algorithms to tackle different types of ambiguity instances: LogitBoost for coordination ambiguity and Naive Bayes for anaphora ambiguity. The main reason is that coordination heuristics returned numeric values, whereas the anaphora heuristics were Boolean. Our method assumes tailoring of the ML algorithm to the choice of heuristic. These limitations indicate that the methodology has a high degree of flexibility, but also that it has several interdependent components and background assumptions that have to be managed if an application is to be developed.

7 Related Work

Many researchers have remarked on the fact that some ambiguities are more likely than others to lead to misunderstandings, and suggested classifying them accordingly. Poesio (1996) discussed cases where multiple readings are intended to coexist, and distinguished between language inherent and human disambiguation factors from a philosophical perspective. His notion of '*perceived ambiguity*' suggests that human perceptions are what actually cause an ambiguity to be misunderstood. Van Deemter's (2004) '*vicious ambiguity*' refers to an ambiguity that has no single, strongly preferred interpretation. He proposed quantifying 'viciousness' using probabilities taken from corpus data. Van Rooy (2004) defined a notion of '*true ambiguity*': a sentence is truly ambiguous only if there are at least two interpretations that are optimally relevant. These last two approaches rely on probability analysis of language usage, and not directly on human perception, which we believe to be the key to evaluating ambiguity. Our work differs in that it takes into account the distribution of interpretations arrived at by a group of human judges engaged with a text. Our model treats ambiguity not as a property of a linguistic construct or a text, or a relation between a text and the perceptions of a single reader, but seeks to understand the mechanisms that lead to misunderstandings between people in a group or process.

Poesio *et al* (2006) have pointed out that disambiguation is not always necessary; for instance, in some complex anaphora cases, the final interpretation may not be fully specified, but only 'good enough'. Our work does not attempt disambiguation. It seeks to highlight the risk of multiple interpretations (whatever those are).

8 Conclusions and Future Work

We have presented a general methodology for automatically identifying nocuous ambiguity (i.e. cases of ambiguity where there is a risk that people will hold different interpretations) relative to some tolerance level set for such a risk. The methodology has been implemented in a ML based architecture, which combines a number of heuristics each highlighting factors which may affect how humans interpret ambiguous constructs. We have validated the methodology by identifying instances of nocuous ambiguity in coordination and anaphoric constructs. Human judgments were collected in a dataset used for training the ML algorithm and evaluation. Results are encouraging, showing an improvement of approximately 21% on accuracy for coordination ambiguity and about 3.4% on F-measure for anaphora ambiguity compared with naive baselines at different ambiguity threshold levels. We showed, by comparison with results reported in Willis et al (2008) that the methodology can be fine tuned, and extended to other ambiguity types, by including different heuristics.

Our method can highlight the risk of different interpretations arising: this is not a task a single human could perform, as readers typically have access only to their own interpretation and are not routinely aware that others hold a different one. Nonetheless, our approach has limitations, particularly around data collection, and for anaphora ambiguity at low thresholds. We envisage further work on the implementation of ambiguity tolerance thresholds

Several interesting issues remain to be investigated to improve our system's performance and validate its use in practice. We need to explore how to include different and complex ambiguity types (e.g., PP attachment and quantifier scoping), and investigate whether these are equally amenable to a heuristics based approach.

Abstract

In this paper we investigate the challenges of applying statistical machine translation to meeting conversations, with a particular view towards analyzing the importance of modeling contextual factors such as the larger discourse context and topic/domain information on translation performance. We describe the collection of a small corpus of parallel meeting data, the development of a statistical machine translation system in the absence of genre-matched training data, and we present a quantitative analysis of translation errors resulting from the lack of contextual modeling inherent in standard statistical machine translation systems. Finally, we demonstrate how the largest source of translation errors (lack of topic/domain knowledge) can be addressed by applying document-level, *unsupervised* word sense disambiguation, resulting in performance improvements over the baseline system.

1 Introduction

Although statistical machine translation (SMT) has made great progress over the last decade, most SMT research has focused on the translation of structured input data, such as newswire text or parliamentary proceedings. Spoken language translation has mostly concentrated on two-person dialogues, such as travel expressions or patient-provider interactions in the medical domain. Recently, more advanced spoken-language data has been addressed, such as speeches (Stüker et al., 2007), lectures (Waibel and Fügen, 2008), and broadcast conversations (Zheng et al., 2008). Problems for machine translation in these genres include the nature of spontaneous speech input (e.g. disfluencies, incomplete sentences, etc.) and the lack of high-quality training data. Data that match the desired type of spoken-language interaction in topic, domain, and, most importantly, in style, can only be obtained by transcribing and translating conversations, which is a costly and time-consuming process. Finally, many spoken-language interactions, especially those involving more than two speakers, rely heavily on the participants' shared contextual knowledge about the domain and topic of the discourse, relationships between speakers, objects in the real-world environment, past interactions, etc. These are typically not modelled in standard SMT systems.

The problem of speech disfluencies has been addressed by disfluency removal techniques that are applied prior to translation (Rao et al., 2007; Wang et al., 2010). Training data sparsity has been addressed by adding data from out-of-domain resources (e.g. (Matusov et al., 2004; Hildebrandt et al., 2005; Wu et al., 2008)), exploiting comparable rather than parallel corpora (Munteanu and Marcu, 2005), or paraphrasing techniques (Callison-Burch et al., 2006). The lack of contextual modeling, by contrast, has so far not been investigated in depth, although it is a generally recognized problem in machine translation. Early attempts at modeling contextual information in machine translation include (Mima et al., 1998), where information about the role, rank and gender of speakers and listeners was utilized in a transfer-based spoken-language translation system for travel dialogs. In (Kumar et al., 2008)

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 1227–1235,
Beijing, August 2010

statistically predicted dialog acts were used in a phrase-based SMT system for three different dialog tasks and were shown to improve performance. Recently, contextual source-language features have been incorporated into translation models to predict translation phrases for traveling domain tasks (Stroppa et al., 2007; Haque et al., 2009). However, we are not aware of any work addressing contextual modeling for statistical translation of spoken meeting-style interactions, not least due to the lack of a relevant corpus.

The first goal of this study is to provide a quantitative analysis of the impact of the lack of contextual modeling on translation performance. To this end we have collected a small corpus of parallel multi-party meeting data. A baseline SMT system was trained for this corpus from freely available data resources, and contextual translation errors were manually analyzed with respect to the type of knowledge sources required to resolve them. Our analysis shows that the largest error category consists of word sense disambiguation errors resulting from a lack of topic/domain modeling. In the second part of this study we therefore present a statistical way of incorporating such knowledge by using a graph-based unsupervised word sense disambiguation algorithm at a *global* (i.e. document) level. Our evaluation on real-world meeting data shows that this technique improves the translation performance slightly but consistently with respect to position-independent word error rate (PER).

2 Data

2.1 Parallel Conversational Data

For our investigations we used a subset of the AMI corpus (McCowan, 2005), which is a collection of multi-party meetings consisting of approximately 100 hours of multimodal data (audio and video recordings, slide images, data captured from digital whiteboards, etc.) with a variety of existing annotations (audio transcriptions, topic segmentations, summaries, etc.). Meetings were recorded in English and fall into two broad types: scenario meetings, where participants were asked to act out roles in a pre-defined scenario, and non-scenario meetings where participants were not restricted by role assignments. In the first case, the scenario was a project meeting about the development of a new TV remote control; participant roles were project manager, industrial designer, marketing expert, etc. The non-scenario meetings are about the move of an academic lab to a new location on campus. The number of participants is four. For our study we selected 10 meetings (5 scenario meetings and 5 non-scenario meetings) and had their audio transcriptions translated into German (our chosen target language) by two native speakers each. Translators were able to simultaneously read the audio transcription of the meeting, view the video, and listen to the audio, when creating the translation. The translation guidelines were designed to obtain translations that match the source text as closely as possible in terms of style – for example, translators were asked to maintain the same level of colloquial as opposed to formal language, and to generally ensure that the translation was pragmatically adequate. Obvious errors in the source text (e.g. errors made by non-native English speakers among the meeting participants) were not rendered by equivalent errors in the German translation but were corrected prior to translation. The final translations were reviewed for accuracy and the data were filtered semi-automatically by eliminating incomplete sentences, false starts, fillers, repetitions, etc. Although these would certainly pose problems in a real-world application of spoken language translation, the goal of this study is not to analyze the impact of speech-specific phenomena on translation performance (which, as discussed in Section 1, has been addressed before) but to assess the impact of contextual information such as discourse and knowledge of the real-world surroundings. Finally, single-word utterances such as *yeah, oh, no, sure*, etc. were downsampled since they are trivial to translate and were very frequent in the corpus; their inclusion would therefore bias the development and tuning of the MT system towards these short utterances at the expense of longer, more informative utterances.

Table 1 shows the word counts of the translated meetings after the preprocessing steps described above. As an indicator of inter-translator

TS3005a	S	245	2339	28.1

Table 1: Sizes and symmetric BLEU scores for translated meetings from the AMI corpus (S = scenario meeting, NS = non-scenario meeting).

agreement we computed the symmetric BLEU (S-BLEU) scores on the reference translations (i.e. using one translation as the reference and the other as the hypothesis, then switching them and averaging the results). As we can see, scores are fairly low overall, indicating large variation in the translations. This is due to (a) the nature of conversational speech, and (b) the linguistic properties of the target language. Conversational data contain a fair amount of colloquialisms, referential expressions, etc. that can be translated in a variety of ways. Additionally, German as the target language permits many variations in word order that convey slight differences in emphasis, which is turn is dependent on the translators' interpretation of the source sentence. German also has rich inflectional morphology that varies along with the choice of words and word order (e.g. verbal morphology depends on which subject is chosen).

2.2 SMT System Training Data

Since transcription and translation of multi-party spoken conversations is extremely time-consuming and costly, it is unlikely that parallel conversational data will ever be produced on a sufficiently large scale for a variety of different meeting types, topics, and target languages. In order to mimic this situation we trained an initial English-German SMT system on freely available out-of-domain data resources. We considered the following parallel corpora: news text (de-news[1], 1.5M words), EU parliamentary proceedings (Europarl (Koehn, 2005), 24M words) and EU legal documents (JRC Acquis[2], 35M words), as well as two generic English-German machine-readable dictionaries[3],[4] (672k and 140k entries, respectively).

3 Translation Systems

We trained a standard statistical phrase-based English-German translation system from the resources described above using Moses (Hoang and Koehn, 2008). Individual language models were trained for each data source and were then linearly interpolated with weights optimized on the development set. Similarly, individual phrase tables were trained and were then combined into a single table. Binary indicator features were added for each phrase pair, indicating which data source it was extracted from. Duplicated phrase pairs were merged into a single entry by averaging their scores (geometric mean) over all duplicated entries. The weights for binary indicator features were optimized along with all other standard features on the development set. Our previous experience showed that this method worked better than the two built-in features in Moses for handling multiple translation tables. We found that the JRC corpus obtained very small weights; it was therefore omitted from further system development. Table 2 reports results from six different systems: the first (System 1) is a system that only uses the parallel corpora but not the external dictionaries listed in Section 2.2. System 2 additionally uses the external dictionaries. All systems use two meetings (IB4002 and IS1008b) as a development set for tuning model parameters and five meetings for testing (IB4003-5,IS1008c,TS3005a). For comparison we also trained a version of the system where a small in-domain data set (meetings ES2008a, IB4001, and IS1008a) was added to the training data (System 3). Finally, we also compared our performance against Google Translate, which is a state-of-the-art statistical MT system with unconstrained ac-

System 5	System 4 + web data	1.2	12.8	26.0	45.9	2.5	15.8	22.1	48.1
System 6	Google Translate	–	–	25.1	49.1	–	–	23.7	50.8

Table 2: System performance using out-of-domain (OOD) parallel data only vs. combination with a small amount of in-domain (ID) data and generic dictionaries. For each of the development (DEV) and evaluation (Eval) set, the table displays the percentages of unknown word types (OOV) for English (EN) and German (DE), as well as the translation scores of BLEU (%) and PER.

cess to the web as training data (System 6). As expected, translation performance is fairly poor compared to the performance generally obtained on more structured genres. The use of external dictionaries helps primarily in reducing PER scores while BLEU scores are only improved noticeably by adding in-domain data. System 6 shows a more even performance across dev and eval sets than our trained system, which may reflect some degree of overtuning of our systems to the relatively small development set (about 7K words). However, the PER scores of System 6 are significantly worse compared to our in-house systems.

In order to assess the impact of adding web data specifically collected to match our meeting corpus we queried a web portal[5] that searches a range of English-German bilingual web resources and returns parallel text in response to queries in either English or German. As queries we used English phrases from our development and evaluation sets that (a) did not already have phrasal translations in our phrase tables, (b) had a minimum length of four words, and (c) occurred at least twice in the test data. In those cases where the search engine returned results with an exact match on the English side, we word-aligned the resulting parallel text (about 600k words) by training the word alignment together with the news text corpus. We then extracted new phrase pairs (about 3k) from the aligned data. The phrasal scores assigned to the new phrase pairs were set to 1; the lexical scores were computed from a word lexicon trained over both the baseline data resources and the parallel web data. However, results (Row 5 in Table 2) show that performance hardly improved, indicating the difficulty in finding matching data sources for conversational speech.

Table 2 also shows the impact of different data resources on the percentages of unknown word types (OOV) for both the source and target languages. The use of external dictionaries gave the largest reduction of OOV rates (System 1 vs. System 2 and System 3 vs. System 4), followed by the use of in-domain data (System 1 vs. System 3 and System 2 vs. System 4). Since they were retrieved by multi-word query phrases, adding the web data did not lead to significant reduction on the OOV rates (System 4 vs. System 5).

Finally, we also explored a hierarchical phrase-based system as an alternative baseline system. The system was trained using the Joshua toolkit (Li et al., 2009) with the same word alignments and language models as were used in the standard phrase-based baseline system (System 4). After extracting the phrasal (rule) tables for each data source, they were combined into a single phrasal (rule) table using the same combination approach as for the basic phrase-based system. However, the translation results (BLEU/PER of 24.0/46.6 (dev) and 20.8/47.6 (eval), respectively) did not show any improvement over the basic phrase-based system.

4 Analysis of Baseline Translations: Effect of Contextual Information

The output from System 5 was analyzed manually in order to assess the importance of modeling contextual information. Our goal was not to determine how translation of meeting style data can be improved in general – better translations could certainly be generated by better syntactic modeling, addressing morphological variation in German, and generally improving phrasal coverage, in particular for sentences involving colloquial expressions. However, these are fairly general problems of SMT that have been studied previously. Instead, our goal was to determine the relative importance of modeling different contextual factors, such as discourse-level information or knowledge of the real-world environment, which have not been studied extensively.

We considered three types of contextual information: discourse coherence information (in particular anaphoric relations), knowledge of the topic or domain, and real-world/multimodal information. Anaphoric relations affect the translation of referring expressions in cases where the source and target languages make different grammatical distinctions. For example, German makes more morphological distinctions in noun phrases than English. In order to correctly translate an expression like "the red one" the grammatical features of the target language expression for the referent need to be known. This is only possible if a sufficiently large context is taken into account during translation and if the reference is resolved correctly. Knowledge of the topic or domain is relevant for correctly translating content words and is closely related to the problem of word sense disambiguation. In our current setup, topic/domain knowledge could be particularly helpful because in-domain training data is lacking and many word translations are obtained from generic dictionaries that do not assign probabilities to competing translations. Finally, knowledge of the real-world environment, such as objects in the room, other speakers present, etc. determines translation choices. If a speaker utters the expression "that one" while pointing to an object, the correct translation might depend on the grammatical features of the linguistic expression for that object; e.g. in German, the translation could be "die da", "der da" or "das da". Since the participants in our meeting corpus use slides and supporting documents we expect to see some effect of such exophoric references to external objects.

Error type	% (dev)	% (eval)
Word sense	64.5	68.2
Exophora (addressee)	24.3	23.4
Anaphora	10.2	7.8
Exophora (other)	1.0	0.6

Table 3: Relative frequency of different error types involving contextual knowledge. The total number of errors is 715, for 315 sentences.

In order to quantify the influence of contextual information we manually analyzed the 1-best output of System 5, identified those translation errors that require knowledge of the topic/domain, larger discourse, or external environment for their resolution, classified them into different categories, and computed their relative frequencies. We then corrected these errors in the translation output to match at least one of the human references, in order to assess the maximum possible improvement in standard performance scores that could be obtained from contextual modeling. The results are shown in Tables 3 and 4. We observe that out of all errors that can be related to the lack of contextual knowledge, word sense confusions are by far the most frequent. A smaller percentage of errors is caused by anaphoric expressions. Contrary to our expectations, we did not find a strong impact of exophoric references; however, there is one crucial exception where real-world knowledge does play an important role. This is the correct translation of the addressee *you*. In English, this form is used for the second person singular, second person plural, and the generic interpretation (as in "one", or "people"). German has three distinct forms for these cases and, additionally, formal and informal versions of the second-person pronouns. The required formal/informal pronouns can only be determined by prior knowledge of the relationships among the meeting participants. However, the singular-plural-generic distinction can potentially be resolved by multimodal informa-

	Original		Corrected	
	BLEU (%)	PER	BLEU (%)	PER
dev	26.0	45.9	27.5	44.0
eval	22.1	48.1	23.3	46.0

Table 4: Scores obtained by correcting errors due to lack of contextual knowledge.

tion such as gaze, head turns, body movements, or hand gestures of the current speaker. Since these errors affect mostly single words as opposed to larger phrases, the impact of the corrections on BLEU/PER scores is not large. However, for practical applications (e.g. information extraction or human browsing of meeting translations) the correct translation of content words and referring expressions would be very important. In the remainder of the paper we therefore describe initial experiments designed to address the most important source of contextual errors, viz. word sense confusions.

5 Resolving Word Sense Disambiguation Errors

The problem of word sense disambiguation (WSD) in MT has received a fair amount of attention before. Initial experiments designed at integrating a WSD component into an MT system (Carpuat and Wu, 2005) did not meet with success; however, WSD was subsequently demonstrated to be successful in data-matched conditions (Carpuat and Wu, 2007; Chan et al., 2007). The approach pursued by these latter approaches is to train a supervised word sense classifier on different phrase translation options provided by the phrase table of an initial baseline system (i.e. the task is to separate different phrase senses rather than word senses). The input features to the classifier consist of word features obtained from the immediate context of the phrase in questions, i.e. from the same sentence or from the two or three preceding sentences. The classifier is usually trained only for those phrases that are sufficiently frequent in the training data.

By contrast, our problem is quite different. First, many of the translation errors caused by choosing the wrong word sense relate to words obtained from an external dictionary that do not occur in the parallel training data; there is also little in-domain training data available in general. For these reasons, training a supervised WSD module is not an option without collecting additional data. Second, the relevant information for resolving a word sense distinction is often not located in the immediately surrounding context but it is either at a more distant location in the discourse, or it is part of the participants' background knowledge. For example, in many meetings the opening remarks refer to slides and an overhead projector. It is likely that subsequent mentioning of *slide* later on during the conversation also refer to overhead slides (rather than e.g. *slide* in the sense of “playground equipment”), though the contextual features that could be used to identify this word sense are not located in the immediately preceding sentences. Thus, in contrast to supervised, local phrase sense disambiguation employed in previous work, we propose to utilize unsupervised, *global* word sense disambiguation, in order to obtain better modeling of the topic and domain knowledge that is implicitly present in meeting conversations.

5.1 Unsupervised Word Sense Disambiguation

Unsupervised WSD algorithms have been proposed previously (e.g. (Navigli and Lapata, 2007; Cheng et al., 2009)). The general idea is to exploit measures of word similarity or relatedness to jointly tag all words in a text with their correct sense. We adopted the graph-based WSD method proposed in (Sinha and Mihalcea, 2007), which represents all word senses in a text as nodes in an undirected graph $G = (V, E)$. Pairs of nodes are linked by edges weighted by scores indicating the similarity or relatedness of the words associated with the nodes. Given such a graph, the likelihood of each node is derived by the PageRank algorithm (Brin and Page, 1998), which measures the relative importance of each node to the entire graph by considering the amount of “votes” the node receives from its neighboring nodes. The PageRank algorithm was originally designed for directed graphs, but can be easily extended to an undirected graph. Let $PR(v_i)$ denote the PageRank score of v_i. The PageRank algorithm iteratively updates this score as follows:

$$PR(v_i) = (1-d) + d \sum_{(v_i,v_j)\in E} PR(v_j)\frac{w_{ij}}{\sum_k w_{kj}}$$

where w_{ij} is the similarity weight of the undirected edge (v_i, v_j) and d is a damping factor, which is typically set to 0.85 (Brin and Page, 1998). The outcome of the PageRank algorithm is numerical weighting of each node in the graph. The sense with the highest score for each word identifies its most likely word sense. For our purposes, we modified the procedure as follows. Given a document (meeting transcription), we first identify all content words in the source document. The graph is then built over all target-language translation candidates, i.e. each node represents a word translation. Edges are then established between all pairs of nodes for which a word similarity measure can be obtained.

5.2 Word Similarity Measures

We follow (Zesch et al., 2008a) in computing the semantic similarity of German words by exploiting the Wikipedia and Wiktionary databases. We use the publicly available toolkits JWPL and JWKTL (Zesch et al., 2008b) to retrieve relevant articles in Wikipedia and entries in Wiktionary for each German word – these include the first paragraphs of Wikipedia articles entitled by the German word, the content of Wiktionary entries of the word itself as well as of closely related words (hypernyms, hyponyms, synonyms, etc.). We then concatenate all retrieved material for each word to construct a pseudo-gloss. We then lowercase and lemmatize the pseudo-glosses (using the lemmatizer available in the TextGrid package [6]), exclude function words by applying a simple stop-word list, and compute a word similarity measure for a given pair of words by counting the number of common words in their glosses.

We need to point out that one drawback in this approach is the low coverage of German content words in the Wikipedia and Wiktionary databases. Although the English edition contains millions of entries, the German edition of Wikipedia and Wiktionary is much smaller – the coverage of all content words in our task ranges between 53% and 56%, depending on the meeting, which leads to graphs with roughly 3K to 5K nodes and 8M to 13M edges. Words that are not covered mostly include rare words, technical terms, and compound words.

5.3 Experiments and Results

For each meeting, the derived PageRank scores were converted into a positive valued feature, referred to as the WSD feature, by normalization and exponentiation:

$$f_{WSD}(w_g|w_e) = \exp\left\{\frac{PR(w_g)}{\sum_{w_g\in H(w_e)} PR(w_g)}\right\}$$

where $PR(w_g)$ is the PageRank score for the German word w_g and $H(w_e)$ is the set of all translation candidates for the English word w_e. Since they are not modeled in the graph-based method, multi-words phrases and words that are not found in the Wikipedia or Wiktionary databases will receive the default value 1 for their WSD feature. The WSD feature was then integrated into the phrase table to perform translation. The new system was optimized as before.

It should be emphasized that the standard measures of BLEU and PER give an inadequate impression of translation quality, in particular because of the large variation among the reference translations, as discussed in Section 4. In many cases, better word sense disambiguation does not result in better BLEU scores (since higher gram matches are not affected) or even PER scores because although a feasible translation has been found it does not match any words in the reference translations. The best way of evaluating the effect of WSD is to obtain human judgments – however, since translation hypotheses change with every change to the system, our original error annotation described in Section 4 cannot be re-used, and time and resource constraints prevented us from using manual evaluations at every step during system development.

In order to loosen the restrictions imposed by having only two reference translations, we utilized a German thesaurus[7] to automatically extend the content words in the references with synonyms. This can be seen as an automated way of

[6] http://www.textgrid.de/en/beta.html

IB4005	25.4	45.9	42.4	25.3	45.6	42.2
IS1008c	15.9	52.9	50.0	14.9	52.3	48.6
TS3005a	23.1	45.2	41.9	23.2	45.3	41.7

Table 5: Performance of systems with and without WSD for dev and eval sets as well as individual meetings in the eval set.

approximating the larger space of feasible translations that could be obtained by producing additional human references. Note that the thesaurus provided synonyms for only roughly 50% of all content words in the dev and eval set. For each of them, on average three synonyms are found in the thesaurus. We use these extended references to recompute the PER score as an indicator of correct word selection. All results (BLEU, PER and extended PER (or XPER)) are shown in Table 5. As expected, BLEU is not affected but WSD improves the PER and XPER slightly but consistently. Note that this is despite the fact that only roughly half of all content words received disambiguation scores.

Finally, we provide a concrete example of translation improvements, with improved words highlighted:
Source:
on the balcony
there's that **terrace**
there's no place inside the building
Translation, no WSD:
auf dem balkon
es ist das **absatz**
es gibt keinen platz innerhalb des gebäudes
Translation, with WSD:
auf dem balkon
es ist das **terrasse**
es gibt keinen platz gebäudeintern
References:
auf dem balkon / auf dem balkon
da gibt es die **terrasse** */ da ist die* **terrasse**
es gibt keinen platz im gebäude / es gibt keinen platz innen im gebäude

6 Summary and Conclusions

We have presented a study on statistical translation of meeting data that makes the following contributions: to our knowledge it presents the first quantitative analysis of contextual factors in the statistical translation of multi-party spoken meetings. This analysis showed that the largest impact could be obtained in the area of word sense disambiguation using topic and domain knowledge, followed by multimodal information to resolve addressees of *you*. Contrary to our expectations, further knowledge of the real-world environment (such as objects in the room) did not show an effect on translation performance. Second, it demonstrates the application of *unsupervised, global* WSD to SMT, whereas previous work has focused on supervised, local WSD. Third, it explores definitions derived from collaborative Wiki sources (rather than WordNet or existing dictionaries) for use in machine translation. We demonstrated small but consistent improvements even though word coverage was incomplete. Future work will be directed at improving word coverage for the WSD algorithm, investigating alternative word similarity measures, and exploring the combination of global and local WSD techniques.

A Working Report on Statistically Modeling Dative Variation in Mandarin Chinese

Abstract

Dative variation is a widely observed syntactic phenomenon in world languages (e.g. *I gave John a book* and *I gave a book to John*). It has been shown that which surface form will be used in a dative sentence is not a completely random choice, rather, it is conditioned by a wide range of linguistic factors. Previous work by Bresnan and colleagues adopted a statistical modeling approach to investigate the probabilistic trends in English dative alternation. In this paper, we report a similar study on Mandarin Chinese. We further developed Bresnan et al.'s models to suit the complexity of the Chinese data. Our models effectively explain away a large proportion of the variation in the data, and unveil some interesting probabilistic features of Chinese grammar. Among other things, we show that Chinese dative variation is sensitive to heavy NP shift in both left and right directions.

1 Introduction

1.1 Overview

In traditional linguistic research, the study of syntax is most concerned with grammaticality. Sentences are either grammatical or ungrammatical, and syntactic theories are proposed to explain the structural features that cause (un)grammaticality. Meanwhile, little attention has been paid to the relative acceptability of grammatical sentences. If two sentences are both grammatical and basically express the same meaning, are they equally likely to occur in the language? The answer is probably *no*. For example, in English, the sentence *I have read that book* is much more frequent than *That book I have read*. The latter topicalized sentence is only used when the entity denoted by *That book* is in focus. This indicates that the choice of surface sentence form is not entirely random, but conditioned by some factors including information status.

Thus, instead of categorizing sentences as grammatical or ungrammatical, a better way to express the degree of grammaticality would be to use a likelihood continuum, from 0 to 1, where ungrammatical sentences have zero likelihood and grammatical sentences fall somewhere between 0 and 1, with some being more likely than others. The idea of associating linguistic forms with various probabilities has been around for a while (see Jurafsky, 2003 and Manning, 2003 for an extensive review). Recent psycholinguistic research has shown that just like grammaticality, the likelihoods of sentence forms are also part of the user's linguistic knowledge. Sentences with high probabilities are in general easier to comprehend and produce, and their production is more prone to phonetic reduction (Bresnan, 2007; Gahl and Garnsey, 2004; Levy, 2008; among others). The famous example of garden path sentences also exemplifies the difficulty of comprehension in low-probability sentence forms.

If we accept the premise of probabilistic syntax, then an immediate question is what determines these probabilities. In the current work, we address this question by investigating a particular type of probabilistic phenomenon, i.e. dative variation in Chinese. We show that the probabilities of

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 1236–1244,
Beijing, August 2010

various surface forms of Chinese dative sentences can be well estimated by a linear combination of a set of formal and semantic features.

The remainder of this paper is organized as follows. Section 1.2 briefly reviews previous work on English dative variation. Section 1.3 introduces dative variation in Chinese. Section 2 describes the dataset and the statistical models used in the current study. Section 3 presents modeling results, followed by a discussion in Section 4. Section 5 concludes the paper with a short summary. To preview the results, we show that dative variation in Chinese is more complicated than in English, in that it features two levels of variation, which exhibit different (sometimes even opposite) probabilistic patterns.

1.2 Dative variation in English

A dative sentence is a sentence that encodes a transfer event. Typical verbs of transfer in English include *give, send, mail*, etc. A characterizing property of transfer events is that they often involve two objects. In addition to the direct object (DO), the verb also takes an indirect object (IO) which usually denotes the recipient of the transfer action. For instance, in sentence 1a, the direct object is *a book* and the indirect object is *John*.

Cross-linguistically, it has been documented that many languages in the world have multiple syntactic forms for encoding the same transfer event (Margetts and Austin, 2007 , among others). In English, both 1a and 1b describe the same event, but 1a is a double object form (V IO DO) while 1b takes a prepositional phrase (V DO *to* IO).

(1) a. I gave John a book. → V IO DO
b. I gave a book to John. → V DO *to* IO

A number of conditioning factors have been identified for the alternation between the two surface forms. For instance, when the indirect object is a pronoun (e.g. *him*), it is more likely to have the double object form (i.e. *I gave him a book*) than the PP form (i.e. *I gave a book to him*). On the other hand, if the indirect object is a complex NP (with relative clauses), it tends to occur at the end of the sentence. Since most of these effects are subtle and often correlated with each other (e.g. definiteness, pronominality and syntactic complexity), investigating individual factors can give convoluted and unreliable results. To avoid this problem, many recent works in the field adopted a statistical modeling approach (Bresnan et al., 2007; Wasow and Arnold, 2003, among others). Instead of investigating separate factors, statistical models are built on large-scale datasets, using all potential conditioning factors to predict the surface form. In Bresnan et al. (2007), a dozen predictors relating to the verb (type of transfer event), the two object NPs (accessibility, pronominality, definiteness, syntactic complexity, etc), and the discourse (presence of parallel structures) were used to make the prediction. Using data input from 2,360 dative sentences from the Switchboard corpus, the model correctly predicted surface form in 97% of the sentences, which was a great improvement over the baseline prediction accuracy of 79% (i.e. the percentage of correct responses if the model knows nothing but which variant is more frequently used). It also showed that dative variation in English was indeed sensitive to all the predictors in the model.

1.3 Dative variation in Chinese

Dative variation in Chinese is much more complicated than in English. In addition to the two word orders that exist in English (2a, 2b), it is also common for direct object to appear before the verb, as in a BA construction or a topicalized sentence (2c). Besides, indirect object can also precede the verb, as shown in 2d. Another dimension of variation is in the use of coverbs *gei* and *ba*, both of which can be optional (2b, 2c; see Li and Thompson, 1981 for a detailed discussion on this), or replaced by other morphemes (*zhu, yu, jiang*, etc).

(2) a. John song-le shu gei Mary.
John give-ASP book to Mary
John gave one/some book(s) to Mary.
→ V DO IO

b. John song (gei) Mary yiben shu.
John gave (to) Mary one book
John gave Mary a book.
→ V IO DO

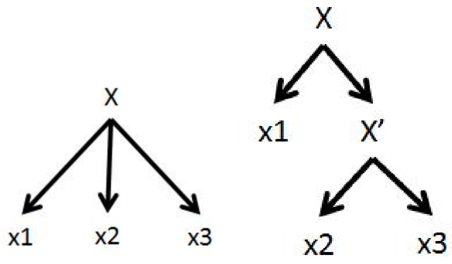
c. John ba shu song (gei) Mary, (ba)
John BA book gave (to) Mary (BA)

jiu song (gei) Kate.
wine gave (to) Kate
John gave the book(s) to Mary and gave the wine to Kate.
→ DO V IO

d. Ta meiren fa-le yiben shu.
He everyone allocated one book
He gave everyone a book.
→ IO V DO

For the purpose of the current study, we will ignore the existence (hence also the variation) of *gei* and *ba*, and concentrate on the variation in the relative order of V, DO and IO. In addition, our corpus search shows that sentences in the form of IO V DO are the least frequent (<9%) and mostly limited to a small set of verbs (mostly *fa* "to allocate" and *banfa* "to award"), so we drop this category from the current study. Thus the three remaining word order variants are: DO V IO, V DO IO, and V IO DO.

Generally speaking, there are two ways of modeling a variation phenomenon involving three variants. One way is to assume that the three variants are equally dissimilar from one another and the selection process is just to pick one out of three (Fig. 1a). The other approach is to assume a hierarchical structure: two of the variants are more similar to each other than they are to the third one and thus form a subcategory first before they join the third variant (Fig. 1b). In the selection process, the user first selects the subcategory (i.e. **x1** or **x'** in Fig 1b), and depending on which subcategory is chosen, they might need to make a second choice between two end nodes (i.e. **x2** and **x3**).



(a) (b)

Figure 1: Two possible schemas

We argue that the variation among the three word order variants in the current study is better modeled by a schema like Fig 1b, for both theoretical and methodological reasons. First, V DO IO and V IO DO are structurally more similar to each other than they are to DO V IO. Both V DO IO and V IO DO are in canonical word order of Chinese but the form DO V IO features the preposing (or topicalization) of the DO, whether or not the BA morpheme is present. Object preposing also exists outside ditransitive sentences (e.g. 3). Previous research has associated object preposing with the disposal meaning of the verb phrase, and the definiteness, givenness and weight of the object NP (Li and Thompson, 1981; Liu, 2007).

(3) a. Wo ba fan chi wan le.
I BA rice eat finish SEP
I have finished the rice.

b. Ta zhe dianying kan-le henduo bian.
he this movie saw many time
He has watched this movie for many times.

There is also a methodological motivation for adopting a hierarchical schema. Though it is not impossible to model a categorical variation with more than two variants (using multinomial logistic regression), binary variation is much easier to model and the interpretation of the results is more straightforward (this is especially true when random effects are present).

In view of the above, we propose the schema in Fig 2 for modeling the current variation phenomenon. We refer to sentences in the form of DO V IO as preverbal ditransitive sentences (since DO is before the verb), while both V DO IO and V IO DO are postverbal ditransitives. The distinction between the latter two forms regards whether DO is before or after IO, therefore one is termed as pre-IO and the other post-IO. Compared with the upper-level preverbal-postverbal distinction, the lower-level variation is much less studied in the literature (though see Liu, 2006 for a relevant discussion).

Corresponding to the schema in Fig 2, we constructed two separate models, one for the upper-level variation ("upper model") and the other for the lower-level variation ("lower model").

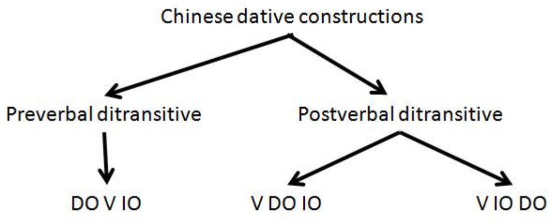


Figure 2: A two-level schema for Chinese dative variation

2 Methodology

2.1 Corpus and dataset

The data we use are from the Sinica Corpus of Modern Chinese (v3.1; Huang et al., 1995). We first compiled a list of 36 verbs that could be used ditransitively (see Appendix A) and then extracted from the corpus all sentences containing these words (n= 48,825 sentences). We then manually went through the sentences and selected those that (a) featured the ditransitive sense of the target verb, with both object NPs being overt, and (b) were in the form of any of the three form variants. 1,574 sentences remained after step (a) [1] and 1,433 after step (b) [2].

Further removal was conducted on verbs that were too sparse in the dataset. In each variation model, we removed verbs with fewer than two occurrences under either form variant. The final dataset for the upper model has 1149 sentences (of 20 verb types) while the dataset for the lower model has 801 sentences (of 14 verb types). The latter dataset is largely but not fully contained in the former due to the elimination of low-frequency verbs.

2.2 Data annotation

Similar to Bresnan et al.'s work on English, we annotated each data sentence for a wide range of features pertaining to the verb and the two NPs (see Appendix B for a complete list of annotated factors). Specifically, the verb was coded either as expressing a canonical transfer event, such as *ji* "to mail", or an extended transfer event, such as *jieshao* "to introduce". Semantic annotation of the two NPs is much trickier in Chinese than in English due to the lack of morphology. In practice, we used Bresnan et al.'s criteria for English, whenever applicable (e.g. accessibility, person, concreteness, animacy). In cases where the English rules did not apply (e.g. definiteness and number of bare NPs in Chinese), we developed working principles based on phrasal substitution. For example, if a bare NP can take a specifier like *yige/yizhi* "one" without changing sentence meaning, it is considered to be indefinite. Conversely, if a bare NP is better replaced with a full NP with a demonstrative *zhege* "this" or *nage* "that", it is coded as definite. Similar rules were used to assist annotating the number feature, using specifiers *yige/nage* "one"/"that" and *yixie/naxie* "some"/"those".

In addition to the factors in the English model, we also coded a set of structural features, including the presence of a following verb after the ditransitive construction, the presence of quantifiers/numerals in the NPs, and whether or not the ditransitive structure is embedded, nominalized, or relativized, etc. We suspect that since semantic features are often covert in Chinese words, it is possible that overt marking (e.g. the use of quantifiers/numerals) plays a more important role in conditioning surface form variation.

Finally we also included genre in the model. Sentences listed under the categories of dialogue and speech in the Sinica corpus were coded as "spoken" and the rest are coded as "written".

Altogether 24 factors were annotated and included in the statistical models as predictor variables. All variables are categorical except for the (log) length difference between DO and IO, which is numerical.

2.3 Statistical models

The statistical tool we use is mixed-effects logistic regression models. Compared with regular logistic regression models, mixed-effects models are more sophisticated in that they allow the user to specify factors that might introduce ran-

[1] A vast number of sentences were removed because the target verb was not used as a verb, or used with a different sense, or used as part of a different verb phrase, e.g. *fa* to allocate could also mean to bloom or be used in *fazhan* to develop, *faxian* to discover, etc.

[2] 141 sentences were removed because they were in the form of IO V DO.

dom variation in the dataset. In the current study, the datasets in both models contain sentences with different verbs. It is possible that different verbs have different intrinsic tendencies toward a certain word order variant.[3] Incorporating this piece of information into the model makes it more powerful and less affected by the unbalanced distribution of verb types. The mathematical formula of the mixed-effects logistic regression model is given below.

(4) Probability(V DO IO) = $\frac{1}{1+e^{-(\alpha_i + x\beta)}}$, where α_i is the verb-specific intercept of the verb v_i , x is a vector of predictors and β is a vector of corresponding coefficients.

Using the annotated datasets described in 2.2, we built an upper model and a lower model, corresponding to the schema in Fig 2. The general procedure of statistical analysis (which is the same for both models) is described as follows.

We first run the model with all 24 predictors, which will generate a coefficient and a p value for each predictor. Then we refit the model with only significant predictors (i.e. $p < 0.05$). The purpose of doing so is to filter out the noise in the model fit created by the large number of insignificant predictors. Only predictors that remain significant in the simplified model with largely unchanged coefficients are considered to be reliably significant.

Two model evaluation techniques are used to check the model results: cross-validation and separate analysis of high-frequency verbs. A potential problem in any statistical model is that it might overfit the data. After all, what we are interested in is the general probabilistic trends in dative variation, not the trends in a particular set of sentences featuring a particular set of verbs. A cross-validation test helps us evaluate the generalizability of model results by running the same model on a randomly sampled subset of the data. In doing so, it simulates the effect of having different datasets. In practice, we use two types of cross-validation procedures: one randomly samples sentences and the other samples verbs. Each procedure is executed on 100 randomly sampled subset of half the sentences/verbs. Only predictors with consistent performance over all iterations in both tests will be considered as stable.

Another concern in the model design is the effect of verb frequency. In the current dataset, one verb, i.e. *tigong* “to provide”, is extremely frequent. 37.3% of the sentences in the upper model and 50.9% in the lower model come from this verb. Though in theory, verb frequency is already taken care of by using mixed-effects models and running cross-validation on samples of the verb set, it is still necessary to test *tigong* separately from the rest of the verbs, due to its extremely high frequency. In the next section, we will report in detail the results from the two regression models.

3 Results

3.1 Upper model: predicting preverbal and postverbal variation

In the upper model, the distinction is between preverbal (DO V IO; coded as 1) and postverbal ditransitives (V DO IO and V IO DO; both coded as 0). The dataset in this model contains 1,149 sentences (of 20 verb types), with 379 preverbal and 770 postverbal. The distribution of the verbs is highly skewed. The most frequent verb is *tigong* “to provide” (n=428 tokens), followed by *song* “to send” (135) and *jiao* “to hand; to transfer” (117). The remaining 17 verbs have between 5 and 54 occurrences in the dataset.

10 out of 24 predictors in the full model are significant and most of them remain significant when the other 14 predictors are removed from the model. Table 1 below summarizes the results of the simplified model.

Judging from the signs of the coefficients in Table 1, a dative sentence is more likely to take the preverbal form (as opposed to the postverbal form) when (a) the verb expresses canonical transfer event, (b) DO is definite, plural, abstract and given in the previous context, with no quantifiers or numerals, (c) IO is not a pronoun and is not given in the previous context, and (d) DO is longer

[3] The same can be said about individual speakers, as some speakers might be more inclined to use certain forms than other speakers. However, since the sentences in the current datasets were sampled from a vast pool of speakers/writers (given the way the corpus is developed), individual differences among speakers is not considered in the current model.

Predictor	β	***p***
verb is canonical	1.71	0.03
DO is given	1.22	<0.001
DO is definite	4.89	<0.001
DO is plural	1.4	<0.001
DO is concrete	-1.13	0.004
quan/num in DO	-0.99	0.005
IO is pronoun	-1.64	<0.001
IO is given	-0.9	0.007
quan/num in IO	1.32	0.07 (n.s.)
Len(DO)-Len(IO)	0.53	0.002

Table 1: Fixed effects in the simplified upper model

than IO.

Table 2 shows the accuracy of the simplified model. If 0.5 is used as the cutoff probability, the model correctly predicts for (737+338)/1149=93.6% of the sentences. For comparison, the baseline accuracy is only 770/1049=-67% (i.e. by guessing postverbal every time). In other words, the model only needs to include 10 predictors to achieve an increase of around 39% (93.6-67)/67) in model accuracy.

		Predicted	
		preverbal	postverbal
observed	preverbal	338	41
	postverbal	33	737

Table 2: Prediction accuracy of the simplified upper model

Results from the two cross-validation tests confirm all the predictors regarding DO in Table 1, as well as the pronominality of IO and the length difference between DO and IO. Verb category and the givenness of IO do not survive the cross-validation tests.

Separate analysis of tigong shows that indeed, the extremely high-frequency verb exhibits vastly different patterns than other verbs. Only one predictor turns out to be significant for *tigong* sentences, that is, the definiteness of DO (β = 6.17, $p < 0.001$). A closer look at these sentences suggests that they are strongly biased toward postverbal word order, in that 400 out of 428 (95.4%) *tigong* sentences are postverbal (compared with the average level of 67% in all sentences). In other words, just by guessing postverbal every time, one is able to make the correct prediction for *tigong* over 95% of the time. Not surprisingly, there is little need for additional predictors. For non-*tigong* sentences, all factors in Table 1 are significant except for verb category and the presence of quantifiers/numerals in IO. Overall, the non-*tigong* model has an accuracy of 91.5% (baseline = 50.6%).

To sum up, we are confident to say that the semantic features of DO, as well as pronominality of IO and the length difference between the two objects, play important roles in conditioning the preverbal-postverbal variation. Knowing these factors boosts the model s predicting power by a great deal.

3.2 Lower model: predicting pre-IO and post-IO variation

In the lower model, the distinction is between pre-IO sentences (i.e. V DO IO; coded as 1) and post-IO sentences (i.e. V IO DO; coded as 0). The dataset consists of 801 sentences of 14 verb types, among which 161 are pre-IO and 640 are post-IO. The most frequent verb is again, *tigong* (n=408 tokens), followed by *dai* "to bring" (137) and *song* "to send" (89).

Table 3 below summarizes the results of the simplified version of the lower model (constructed in the same fashion as described in Section 3.1).

Predictor	β	***p***
DO is definite	1.59	0.006
DO is concrete	1.06	<0.001
DO is plural	-0.57	0.04
followed by a verb	2.29	<0.001
normalized verb phrase	1.36	0.13 (n.s.)
Len(DO) - Len(IO)	-1.37	<0.001

Table 3: Fixed effects in the simplified lower model

Compared to the upper model, fewer predictors are significant in the lower model. Everything else being equal, a postverbal ditransitive sentence is more likely to take the pre-IO form (V DO IO) if (a) DO is definite and concrete, (b) IO is singular, (c) DO is shorter than IO, and (d) the ditransitive construction is followed by another verb. The last point is illustrated in sentence 5a, which is adapted from a real sentence in the corpus. In 5a, the NP *women* "we" is both the recipient of the first verb *song* "to send" and the agent of the second verb *chi* "to eat". Thus, by using a pre-IO form, the NP *women* is in effect adjacent to the second verb chi, which might give an advantage in sentence processing. Notice though, if the other form (V IO DO) is used, the sentence is still grammatical (see 5b).

(5) a. Ta hai song xiaoye gei wo chi.
he also sent snacks to me eat
He also sent snacks for me to eat.

b. Ta hai song (gei) wo xiaoye chi.
he also sent (to) me snacks eat
He also sent me snacks to eat.

Overall the lower model is not as successful as the upper model. The prediction accuracy is 87.7% (baseline accuracy is 79.9%; see Table 4).

		Predicted	
		pre-IO	post-IO
observed	pre-IO	85	76
	post-IO	22	618

Table 4: Prediction accuracy of the simplified lower model

Moreover, cross-validation and the analysis of *tigong* show that only two factors, the presence of the following verb and length difference, are stable across subsets of the data. In fact, with length difference alone, the model generates correct predictions for 86.8% of the sentences (only 1% less than the accuracy reported in Table 4).

However, before we hastily conclude that length difference is the only thing that matters in the lower-level variation, it is important to point out that when the length factor is removed from the model, some predictors (such as the accessibility of DO) turn out to be significant and the model still manages to achieve an accuracy of 85.3%. Therefore, a more plausible explanation is that length difference is the strongest predictors for lower-level dative variation. Though the part of variation it accounts for can also be explained by other predictors, it is more effective in doing so. Therefore the existence of this variable tends to mask other predictors in the model.

4 Discussion

4.1 Comparing he two models

In the current study, we propose a two-level hierarchical schema for modeling the variation among three major word orders of Chinese dative sentences. On the upper level, there is a distinction between sentences with preverbal DOs and those with postverbal DOs. On the lower level, among postverbal sentences, there is a further distinction between pre-IO sentences (i.e. with prepositional phrases), and post-IO sentences (i.e. double object forms). This schema is promoted by structural as well as methodological concerns.

Our modeling results show that the two levels of variation are indeed characterized by different probabilistic patterns, which in turn provide evidence for our original proposal. As presented in Section 3, the upper-level distinction is mostly conditioned by the semantic features of the DO. However, in the lower-level variation, the two best predictors are length difference and the presence of a following verb. Overall, the upper-level model is more successful (accuracy = 93.6%, baseline = 67%) than the lower-level model (accuracy = 87.7%, baseline = 79.9%).

A more striking difference between the two models is that they exhibit weight effects in opposite directions. In both models, length difference between DO and IO plays an important role. Nevertheless, in the upper model, length difference has a positive sign (β = 0.53), meaning that the longer the DO is (compared to the IO), the more likely it is to prepose DO before the verb. Conversely, in the lower-level model, this factor has a negative sign (β = - 1.37), which means that the longer the DO is (compared to the IO), the less likely it is for DO to be before IO. That is to say, everything else being equal, if a DO is long, it will probably be preposed before the verb, but if it is already after the verb, then it will more likely be placed after IO, at the end of the construction.

The difference in directionality explains why it is only in the lower-level model that the weight effect overshadows other predictors. Features like pronominality, definiteness, and accessibility are inherently correlated with weight. Pronouns are shorter than full NPs; definite NPs tend to be shorter than indefinite NPs (which often take quantifiers and numerals); NPs that have appeared before tend to be in shorter forms than their first occurrences. In both models, a general trend is that NPs that are more prominent in the context (e.g. pronouns, definite NPs, NPs with antecedents) tend to occur earlier in the construction. Thus, in the lower model, the general trend of prominence is confluent with the short before long weight effect, but in the upper model, it is pulling away from the long before short weight effect. As a result, weight effect only masks semantic predictors in the lower model, not in the upper model.

4.2 Comparing with English dative variation

Compared with Bresnan et al.s models, the current results reveal a number of interesting differences between Chinese and English dative variation.

First, the variation phenomenon in Chinese involves at least one more major variant, that is, the preverbal word order, which significantly increases the complexity of the phenomenon. The fact that overall the English model has greater prediction accuracy than the Chinese models might have to do with the fact that the variation phenomenon is more complicated and harder to model in Chinese.

Second, dative variation in Chinese seems to be less sensitive to semantic features. If we only consider the lower-level variation in Chinese, which involves the same form variants as in English (i.e. V DO IO and V IO DO), the Chinese model is best predicted by the length difference between DO and IO and most other predictors are muted by the presence of this factor. In the English model, semantic features are still significant even when length difference is controlled.

Last but not least, as discussed at length in the previous section, the two levels of dative variation in Chinese exhibit weight effects in opposite directions. The English variation is also sensitive to weight, but only in the short before long direction, which is the same as the lower-level variation in Chinese.

5 Conclusion

In this work, we present a corpus-based statistical modeling study on Chinese dative variation. In doing so, we show that this new methodology, which combines corpus data and statistical modeling, is a powerful tool for studying complex variation phenomena in Chinese. The statistical models built in the current study achieve high accuracy in predicting surface forms in Chinese dative sentences. More importantly, the models unveil probabilistic tendencies in Chinese grammar that are otherwise hard to notice.

A remaining question in the current study is *why would Chinese dative variation exhibit weight effects in both directions*. The answer to this question awaits further investigation.

Acknowledgement

We would like to thank three anonymous reviewers for helpful comments on an earlier version of the paper. We owe special thanks to Joan Bresnan and her colleagues in the Spoken Syntax Lab at Stanford University, for sharing working manuals and for valuable discussions.

Abstract

This paper proposes an efficient online method that trains a classifier with many conjunctive features. We employ kernel computation called *kernel slicing*, which explicitly considers conjunctions among frequent features in computing the polynomial kernel, to combine the merits of linear and kernel-based training. To improve the scalability of this training, we reuse the temporal margins of partial feature vectors and terminate unnecessary margin computations. Experiments on dependency parsing and hyponymy-relation extraction demonstrated that our method could train a classifier orders of magnitude faster than kernel-based online learning, while retaining its space efficiency.

1 Introduction

The past twenty years have witnessed a growing use of machine-learning classifiers in the field of NLP. Since the classification target of complex NLP tasks (*e.g.*, dependency parsing and relation extraction) consists of more than one constituent (*e.g.*, a head and a dependent in dependency parsing), we need to consider *conjunctive features*, i.e., conjunctions of primitive features that focus on the particular clues of each constituent, to achieve a high degree of accuracy in those tasks.

Training with conjunctive features involves a space-time trade-off in the way conjunctive features are handled. Linear models, such as log-linear models, explicitly estimate the weights of conjunctive features, and training thus requires a great deal of memory when we take higher-order conjunctive features into consideration. Kernel-based models such as support vector machines, on the other hand, ensure space efficiency by using the kernel trick to implicitly consider conjunctive features. However, training takes quadratic time in the number of examples, even with online algorithms such as the (kernel) perceptron (Freund and Schapire, 1999), and we cannot fully exploit ample 'labeled' data obtained with semi-supervised algorithms (Ando and Zhang, 2005; Bellare et al., 2007; Liang et al., 2008; Daumé III, 2008).

We aim at resolving this dilemma in training with conjunctive features, and propose online learning that combines the time efficiency of linear training and the space efficiency of kernel-based training. Following the work by Goldberg and Elhadad (2008), we explicitly take conjunctive features into account that frequently appear in the training data, and implicitly consider the other conjunctive features by using the polynomial kernel. We then improve the scalability of this training by a method called *kernel slicing*, which allows us to reuse the temporal margins of partial feature vectors and to terminate computations that do not contribute to parameter updates.

We evaluate our method in two NLP tasks: dependency parsing and hyponymy-relation extraction. We demonstrate that our method is orders of magnitude faster than kernel-based online learning while retaining its space efficiency.

The remainder of this paper is organized as follows. Section 2 introduces preliminaries and notations. Section 3 proposes our training method. Section 4 evaluates the proposed method. Section 5 discusses related studies. Section 6 concludes this paper and addresses future work.

```

2 Preliminaries

This section first introduces a passive-aggressive algorithm (Crammer et al., 2006), which we use as a base learner. We then explain fast methods of computing the polynomial kernel.

Each example $\boldsymbol{x}$ in a classification problem is represented by a *feature vector* whose element x_j is a value of a feature function, $f_j \in \mathcal{F}$. Here, we assume a binary feature function, $f_j(\boldsymbol{x}) \in \{0, 1\}$, which returns one if particular context data appear in the example. We say that feature f_j is *active* in example $\boldsymbol{x}$ when $x_j = f_j(\boldsymbol{x}) = 1$. We denote a binary feature vector, $\boldsymbol{x}$, as a set of active features $\boldsymbol{x} = \{f_j \mid f_j \in \mathcal{F}, f_j(\boldsymbol{x}) = 1\}$ for brevity; $f_j \in \boldsymbol{x}$ means that f_j is active in $\boldsymbol{x}$, and $|\boldsymbol{x}|$ represents the number of active features in $\boldsymbol{x}$.

2.1 Kernel Passive-Aggressive Algorithm

A passive-aggressive algorithm (PA) (Crammer et al., 2006) represents online learning that updates parameters for given labeled example $(\boldsymbol{x}, y)_t \in \mathcal{T}$ in each round t. We assume a binary label, $y \in \{-1, +1\}$, here for clarity. Algorithm 1 is a variant of PA (PA-I) that incorporates a kernel function, k. In round t, PA-I first computes a *(signed) margin* $m_t(\boldsymbol{x})$ of $\boldsymbol{x}$ by using the kernel function with support set $\mathcal{S}_{t-1}$ and coefficients $\boldsymbol{\alpha}_{t-1}$ (Line 4). PA-I then suffers a hinge-loss, $\ell_t = \max\{0, 1 - y m_t(\boldsymbol{x})\}$ (Line 5). If $\ell_t > 0$, PA-I adds $\boldsymbol{x}$ to $\mathcal{S}_{t-1}$ (Line 7). Hyperparameter C controls the aggressiveness of parameter updates.

The kernel function computes a dot product in $\mathbb{R}^{\mathcal{H}}$ space without mapping $\boldsymbol{x} \in \mathbb{R}^n$ to $\boldsymbol{\phi}(\boldsymbol{x}) \in \mathbb{R}^{\mathcal{H}}$ ($k(\boldsymbol{x}, \boldsymbol{x}') = \boldsymbol{\phi}(\boldsymbol{x})^{\mathrm{T}}\boldsymbol{\phi}(\boldsymbol{x}')$). We can implicitly consider (weighted) d or less order conjunctions of primitive features by using *polynomial kernel function* $k_d(\boldsymbol{s}, \boldsymbol{x}) = (\boldsymbol{s}^{\mathrm{T}}\boldsymbol{x} + 1)^d$. For example, given support vector $\boldsymbol{s} = (s_1, s_2)^{\mathrm{T}}$ and input example $\boldsymbol{x} = (x_1, x_2)^{\mathrm{T}}$, the second-order polynomial kernel returns $k_2(\boldsymbol{s}, \boldsymbol{x}) = (s_1x_1 + s_2x_2 + 1)^2 = 1 + 3s_1x_1 + 3s_2x_2 + 2s_1x_1s_2x_2$ ($\because s_i, x_i \in \{0, 1\}$). This function thus implies mapping $\boldsymbol{\phi}_2(\boldsymbol{x}) = (1, \sqrt{3}x_1, \sqrt{3}x_2, \sqrt{2}x_1x_2)^{\mathrm{T}}$.

Although online learning is generally efficient, the kernel spoils its efficiency (Dekel et al., 2008). This is because the kernel evaluation (Line 4) takes $\mathcal{O}(|\mathcal{S}_{t-1}||\boldsymbol{x}|)$ time and $|\mathcal{S}_{t-1}|$ increases as training continues. The learner thus takes the most amount of time in this margin computation.

2.2 Kernel Computation for Classification

This section explains fast, exact methods of computing the polynomial kernel, which are meant to test the trained model, $(\mathcal{S}, \boldsymbol{\alpha})$, and involve substantial computational cost in preparation.

2.2.1 Kernel Inverted

Kudo and Matsumoto (2003) proposed *polynomial kernel inverted* (PKI), which builds inverted indices $h(f_j) \equiv \{\boldsymbol{s} \mid \boldsymbol{s} \in \mathcal{S}, f_j \in \boldsymbol{s}\}$ from each feature f_j to support vector $\boldsymbol{s} \in \mathcal{S}$ to only consider support vector $\boldsymbol{s}$ relevant to given $\boldsymbol{x}$ such that $\boldsymbol{s}^{\mathrm{T}}\boldsymbol{x} \neq 0$. The time complexity of PKI is $\mathcal{O}(B \cdot |\boldsymbol{x}| + |\mathcal{S}|)$ where $B \equiv \frac{1}{|\boldsymbol{x}|}\sum_{f_j \in \boldsymbol{x}} |h(f_j)|$, which is smaller than $\mathcal{O}(|\mathcal{S}||\boldsymbol{x}|)$ if $\boldsymbol{x}$ has many rare features f_j such that $|h(f_j)| \ll |\mathcal{S}|$.

To the best of our knowledge, this is the only exact method that has been used to speed up margin computation in the context of kernel-based online learning (Okanohara and Tsujii, 2007).

2.2.2 Kernel Expansion

Isozaki and Kazawa (2002) and Kudo and Matsumoto (2003) proposed *kernel expansion*, which explicitly maps both support set $\mathcal{S}$ and given example $\boldsymbol{x} \in \mathbb{R}^n$ into $\mathbb{R}^{\mathcal{H}}$ by mapping $\boldsymbol{\phi}_d$ imposed by k_d:

$$m(\boldsymbol{x}) = \left(\sum_{\boldsymbol{s}_i \in \mathcal{S}} \alpha_i \boldsymbol{\phi}_d(\boldsymbol{s}_i)\right)^{\mathrm{T}} \boldsymbol{\phi}_d(\boldsymbol{x}) = \sum_{f_i \in \boldsymbol{x}^d} w_i,$$

where $\boldsymbol{x}^d \in \{0,1\}^{\mathcal{H}}$ is a binary feature vector in which $x_i^d = 1$ for $(\boldsymbol{\phi}_d(\boldsymbol{x}))_i \neq 0$, and $\boldsymbol{w}$ is a weight vector in the expanded feature space, $\mathcal{F}^d$. The weight vector $\boldsymbol{w}$ is computed from $\mathcal{S}$ and $\boldsymbol{\alpha}$:

$$\boldsymbol{w} = \sum_{\boldsymbol{s}_i \in \mathcal{S}} \alpha_i \sum_{k=0}^{d} c_d^k I_k(\boldsymbol{s}_i^d), \qquad (1)$$

where c_d^k is a squared coefficient of k-th order conjunctive features for d-th order polynomial kernel (*e.g.*, $c_2^0 = 1$, $c_2^1 = 3$, and $c_2^2 = 2$)[1] and $I_k(\boldsymbol{s}_i^d)$ is $\boldsymbol{s}_i^d \in \{0,1\}^{\mathcal{H}}$ whose dimensions other than those of k-th order conjunctive features are set to zero.

The time complexity of kernel expansion is $\mathcal{O}(|\boldsymbol{x}^d|)$ where $|\boldsymbol{x}^d| = \sum_{k=0}^{d} \binom{|\boldsymbol{x}|}{k} \propto |\boldsymbol{x}|^d$, which can be smaller than $\mathcal{O}(|\mathcal{S}||\boldsymbol{x}|)$ in usual NLP tasks ($|\boldsymbol{x}| \ll |\mathcal{S}|$ and $d \leq 4$).

2.2.3 Kernel Splitting

Since kernel expansion demands a huge memory volume to store the weight vector, $\boldsymbol{w}$, in $\mathbb{R}^{\mathcal{H}}$ ($\mathcal{H} = \sum_{k=0}^{d} \binom{|\mathcal{F}|}{k}$), Goldberg and Elhadad (2008) only explicitly considered conjunctions among features $f_C \in \mathcal{F}_C$ that commonly appear in support set $\mathcal{S}$, and handled the other conjunctive features relevant to rare features $f_R \in \mathcal{F} \setminus \mathcal{F}_C$ by using the polynomial kernel:

$$\begin{aligned} m(\boldsymbol{x}) &= m(\tilde{\boldsymbol{x}}) + m(\boldsymbol{x}) - m(\tilde{\boldsymbol{x}}) \\ &= \sum_{f_i \in \tilde{\boldsymbol{x}}^d} \tilde{w}_i + \sum_{\boldsymbol{s}_i \in \mathcal{S}_R} \alpha_i k'_d(\boldsymbol{s}_i, \boldsymbol{x}, \tilde{\boldsymbol{x}}), \quad (2) \end{aligned}$$

where $\tilde{\boldsymbol{x}}$ is $\boldsymbol{x}$ whose dimensions of rare features are set to zero, $\tilde{\boldsymbol{w}}$ is a weight vector computed with Eq. 1 for $\mathcal{F}_C^d$, and $k'_d(\boldsymbol{s}, \boldsymbol{x}, \tilde{\boldsymbol{x}})$ is defined as:

$$k'_d(\boldsymbol{s}, \boldsymbol{x}, \tilde{\boldsymbol{x}}) \equiv k_d(\boldsymbol{s}, \boldsymbol{x}) - k_d(\boldsymbol{s}, \tilde{\boldsymbol{x}}).$$

We can space-efficiently compute the first term of Eq. 2 since $|\tilde{\boldsymbol{w}}| \ll |\boldsymbol{w}|$, while we can quickly compute the second term of Eq. 2 since $k'_d(\boldsymbol{s}_i, \boldsymbol{x}, \tilde{\boldsymbol{x}}) = 0$ when $\boldsymbol{s}_i^{\mathrm{T}} \boldsymbol{x} = \boldsymbol{s}_i^{\mathrm{T}} \tilde{\boldsymbol{x}}$; we only need to consider a small subset of the support set, $\mathcal{S}_R = \bigcup_{f_R \in \boldsymbol{x} \setminus \tilde{\boldsymbol{x}}} h(f_R)$, that has at least one of the rare features, f_R, appearing in $\boldsymbol{x} \setminus \tilde{\boldsymbol{x}}$ ($|\mathcal{S}_R| \ll |\mathcal{S}|$).

Counting the number of features examined, the time complexity of Eq. 2 is $\mathcal{O}(|\tilde{\boldsymbol{x}}^d| + |\mathcal{S}_R||\tilde{\boldsymbol{x}}|)$.

3 Algorithm

This section first describes the way kernel splitting is integrated into PA-I (Section 3.1). We then propose *kernel slicing* (Section 3.2), which enables us to reuse the temporal margins computed in the past rounds (Section 3.2.1) and to skip unnecessary margin computations (Section 3.2.2).

In what follows, we use PA-I as a base learner. Note that an analogous argument can be applied to other perceptron-like online learners with the additive weight update (Line 7 in Algorithm 1).

3.1 Base Learner with Kernel Splitting

A problem in integrating kernel splitting into the base learner presented in Algorithm 1 is how to determine $\mathcal{F}_C$, features among which we explicitly consider conjunctions, without knowing the final support set, $\mathcal{S}_{|\mathcal{T}|}$. We heuristically solve this by ranking feature f according to their frequency in the training data and by using the top-N frequent features in the training data as $\mathcal{F}_C$ ($= \{f \mid f \in \mathcal{F}, \textsc{rank}(f) \leq N\}$).[2] Since $\mathcal{S}_{|\mathcal{T}|}$ is a subset of the examples, this approximates the selection from $\mathcal{S}_{|\mathcal{T}|}$. We empirically demonstrate the validity of this approach in the experiments.

We then use $\mathcal{F}_C$ to construct a base learner with kernel splitting; we replace the kernel computation (Line 4 in Algorithm 1) with Eq. 2 where $(\mathcal{S}, \boldsymbol{\alpha}) = (\mathcal{S}_{t-1}, \boldsymbol{\alpha}_{t-1})$. To compute $m_t(\tilde{\boldsymbol{x}})$ by using kernel expansion, we need to additionally maintain the weight vector $\tilde{\boldsymbol{w}}$ for the conjunctions of common features that appear in $\mathcal{S}_{t-1}$.

The additive parameter update of PA-I enables us to keep $\tilde{\boldsymbol{w}}$ to correspond to $(\mathcal{S}_{t-1}, \boldsymbol{\alpha}_{t-1})$. When we add $\boldsymbol{x}$ to support set $\mathcal{S}_{t-1}$ (Line 7 in Algorithm 1), we also update $\tilde{\boldsymbol{w}}$ with Eq. 1:

$$\tilde{\boldsymbol{w}} \leftarrow \tilde{\boldsymbol{w}} + \tau_t y \sum_{k=0}^{d} c_d^k I_k(\tilde{\boldsymbol{x}}^d).$$

Following (Kudo and Matsumoto, 2003), we use a trie (hereafter, *weight trie*) to maintain conjunctive features. Each edge in the weight trie is labeled with a primitive feature, while each path

[1] Following Lemma 1 in Kudo and Matsumoto (2003), $c_d^k = \sum_{l=k}^{d} \binom{d}{l} \left(\sum_{m=0}^{k} (-1)^{k-m} \cdot m^l \binom{k}{m}\right)$.

[2] The overhead of counting features is negligible compared to the total training time. If we want to run the learner in a purely online manner, we can alternatively choose first N features that appear in the processed examples as $\mathcal{F}_C$.

represents a conjunctive feature that combines all the primitive features on the path. The weights of conjunctive features are retrieved by traversing nodes in the trie. We carry out an analogous traversal in updating the parameters of conjunctive features, while registering a new conjunctive feature by adding an edge to the trie.

The base learner with kernel splitting combines the virtues of linear training and kernel-based training. It reduces to linear training when we increase N to $|\mathcal{F}|$, while it reduces to kernel-based training when we decrease N to 0. The output is support set $\mathcal{S}_{|\mathcal{T}|}$ and coefficients $\boldsymbol{\alpha}_{|\mathcal{T}|}$ (optionally, $\tilde{\boldsymbol{w}}$), to which the efficient classification techniques discussed in Section 2.2 and the one proposed by Yoshinaga and Kitsuregawa (2009) can be applied.

Note on weight trie construction The time and space efficiency of this learner strongly depends on the way the weight trie is constructed. We need to address two practical issues that greatly affect efficiency. First, we traverse the trie from the rarest feature that constitutes a conjunctive feature. This rare-to-frequent mining helps us to avoid enumerating higher-order conjunctive features that have not been registered in the trie, when computing margin. Second, we use $\text{RANK}(f)$ encoded into a $\lceil \log_{128} \text{RANK}(f) \rceil$-byte string by using variable-byte coding (Williams and Zobel, 1999) as f's representation in the trie. This encoding reduces the trie size, since features with small $\text{RANK}(f)$ will appear frequently in the trie.

3.2 Base Learner with Kernel Slicing

Although a base learner with kernel splitting can enjoy the merits of linear and kernel-based training, it can simultaneously suffer from their demerits. Because the training takes polynomial time in the number of common features in $\boldsymbol{x}$ ($|\tilde{\boldsymbol{x}}^d| = \sum_{k=0}^{d} \binom{|\tilde{\boldsymbol{x}}|}{k} \propto |\tilde{\boldsymbol{x}}|^d$) at each round, we need to set N to a smaller value when we take higher-order conjunctive features into consideration. However, since the margin computation takes linear time in the number of support vectors $|\mathcal{S}_R|$ relevant to rare features $f_R \in \mathcal{F} \setminus \mathcal{F}_C$, we need to set N to a larger value when we handle a larger number of training examples. The training thereby slows down when we train a classifier with high-order conjunctive features and a large number of training examples.

We then attempt to improve the scalability of the training by exploiting a characteristic of labeled data in NLP. Because examples in NLP tasks are likely to be redundant (Yoshinaga and Kitsuregawa, 2009), the learner computes margins of examples that have many features in common. If we can reuse the 'temporal' margins of partial feature vectors computed in past rounds, this will speed up the computation of margins.

We propose *kernel slicing*, which generalizes kernel splitting in a purely feature-wise manner and enables us to reuse the temporal partial margins. Starting from the most frequent feature f_1 in $\boldsymbol{x}$ ($f_1 = \text{argmin}_{f \in \boldsymbol{x}} \text{RANK}(f)$), we incrementally compute $m_t(\boldsymbol{x})$ by accumulating a *partial margin*, $m_t^j(\boldsymbol{x}) \equiv m_t(\boldsymbol{x}_j) - m_t(\boldsymbol{x}_{j-1})$, when we add the j-th frequent feature f_j in $\boldsymbol{x}$:

$$m_t(\boldsymbol{x}) = m_t^0 + \sum_{j=1}^{|\boldsymbol{x}|} m_t^j(\boldsymbol{x}), \tag{3}$$

where $m_t^0 = \sum_{\boldsymbol{s}_i \in \mathcal{S}_{t-1}} \alpha_i k_d(\boldsymbol{s}_i, \varnothing) = \sum_i \alpha_i$, and $\boldsymbol{x}_j$ has the j most frequent features in $\boldsymbol{x}$ ($\boldsymbol{x}_0 = \varnothing$, $\boldsymbol{x}_j = \bigsqcup_{k=0}^{j-1} \{\text{argmin}_{f \in \boldsymbol{x} \setminus \boldsymbol{x}_k} \text{RANK}(f)\}$).

Partial margin $m_t^j(\boldsymbol{x})$ can be computed by using the polynomial kernel:

$$m_t^j(\boldsymbol{x}) = \sum_{\boldsymbol{s}_i \in \mathcal{S}_{t-1}} \alpha_i k'_d(\boldsymbol{s}_i, \boldsymbol{x}_j, \boldsymbol{x}_{j-1}), \tag{4}$$

or by using kernel expansion:

$$m_t^j(\boldsymbol{x}) = \sum_{f_i \in \boldsymbol{x}_j^d \setminus \boldsymbol{x}_{j-1}^d} \tilde{w}_i. \tag{5}$$

Kernel splitting is a special case of kernel slicing, which uses Eq. 5 for $f_j \in \mathcal{F}_C$ and Eq. 4 for $f_j \in \mathcal{F} \setminus \mathcal{F}_C$.

3.2.1 Reuse of Temporal Partial Margins

We can speed up both Eqs. 4 and 5 by reusing a temporal partial margin, $\delta_{t'}^j = m_{t'}^j(\boldsymbol{x})$ that had been computed in past round $t'(< t)$:

$$m_t^j(\boldsymbol{x}) = \delta_{t'}^j + \sum_{\boldsymbol{s}_i \in \mathcal{S}_j} \alpha_i k'_d(\boldsymbol{s}_i, \boldsymbol{x}_j, \boldsymbol{x}_{j-1}), \tag{6}$$

where $\mathcal{S}_j = \{\boldsymbol{s} \mid \boldsymbol{s} \in \mathcal{S}_{t-1} \setminus \mathcal{S}_{t'-1}, f_j \in \boldsymbol{s}\}$.

Algorithm 2 Kernel Slicing

```
INPUT: $\boldsymbol{x} \in 2^{\mathcal{F}}, \mathcal{S}_{t-1}, \boldsymbol{\alpha}_{t-1}, \mathcal{F}_C \subseteq \mathcal{F}, \boldsymbol{\delta} : 2^{\mathcal{F}} \mapsto \mathbb{N} \times \mathbb{R}$
OUTPUT: $m_t(\boldsymbol{x})$
 1: initialize: $\boldsymbol{x}_0 \leftarrow \varnothing, j \leftarrow 1, m_t(\boldsymbol{x}) \leftarrow m_t^0$
 2: repeat
 3:     $\boldsymbol{x}_j \leftarrow \boldsymbol{x}_{j-1} \sqcup \{\text{argmin}_{f \in \boldsymbol{x} \setminus \boldsymbol{x}_{j-1}} \text{RANK}(f)\}$
 4:     retrieve partial margin: $(t', \delta^j_{t'}) \leftarrow \boldsymbol{\delta}(\boldsymbol{x}_j)$
 5:     if $f_j \in \mathcal{F} \setminus \mathcal{F}_C$ or Eq. 7 is true then
 6:         compute $m^j_t(\boldsymbol{x})$ using Eq. 6 with $\delta^j_{t'}$
 7:     else
 8:         compute $m^j_t(\boldsymbol{x})$ using Eq. 5
 9:     end if
10:     update partial margin: $\boldsymbol{\delta}(\boldsymbol{x}_j) \leftarrow (t, m^j_t(\boldsymbol{x}))$
11:     $m_t(\boldsymbol{x}) \leftarrow m_t(\boldsymbol{x}) + m^j_t(\boldsymbol{x})$
12: until $\boldsymbol{x}_j \neq \boldsymbol{x}$
13: return $m_t(\boldsymbol{x})$
```

Eq. 6 is faster than Eq. 4,[3] and can even be faster than Eq. 5.[4] When $\text{RANK}(f_j)$ is high, $\boldsymbol{x}_j$ appears frequently in the training examples and $|\mathcal{S}_j|$ becomes small since t' will be close to t. When $\text{RANK}(f_j)$ is low, $\boldsymbol{x}_j$ rarely appears in the training examples but we can still expect $|\mathcal{S}_j|$ to be small since the number of support vectors in $\mathcal{S}_{t-1} \backslash \mathcal{S}_{t'-1}$ that have rare feature f_j will be small.

To compute Eq. 3, we now have the choice to choose Eq. 5 or 6 for $f_j \in \mathcal{F}_C$. Counting the number of features to be examined in computing $m^j_t(\boldsymbol{x})$, we have the following criteria to determine whether we can use Eq. 6 instead of Eq. 5:

$$1 + |\mathcal{S}_j||\boldsymbol{x}_{j-1}| \leq |\boldsymbol{x}^d_j \setminus \boldsymbol{x}^d_{j-1}| = \sum_{k=1}^{d} \binom{j-1}{k-1},$$

where the left- and right-hand sides indicate the number of features examined in Eq. 6 for the former and Eq. 5 for the latter. Expanding the right-hand side for $d = 2, 3$ and dividing both sides with $|\boldsymbol{x}_{j-1}| = j - 1$, we have:

$$|\mathcal{S}_j| \leq \left\{ \begin{array}{ll} 1 & (d = 2) \\ \frac{j}{2} & (d = 3) \end{array} \right. . \qquad (7)$$

If this condition is met after retrieving the temporal partial margin, $\delta^j_{t'}$, we can compute partial margin $m^j_t(\boldsymbol{x})$ with Eq. 6. This analysis reveals that we can expect little speed-up for the second-order polynomial kernel; we will only use Eq. 6 with third or higher-order polynomial kernel.

Algorithm 2 summarizes the margin computation with kernel slicing. It processes each feature $f_j \in \boldsymbol{x}$ in frequent-to-rare order, and accumulates partial margin $m^j_t(\boldsymbol{x})$ to have $m_t(\boldsymbol{x})$. Intuitively speaking, when the algorithm uses the partial margin, it only considers support vectors on each feature that have been added since the last evaluation of the partial feature vector, to avoid the repetition in kernel evaluation as much as possible.

3.2.2 Termination of Margin Computation

Kernel slicing enables another optimization that exploits a characteristic of online learning. Because we need an exact margin, $m_t(\boldsymbol{x})$, only when hinge-loss $\ell_t = 1 - y m_t(\boldsymbol{x})$ is positive, we can finish margin computation as soon as we find that the lower-bound of $y m_t(\boldsymbol{x})$ is larger than one.

When $y m_t(\boldsymbol{x})$ is larger than one after processing feature f_j in Eq. 3, we quickly examine whether this will hold even after we process the remaining features. We can compute a possible range of partial margin $m^k_t(\boldsymbol{x})$ with Eq. 4, having the upper- and lower-bounds, $\hat{k}'_d$ and $\check{k}'_d$, of $k'_d(\boldsymbol{s}_i, \boldsymbol{x}_k, \boldsymbol{x}_{k-1})$ $(= k_d(\boldsymbol{s}_i, \boldsymbol{x}_k) - k_d(\boldsymbol{s}_i, \boldsymbol{x}_{k-1}))$:

$$m^k_t(\boldsymbol{x}) \leq \hat{k}'_d \sum_{\boldsymbol{s}_i \in \mathcal{S}^+_k} \alpha_i + \check{k}'_d \sum_{\boldsymbol{s}_i \in \mathcal{S}^-_k} \alpha_i \qquad (8)$$

$$m^k_t(\boldsymbol{x}) \geq \check{k}'_d \sum_{\boldsymbol{s}_i \in \mathcal{S}^+_k} \alpha_i + \hat{k}'_d \sum_{\boldsymbol{s}_i \in \mathcal{S}^-_k} \alpha_i, \qquad (9)$$

where $\mathcal{S}^+_k = \{\boldsymbol{s}_i \,|\, \boldsymbol{s}_i \in \mathcal{S}_{t-1}, f_k \in \boldsymbol{s}_i, \alpha_i > 0\}$, $\mathcal{S}^-_k = \{\boldsymbol{s}_i \,|\, \boldsymbol{s}_i \in \mathcal{S}_{t-1}, f_k \in \boldsymbol{s}_i, \alpha_i < 0\}$, $\hat{k}'_d = (k+1)^d - k^d$ and $\check{k}'_d = 2^d - 1$ ($\because 0 \leq \boldsymbol{s}_i^{\mathrm{T}} \boldsymbol{x}_{k-1} \leq |\boldsymbol{x}_{k-1}| = k - 1$, $\boldsymbol{s}_i^{\mathrm{T}} \boldsymbol{x}_k = \boldsymbol{s}_i^{\mathrm{T}} \boldsymbol{x}_{k-1} + 1$ for all $\boldsymbol{s}_i \in \mathcal{S}^+_k \cup \mathcal{S}^-_k$).

We accumulate Eqs. 8 and 9 from rare to frequent features, and use the intermediate results to estimate the possible range of $m_t(\boldsymbol{x})$ before Line 3 in Algorithm 2. If the lower bound of $y m_t(\boldsymbol{x})$ turns out to be larger than one, we terminate the computation of $m_t(\boldsymbol{x})$.

As training continues, the model becomes discriminative and given $\boldsymbol{x}$ is likely to have a larger margin. The impact of this termination will increase as the amount of training data expands.

[3] When a margin of $\boldsymbol{x}_j$ has not been computed, we regard $t' = 0$ and $\delta^j_{t'} = 0$, which reduces Eq. 6 to Eq. 4.

[4] We associate partial margins with partial feature sequences whose features are sorted by frequent-to-rare order, and store them in a trie (*partial margin trie*). This enables us to retrieve partial margin $\delta^j_{t'}$ for given $\boldsymbol{x}_j$ in $\mathcal{O}(1)$ time.

4 Evaluation

We evaluated the proposed method in two NLP tasks: dependency parsing (Sassano, 2004) and hyponymy-relation extraction (Sumida et al., 2008). We used labeled data included in open-source softwares to promote the reproducibility of our results.[5] All the experiments were conducted on a server with an Intel® Xeon™ 3.2 GHz CPU. We used a double-array trie (Aoe, 1989; Yata et al., 2009) as an implementation of the weight trie and the partial margin trie.

4.1 Task Descriptions

Japanese Dependency Parsing A parser inputs a sentence segmented by a *bunsetsu* (base phrase in Japanese), and selects a particular pair of bunsetsus (dependent and head candidates); the classifier then outputs label $y = +1$ (dependent) or -1 (independent) for the pair. The features consist of the surface form, POS, POS-subcategory and the inflection form of each bunsetsu, and surrounding contexts such as the positional distance, punctuations and brackets. See (Yoshinaga and Kitsuregawa, 2009) for details on the features.

Hyponymy-Relation Extraction A hyponymy relation extractor (Sumida et al., 2008) first extracts a pair of entities from hierarchical listing structures in Wikipedia articles (hypernym and hyponym candidates); a classifier then outputs label $y = +1$ (correct) or -1 (incorrect) for the pair. The features include a surface form, morphemes, POS and the listing type for each entity, and surrounding contexts such as the hierarchical distance between the entities. See (Sumida et al., 2008) for details on the features.

4.2 Settings

Table 1 summarizes the training data for the two tasks. The examples for the Japanese dependency parsing task were generated for a transition-based parser (Sassano, 2004) from a standard data set.[6] We used the dependency accuracy of the parser as model accuracy in this task. In the hyponymy-relation extraction task, we randomly chosen two sets of 10,000 examples from the labeled data for development and testing, and used the remaining examples for training. Note that the number of active features, $|\mathcal{F}^d|$, dramatically grows when we consider higher-order conjunctive features.

DATA SET	DEP	REL

$\lvert\mathcal{F}^3\rvert$	58,361,669	64,249,234

Table 1: Training data for dependency parsing (DEP) and hyponymy-relation extraction (REL).

We compared the proposed method, PA-I SL (Algorithm 1 with Algorithm 2), to PA-I KERNEL (Algorithm 1 with PKI; Okanohara and Tsujii (2007)), PA-I KE (Algorithm 1 with kernel expansion; viz., kernel splitting with $N = |\mathcal{F}|$), SVM (batch training of support vector machines),[7] and ℓ_1-LLM (stochastic gradient descent training of the ℓ_1-regularized log-linear model: Tsuruoka et al. (2009)). We refer to PA-I SL that does not reuse temporal partial margins as PA-I SL*. To demonstrate the impact of conjunctive features on model accuracy, we also trained PA-I without conjunctive features. The number of iterations in PA-I was set to 20, and the parameters of PA-I were averaged in an efficient manner (Daumé III, 2006). We explicitly considered conjunctions among top-N ($N = 125 \times 2^n; n \geq 0$) features in PA-I SL and PA-I SL*. The hyperparameters were tuned to maximize accuracy on the development set.

4.3 Results

Tables 2 and 3 list the experimental results for the two tasks (due to space limitations, Tables 2 and 3 list PA-I SL with parameter N that achieved the fastest speed). The accuracy of the models trained with the proposed method was better than ℓ_1-LLMs and was comparable to SVMs. The infe-

PA-I SL$_{N=250}$	3	90.89%	**262s**	175MB

Table 2: Training time for classifiers used in dependency parsing task.

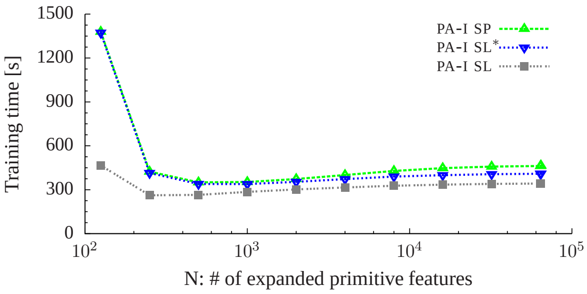

Figure 1: Training time for PA-I variants as a function of the number of expanded primitive features in dependency parsing task ($d = 3$).

rior accuracy of PA-I ($d = 1$) confirmed the necessity of conjunctive features in these tasks. The minor difference among the model accuracy of the three PA-I variants was due to rounding errors.

PA-I SL was the fastest of the training methods with the same feature set, and its space efficiency was comparable to the kernel-based learners. PA-I SL could reduce the memory footprint from 993MB[8] to 175MB for $d = 3$ in the dependency parsing task, while speeding up training.

Although linear training (ℓ_1-LLM and PA-I KE) dramatically slowed down when we took higher-order conjunctive features into account, kernel slicing alleviated deterioration in speed. Especially in the hyponymy-relation extraction task, PA-I SL took almost the same time regardless of the order of conjunctive features.

METHOD	d	ACC.	TIME	MEMORY
PA-I	1	91.75%	2s	28MB
ℓ_1-LLM	2	92.67%	136s	1683MB
SVM	2	92.85%	12306s	139MB

Table 3: Training time for classifiers used in hyponymy-relation extraction task.

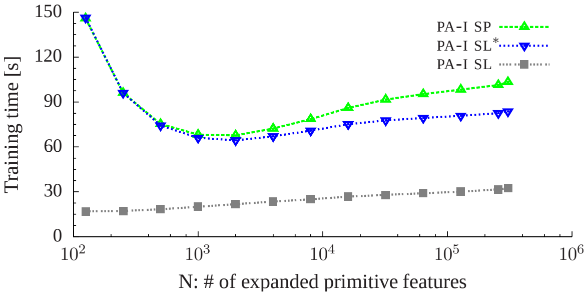

Figure 2: Training time for PA-I variants as a function of the number of expanded primitive features in hyponymy-relation extraction task ($d = 3$).

Figures 1 and 2 plot the trade-off between the number of expanded primitive features and training time with PA-I variants ($d = 3$) in the two tasks. Here, PA-I SP is PA-I with kernel slicing without the techniques described in Sections 3.2.1 and 3.2.2, viz., kernel splitting. The early termination of margin computation reduces the training time when N is large. The reuse of temporal margins makes the training time stable regardless of parameter N. This suggests a simple, effective strategy for calibrating N; we start the training with $N = |\mathcal{F}|$, and when the learner reaches the allowed memory size, we shrink N to $N/2$ by pruning sub-trees rooted by rarer features with $\text{RANK}(f) > N/2$ in the weight trie.

Figures 3 and 4 plot training time with PA-I variants ($d = 3$) for the two tasks as a function of the training data size. PA-I SP inherited the demerit of PA-I KERNEL which takes quadratic time in the number of examples, while PA-I SL took almost linear time in the number of examples.

[8] ℓ_1-LLM took much more memory than PA-I KE mainly because ℓ_1-LLM expands conjunctive features in the examples prior to training, while PA-I KE expands conjunctive features in each example on the fly during training. Interested readers may refer to (Chang et al., 2010) for this issue.

5 Related Work

There are several methods that learn 'simpler' models with fewer variables (features or support vectors), to ensure scalability in training.

Researchers have employed feature selection to assure space-efficiency in linear training. Wu et al. (2007) used frequent-pattern mining to select effective conjunctive features prior to training. Okanohara and Tsujii (2009) revised grafting for ℓ_1-LLM (Perkins et al., 2003) to prune useless conjunctive features during training. Iwakura and Okamoto (2008) proposed a boosting-based method that repeats the learning of rules represented by feature conjunctions. These methods, however, require us to tune the hyperparameter to trade model accuracy and the number of conjunctive features (memory footprint and training time); note that an accurate model may need many conjunctive features (in the hyponymy-relation extraction task, ℓ_1-LLM needed 15,828,122 features to obtain the best accuracy, 92.86%). Our method, on the other hand, takes all conjunctive features into consideration regardless of parameter N.

Dekel et al. (2008) and Cavallanti et al. (2007) improved the scalability of the (kernel) perceptron, by exploiting redundancy in the training data to bound the size of the support set to given threshold B ($\geq |\mathcal{S}_t|$). However, Orabona et al. (2009) reported that the models trained with these methods were just as accurate as a naive method that ceases training when $|\mathcal{S}_t|$ reaches the same threshold, B. They then proposed budget online learning based on PA-I, and it reduced the size of the support set to a tenth with a tolerable loss of accuracy. Their method, however, requires $\mathcal{O}(|\mathcal{S}_{t-1}|^2)$ time in updating the parameters in round t, which disables efficient training. We have proposed an orthogonal approach that exploits the data redundancy in evaluating the kernel to train the same model as the base learner.

6 Conclusion

In this paper, we proposed online learning with kernel slicing, aiming at resolving the space-time trade-off in training a classifier with many conjunctive features. The kernel slicing generalizes kernel splitting (Goldberg and Elhadad, 2008) in a purely feature-wise manner, to truly combine the merits of linear and kernel-based training. To improve the scalability of the training with redundant data in NLP, we reuse the temporal partial margins computed in past rounds and terminate unnecessary margin computations. Experiments on dependency parsing and hyponymy-relation extraction demonstrated that our method could train a classifier orders of magnitude faster than kernel-based learners, while retaining its space efficiency.

We will evaluate our method with ample labeled data obtained by the semi-supervised methods. The implementation of the proposed algorithm for kernel-based online learners is available from http://www.tkl.iis.u-tokyo.ac.jp/˜ynaga/.

Acknowledgment We thank Susumu Yata for providing us practical lessons on the double-array trie, and thank Yoshimasa Tsuruoka for making his ℓ_1-LLM code available to us. We are also indebted to Nobuhiro Kaji and the anonymous reviewers for their valuable comments.

Abstract

Near-synonyms are useful knowledge resources for many natural language applications such as query expansion for information retrieval (IR) and paraphrasing for text generation. However, near-synonyms are not necessarily interchangeable in contexts due to their specific usage and syntactic constraints. Accordingly, it is worth to develop algorithms to verify whether near-synonyms do match the given contexts. In this paper, we consider the near-synonym substitution task as a classification task, where a classifier is trained for each near-synonym set to classify test examples into one of the near-synonyms in the set. We also propose the use of discriminative training to improve classifiers by distinguishing positive and negative features for each near-synonym. Experimental results show that the proposed method achieves higher accuracy than both pointwise mutual information (PMI) and n-gram-based methods that have been used in previous studies.

1 Introduction

Near-synonym sets represent groups of words with similar meaning, which are useful knowledge resources for many natural language applications. For instance, they can be used for query expansion in information retrieval (IR) (Moldovan and Mihalcea, 2000; Bhogal et al., 2007), where a query term can be expanded by its near-synonyms to improve the recall rate. They can also be used in an intelligent thesaurus that can automatically suggest alternative words to avoid repeating the same word in the composing of text when there are suitable alternatives in its synonym set (Inkpen and Hirst, 2006; Inkpen, 2007). These near-synonym sets can be derived from manually constructed dictionaries such as WordNet (called synsets) (Fellbaum, 1998), EuroWordNet (Rodríguez et al., 1998), or clusters derived using statistical approaches (Lin, 1998).

Although the words in a near-synonym set have similar meaning, they are not necessarily interchangeable in practical use due to their specific usage and collocational constraints. Pearce (2001) presented an example of collocational constraints for the context " ____ coffee". In the given near-synonym set {strong, powerful}, the word "strong" is more suitable than "powerful" to fill the gap, since "powerful coffee" is an anti-collocation. Inkpen (2007) also presented several examples of collocations (e.g. ghastly mistake) and anti-collocations (e.g. ghastly error). Yu *et al.* (2007) described an example of the context mismatch problem for the context " ____ under the bay" and the near-synonym set {bridge, overpass, viaduct, tunnel} that represents the meaning of a physical structure that connects separate places by traversing an obstacle. The original word (target word) in the given context is "tunnel", and cannot be substituted by the other words in the same set since all the substitutions are semantically implausible. Accordingly, it is worth to develop algorithms to verify whether near-synonyms do match the given contexts. Applications can benefit from this ability to provide more effective services. For instance, a writing support system can assist users to select an alternative word that best fits a given context from a list of near-synonyms.

In measuring the substitutability of words, the co-occurrence information between a target word

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 1254–1262,
Beijing, August 2010

(the gap) and its context words is commonly used in statistical approaches. Edmonds (1997) built a lexical co-occurrence network from 1989 Wall Street Journal to determine the near-synonym that is most typical or expected in a given context. Inkpen (2007) used the pointwise mutual information (PMI) formula to select the best near-synonym that can fill the gap in a given context. The PMI scores for each candidate near-synonym are computed using a larger web corpus, the Waterloo terabyte corpus, which can alleviate the data sparseness problem encountered in Edmonds' approach. Following Inkpen's approach, Gardiner and Dras (2007) also used the PMI formula with a different corpus (the Web 1T 5-gram corpus) to explore whether near-synonyms differ in attitude.

Yu *et al.* (2007) presented a method to compute the substitution scores for each near-synonym based on n-gram frequencies obtained by querying Google. A statistical test is then applied to determine whether or not a target word can be substituted by its near-synonyms. The dataset used in their experiments are derived from the OntoNotes copus (Hovy et al., 2006; Pradhan et al., 2007), where each near-synonym set corresponds to a *sense pool* in OntoNotes. Another direction to the task of near-synonym substitution is to identify the senses of a target word and its near-synonyms using word sense disambiguation (WSD), comparing whether they were of the same sense (McCarthy, 2002; Dagan et al., 2006). Dagan *et al.* (2006) described that the use of WSD is an indirect approach since it requires the intermediate sense identification step, and thus presented a sense matching technique to address the task directly.

In this paper, we consider the near-synonym substitution task as a classification task, where a classifier is trained for each near-synonym set to classify test examples into one of the near-synonyms in the set. However, near-synonyms share more common context words (features) than semantically dissimilar words in nature. Such similar contexts may decrease classifiers' ability to discriminate among near-synonyms. Therefore, we propose the use of a supervised discriminative training technique (Ohler et al., 1999; Kuo and Lee, 2003; Zhou and He, 2009) to improve classifiers by distinguishing positive and negative features for each near-synonym. To our best knowledge, this is the first study that uses discriminative training for near-synonym or lexical substitution. The basic idea of discriminative training herein is to adjust feature weights according to the minimum classification error (MCE) criterion. The features that contribute to discriminating among near-synonyms will receive a greater positive weight, whereas the noisy features will be penalized and might receive a negative weight. This re-weighting scheme helps increase the separation of the correct class against its competing classes, thus improves the classification performance.

Sentence: This will make the _______ message easier to interpret.

Original word: error

Near-synonym set: {error, mistake, oversight}

Figure 1. Example of a near-synonym set and a sentence to be evaluated.

The proposed supervised discriminative training is compared with two unsupervised methods, the PMI-based (Inkpen, 2007) and n-gram-based (Yu *et al.*, 2007) methods. The goal of the evaluation is described as follows. Given a near-synonym set and a sentence with one of the near-synonyms in it, the near-synonym is deleted to form a gap in this sentence. Figure 1 shows an example. Each method is then applied to predict an answer (best near-synonym) that can fill the gap. The possible candidates are all the near-synonyms (including the original word) in the given set. Ideally, the correct answers should be provided by human experts. However, such data is usually unavailable, especially for a large set of test examples. Therefore, we follow Inkpen's experiments to consider the original word as the correct answer. The proposed methods can then be evaluated by examining whether they can restore the original word by filling the gap with the best near-synonym.

The rest of this work is organized as follows. Section 2 describes the PMI and n-gram-based methods for near-synonym substitution. Section 3 presents the discriminative training technique. Section 4 summarizes comparative results. Conclusions are finally drawn in Section 5.

2 Unsupervised Methods

2.1 PMI-based method

The mutual information can measure the co-occurrence strength between a near-synonym and the words in a given context. A higher mutual information score indicates that the near-synonym fits well in the given context, thus is more likely to be the correct answer. The pointwise mutual information (Church and Hanks, 1991) between two words *x* and *y* is defined as

$$PMI(x,y) = \log_2 \frac{P(x,y)}{P(x)P(y)}, \tag{1}$$

where $P(x,y) = C(x,y)/N$ denotes the probability that x and y co-occur; $C(x,y)$ is the number of times *x* and *y* co-occur in the corpus, and *N* is the total number of words in the corpus. Similarly, $P(x) = C(x)/N$, where *C*(*x*) is the number of times *x* occurs in the corpus, and $P(y) = C(y)/N$, where *C*(*y*) is the number of times *y* occurs in the corpus. Therefore, (1) can be re-written as

$$PMI(x,y) = \log_2 \frac{C(x,y)\cdot N}{C(x)\cdot C(y)}. \tag{2}$$

Inkpen (2007) computed the PMI scores for each near-synonym using the Waterloo terabyte corpus and a context window of size 2*k* (*k*=2). Given a sentence *s* with a gap, $s = ...w_1...w_k \underline{\qquad} w_{k+1}...w_{2k}...$, the PMI score for a near-synonym NS_i to fill the gap is defined as

$$PMI(NS_j,s) = \sum\nolimits_{i=1}^{k} PMI(NS_j,w_i) + \sum\nolimits_{i=k+1}^{2k} PMI(NS_j,w_i). \tag{3}$$

The near-synonym with the highest score is considered as the answer. In this paper, we use the Web 1T 5-gram corpus to compute PMI scores, the same as in (Gardiner and Dras, 2007). The frequency counts *C*(·) are retrieved from this corpus in the same manner within the 5-gram boundary.

2.2 N-gram-based method

The n-grams can capture contiguous word associations in given contexts. Given a sentence with a gap, the n-gram scores for each near-synonym are computed as follows. First, all possible n-grams containing the gap are extracted from the sentence. Each near-synonym then fills the gap to compute a normalized frequency according to

$$Z(ngram^i_{NS_j}) = \frac{\log\left(C(ngram^i_{NS_j})+1\right)}{\log C(NS_j)}, \tag{4}$$

where $C(ngram^i_{NS_j})$ denotes the frequency of an n-gram containing a near-synonym, $C(NS_j)$ denotes the frequency of a near-synonym, and $Z(ngram^i_{NS_j})$ denotes the normalized frequency of an n-gram, which is used to reduce the effect of high frequencies on measuring n-gram scores. All of the above frequencies are retrieved from the Web 1T 5-gram corpus.

The n-gram score for a near-synonym to fill the gap is computed as

$$NGRAM(NS_j,s) = \frac{1}{R}\sum_{i=1}^{R} Z(ngram^i_{NS_j}), \tag{5}$$

where $NGRAM(NS_j,s)$ denotes the n-gram score of a near-synonym, which is computed by averaging the normalized frequencies of all the n-grams containing the near-synonym, and *R* is the total number of n-grams containing the near-synonym. Again, the near-synonym with the highest score is the proposed answer. We herein use the 4-gram frequencies to compute n-gram scores as Yu *et al.* (2007) reported that the use of 4-grams achieved higher performance than the use of bigrams and trigrams.

3 Discriminative Training

3.1 Classifier

The supervised classification technique can also be applied to for near-synonym substitution. Each near-synonym in a set corresponds to a class. The classifiers for each near-synonym set are built from the labeled training data, i.e., a collection of sentences containing the near-synonyms. Such training data is easy to obtain since it requires no human annotation. The training data used herein is collected by extracting the 5-grams containing the near-synonyms from the Web 1T 5-gram corpus. The features used for training are the words occurring in the context of the near-synonyms in the 5-grams.

	Example		
	1	2	3
$g_1(x,M)=\cos(x,m_1)$	0.9*	0.6*	0.8
$g_2(x,M)=\cos(x,m_2)$	0.3	0.5	0.3*
$g_3(x,M)=\cos(x,m_3)$	0.2	0.4	0.1
$\max_{j\neq k} g_i(x,M)=$	0.3	0.5	0.8
$d_k(x,M)=$	-0.6	-0.1	0.5
$l_k(x,M)=$ (γ=5)	0.047	0.378	0.924

Table 1. Examples of correct classification and misclassification. * denotes the scores of the correct class.

For each near-synonym set, an $F \times K$ feature-class matrix, denoted as *M*, is created for classification. The rows represent the *F* distinct words (features) and the columns represent the *K* near-synonyms (classes) in the same set. Each entry in the matrix, m_{ij}, represents a weight of word *i* respect to near-synonym *j*, which is computed as the number of times word *i* appears in the contexts of near-synonym *j* divided by the total number of context words of near-synonym *j*. This frequency-based weight can then be transformed into a probabilistic form, i.e., divided by the sum of the weights of word *i* respect to all near-synonyms. Each test sentence is also transformed into an *F*-dimensional feature vector. Let $x=[x_1,...,x_i,...,x_F]$ denote the feature vector of an input sentence. The classification is performed by computing the cosine similarity between *x* and the column vectors (near-synonyms) in the matrix, defined as

$$\begin{aligned} NS_{\hat{j}} &= \arg\max_j \cos(x,m_j) \\ &= \arg\max_j \frac{x \bullet m_j}{\|x\|\|m_j\|} \qquad (6) \\ &= \arg\max_j \frac{\sum_{i=1}^{F} x_i m_{ij}}{\sqrt{\sum_{i=1}^{F} x_i^{\,2}}\sqrt{\sum_{i=1}^{F} m_{ij}^{\,2}}}, \end{aligned}$$

where m_j is the *j*-th column vector in the matrix *M*. The near-synonym with the highest cosine similarity score, $NS_{\hat{j}}$, is the predicted class of the classifier.

3.2 Minimum classification error criterion

According to the decision rule of the classifier, a classification error will occur when the near-synonym with the highest cosine score is not the correct class. Table 1 shows some examples, where Example 3 is an example of misclassification. On the other hand, although Example 2 is a correct classification, it might be an ambiguous case to classifiers since the scores are close among classes. Therefore, if we can increase the separation of the correct class from its competing ones, then the classification performance can be improved accordingly. This can be accomplished by adjusting the feature weights of the matrix *M* that have direct influence on the computation of cosine scores. The discriminative training performs the adjustment in the training phase according to the minimum classification error criterion. The detailed steps are as follows.

Given an input vector *x*, the classifier computes the cosine scores between *x* and each class using (6). The discriminant function for a class can thus be defined as the cosine measure; that is,

$$g_j(x,M)=\cos(x,m_j). \qquad (7)$$

where *j* denotes a class in *K*. Since the correct class of each input vector is known in the training phase, we can determine whether or not the input vector is misclassified by comparing the discriminant function (cosine score) of the correct class against its competing classes. In the case of misclassification, the cosine score of the correct class will be smaller than the competing cosine scores. Let *k* be the correct class of *x*, the misclassification function can be defined as

$$d_k(x,M)=-\,g_k(x,M)\;+\;G_k(x,M), \qquad (8)$$

where $g_k(x,M)$ is the discriminant function for the correct class *k*, and $G_k(x,M)$ is the anti-discriminant function that represents the other $K-1$ competing classes, defined as

$$G_k(x,M)=\left[\frac{1}{K-1}\sum_{j\neq k} g_j(x,M)^{\eta}\right]^{\frac{1}{\eta}}, \qquad (9)$$

When $\eta=1$, the anti-discriminant function $G_k(x,M)$ is the average of all the competing cosine scores. With the increase of η, $G_k(x,M)$ is gradually dominated by the biggest competing class. In the extreme case, i.e., $\eta \to \infty$, the anti-discriminant function becomes

$$G_k(x,M) = \max_{j \neq k} g_j(x,M). \quad (10)$$

The misclassification function in (8) can thus be rewritten as

$$d_k(x,M) = -g_k(x,M) + \max_{j \neq k} g_j(x,M), \quad (11)$$

In this case, the classification error is determined by comparing the discriminant function of the correct class against that of the biggest competing class. Obviously, $d_k(x,M) > 0$ implies a classification error. For instance, in Example 3, the discriminant function for the correct class is $g_2(x,M) = 0.3$, and that of the biggest competing class is $\max(g_1(x,M), g_3(x,M)) = 0.8$, thus the classification error is $d_k(x,M) = 0.5$. On the other hand, the classification error will be a negative value for correct classifications, as shown in Example 1 and 2.

Intuitively, a greater classification error also results in a greater loss. We herein use the sigmoid function as the class loss function; that is,

$$l_k(x,M) = l(d_k) = \frac{1}{1+\exp^{-\gamma d_k}}, \quad (12)$$

where γ is a constant that controls the slope of the sigmoid function. The sigmoid function maps the values of classification error within the range of 0 to 1. For correct classifications, a greater separation of the correct class from the biggest competing class leads to a greater negative value of d_k, i.e., a smaller classification error, resulting in a smaller loss tends asymptotically to 0 (Example 1), whereas a moderate loss is yielded if the separation was close (Example 2). For the cases of misclassification, a greater separation leads to a greater positive value of d_k, i.e., a greater classification error, resulting in a greater loss tends asymptotically to 1 (Example 3). The overall loss of the entire training set can then be estimated as

$$L(M) = \frac{1}{Q}\sum_{k=1}^{K}\sum_{x \in C_k} l_k(x,M), \quad (13)$$

where C_k denotes the set of training vectors of class *k*, and *Q* is the total number of vectors in the training set. The goal now is to minimize the loss. According to the above discussions on the three examples, to minimize the loss is to minimize the classification error, and to improve the separation of the correct class against its competing classes. This can be accomplished by adjusting the feature weights of the matrix *M* to distinguish positive and negative features for each class. We herein adopt a gradient descent method such as the generalized probabilistic descent (GPD) algorithm (Katagiri et al., 1998) to update the matrix *M*. The detailed steps are as follows.

Let the feature weights of the matrix *M* be the parameter set to be adjusted. The adjustment is performed iteratively according to the following update formula.

$$M^{(t+1)} = M^{(t)} - \varepsilon_t \nabla l_k(x^{(t)}, M^{(t)}), \quad (14)$$

where *t* denotes the *t*-th iteration, ε_t is an adjustment step of a small positive real number, and $\nabla l_k(x^{(t)}, M^{(t)})$ is the gradient of the loss function, which is computed by the following two parts

$$\nabla l_k(x^{(t)}, M^{(t)}) = \frac{\partial l_k}{\partial d_k}\frac{\partial d_k(x^{(t)}, M^{(t)})}{\partial m_{ij}}, \quad (15)$$

where

$$\frac{\partial l_k}{\partial d_k} = \gamma l_k(d_k)(1 - l_k(d_k)), \quad (16)$$

and from (7), (8), and (9),

$$\frac{\partial d_k(x^{(t)}, M^{(t)})}{\partial m_{ij}} = \begin{cases} -x_i, & \text{if } j = k \\ x_i \dfrac{G_k(x^{(t)},M) g_j(x^{(t)},M)^{\eta-1}}{\sum_{j \neq k} g_j(x^{(t)},M)^{\eta}}, & \text{if } j \neq k \end{cases}, \quad (17)$$

where x_i is an element of the input vector *x*. By replacing $\nabla l_k(x_t, M_t)$ in (14) with the two parts in (15), at each iteration each feature weight m_{ij} in *M* is adjusted by

$$m_{ij}^{(t+1)} = \begin{cases} m_{ij}^{(t)} + \varepsilon_t \dfrac{\partial l_k}{\partial d_k} x_i, & \text{if } j = k \\ m_{ij}^{(t)} - \varepsilon_t \dfrac{\partial l_k}{\partial d_k} x_i \dfrac{G_k(x^{(t)},M) g_j(x^{(t)},M)^{\eta-1}}{\sum_{j \neq k} g_j(x^{(t)},M)^{\eta}}, & \text{if } j \neq k \end{cases}. \quad (18)$$

The weight x_i represents whether or not a dimension word occurs in an input sentence. A zero weight indicates that the dimension word does not occur in the input sentence, thus the corresponding dimension of each column vector will not be adjusted. On the contrary, the corresponding dimension of the column vector of the correct class ($j = k$) is adjusted by adding a value, while those of the competing classes ($j \neq k$) are adjusted by subtracting a value from them. After a sequence of adjustments over the training set, the positive and negative features can be distinguished by adjusting their weights that result in a greater positive or negative value for each of them. The separation of the correct class against its competing ones can thus be increased.

The weight adjustment in (18) is in proportion to the adjustment step ε_t and the slope of the sigmoid function $\partial l_k / \partial d_k$. The adjustment step ε_t can be determined empirically. As (16) shows, the slope $\partial l_k / \partial d_k$ converges asymptotically to zero as the classification error d_k approaches to a very large (or small) value. This leads to a small weight adjustment. For instance, the weight adjustment in Example 1 is small due to a small value of d_k, or, say, due to a large separation between the correct class and its competing ones. This is reasonable because classifiers often perform well in such cases. Similarly, the weight adjustment in Example 3 (misclassification) is also small due to a large value of d_k. A greater adjustment is not employed because such a large separation is difficult to be reduced significantly. Additionally, over-adjusting some features may introduce negative effects on other useful features in the matrix. Therefore, discriminative training is more effective on the cases with a moderate value of d_k, like Example 2. Such cases usually fall within the decision boundary and tend to be confusing to classifiers. Hence, improving the separation on such cases helps significantly improve the classification performance.

4 Experimental Results

4.1 Experiment setup

1) Data: The near-synonym sets used for experiments included the seven sets (Exp1) and the eleven sets (Exp2) used in the previous studies (Edmonds, 1997; Inkpen, 2007; Gardiner and Dras, 2007), as shown in Table 2. The Web 1T 5-gram corpus was used to build classifiers, where the corpus was randomly split into a training set, a development set, and a test set with an 8:1:1 ratio. For efficiency consideration, we randomly sampled up to 100 5-grams from the test set for each near-synonym. This sampling procedure was repeated five times for evaluation of the classifiers.

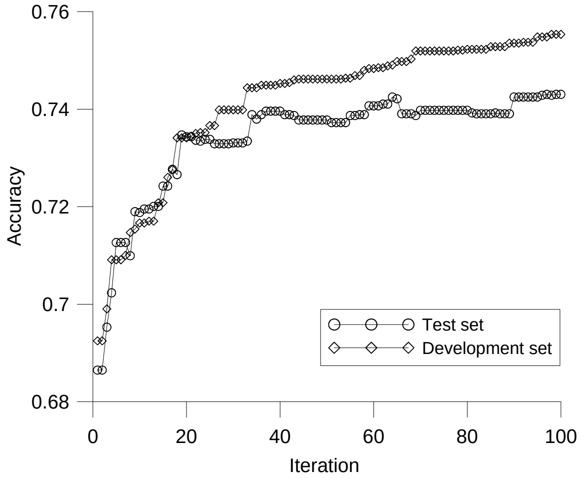

Figure 2. The change of classification accuracy during discriminative training.

2) Classifiers: The classifiers were implemented using PMI, n-grams, and discriminative training (DT) methods, respectively.

PMI: Given a near-synonym set and a test 5-gram with a gap, the PMI scores for each near-synonym were calculated using (3), where the size of the context window *k* was set to 2. The frequency counts between each near-synonym and its context words were retrieved from the training set.

NGRAM: For each test 5-gram with a gap, all possible 4-grams containing the gap were first extracted (excluding punctuation marks). The averaged 4-gram scores for each near-synonym were then calculated using (5). Again, the frequency counts of the 4-grams were retrieved from the training set.

DT: For each near-synonym set, the matrix *M* was built from the training set. Each 5-gram in the development set was taken as input to iteratively compute the cosine score, loss, classification error, respectively, and finally to adjust the feature weights of *M*. The parameters of DT included η for the anti-discriminative function, γ

No.	Near-synonym set	No. of cases	Accuracy (%)			
			NGRAM	PMI	COS	DT
1.	difficult, hard, tough	300	58.60	61.67	60.13	63.13
2.	error, mistake, oversight	300	68.47	78.33	77.20	79.20
3.	job, task, duty	300	68.93	70.40	74.00	75.67

Table 2. Accuracy of classifiers on Exp1 (7 sets) and Exp2 (11 sets). The words marked with * are excluded from the experiments because their 5-grams are very rare in the corpus.

for the sigmoid function, and ε_t for the adjustment step. The settings, $\eta = 25$, $\gamma = 35$, and $\varepsilon_t = 10^{-3}$, were determined by performing DT for several iterations through the training set. These setting were used for the following experiments.

3) Evaluation metric: The answers proposed by each classifier are the near-synonyms with the highest score. The correct answers are the near-synonyms originally in the gap of the test 5-grams. The performance is measure by the accuracy, which is defined as the number of correct answers made by each classifier, divided by the total number of test 5-grams.

In the following sections, we first demonstrate the effect of DT on classification performance, followed by the comparison of the classifiers.

4.2 Evaluation on discriminative training

This experiment is to investigate the performance change during discriminative training. Figure 2 shows the accuracy at the first 100 iterations for both development set and test set, with the 8th set in Exp2 as an example. The accuracy increased rapidly in the first 20 iterations, and stabilized after the 40th iteration. The discriminative training is stopped until the accuracy has not been changed over 30 iterations or the 300th iteration has been reached.

Features	Near-synonym set		
	mistake	error	oversight
made	**0.076**	-0.004	-0.005
biggest	**0.074**	-0.001	-0.004
message	-0.004	**0.039**	-0.010
internal	0.001	**0.026**	-0.001
supervision	-0.001	-0.006	**0.031**
audit	-0.002	-0.003	**0.028**

Table 3. Example of feature weights after discriminative training.

4.3 Comparative results

Table 2 shows the comparative results of the classification accuracy for the 18 near-synonym sets (Exp1 + Exp2). The accuracies for each near-synonym set were the average accuracies of the five randomly sampled test sets. The cosine measure without discrimination training (COS) was also considered for comparison. The results show that NGRAM performed worst among the four classifiers. The major reason is that not all 4-grams of the test examples can be found in the corpus. Instead of contiguous word associations used by NGRAM, PMI considers the words in the contexts independently to select the best synonyms. The results show that PMI achieved better performance than NGRAM. The two supervised methods, COS and DT, outperformed the two unsupervised methods, NGRAM and PMI. As indicated in the bold numbers, using the supervised method alone (without DT), COS yielded higher average accuracy by 5% and 2% over NGRAM and PMI, respectively, on Exp1, and by 6% and 3%, respectively, on Exp2. When DT was employed, the average accuracy was further improved by 4% and 6% on Exp1 and Exp2, respectively, compared with COS.

The use of DT can improve the classification accuracy mainly because it can adjust the feature weights iteratively to improve the separation between the correct class and its competing ones, which helps tackle the ambiguous test examples that fall within the decision boundary. Table 3 presents several positive and negative features for the near-synonym set {mistake, error, oversight}. The feature weights were adjusted according to their contributions to discriminating among the near-synonyms in the set. For instance, the features "made" and "biggest" both received a positive value for the class "mistake", and a negative value for the competing classes "error" and "oversight". These positive and negative weights help distinguish useful features from noisy ones for classifier training. On the other hand, if the feature weights were evenly distributed among the classes, these features would not be unlikely to contribute to the classification performance.

Exp1	Rank 1	Rank 2	Diff.
NGRAM	66.33%	79.35%	+19.63%
PMI	68.50%	88.99%	+29.91%
COS	69.94%	89.93%	+28.58%
DT	72.89%	91.06%	+24.93%
Exp2	Rank 1	Rank 2	Diff.
NGRAM	61.69%	68.48%	+11.01%
PMI	63.32%	79.11%	+24.94%
COS	65.15%	80.52%	+23.59%
DT	69.26%	82.86%	+19.64%

Table 4. Accuracy of Rank 1 and Rank 2 for each classifier.

4.4 Accuracy of Rank 1 and Rank 2

The accuracy presented in Table 2 was computed based on the classification results at Rank 1, i.e., a test sample was considered correctly classified only if the near-synonym with the highest score was the word originally in the gap of the test sample. Similarly, the accuracy at Rank 2 can be computed by considering the top two near-synonyms proposed by each classifier. That is, if either the near-synonym with the highest or the second highest score was the correct answer, the test sample was considered correctly classified. Table 4 shows the accuracy of Rank 1 and Rank 2 for each classifier. The results show that the improvement of Rank 1 accuracy on Exp1 was about 20 to 30 percentage points, and was 25.76 in average. For Exp2, the average improvement was 19.80 percentage points

5 Conclusion

This work has presented the use of discriminative training for near-synonym substitution. The discriminative training can improve classification performance by iteratively re-weighting the positive and negative features for each class. This helps improve the separation of the correct class against its competing ones, making classifiers more effective on ambiguous cases close to the decision boundary. Experimental results show that the supervised discriminative training technique achieves higher accuracy than the two unsupervised methods, the PMI-based and n-gram-based methods. The availability of a large labeled training set also encourages the use of the proposed supervised method.

Future work will investigate on the use of multiple features for discriminating among near-synonyms. For instance, the predicate-argument structure, which can capture long-distance information, will be combined with currently used local contextual features to boost the classification performance. More experiments will also be conducted to evaluate classifiers' ability to rank multiple answers.

Abstract

In distributional semantics studies, there is a growing attention in compositionally determining the distributional meaning of word sequences. Yet, compositional distributional models depend on a large set of parameters that have not been explored. In this paper we propose a novel approach to estimate parameters for a class of compositional distributional models: the additive models. Our approach leverages on two main ideas. Firstly, a novel idea for extracting compositional distributional semantics examples. Secondly, an estimation method based on regression models for multiple dependent variables. Experiments demonstrate that our approach outperforms existing methods for determining a good model for compositional distributional semantics.

1 Introduction

Lexical distributional semantics has been largely used to model word meaning in many fields as computational linguistics (McCarthy and Carroll, 2003; Manning et al., 2008), linguistics (Harris, 1964), corpus linguistics (Firth, 1957), and cognitive research (Miller and Charles, 1991). The fundamental hypothesis is the distributional hypothesis (DH): "similar words share similar contexts" (Harris, 1964). Recently, this hypothesis has been operationally defined in many ways in the fields of physicology, computational linguistics, and information retrieval (Li et al., 2000; Pado and Lapata, 2007; Deerwester et al., 1990).

Given the successful application to words, distributional semantics has been extended to word sequences. This has happened in two ways: (1) via the reformulation of DH for specific word sequences (Lin and Pantel, 2001); and (2) via the definition of compositional distributional semantics (CDS) models (Mitchell and Lapata, 2008; Jones and Mewhort, 2007). These are two different ways of addressing the problem.

Lin and Pantel (2001) propose the *pattern distributional hypothesis* that extends the distributional hypothesis for specific patterns, i.e. word sequences representing partial verb phrases. Distributional meaning for these patterns is derived directly by looking to their occurrences in a corpus. Due to data sparsity, patterns of different length appear with very different frequencies in the corpus, affecting their statistics detrimentally. On the other hand, compositional distributional semantics (CDS) propose to obtain distributional meaning for sequences by composing the vectors of the words in the sequences (Mitchell and Lapata, 2008; Jones and Mewhort, 2007). This approach is fairly interesting as the distributional meaning of sequences of different length is obtained by composing distributional vectors of single words. Yet, many of these approaches have a large number of parameters that cannot be easily estimated.

In this paper we propose a novel approach to es-

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 1263–1271,
Beijing, August 2010

timate parameters for additive compositional distributional semantics models. Our approach leverages on two main ideas. Firstly, a novel way for extracting compositional distributional semantics examples and counter-examples. Secondly, an estimation model that exploits these examples and determines an equation system that represents a regression problem with multiple dependent variables. We propose a method to estimate a solution of this equation system based on the Moore-Penrose pseudo-inverse matrices (Penrose, 1955).

The rest of the paper is organised as follows: Firstly, we shortly review existing compositional distributional semantics (CDS) models (Sec. 2). Then we describe our model for estimating CDS models parameters (Sec. 3). In succession, we introduce a way to extract compositional distributional semantics examples from dictionaries (Sec. 4). Then, we discuss the experimental set up and the results of our linear CDS model with estimated parameters with respect to existing CDS models (Sec. 5).

2 Models for compositional distributional semantics (CDS)

A CDS model is a function $\odot$ that computes the distributional vector of a sequence of words s by combining the distributional vectors of its component words $\mathsf{w}_1 \dots \mathsf{w}_n$. Let $\odot(\mathsf{s})$ be the distributional vector describing s and $\vec{w}_i$ the distributional vectors describing its component word w_i. Then, the CDS model can be written as:

$$\odot(\mathsf{s}) = \odot(\mathsf{w}_1 \dots \mathsf{w}_n) = \vec{w}_1 \odot \dots \odot \vec{w}_n \qquad (1)$$

This generic model has been fairly studied and many different functions have been proposed and tested.

Mitchell and Lapata (2008) propose the following general CDS model for 2-word sequences $\mathsf{s} = \mathsf{xy}$:

$$\odot(\mathsf{s}) = \odot(\mathsf{xy}) = f(\vec{x}, \vec{y}, R, K) \qquad (2)$$

where $\vec{x}$ and $\vec{y}$ are respectively the distributional vectors of x and y, R is the particular syntactic and/or semantic relation connecting x and y, and, K represents the amount of background knowledge that the vector composition process takes into account. Two specialisations of the general CDS model are proposed: the *basic additive* model and the *basic multiplicative* model.

	vector dimensions				
	between	gap	process	social	two
contact	< 11,	0,	3,	0,	11 >
x: *close*	< 27,	3,	2,	5,	24 >
y: *interaction*	< 23,	0,	3,	8,	4 >

Table 1: Example of distributional frequency vectors for the triple $t = (\vec{contact}, \vec{close}, \vec{interaction})$

The *basic additive* model (BAM) is written as:

$$\odot(\mathsf{s}) = \alpha\vec{x} + \beta\vec{y} \qquad (3)$$

where α and β are two scalar parameters. The simplistic parametrisation is $\alpha = \beta = 1$. For example, given the vectors $\vec{x}$ and $\vec{y}$ of Table 1, $\odot_{BAM}(\mathsf{s}) =< 50, 3, 5, 13, 28 >$.

The *basic multiplicative* model (BMM) is written as:

$$s_i = x_i y_i \qquad (4)$$

where s_i, x_i, and y_i are the i-th dimensions of the vectors $\odot(\mathsf{s})$, $\vec{x}$, and $\vec{y}$, respectively. For the example of Table 1, $\odot_{BMM}(\mathsf{s}) =< 621, 0, 6, 40, 96 >$.

Erk and Padó (2008) look at the problem in a different way. Let the general distributional meaning of the word w be $\vec{w}$. Their model computes a different vector $\vec{w}_{\mathsf{s}}$ that represents the specific distributional meaning of w with respect to s, i.e.:

$$\vec{w}_{\mathsf{s}} = \oslash(\mathsf{w}, \mathsf{s}) \qquad (5)$$

In general, this operator gives different vectors for each word w_i in the sequence s, i.e. $\oslash(\mathsf{w}_i, \mathsf{s}) \neq \oslash(\mathsf{w}_j, \mathsf{s})$ if $i \neq j$. It also gives different vectors for a word w_i appearing in different sequences s_k and s_l, i.e. $\oslash(\mathsf{w}_i, \mathsf{s}_k) \neq \oslash(\mathsf{w}_i, \mathsf{s}_l)$ if $k \neq l$.

The model of Erk and Padó (2008) was designed to *disambiguate* the distributional meaning of a word w in the context of the sequence s. However, substituting the word w with the semantic head h of s, allows to compute the distributional meaning of sequence s as shaped by the word that is governing the sequence (c.f. Pollard and Sag (1994)). For example, the distributional meaning of the word sequence *eats mice* is governed by the verb *eats*. Following this model, the distributional vector $\odot(\mathsf{s})$ can be written as:

$$\odot(\mathsf{s}) \approx \oslash(\mathsf{h}, \mathsf{s}) \tag{6}$$

The function $\oslash(\mathsf{h}, \mathsf{s})$ explicitly uses the relation R and the knowledge K of the general equation 2, being based on the notion of selectional preferences. We exploit the model for sequences of two words s=xy where the two words are related with an oriented syntactic relation r (e.g. r=adj_modifier). For making the syntactic relation explicit, we indicate the sequence as: $\mathsf{s} = \mathsf{x} \overset{r}{\leftarrow} \mathsf{y}$.

Given a word w, the model has to keep track of its selectional preferences. Consequently, each word w is represented with a triple:

$$(\vec{w}, R_{\mathsf{w}}, R_{\mathsf{w}}^{-1}) \tag{7}$$

where $\vec{w}$ is the distributional vector of the word w, R_{w} is the set of the vectors representing the direct selectional preferences of the word w, and R_{w}^{-1} is the set of the vectors representing the indirect selectional preferences of the word w. Given a set of syntactic relations $\mathcal{R}$, the set R_{w} and R_{w}^{-1} contain respectively a selectional preference vector $R_{\mathsf{w}}(r)$ and $R_{\mathsf{w}}(r)^{-1}$ for each $r \in \mathcal{R}$. Selectional preferences are computed as in Erk (2007). If x is the semantic head of sequence s, then the model can be written as:

$$\odot(\mathsf{s}) = \oslash(\mathsf{x}, \mathsf{x} \overset{r}{\leftarrow} \mathsf{y}) = \vec{x} \odot R_{\mathsf{y}}(r) \tag{8}$$

Otherwise, if y is the semantic head:

$$\odot(\mathsf{s}) = \oslash(\mathsf{y}, \mathsf{x} \overset{r}{\leftarrow} \mathsf{y}) = \vec{y} \odot R_{\mathsf{x}}^{-1}(r) \tag{9}$$

$\odot$ is in both cases realised using BAM or BMM. We will call these models: *basic additive* model with selectional preferences (BAM-SP) and basic multiplicative model with selectional preferences (BMM-SP).

Both Mitchell and Lapata (2008) and Erk and Padó (2008) experimented with few empirically estimated parameters. Thus, the general additive CDS model has not been adequately explored.

3 Estimating Additive Compositional Semantics Models from Data

The generic *additive* model sums the vectors $\vec{x}$ and $\vec{y}$ in a new vector $\vec{z}$:

$$\odot(\mathsf{s}) = \vec{z} = A\vec{x} + B\vec{y} \tag{10}$$

where A and B are two square matrices capturing the relation R and the background knowledge K of equation 2. Writing matrices A and B by hand is impossible because of their large size. Estimating these matrices is neither a simple classification learning problem nor a simple regression problem. It is a regression problem with multiple dependent variables. In this section, we propose our model to solve this regression problem using a set of training examples E.

The set of training examples E contains triples of vectors $(\vec{z}, \vec{x}, \vec{y})$. $\vec{x}$ and $\vec{y}$ are the two distributional vectors of the words x and y. $\vec{z}$ is the expected distributional vector of the composition of $\vec{x}$ and $\vec{y}$. Note that for an ideal perfectly performing CDS model we can write $\vec{z} = \odot(\mathsf{xy})$. However, in general the expected vector $\vec{z}$ is not guaranteed to be equal to the composed one $\odot(\mathsf{xy})$. Figure 1 reports an example of these triples, i.e., $t = (\vec{contact}, \vec{close}, \vec{interaction})$, with the related distributional vectors. The construction of E is discussed in section 4.

In the rest of the section, we describe how the regression problem with multiple dependent variables can be solved with a linear equation system and we give a possible solution of this equation system. In the experimental section, we refer to our model as the estimated additive model (EAM).

3.1 Setting the linear equation system

The matrices A and B of equation 10 can be joined in a single matrix:

$$\vec{z} = \begin{pmatrix} A & B \end{pmatrix} \begin{pmatrix} \vec{x} \\ \vec{y} \end{pmatrix} \tag{11}$$

For the triple t of table 1, equation 11 is:

$$\vec{contact} = \begin{pmatrix} A & B \end{pmatrix} \begin{pmatrix} \vec{close} \\ \vec{interaction} \end{pmatrix} \tag{12}$$

and it can be rewritten as:

$$\begin{pmatrix} 11 \\ 0 \\ 3 \\ 0 \\ 11 \end{pmatrix} = \begin{pmatrix} A_{5\times 5} & B_{5\times 5} \end{pmatrix} \begin{pmatrix} 27 \\ 3 \\ 2 \\ 5 \\ 24 \\ 23 \\ 0 \\ 3 \\ 8 \\ 4 \end{pmatrix} \tag{13}$$

Focusing on matrix $\begin{pmatrix} AB \end{pmatrix}$, we can transpose the matrices as follows:

$$\begin{aligned} \vec{z}^T &= \left(\begin{pmatrix} A & B \end{pmatrix} \begin{pmatrix} \vec{x} \\ \vec{y} \end{pmatrix} \right)^T \\ &= \begin{pmatrix} \vec{x}^T & \vec{y}^T \end{pmatrix} \begin{pmatrix} A^T \\ B^T \end{pmatrix} \end{aligned} \tag{14}$$

Matrix $\begin{pmatrix} \vec{x}^T & \vec{y}^T \end{pmatrix}$ is known and matrix $\begin{pmatrix} A^T \\ B^T \end{pmatrix}$ is to be estimated.

Equation 14 is the prototype of our final equation system. The larger the matrix $\begin{pmatrix} AB \end{pmatrix}$ to be estimated, the more equations like 14 are needed. Given set E that contains n triples $(\vec{z}, \vec{x}, \vec{y})$, we can write the following system of equations:

$$\begin{pmatrix} \vec{z}_1^T \\ \vec{z}_2^T \\ \vdots \\ \vec{z}_n^T \end{pmatrix} = \begin{pmatrix} \begin{pmatrix} \vec{x}_1^T & \vec{y}_1^T \end{pmatrix} \\ \begin{pmatrix} \vec{x}_2^T & \vec{y}_2^T \end{pmatrix} \\ \vdots \\ \begin{pmatrix} \vec{x}_n^T & \vec{y}_n^T \end{pmatrix} \end{pmatrix} \begin{pmatrix} A^T \\ B^T \end{pmatrix} \tag{15}$$

The vectors derived from the triples can be seen as two matrices of n rows, Z and $\begin{pmatrix} XY \end{pmatrix}$ related to $\vec{z}_i^T$ and $\begin{pmatrix} \vec{x}_i^T & \vec{y}_i^T \end{pmatrix}$, respectively. The overall equation system is then the following:

$$Z = \begin{pmatrix} X & Y \end{pmatrix} \begin{pmatrix} A^T \\ B^T \end{pmatrix} \tag{16}$$

This equation system represents the constraints that matrices A and B have to satisfy in order to be a possible linear CDS model that can at least describe seen examples. We will hereafter call $\Lambda = \begin{pmatrix} A & B \end{pmatrix}$ and $Q = \begin{pmatrix} X & Y \end{pmatrix}$. The system in equation 16 can be simplified as:

$$Z = Q\Lambda^T \tag{17}$$

As Q is a rectangular and singular matrix, it is not invertible and the system in equation 16 has no solutions. It is possible to use the principle of Least Square Estimation for computing an approximation solution. The idea is to compute the solution $\widehat{\Lambda}$ that minimises the residual norm, i.e.:

$$\widehat{\Lambda}^T = \arg\min_{\Lambda^T} \|Q\Lambda^T - Z\|^2 \tag{18}$$

One solution for this problem is the **Moore-Penrose pseudoinverse** Q^+ (Penrose, 1955) that gives the following final equation:

$$\widehat{\Lambda}^T = Q^+ Z \tag{19}$$

In the next section, we discuss how the **Moore-Penrose pseudoinverse** is obtained using singular value decomposition (SVD).

3.2 Computing the pseudo-inverse matrix

The pseudo-inverse matrix can provide an approximated solution even if the equation system has no solutions. We here compute the **Moore-Penrose pseudoinverse** using singular value decomposition (SVD) that is widely used in computational linguistics and information retrieval for reducing spaces (Deerwester et al., 1990).

Moore-Penrose pseudoinverse (Penrose, 1955) is computed in the following way. Let the original matrix Q have n rows and m columns and be of rank r. The SVD decomposition of the original matrix Q is $Q = U\Sigma V^T$ where Σ is a square diagonal matrix of dimension r. Then, the pseudoinverse matrix that minimises the equation 18 is:

$$Q^+ = V\Sigma^+ U^T \tag{20}$$

where the diagonal matrix Σ^+ is the $r \times r$ transposed matrix of Σ having as diagonal elements the reciprocals of the singular values $\frac{1}{\delta_1}, \frac{1}{\delta_2}, ..., \frac{1}{\delta_r}$ of Σ.

Using SVD to compute the pseudo-inverse matrix allows for different approximations (Fallucchi and Zanzotto, 2009). The algorithm for computing the singular value decomposition is iterative (Golub and Kahan, 1965). Firstly derived dimensions have higher singular value. Then, dimension k is more informative than dimension $k' > k$. We can consider different values for k to obtain different SVD for the approximations Q_k^+ of the original matrix Q^+ in equation 20), i.e.:

$$Q_k^+ = V_{n\times k}\Sigma_{k\times k}^+ U_{k\times m}^T \tag{21}$$

where Q_k^+ is a matrix n by m obtained considering the first k singular values.

4 Building positive and negative examples

As explained in the previous section, estimating CDS models, needs a set of triples E, similar to triple t of table 1. This set E should contain positive examples in the form of triples $(\vec{z_i}, \vec{x_i}, \vec{y_i})$. Examples are positive in the sense that $\vec{z_i} = \odot(\mathsf{xy})$ for an ideal CDS. There are no available sets to contain such triples, with the exception of the set used in Mitchell and Lapata (2008) which is designed only for testing purposes. It contains similar and dissimilar pairs of sequences (s_1,s_2) where each sequence is a verb-noun pair (v_i,n_i). From the positive part of this set, we can only derive quadruples where $\odot(\mathsf{v}_1\mathsf{n}_1) \approx \odot(\mathsf{v}_2\mathsf{n}_2)$ but we cannot derive the ideal resulting vector of the composition $\odot(\mathsf{v}_i\mathsf{n}_i)$. Sets used to test multiword expression (MWE) detection models (e.g., (Schone and Jurafsky, 2001; Nicholson and Baldwin, 2008; Kim and Baldwin, 2008; Cook et al., 2008; Villavicencio, 2003; Korkontzelos and Manandhar, 2009)) are again not useful as containing only valid MWE that cannot be used to determine the set of training triples needed here.

As a result, we need a novel idea to build sets of triples to train CDS models. We can leverage on knowledge stored in dictionaries. In the rest of the section, we describe how we build the positive example set E and a control negative example set NE. Elements of the two sets are pairs (t,s) where t is a target word s is a sequence of words. t is the word that represent the distributional meaning of s in the case of E. Contrarily, t is totally unrelated to the distributional meaning of s in NE. The sets E and NE can be used both for training and for testing. In the testing phase, we can use these sets to determine whether a CDS model is good or not and to compare different CDS models.

4.1 Building Positive Examples using Dictionaries

Dictionaries as natural repositories of equivalent expressions can be used to extract positive examples for training and testing CDS models. The basic idea is the following: dictionary entries are *declarations* of equivalence. Words or, occasionally, multi-word expressions t are declared to be semantically similar to their definition sequences s. This happens at least for some sense of the defined words. We can then observe that t ≈ s. For example, we report some sample definitions of *contact* and *high life*:

target word (t)	definition sequence (s)
contact	close interaction
high life	excessive spending

In the first case, a word, i.e. *contact*, is semantically similar to a two-word expression, i.e. *close interaction*. In the second case, two two-word expressions are semantically similar.

Then, the pairs (t, s) can be used to model positive cases of compositional distributional semantics as we know that the word sequence s is compositional and it describes the meaning of the word t. The distributional meaning $\vec{t}$ of t is the expected distributional meaning of s. Consequently, the vector $\vec{t}$ is what the CDS model $\odot(\mathsf{s})$ should compositionally obtain from the vectors of the components $\vec{s_1} \dots \vec{s_m}$ of s. This way of extracting similar expressions has some interesting properties:

First property Defined words t are generally single words. Thus, we can extract stable and meaningful distributional vectors for these words and then compare them to the distributional vectors composed by CDS model. This is an important property as we cannot compare directly the distributional vector $\vec{s}$ of a word sequence s and the vector $\odot(\mathsf{s})$ obtained by composing its components. As the word sequence s grows in length, the reliability of the vector $\vec{s}$ decreases since the sequence s becomes rarer.

Second property Definitions s have a large variety of different syntactic structures ranging from simple structures as Adjective-Noun to more complex ones. This gives the possibility to train and test CDS models that take into account syntax. Table 2 represents the distribution of the more frequent syntactic structures in the definitions of WordNet[1] (Miller, 1995).

[1] Definitions were extracted from WordNet 3.0 and were parsed with the Charniak parser (Charniak, 2000)

4.2 Extracting Negative Examples from Word Etymology

In order to devise complete training and testing sets for CDS models, we need to find a sensible way to extract negative examples. An option is to randomly generate totally unrelated triples for the negative examples set, NE. In this case, due to data sparseness NE would mostly contain triples $(\vec{z}, \vec{x}, \vec{y})$ where it is expected that $\vec{z} \neq \odot(\mathsf{xy})$. Yet, these can be too generic and too loosely related to be interesting cases.

Instead we attempt to extract sets of negative pairs (t,s) comparable with the one used for building the training set E. The target word t should be a single word and s should be a sequence of words. The latter should be a sequence of words related by construction to t but the meaning of t and s should be unrelated.

The idea is the following: many words are etymologically derived from very old or ancient words. These words represent a collocation which is in general not related to the meaning of the target word. For example, the word *philosophy* derives from two Greek words *philos* (beloved) and *sophia* (wisdom). However, the use of the word *philosophy* in not related to the collocation *beloved wisdom*. This word has lost its original compositional meaning. The following table shows some more etymologically complex words along with the compositionally unrelated collocations:

target word	compositionally unrelated seq.
municipal	receive duty
octopus	eight foot

As the examples suggest, we are able to build a set NE with features similar to the features of N. In particular, each target word is paired with a related word sequence derived from its etymology. These etymologically complex words are unrelated to the corresponding compositional collocations. To derive a set NE with the above characteristics we can use dictionaries containing etymological information as Wiktionary[2].

5 Experimental evaluation

In the previous sections, we presented the estimated additive model (EAM): our approach to estimate the parameters of a generic additive model for CDS. In this section, we experiment with this model to determine whether it performs better than existing models: the basic additive model (BAM), the basic multiplicative model (BMM), the basic additive model with selectional preferences (BAM-SP), and the basic multiplicative model with selectional preferences (BMM-SP) (c.f. Sec. 2). In succession, we explore whether our estimated additive model (EAM) is better than any possible BAM obtained with parameter adjustment. In the rest of the section, we firstly give the experimental setup and then we discuss the experiments and the results.

5.1 Experimental setup

Our experiments aim to compare compositional distributional semantic (CDS) models $\odot$ with respect to their ability of detecting statistically significant difference between sets E and NE. In particular, the average similarity $sim(\vec{z}, \odot(\mathsf{xy}))$ for $(\vec{z}, \vec{x}, \vec{y}) \in E$ should be significantly different from $sim(\vec{z}, \odot(\mathsf{xy}))$ for $(\vec{z}, \vec{x}, \vec{y}) \in NE$. In this section, we describe the chosen similarity measure sim, statistical significance testing and construction details for the training and testing set.

Cosine similarity was used to compare the context vector $\vec{z}$ representing the target word z with the composed vector $\odot(\mathsf{xy})$ representing the context vector of sequence $\mathsf{x}\ \mathsf{y}$. Cosine similarity be-

[2] http://www.wiktionary.org

tween two vectors $\vec{x}$ and $\vec{y}$ of the same dimension is defined as:

$$sim(\vec{x},\vec{y}) = \frac{\vec{x}\cdot\vec{y}}{\|\vec{x}\|\;\|\vec{y}\|} \tag{22}$$

where $\cdot$ is the dot product and $\|\vec{a}\|$ is the magnitude of vector $\vec{a}$ computed the Euclidean norm.

To evaluate whether a CDS model distinguishes positive examples E from negative examples NE, we test if the distribution of similarities $sim(\vec{z}, \odot(\mathsf{xy}))$ for $(\vec{z},\vec{x},\vec{y}) \in E$ is statistically different from the distribution of the same similarities for $(\vec{z},\vec{x},\vec{y}) \in NE$. For this purpose, we used Student's t-test for two independent samples of different sizes. t-test assumes that the two distributions are Gaussian and determines the probability that they are similar, i.e., derive from the same underlying distribution. Low probabilities indicate that the distributions are highly dissimilar and that the corresponding CDS model performs well, as it detects statistically different similarities for the positive set E and the negative set NE.

Based on the null hypothesis that the means of the two samples are equal, $\mu_1 = \mu_2$, Student's t-test takes into account the sizes N, means M and variances s^2 of the two samples to compute the following value:

$$t = (M_1 - M_2)\sqrt[-1]{\frac{2(s_1^2+s_2^2)}{df * N_h}} \tag{23}$$

where $df = N_1 + N_2 - 2$ stands for the degrees of freedom and $N_h = 2(N_1^{-1} + N_2^{-1})^{-1}$ is the harmonic mean of the sample sizes. Given the statistic t and the degrees of freedom df, we can compute the corresponding p-value, i.e., the probability that the two samples derive from the same distribution. The null hypothesis can be rejected if the p-value is below the chosen threshold of statistical significance (usually 0.1, 0.05 or 0.01), otherwise it is accepted. In our case, rejecting the null hypothesis means that the similarity values of instances of E are significantly different from instances of NE, and that the corresponding CDS model perform well. p-value can be used as a performance ranking function for CDS models.

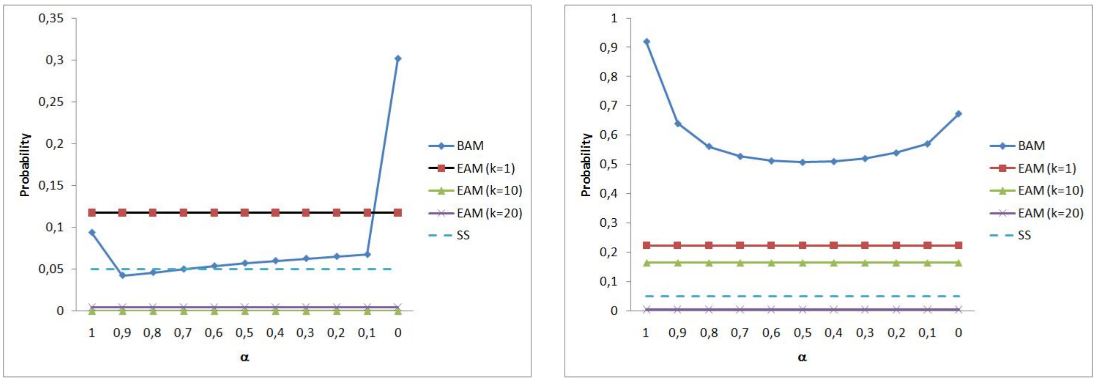
We constructed two sets of instances: (a) a set containing Adjective-Noun or Noun-Noun sequences (*NN* set); and (b) a set containing Verb-Noun sequences (*VN* set). Capturing different syntactic relations, these two sets can support that our results are independent from the syntactic relation between the words of each sequence. For each set, we used WordNet for extracting positive examples E and Wiktionary for extracting negative examples NE as described in Section 4. We obtained the following sets: (a) *NN* consists of 1065 word-sequence pairs from WordNet definitions and 377 pairs extracted from Wiktionary; and (b) *VN* consists of 161 word-sequence pairs from WordNet definitions and 111 pairs extracted from Wiktionary. We have then divided these two sets in two parts of 50% each, for training and testing. Instances of the training part of E have been used to estimate matrices A and B for model EAM, while the testing parts have been used for testing all models. Frequency vectors for all single words occurring in the above pairs were constructed from the British National Corpus using sentences as contextual windows and words as features. The resulting space has 689191 features.

	NN set	*VN* set
BAM	0.05690	0.50753
BMM	0.20262	0.37523
BAM-SP	0.42574	0.01710
BMM-SP	<1.00E-10	0.23552
EAM (k=20)	0.00431	0.00453

Table 3: Probability of confusing E and NE with different CDS models

5.2 Results and Analysis

The first set of experiments compares EAM with other existing CDS models: BAM, BMM, BAM-SP, and BMM-SP. Results are shown in Table 3. The table reports the p-value, i.e., the probability of confusing the positive set E and the negative set NE for all models. Lower probabilities characterise better models. Probabilities below 0.05 indicate that the model detects a statistically significant difference between sets E and NE. EAM has been computed with $k = 20$ different dimensions for the pseudo-inverse matrix. The two basic additive models (BAM and BAM-SP) have been computed for $\alpha = \beta = 1$.



NN set VN *set*

Figure 1: p-values of BAM with different values for parameter α (where $\beta = 1 - \alpha$) and of EAM for different approximations of the SVD pseudo-inverse matrix (k)

The first observation is that EAM models significantly separate positive from negative examples for both sets. This is not the case for any of the other models. Only, the selectional preferences based models in two cases have this property, but this cannot be generalised: BAM-SP on the *VN* set and BMM-SP on the *NN* set. In general, these models do not offer the possibility of separating positive from negative examples.

In the second set of experiments, we attempt to investigate whether simple parameter adjustment of BAM can perform better than EAM. Results are shown in figure 1. Plots show the basic additive model (BAM) with different values for parameter α (where $\beta = 1 - \alpha$) and EAM computed for different approximations of the SVD pseudo-inverse matrix (i.e., with different k). The x-axis of the plots represents parameter α and the y-axis represents the probability of confusing the positive set E and the negative set NE. The representation focuses on the performance of BAM with respect to different α values. The performance of EAM for different k values is represented with horizontal lines. Probabilities of different models are directly comparable. Line SS represents the threshold of statistical significance; the value below which the detected difference between the E and NE sets becomes statistically significant.

Experimental results show some interesting facts: While BAM for $\alpha > 0$ perform better than EAM computed with $k = 1$ in the NN set, they do not perform better in the VN set. EAM with $k = 1$ has 1 degree of freedom corresponding to 1 parameter, the same as BAM. The parameter of EAM is tuned on the training set, in contrast to α, the parameter of BAM. Increasing the number of considered dimensions, k of EAM, estimated models outperform BAM for all values of parameter α. Moreover, EAM detect a statistically significant difference between the E and the NE sets for $k \geq 10$ and $k = 20$ for the *NN* set and the *VN* set set, respectively. Simple parametrisation of a BAM does not outperform the proposed estimated additive model.

6 Conclusions

In this paper, we presented an innovative method to estimate linear compositional distributional semantics models. The core of our approach consists on two parts: (1) providing a method to estimate the regression problem with multiple dependent variables and (2) providing a training set derived from dictionary definitions. Experiments showed that our model is highly competitive with respect to state-of-the-art models for compositional distributional semantics.

Abstract

In opinion mining of product reviews, one often wants to produce a summary of opinions based on product features/attributes. However, for the same feature, people can express it with different words and phrases. To produce a meaningful summary, these words and phrases, which are domain synonyms, need to be grouped under the same feature group. This paper proposes a constrained semi-supervised learning method to solve the problem. Experimental results using reviews from five different domains show that the proposed method is competent for the task. It outperforms the original EM and the state-of-the-art existing methods by a large margin.

1 Introduction

One form of opinion mining in product reviews is to produce a feature-based summary (Hu and Liu, 2004a; Liu, 2010). In this model, product features are first identified, and positive and negative opinions on them are aggregated to produce a summary on the features. Features of a product are attributes, components and other aspects of the product, e.g., “picture quality”, “battery life” and “zoom” of a digital camera.

In reviews (or any writings), people often use different words and phrases to describe the same product feature. For example, “picture” and “photo” refer to the same feature for cameras. Grouping such synonyms is critical for effective opinion summary. Although WorldNet and other thesaurus dictionaries can help to some extent, they are far from sufficient due to a few reasons. First, many words and phrases that are not synonyms in a dictionary may refer to the same feature in an application domain. For example, “appearance” and “design” are not synonymous, but they can indicate the same feature, *design*. Second, many synonyms are domain dependent. For example, “movie” and “picture” are synonyms in movie reviews, but they are not synonyms in camera reviews as “picture” is more likely to be synonymous to “photo” while “movie” to “video”. Third, determining which expressions indicate the same feature can be dependent on the user’s application need. For example, in car reviews, internal design and external design can be regarded as two separate features, but can also be regarded as one feature, called “design”, based to the level of details that the user needs to study. In camera reviews, one may want to study battery as a whole (one feature), or as more than one feature, e.g., battery weight, and battery life. Due to this reason, in applications the user needs to be involved in synonym grouping.

Before going further, let us introduce two concepts, *feature group* and *feature expression*. Feature group (or *feature* for short) is the name of a feature (given by the user), while a feature expression of a feature is a word or phrase that actually appears in a review to indicate the feature. For example, a feature group could be named “picture quality”, but there are many possible expressions indicating the feature, e.g., “picture”, “photo”, “image”, and even the “picture quality” itself. All the feature expressions in a feature group signify the same feature.

Grouping feature expressions manually into suitable groups is time consuming as there are

*Supported by National Natural Science Foundation of China (Grant No: 60875073).

This work was done when the first author was visiting Bing Liu’s group at the University of Illinois at Chicago.

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 1272–1280,
Beijing, August 2010

often hundreds of feature expressions. This paper helps the user to perform the task more efficiently. To focus our research, we assume that feature expressions have been discovered from a review corpus by an existing system such as those in (Hu and Liu, 2004b; Popescu and Etzioni, 2005; Kim and Hovy, 2006; Kobayashi *et al.*, 2007; Mei *et al.*, 2007; Stoyanov and Cardie, 2008; Jin *et al.*, 2009; Ku *et al.*, 2009).

To reflect the user needs, he/she can manually label a small number of seeds for each feature group. The feature groups are also provided by the user based on his/her application needs. The system then assigns the rest of the feature expressions to suitable groups. To the best of our knowledge, this problem has not been studied in opinion mining (Pang and Lee, 2008).

The problem can be formulated as semi-supervised learning. The small set of seeds labeled by the user is the labeled data, and the rest of the discovered feature expressions are the unlabeled data. This is the transductive setting (Joachims, 1999) because the unlabeled set is used in learning and also in testing since our objective is to assign unlabeled expressions to the right feature groups.

Any semi-supervised learning method can be applied to tackle the problem. In this work, we use the Expectation-Maximization (EM) algorithm (Dempster *et al.*, 1977). Specifically, we use the naïve Bayesian EM formulation in (Nigam *et al.*, 2000), which runs a Bayesian classifier iteratively on the labeled and unlabeled data until the probabilities for the unlabeled data converge. When the algorithm ends, each unlabeled example is assigned a posterior probability of belonging to each group.

However, we can do better since the EM algorithm only achieves local optimal. What local optimal it achieves depends on the initialization, i.e., the initial seeds. We show that some prior knowledge can help provide a better initialization, and consequently generate better grouping results. Thus, we propose to create another set of data extracted from the unlabeled set based on two pieces of natural language knowledge:

1. Feature expressions sharing some common words are likely to belong to the same group, e.g., “battery life” and “battery power”.
2. Feature expressions that are synonyms in a dictionary are likely to belong to the same group, e.g., “movie” and “picture”.

We call these two pieces of prior knowledge *soft constraints* because they constrain the feature expressions to be in the same feature group. The constraints are soft (rather than hard) as they can be relaxed in the learning process. This relaxation is important because the above two constraints can result in wrong groupings. The EM algorithm is allowed to re-assign them to other groups in the learning process.

We call the proposed framework constrained semi-supervised learning. Since we use EM and soft constraints, we call the proposed method *SC-EM.* Clearly, the problem can also be attempted using some other techniques, e.g., topic modeling (e.g, LDA (Blei *et al.*, 2003)), or clustering using distributional similarity (Pereira *et al.*, 1993; Lin, 1998; Chen *et al.*, 2006; Sahami and Heilman, 2006). However, our results show that these methods do not perform as well.

The input to the proposed algorithm consists of: a set of reviews *R*, and a set of discovered feature expressions *F* from *R* (using an existing algorithm). The user labels a small set of feature expressions, i.e., assigning them to the user-specified feature groups. The system then assigns the rest of the discovered features to the feature groups. EM is run using the distributional (or surrounding words) contexts of feature expressions in review set *R* to build a naïve Bayesian classifier in each iteration.

Our evaluation was conducted using reviews from 5 different domains (insurance, mattress, vacuum, car and home-theater). The results show that the proposed method outperforms different variations of the topic modeling method LDA, *k*-means clustering, and the recent unsupervised feature grouping method mLSA.

In summary, this paper makes three main contributions:

1. It proposes a new sub-problem of opinion mining, i.e., grouping feature expressions in the context of semi-supervised learning. Although there are existing methods for solving the problem based on unsupervised learning, we argue that for practical use some form of supervision from the user is necessary to let the system know what the user wants.
2. An EM formulation is used to solve the problem. We augment EM with two soft constraints. These constraints help guide EM to

produce better solutions. We note that these constraints can be relaxed in the process to correct the imperfection of the constraints.

3. It is shown experimentally the new method outperforms the main existing state-of-the-art methods that can be applied to the task.

2 Related Work

This work is mainly related to existing research on synonyms grouping, which clusters words and phrases based on some form of similarity.

The methods for measuring word similarity can be classified into two main types (Agirre *et al.*, 2009): those relying on *pre-existing knowledge resources* (e.g., thesauri, or taxonomies) (Yang and Powers, 2005; Alvarez and Lim, 2007; Hughes and Ramage, 2007), and those based on *distributional properties* (Pereira *et al.*, 1993; Lin, 1998; Chen *et al.*, 2006; Sahami and Heilman, 2006; Pantel *et al.*, 2009).

In the category that relies on existing knowledge sources, the work of Carenini *et al.* (2005) is most related to ours. The authors proposed a method to map feature expressions to a given domain feature taxonomy, using several similarity metrics on WordNet. This work does not use the word distribution information, which is its main weakness because many expressions of the same feature are not synonyms in WordNet as they are domain/application dependent. Dictionaries do not contain domain specific knowledge, for which a domain corpus is needed.

Another related work is distributional similarity, i.e., words with similar meaning tend to appear in similar contexts (Harris, 1968). As such, it fetches the surrounding words as context for each term. Similarity measures such as *Cosine*, *Jaccard*, *Dice*, etc (Lee, 1999), can be employed to compute the similarities between the seeds and other feature expressions. To suit our need, we tested the *k*-means clustering with distributional similarity. However, it does not perform as well as the proposed method.

Recent work also applied topic modeling (e.g., LDA) to solve the problem. Guo *et al.* (2009) proposed a multilevel latent semantic association technique (called *mLSA*) to group product feature expressions, which runs LDA twice. However, *mLSA* is an unsupervised approach. For our evaluation, we still implemented the method and compared it with our SC-EM method.

Our work is also related to constrained clustering (Wagstaff *et al.*, 2001), which uses two forms of constraints, must-link and cannot-link. Must-links state that some data points must be in the same cluster, and cannot-links state that some data points cannot be in the same cluster. In (Andrzejewski *et al.*, 2009), the two constraints are added to LDA, called *DF-LDA*. We show that both these methods do not perform as well as our semi-supervised learning method *SC-EM.*

3 The Proposed Algorithm

Since our problem can be formulated as semi-supervised learning, we briefly describe the setting in our context. Given a set C of classes (our feature groups), we use L to denote the small set of labeled examples (labeled feature expressions or seeds), and U the set of unlabeled examples (unlabeled feature expressions). A classifier is built using L and U to classify every example in U to a class. Several existing algorithms can be applied. In this work, we use EM as it is efficient and it allows prior knowledge to be used easily. Below, we first introduce the EM algorithm that we use, and then present our augmented EM. The constraints and their conflict handling are discussed in Section 4.

3.1 Semi-Supervised Learning Using EM

EM is a popular iterative algorithm for maximum likelihood estimation in problems with missing data. In our case, the group memberships of the unlabeled expressions are considered missing because they come without group labels.

We use the EM algorithm based on naïve Bayesian classification (Nigam *et al.*, 2000). Although it is involved to derive, using it is simple. First, a classifier f is learned using only the labeled data L (Equations 1 and 2). Then, f is applied to assign a probabilistic label to each unlabeled example in U (see Equation 3). Next, a new classifier f is learned using both L and the newly probabilistically labeled unlabeled examples in U_{PL}, again using Equations 1 and 2. These last two steps iterate until convergence.

We now explain the notations in the Equations. Given a set of training documents D, each document d_i in D is considered as an ordered list of words. $w_{d_i,k}$ denotes the k^{th} word in d_i, where each word is from the vocabulary $V=\{w_1, w_{2,\dots,} w_{|V|}\}$. $C=\{c_1, c_{2,\dots,} c_{|C|}\}$ is the set of pre-defined

$$\mathrm{P}(w_t|c_j) = \frac{1 + \sum_{i=1}^{|D|} N_{ti}\mathrm{P}(c_j|d_i)}{|V| + \sum_{m=1}^{|V|}\sum_{i=1}^{|D|} N_{mi}\mathrm{P}(c_j|d_i)} \tag{1^1}$$

$$\mathrm{P}(c_j) = \frac{1 + \sum_{i=1}^{|D|} \mathrm{P}(c_j|d_i)}{|C| + |D|} \tag{2^1}$$

$$\mathrm{P}(c_j|d_i) = \frac{\mathrm{P}(c_j)\prod_{\mathrm{k}=1}^{|d_i|}\mathrm{P}(w_{d_i,k}|c_j)}{\sum_{\mathrm{r}=1}^{|C|}\mathrm{P}(c_r)\prod_{\mathrm{k}=1}^{|d_i|}\mathrm{P}(w_{d_i,k}|c_r)} \tag{3}$$

classes or groups. N_{ti} is the number of times the word w_t occurs in document d_i.

For our problem, the surrounding words contexts of the labeled seeds form *L*, while the surrounding words of the non-seed feature expressions form *U*. When EM converges, the classification labels of the unlabeled feature expressions give us the final grouping. Surrounding words contexts will be discussed in Section 5.

3.2 Proposed Soft-Constrained EM

Although EM can be directly applied to deal with our problem, we can do better. As we discussed earlier, EM only achieves local optimal based on the initialization, i.e., the labeled examples or seeds. We show that natural languages constraints can be used to provide a better initialization, i.e., to add more seeds that are likely to be correct, called *soft-labeled examples* or *soft seeds* (*SL*). Soft-labeled examples are handled differently from the original labeled examples in *L*. With the soft seeds, we have the proposed soft-constrained EM (called SC-EM).

Compared with the original EM, SC-EM has two main differences:

- Soft constraints are applied to *L* and *U* to produce a set *SL* of soft-labeled examples (or soft seeds) to initialize EM in addition to *L*. *SL* is thus a subset of *U*. The training set size is increased, which helps produce better results as our experimental results show.
- In the first iteration of EM, soft-labeled examples *SL* are treated in the same way as the labeled examples in *L*. Thus both *SL* and *L* are used as labeled examples to learn the initial classifier f_0. However, in the subsequent iterations, *SL* is treated in the same way as any examples in *U*. That is, the classifier f_x from each iteration *x* (including f_0) will predict *U*. After that, a new classifier is built using both *L* and U_{PL} (which is *U* with probabilistic labels). Clearly, this implies that the class labels of the examples in *SL* are allowed to change. That is also why we call *SL* the soft-labeled set in contrast to the hard-labeled set *L*, i.e., the examples in *L* will not change labels in EM. The reason that *SL* is allowed to change labels/classes is because the constraints can make mistakes. EM may be able to correct some of the mistakes.

```
Input:
-  Labeled examples $L$
-  Unlabeled examples $U$
Extract $SL$ from $U$ using constraints (Section 4);
Learn an initial naïve Bayesian classifier $f_0$ using $L \cup SL$ and Equations 1 and 2;
repeat
    // E-Step
    for each example $d_i$ in $U$ (including $SL$) do
        Using the current classifier $f_x$ to compute $P(c_j|d_i)$ using Equation 3.
    end
    // M-Step
    Learn a new naïve Bayesian classifier $f_x$ from $L$ and $U$ by computing $P(w_t|c_j)$ and $P(c_j)$ using Equations 1 and 2.
until the classifier parameters stabilize
Output: the classifier $f_x$ from the last iteration.
```

Figure 1. The proposed SC-EM algorithm

The detailed algorithm is given in Figure 1. The constraints are discussed in Section 4.

4 Generating SL Using Constraints

As mentioned earlier, two forms of constraints are used to induce the soft-labeled set *SL*. For easy reference, we reproduce them here:

1. Feature expressions sharing some common words are likely to belong to the same group.
2. Feature expressions that are synonyms in a dictionary are likely to belong to one group.

According to the number of words, feature expressions can be categorized into single-word expressions and phrase expressions. They are handled differently. The detailed algorithm is given in Figure 2. In the algorithm, *L* is the labeled set and *U* is the unlabeled set. *L*, in fact, consists of a set of sets, $L = \{L_1, L_2, \ldots, L_{|L|}\}$. Each L_i contains a set of labeled examples (feature expressions) of the i^{th} class (feature group). Similarly, the output set *SL* (the soft-labeled set) also consists of a set of sets, i.e., $SL = \{SL_1, SL_2, \ldots, SL_{|L|}\}$. Each SL_i is a set of soft-labeled examples (feature expressions) of the i^{th} class

[1] Laplace smoothing is used to prevent zero probabilities for infrequently occurring words.

(feature group). Thus L_i and SL_i correspond to each other as they represent the original labeled examples and the newly soft-labeled examples of the i^{th} class (or feature group) respectively.

The algorithm basically compares each feature expression u in U (line 1) with each feature expression e (line 4) in every labeled subset L_i (line 2) based on the above two constraints. If any of the constraints is satisfied (lines 5-17), it means that u is likely to belong to L_i (or the i^{th} class or feature group), and it is added to SL_i.

There are conflict situations that need to be resolved. That is, u may satisfy a constraint of more than one labeled sub-set L_i. For example, if u is a single word, it may be synonyms of feature expressions from more than one feature groups. The question is which group it is likely to belong. Further, u may be synonyms of a few single-word feature expressions in L_i. Clearly, u being a synonym of more than one word in L_i is better than it is only the synonym of one word in L_i. Similar problems also occur when u is an element of a feature expression phrase e.

To match u and e, there are a few possibilities. If both u and e are single words (lines 5-6), the algorithm checks if they are synonyms (line 7). The score in line 8 is discussed below. When one of u and e is a phrase, or both of them are phrases, we see whether they have shared words. Again, conflict situations can happen with multiple classes (feature groups) as discussed above. Note that in these cases, we do not use the synonym constraint, which does not help in our test.

Given these complex cases, we need to decide which class that u should be assigned to or should not be assigned to any class (as it does not meet any constraint). We use a score to record the level of satisfaction. Once u is compared with each e in every class, the accumulated score is used to determine which class L_i has the strongest association with u. The class j with the highest score is assigned to u. In other words, u is added to SL_j. Regarding the score value, synonyms gets the score of 1 (line 8), and intersection (shared words) gets the score equal to the size of the intersection (lines 10-17).

```
1  for each feature expression $u \in U$ do
2      for each feature group $L_i \in L$ do
3          score($L_i$) ← 0;
4          for each feature expression $e \in L_i$ do
5              if $u$ is a single word expression then
6                  if $e$ is a single word expression then
7                      if $u$ and $e$ are synonyms then
8                          score($L_i$) ← score($L_i$) + 1;
9                  else if $w \in e$ then  // $e$ is a phrase
10                     score($L_i$) ← score($L_i$) + 1
11             else  // $u$ is a phrase
12                 if $e$ is a single word expression then
13                     if $e \in u$ then  // $u$ is a phrase
14                         score($L_i$) ← score($L_i$) + 1
15                 else
16                     $s \leftarrow e \cap u$;
17                     score($L_i$) ← score($L_i$) + $|s|$
18     $u$ is added to $SL_j$ s.t. $\text{argmax}_{L_i}\, score(L_i)$
```

Figure 2. Generating the soft-labeled set SL

5 Distributional Context Extraction

To apply the proposed algorithm, a document d_i needs to be prepared for each feature expression e_i for naïve Bayesian learning. d_i is formed by aggregating the distributional context of each sentence s_{ij} in our corpus that contains the expression e_i. The context of a sentence is the surrounding words of e_i in a text window of [-t, t], including the words in e_i. Given a relevant corpus R, the document d_i for each feature expression e_i in L (or U) is generated using the algorithm in Figure 3. Stopwords are removed.

```
for each feature expression $e_i$ in $L$ (or $U$) do
    $S_i$ ← all sentences containing $e_i$ in $R$;
    for each sentence $s_{ij} \in S_i$ do
        $d_{ij}$ ← words in a window of [-$t$, $t$] on the left
                and right (including the words in $e_i$);
    $d_i$ ← words from all $d_{ij}$, $j$ = 1, 2, …, $|S_i|$;
                // duplicates are kept as it is not union
```

Figure 3. Distributional context extraction

For example, a feature expression from L (or U) is e_i = "*screen*" and there are two sentences in our corpus R that contain "*screen*"

s_{i1} = "*The LCD* ***screen*** *gives clear picture*".

s_{i2} = "*The picture on the* ***screen*** *is blur*"

We use the window size of [-3, 3]. Sentence s_{i1}, gives us d_{i1} = <LCD, screen, give, clear, picture> as a bag of words. "the" and "is" are removed as stopwords. s_{i2} gives us d_{i2} = <picture, screen, blur>. "on", "the" and "is" are removed as stopwords. Finally, we obtain the document d_i for feature expression e_i as a bag of words:

d_i = <LCD, screen, give, clear, picture,
picture, screen, blur>

6 Empirical Evaluation

This section evaluates the SC-EM algorithm and compares it with the main existing methods that can be applied to solve the problem.

6.1 Review Data Sets and Gold Standards

To demonstrate the generality of the proposed method, experiments were conducted using reviews from five domains: *Hometheater, Insurance, Mattress, Car* and *Vacuum*. All the data sets and the *gold standard* feature expressions and groups were from a company that provides opinion mining services. The details of the data sets and the gold standards are given in Table 1.

	Hometheater	Insurance	Mattress	Car	Vacuum
#Sentences	6355	12446	12107	9731	8785
#Reviews	587	2802	933	1486	551
#Feature expressions	237	148	333	317	266
#Feature groups	15	8	15	16	28

Table 1. Data sets and gold standards

6.2 Evaluation Measures

Since SC-EM is based on semi-supervised learning, we can use classification accuracy to evaluate it. We can also see it as clustering with initial seeds. Thus we also use clustering evaluation methods. Given gold standards, two popular clustering evaluation measures are *Entropy* and *Purity* (Liu, 2006). As *accuracy* is fairly standard, we will not discuss it further. Below, we briefly describe entropy and purity.

Given a data set *DS*, its gold partition is $G = \{g_1,\dots, g_j,\dots, g_k\}$, where *k* is the known number of clusters. The groups partition *DS* into *k* disjoint subsets, $DS_1,\dots, DS_i, \dots, DS_k$.

Entropy: For each resulting cluster, we can measure its entropy using Equation 4, where $\mathrm{P}_i(g_j)$ is the proportion of g_j data points in DS_i. The total entropy of the clustering (considering all clusters) is calculated by Equation 5.

$$entropy(DS_i) = -\sum\nolimits_{j=1}^{k} \mathrm{P}_i(g_j) log_2 \mathrm{P}_i(g_j) \qquad (4)$$

$$entropy_{total} = \sum\nolimits_{i=1}^{k} \frac{|DS_i|}{|DS|} entropy(DS_i) \qquad (5)$$

Purity: Purity measures the extent that a cluster contains only data from one gold-partition. Each cluster's purity is computed by Equation 6, and the total purity of the whole clustering is computed with Equation 7.

$$purity(DS_i) = \max_j \mathrm{P}_i(g_j) \qquad (6)$$

$$purity_{total} = \sum\nolimits_{i=1}^{k} \frac{|DS_i|}{|DS|} purity(DS_i) \qquad (7)$$

In testing, the unlabeled set *U* is also our test set. This is justified because our purpose is to assign unlabeled data to appropriate groups.

6.3 Baseline Methods and Settings

The proposed ***SC-EM*** method is compared with a set of existing methods, which can be categorized into unsupervised and semi-supervised methods. We list the *unsupervised* methods first.

LDA: *LDA* is a popular topic modeling method (see Section 2). Given a set of documents, it outputs groups of terms of different topics. In our case, each feature expression is a term, and the documents refer to the distributional contexts of each feature expressions (see Section 5).

mLSA: This is a state-of-the-art unsupervised method for solving the problem. It is based on LDA, and has been discussed in related work.

Kmeans: This is the *k*-means clustering method (MacQueen, 1966) based on distributional similarity with cosine as the similarity measure.

In the *semi-supervised* category, the methods are further classified into un-constrained, hard-constrained, and soft-constrained methods.

For the *un-constrained* subclass (no constraints are used), we have the following:

LDA*(*L, H*)**: This method is based on ***LDA, but the labeled examples *L* are used as seeds for each group/topic. All examples in *L* will always stay in the same topic. We call this hard initialization (*H*). *L* is handled similarly below.

DF-LDA*(*L, H*)**. *DF-LDA* is the *LDA* method (Andrzejewski *et al.*, 2009) that takes must-links and cannot-links. Our *L* set can be expressed as a combination of must-links and cannot-links. Unfortunately, only must-links can be used because the number of cannot-links is huge and crashes the system. For example, for the car data, the number of cannot-links is 194,400 for 10% labeled data (see Section 6.4) and for 20% it is 466,560,000. DF-LDA also has a parameter η controlling the link strength, which is set very high (=1000) to reflect the hard initialization. We did not use *DF-LDA* in the unsupervised subclass above as without constraints it reduces to ***LDA.

***Kmeans*(*L, H*)**: This method is based on *Kmeans*, but the clusters of the labeled seeds are fixed at the initiation and remain unchanged.

***EM*(*L, H*)**: This is the original EM for semi-supervised learning. Only the labeled examples are used as the initial seeds.

For the *hard-constrained* (*H*) subclass (our two constraints are applied and cannot be violated), we have the following methods (*LC* is *L* plus *SL* produced by the constraints (C):

***Rand*(*LC, H*):** This is an important baseline. It shows whether the constraints alone are sufficient to produce good results. That is, the final result is the expanded seeds *SL* plus the rest of *U* assigned randomly to different groups.

***LDA*(*LC, H*)**: It is similar to *LDA*(*L,H*), but both the initial seeds *L* and the expanded seeds *SL* are considered as labeled examples. They also stay in the same topics/groups in the process. Note that although *SL* is called a set of soft-labeled examples (seeds) in the proposed algorithm, they are treated as hard-labeled examples here just for experimental comparison.

***DF-LDA*(*LC, H*)**: This is *DF-LDA* with both *L* and *SL* expressed as must-links. Again, a large η (= 1000) is used to make sure that must-links for *L* and *SL* will not be violated.

***Kmeans*(*LC,H*)**: It is similar to *Kmeans*(*L,H*), but both *L* and *SL* stay in their assigned clusters.

***EM*(*LC, H*)**: It is similar to *SC-EM*, but *SL* is added to the labeled set *L*, and their classes are not allowed to change in the EM iterations.

For the *soft-constrained* (*S*) subclass, our two constraints can be violated. Initially, both the initial seeds *L* and the expanded seeds *SL* are considered as labeled data, but subsequently, only *L* is taken as the labeled data (i.e., staying in the same classes). The algorithm will re-estimate the label of each feature expression in *SL*. This subclass has the following methods:

***LDA*(*LC, S*)**: This is in contrast to *LDA*(*LC, H*). It allows the *SL* set to change topics/groups.

***Kmeans*(*LC, S*)**: This is in contrast to *Kmeans*(*LC, H*).

A soft *DF-LDA* is not included here because different η values give different results, and they are generally worse than *DF-LDA*(*LC, H*).

For all *LDA* based methods, the topic modeling parameters were set to their default values. The number of iteration is 1000. We used the *LDA* in MALLET[2], and modified it to suit different *LDA*-based methods except *DF-LDA*, which was downloaded from its authors' website[3]. We implemented *mLSA*, *Kmeans* and changed EM[4] to take soft seeds. For all *Kmeans* based methods, the distance function is the cosine similarity.

6.4 Evaluation Results

We now compare the results of *SC-EM* and the 14 baseline methods. To see the effects of different numbers of labeled examples (seeds), we experimented with 10%, 20%, 30%, 40%, and 50% of the feature expressions from the gold standard data as the labeled set *L*, and the rest as the unlabeled set *U*. All labeled data were selected randomly. For each setting, we run the algorithms 30 times and report the average results. Due to space limitations, we can only show the detailed *purity* (Pur), *entropy* (Ent) and *accuracy* (Acc) results for 30% as the labeled data (70% as unlabeled) in Table 2. For the other proportions of labeled data, we summarize them in Table 3. Each result in Table 3 is thus the average of the 5 data sets. All the results were obtained from the unlabeled set *U*, which was our test set. For entropy, the smaller the value is the better, but for purity and accuracy, the larger the better. For these experiments, we used the window size $t = 5$. Section 6.5 studies the effects of window sizes.

Tables 2 and 3 clearly show that the proposed algorithm (***SC-EM***) outperforms all 14 baseline methods by a large margin on every dataset. In detail, we observe the following:

- *LDA*, *mLSA* and *Kmeans* with no seeds (labeled data) perform the worst. Seeds help to improve the results, which is intuitive. Without seeds, *DF-LDA* is the same as *LDA*.
- *LDA* based methods seems to be the weakest. *Kmeans* based methods are slightly better, but EM based methods are the best. This clearly indicates that classification (EM) performs better than clustering. Comparing *DF-LDA* and *Kmeans*, their results are similar.
- For *LDA*, and *Kmeans*, hard-constrained methods (i.e., *LDA*(*L, H*), and *Kmeans*(*L, H*)) perform better than soft-constrained methods (i.e., *LDA*(*LC, S*) and *Kmeans*(*LC, S*)). This indicates that soft-constrained versions may change some correctly constrained expressions into wrong groups. However, for the EM based methods, the soft-constrained method (*SC-EM*) performs markedly better than the hard-constrained version (*EM*(*LC, H*)). This indicates that Bayesian classifier used in EM can take advantage of the soft constraints and correct some wrong assignments made by constraints. Much weaker results of *Rand*(*LC, H*) than *SC-EM* in different settings show that

Table 3. Influence of the seeds' proportion (which reflects the size of the labeled set *L*)

constraints alone (i.e., synonyms and sharing of words) are far from sufficient. EM can improve it considerably.

- Comparing EM based methods, we can see that soft seeds in *SL* make a big difference for all data sets. *SC-EM* is clearly the best.
- As the number of labeled examples increases (from 10% to 50%), the results improve for every method (except those for *DF-LDA*, which does not change much).

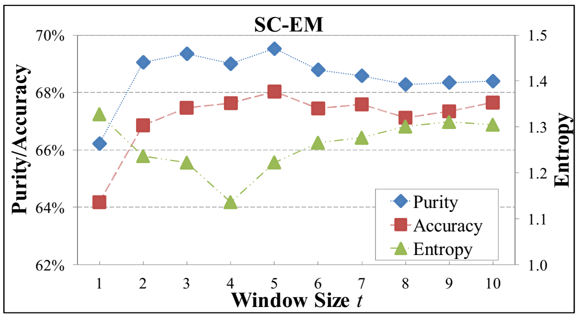

Figure 4. Influence of context window size

6.5 Varying the Context Window Size

We varied the text window size *t* from 1 to 10 to see how it impacts on the performance of *SC-EM*. The results are given in Figure 4 (they are averages of the 5 datasets). Again for purity and accuracy, the greater the value the better, while for entropy it is the opposite. It is clear that the window sizes of 2~6 produce similar good results. All evaluations reported above used *t* = 5.

7 Conclusion

This paper proposed the task of feature grouping in a semi-supervised setting. It argued that some form of supervision is needed for the problem because its solution depends on the user application needs. The paper then proposed to use the EM algorithm to solve the problem, which was improved by considering two soft constraints. Empirical evaluations using 5 real-life data sets show that the proposed method is superior to 14 baselines. In our future work, we will focus on further improving the accuracy.

Abstract

Supertagging is an important technique for deep syntactic analysis. A supertagger is usually trained independently of the parser using a sequence labeling method. This presents an inconsistent training objective between the supertagger and the parser. In this paper, we propose a forest-guided supertagger training method to alleviate this problem by incorporating global grammar constraints into the supertagging process using a CFG-filter. It also provides an approach to make the supertagger and the parser more tightly integrated. The experiment shows that using the forest-guided trained supertagger, the parser got an absolute 0.68% improvement from baseline in F-score for predicate-argument relation recognition accuracy and achieved a competitive result of 89.31% with a faster parsing speed, compared to a state-of-the-art HPSG parser.

1 Introduction

Deep syntactic analysis by lexicalized grammar parsing, which provides linguistic-rich information for many NLP tasks, has recently received more and more attention from the NLP community. To use a deep parser in real large-scale applications, speed is an important issue to take into consideration. Supertagging is one of the speed-up technique widely used for lexicalized grammar parsing. A supertagger is used to limit the number of plausible lexical entries fed to the parser, this can greatly reduce the search space for the parser. Supertagging was first proposed for Lexicalized Tree Adjoining Grammar (LTAG) (Bangalore and Joshi, 1999), and then successfully applied to Combinatory Categorial Grammar (CCG) (Clark, 2002) and Head-driven Phrase Structure Grammar (HPSG) (Ninomiya et al., 2006). In addition, supertags can also be used for other NLP tasks besides parsing, such as semantic role labeling (Chen and Rambow, 2003) and machine translation (Birch et al., 2007; Hassan et al., 2007) to utilize syntactic information in the supertags.

In lexicalized grammar parsing, supertagging is usually treated as a sequence labeling task independently trained from the parser. Previous research (Clark, 2002) showed that even a pointwise classifier not considering context edge features is effective when used as a supertagger. To make up for the insufficient accuracy as a single-tagger, more than one supertag prediction is reserved and the parser takes the burden of resolving the rest of the supertag ambiguities.

A non-trivial problem raised by the separate training of the supertagger is that the prediction score provided by the supertagger might not be suitable for direct use in the parsing process, since a separately trained supertagger that does not take into account grammar constraints has a training objective which is inconsistent with the parser. Although the scores provided by the supertagger can be ignored (e.g., in some CCG parsers), this may also discard some useful information for effective beam search and accurate disambiguation.

Based on this observation, we assume that considering global grammar constraints during the supertagger training process would make the supertagger and the parser more tightly integrated.

In this paper, we propose an on-line forest-guided training method for a supertagger to make the training objective of a supertagger more closely related to the parsing task. We implemented this method on a large-scale HPSG grammar. We used a CFG grammar to approximate the original HPSG grammar in the supertagging stage and applied best-first search to select grammar-satisfying supertag sequences for the parameter updating. The experiments showed that the HPSG parser is improved by considering structure constraints in the supertagging training process. For the standard test set (Penn Treebank Section 23), we accomplished an absolute 0.68% improvement from baseline in F-score for predicate-argument relation recognition and got a competitive result of 89.31% with a faster parsing speed, compared to a state-of-the-art HPSG parser.

The remainder of the paper is organized as follows: in section 2 we provide the necessary background regarding HPSG parsing. In section 3, we introduce the on-line forest-guided supertagger training method. Section 4 shows the experiment results and the related analysis. Section 5 compares the proposed approach with related work and section 6 presents our conclusions and future work.

2 Background

2.1 Statistical HPSG Parsing

HPSG (Pollard and Sag, 1994) is a lexicalist grammar framework. In HPSG, a large number of lexical entries are used to express word-specific characteristics, while only a small number of rule schemata are used to describe general construction rules. Typed feature structures named "signs" are used to represent both lexical entries and phrasal constituents. A classic efficient statistical HPSG parsing process is depicted in Figure 1. Given a word and part-of-speech sequence (w, p) as input, the first step (called "supertagging") in HPSG parsing is to assign possible lexical entries. In practice, for each word, more than one supertag is reserved for the parser. Then, the parser searches the given lexical entry space to construct a HPSG tree using the rule schemata to combine possible signs. Constituent-based methods and transition-based methods can be used for tree structure disambiguation. This parsing framework using supertagging is also used in other lexicalized grammars, such as LTAG and CCG.

2.2 HPSG Supertagging

Like other lexicalized grammar, the lexical entries defined in HPSG are referred to as "supertags". For example, the word "like" is assigned a lexical entry for transitive verbs in non-3rd person present form, which indicates that the head syntactic category of "like" is verb and it has an NP subject and an NP complement. With such fine-grained grammatical type distinctions, the number of supertags is very large. Compared to the 45 part-of-speech (POS) tags defined in the PennTreebank, the HPSG grammar we used contains 2,308 supertags. The large number and the complexity of the supertags makes supertagging harder than the POS tagging task.

Supertagging can be formulated as a sequence labeling task. Here, we follow the definition of Collins' perceptron (Collins, 2002). The training objective of supertagging is to learn the mapping from a POS-tagged word sentence $\boldsymbol{w} = (w_1/p_1, ..., w_n/p_n)$ to a sequence of supertags $\boldsymbol{s} = (s_1, ..., s_n)$. We use function $\boldsymbol{GEN(w)}$ to indicate all candidates of supertag sequences given input $\boldsymbol{w}$. Feature function $\boldsymbol{\Phi}$ maps a sample $(\boldsymbol{w}, \boldsymbol{s})$ to a point in the feature space R^d. $\boldsymbol{\theta}$ is the vector of feature weights. Given an input $\boldsymbol{w}$, the most plausible supertag sequence is found by the prediction function defined as follows:

$$F(\boldsymbol{w}) = \underset{\boldsymbol{s} \in \boldsymbol{GEN(w)}}{argmax} \; \theta \cdot \Phi(\boldsymbol{w}, \boldsymbol{s}) \qquad (1)$$

2.3 CFG-filtering

CFG-filtering (Kiefer and Krieger, 2000) is a technique to find a superset of (packed) HPSG parse trees that satisfy the constraints in a grammar. A CFG that approximates the original HPSG grammar is used for efficiently finding such trees without doing full-fledged HPSG parsing that is computationally demanding because the schema application involves unification operations among large feature structures (signs). The number of possible signs is infinite in general and hence

some features (e.g., the number agreement feature) are ignored in the approximating CFG so that the set of possible signs can be approximated by a finite set of non-terminal symbols in the CFG. By this construction, some illegal trees may be included in the set of trees licensed by the approximating CFG, but none of the well-formed trees (i.e., those satisfying all constraints in the grammar) are excluded by the approximation. We use the algorithm described by Kiefer and Krieger (2000) to obtain the approximating CFG for the original HPSG. The technical details regarding the algorithm can be found in Kiefer and Krieger (2000).

3 Forest-guided Training for Supertagging

3.1 Motivation

In lexicalized grammar parsing, a parser aims to find the most plausible syntactic structure for a given sentence based on the supertagging results. One efficient parsing approach is to use prediction scores provided by the supertagger. Usually, the supertagger is trained separately from the structure disambiguation in a later stage. This pipeline parsing strategy poses a potential problem in that the training objective of a supertagger can deviate from the final parser, if the global grammar constraints are not considered. For example, the supertag predictions for some words can contribute to high supertagging accuracy, but cause the parser to fail. Therefore, considering the global grammar constraints in the supertagging training stage can make the supertagger and the parser more tightly related, which will contribute towards the performance of the parser.

Algorithm 1: Forest-guided supertagger training

```
Input: Training Sample $(w_i, s_i)_{i=1,...,N}$,
       Number of iterations T
$\theta \leftarrow (0, ..., 0)$, $\theta_{sum} \leftarrow (0, ..., 0)$
for $iterNum \leftarrow$ 1 to T do
    for i $\leftarrow$ 1 to N do
        Generate supertag lattice using
        the point-wise classifier with current $\theta$
        Select $\hat{s}_i$ from the lattice
        which can construct a tree
        with largest sequence score
        if( No $\hat{s}_i$ satisfied grammar constraints)
        $\hat{s}_i \leftarrow \arg\max_{s \in \mathbf{GEN}(w_i)} \theta_i \cdot \Phi(w_i, s_i)$
        if $\hat{s}_i \neq s_i$ then
            $\theta_{i+1} \leftarrow \theta_i + \Phi(w_i, s_i) - \Phi(w_i, \hat{s}_i)$
            $\theta_{sum} \leftarrow \theta_{sum} + \theta_{i+1}$
Return: $\theta_{\text{sum}}/NT$
```

3.2 Training Algorithm

Based on the motivation above, we propose a forest-guided supertagger training method to make the supertagger more tightly integrated with the parser. This method is based on the averaged perceptron training algorithm. The training process is given in Algorithm 1.

The most important difference of the proposed algorithm compared to the traditional supertagger training method is that the current best-scored supertag sequence is searched only within the space of the supertag sequences that are allowed by the grammar. As for whether the grammar constraints are satisfied, we judge it by whether a possible syntactic tree can be constructed using the given supertag sequence. We do not require the constructed syntactic tree to be identical to the gold tree in the corpus. For this reason we call it "forest-guided".

In the forest-guided training of the supertagger, an approximating CFG is used to filter out the supertag sequences from which no well-formed tree can be built. It is implemented as a best-first CFG parser wherein the score of a constituent is the score of the supertag (sub-)sequence on the fringe of the constituent, which is calculated using the current value of the parameters. Note that the best-first parser can find the best-scored supertag sequence very efficiently given proper scoring for the candidate supertag set for each token; this is actually the case in the course of training except for the initial phase of the training, wherein the parameter values are not well-tuned. The efficiency is due to the sparseness of the approximating CFG (i.e., the production rule set includes only a tiny fraction of the possible parent-children combinations of symbols) and highest-scored supertags often have a well-formed tree on top of them.

As is clear from the above description, the use of CFG-filter in the forest-guided training of the supertagger is not essential but is only a subsidiary technique to make the training faster. The improvement by the forest-guided training should however depend on whether the CFG approximation is reasonably tight or not. Actually, we managed to obtain a manageable size out of a CFG grammar, which includes 80 thousand nonterminal symbols and 10 million rules, by eliminating only a small number of features (semantics, case and number agreement, and fine distinctions in nouns, adjectives and complementizers). We thus believe that the approximation is fairly tight.

This training algorithm can also be explained in a search-based learning framework (Hal Daumé III and Daniel Marcu, 2005). In this framework, the objective of learning is to optimize the $\boldsymbol{\theta}$ for the enqueue function to make the good hypotheses rank high in the search queue. The rank score $\boldsymbol{r}$ consists of two components: path score $\boldsymbol{g}$ and heuristic score $\boldsymbol{h}$. In the forest-guided training method, $\boldsymbol{r}$ can be rewritten as follows:

$$\begin{aligned} r &= g + h \\ &= \theta \cdot \Phi(x, \hat{y}) + 1_{[Tree(\hat{y})]} * Penalty \end{aligned} \quad (2)$$

The heuristic part $\boldsymbol{h}$ checks whether the supertag candidate sequence satisfies the grammar constraints: if no CFG tree can be constructed, -∞ penalty is imposed to the candidate sequence in the forest-guided training method.

4 Experiments

We mainly evaluated the proposed forest-guided supertagger training method on HPSG parsing. Supertagging accuracy[1] using different training methods was also investigated.

4.1 Corpus Description

The HPSG grammar used in the experiments is Enju version 2.3[2]. It is semi-automatically converted from the WSJ portion of PennTreebank (Miyao, 2006). The grammar consists of 2,308 supertags in total. Sections 02-21 were used to train different supertagging models and the HPSG parser. Section 22 and section 23 were used as the development set and the test set respectively. We evaluated the HPSG parser performance by labeled precision (LP) and labeled recall (LR) of predicate-argument relations of the parser's output as in previous works (Miyao, 2005). All experiments were conducted on an AMD Opteron 2.4GHz server.

Template Type	Template
Word	w_i,w_{i-1},w_{i+1}, w_{i-1}&w_i, w_i&w_{i+1}
POS	$p_i, p_{i-1}, p_{i-2}, p_{i+1}$, p_{i+2}, p_{i-1}&p_i, p_{i-2}&p_{i-1}, p_{i-1}&p_{i+1}, p_i&p_{i+1}, p_{i+1}&p_{i+2}
Word-POS	p_{i-1}&w_i, p_i&w_i, p_{i+1}&w_i

Table 1: Feature templates used for supertagging models.

[1] "UNK" supertags are ignored in evaluation as in previous works.

[2] http://www-tsujii.is.s.u-tokyo.ac.jp/enju/index.html

4.2 Baseline Models and Settings

We used a point-wise averaged perceptron (PW) to train a baseline supertagger. Point-wise classifiers have been reported to be very effective and with competitive results for the supertagging task (Clark, 2002; Zhang et al., 2009). The number of training iterations was set to 5. The features used in the supertaggers are described in Table 1. For comparison, these features are identical to the features used in the previous works (Matsuzaki et al., 2007; Ninomiya et al., 2007). To make the training efficient, we set the default chart size limit for the forest-guided supertagger training to be 20k by tuning it on the development set.

We combined the supertagger trained under forest-guidance with a supertagging-based HPSG parser (Matsuzaki et al., 2007) and evaluated the contribution of the improved supertagger training procedure for the final HPSG parsing by the accuracy of the predicate-argument relations output of the parser. The parser crucially depends on the supertagger's performance in that it outputs the first well-formed tree successfully constructed on the highest scored supertag sequence. The highest-scored supertag sequences are enumerated one by one in descending order in regards to their score. The enumeration is actually implemented as n-best parsing on the supertag candidates using an approximating CFG. The HPSG tree construction on a supertag sequence is done using a shift-reduce style parsing algorithm equipped with a classifier-based action selection mechanism.

The automatically assigned POS tags were given by a maximum entropy tagger with roughly 97% accuracy.

4.3 Supertagging Results

Although we mainly focused on improving the final HPSG parsing performance through the improved supertagger training, it is also very interesting to investigate the supertagger performance using different training methods. To evaluate the forest-guided training method for a supertagger, we also need to incorporate structure constraints in the test stage. To make fair comparisons, for the averaged perceptron trained supertagger we also add structure constraints in its testing. For simplicity, throughout this paper, we call the forest-guided trained supertagger "FT" in short, while the "PW" is used to represent the baseline point-wise averaged perceptron supertagger. "ME" is the re-implemented maximum entropy supertagger described in Matsuzaki et al. (2007).

	Model Name	**Acc%**
auto-POS	FT+CFG	**92.77**
	PW+CFG	92.47
	PW	91.14
	ME	91.45
gold-POS	FT+CFG	**93.98**
	PW+CFG	93.70
	PW	92.48
	ME	92.78

Table 2: Supertagging results in section 23. "FT" represents the forest-guided trained supertagger. "PW" is the baseline average perceptron trained supertagger. "ME" is the supertagger trained by using the maximum entropy method. "+CFG" indicates the use of the CFG-filter for the supertagger results. The accuracy of automatically assigned POS tags in this section is 97.39%.

For the PW supertagger, the performance was roughly 0.3% below the ME supertagger. Similar results were reported by Zhang et al. (2009), which used a Bayes point machine to reduce the gap between the averaged perceptron supertagger and the maximum entropy supertagger. Although we expected the ME supertagger using CFG-filter to give better results than the PW supertagger, implementing forest-guided supertagger training in a maximum entropy framework is different and more sophisticated than the current on-line training method. Considering that the performance of the PW supertagger and the ME supertagger were at a similar level, we chose the PW supertagger as our baseline.

We used a CFG-filter to incorporate global grammar constraints into both the training and the testing phase. Compared to the PW supertagger, the PW+CFG supertagger incorporated global grammar constraints only in the test phase, while for the FT+CFG supertagger, the global grammar constraints were incorporated both in

Iter NUM Training Method	1	2	3	4	5	Total Time
FT	6684s	4189s	3524s	3285s	3086s	≈ 5.8h
PW	99s	116s	117s	117s	117s	≈ 10 min
ME	/					≈ 3h

Table 3: Supertagger training time on section 02-21. "FT" and "PW" represent forest-guided training and point-wise averaged perceptron training separately. "ME" is the point-wise maximum entropy training reported in Matsuzaki et al. (2007).

the training and the testing stage. The supertagging accuracy for different models is shown in Table 2. Firstly, incorporating grammar constraints only in the testing phase (PW+CFG) gave an absolute 1.22% (gold POS) and 1.33% (auto POS) increase in F-score compared to the PW supertagger. Secondly, incorporating grammar constraints into both the training and the testing stage (FT+CFG) gave an additional 0.28% (gold POS) and 0.3% (auto POS) improvement over the PW+CFG supertagger with p-values 0.0018 (gold POS) and 0.0016 (auto POS).

This also indicates that the supertagger and the parser are closely related to each other. The original motivation for supertagging is using simple models to resolve lexical ambiguities, which can efficiently reduce the search space of the parser. A better supertagger can contribute to more efficient and more accurate lexicalized grammar parsing. Actually, a supertagger can act as a coarse parser for the whole parsing process as well, as long as the coarse parser is efficient. Since supertag disambiguation is highly constrained by the grammar, incorporating grammar constraints into supertagging (including training and testing) by using the CFG-filter can further improve the supertagging performance, as shown in Table 2.

As for the supertagger training time, incorporating grammar constraints inevitably increases the training time. As shown in Table 3, the total training time of forest-guided training (default settings, with chart size limited to 20k) was about 5.8 hours. For each iteration of the FT model, we find that the training time gradually decreases with each successive iteration. This hints that we can do better model initialization to further reduce the training time.

4.4 HPSG Parsing Results

We evaluated the HPSG parsers using different supertagger training methods. For the baseline HPSG parser, a CFG-filter is already incorporated to accelerate the parsing process. In the following experiments, we fed the parser all the possible supertag candidates with the prediction scores generated by the supertaggers. We controlled the upper bound of the chart size in the CFG-filter to make the parser more efficient.

Table 4 shows the results of the different parsing models. We first compared the baseline parsers using different supertaggers. The forest-guided supertagger improved the final FT parser's F-score by 0.68% (statistically significant) over the PW parser using the PW supertagger, which did not consider global grammar constraints during the supertagger training process. The parsing time of the FT parser was very close to that of the PW parser (108s vs. 106s), which was also efficient. The result empirically reflects that incorporating the global grammar constraints into the supertagger training process can refine supertag predicting scores, which become more consistent and compatible with the parser.

We also compared our results with a state-of-the-art HPSG parser using the same grammar. Enju (Miyao, 2005; Ninomiya et al., 2007) is a log-linear model based HPSG parser, which uses a maximum entropy model for the structure disambiguation. In contrast to our baseline parser, full HPSG grammar is directly used with CKY algorithm in the parsing stage. As for the parsing performance, our baseline PW parser using the PW supertagger was 0.23% below the Enju parser. However, by using the forest-guided trained supertagger, our improved FT parser per-

Parser	**UP**	**UR**	**LP**	**LR**	**F-score**	**Time** †
FT Parser	92.28	92.14	89.38	89.23	**89.31**	108s
PW Parser	91.88	91.63	88.75	88.51	88.63	106s
Enju 2.3	92.26	92.21	88.89	88.84	88.86	775s

Table 4: Parser performance on Section 23. “FT Parser” represents baseline parser which uses forest-guided trained supertagger. “PW Parser” represents the baseline parser which uses the point-wise averaged perceptron trained supertagger. (†) The time is the total time of both supertagging and parsing and it was calculated on all 2291 sentences of the Section 23.

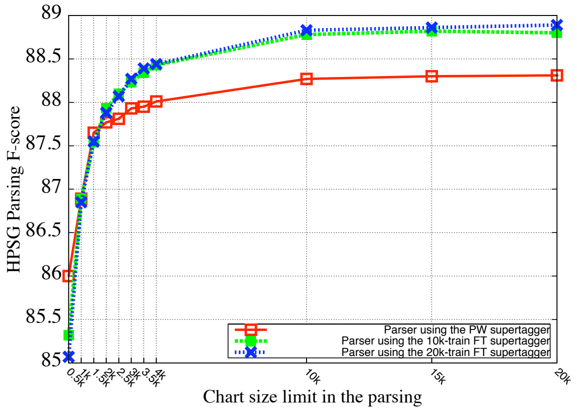

Figure 2: The F-score of the HPSG parsers on section 22 using different settings for the chart size limit in supertagger training and parsing.

formed 0.45% better than the Enju parser (default settings) in F-score. In addition, our shift-reduce style parser was faster than the Enju parser.

Beam size plays an important role for the forest-guided supertagger training method, since a larger beam size reduces the possibility of search errors. Precisely speaking, we control the beam size by limiting the number of edges in the chart in both the forest-guided supertagger training process and the final parsing. Figure 2 shows the results of setting different limits for the chart size during supertagger training and parsing on the development set. The X-axis represents the chart size limitation for the parsing. “10k-train” represents the chart size to be limited to 10k during FT supertagger training phase. A similar representation is used for “20k-train”. There is no tree structure search process for the baseline PW supertagger. We evaluated the F-score of the parsers using different supertaggers. As shown in Figure 2, when the chart size of the parser was more than 10k, the benefit of using forest-guided supertaggers were obvious (around an absolute 0.5% improvement in F-score, compared to the parser using the baseline PW supertagger). The performance of the parser using “10k-train” FT supertagger was already approaching to that of the parser using “20k-train” FT supertagger. When the chart size of the parser was less than 2000, the forest-guided supertaggers were not work. Similar to the results showed in previous research (Hal Daumé III and Daniel Marcu, 2005), it is better to use the same chart size limit in the forest-guided supertagger training and the final parsing.

5 Related Work

Since the supertagging technique is well known to drastically improve the parsing speed and accuracy, there is work concerned with tightly integrating a supertagger with a lexicalized grammar parser. Clark and Curran (2004) investigated a multi-tagger supertagging technique for CCG. Based on the multi-tagging technique, supertagger and parser are tightly coupled, in the sense that the parser requests more supertags if it fails. They (Clark and Curran, 2007) also used the perceptron algorithm to train a CCG parser. Different from their work, we focused on improving the performance of the deep parser by refining the training method for supertagging. Ninomiya et al. (2007) used the supertagging probabilities as a reference distribution for the log-linear model for HPSG, which aimed to consistently integrate supertagging into probabilistic HPSG parsing. Prins et al. (2001) trained a POS-tagger on an automatic parser-generated lexical entry corpus as a filter for Dutch HPSG parsing to improve the parsing speed and accuracy.

The existing work most similar to ours is Boullier (2003). He presented a non-statistical parsing-based supertagger for LTAG. Similar to his method, we used a CFG to approximate the original lexicalized grammar. The main difference between these two methods is that we consider the grammar constraints in the training phase of the supertagger, not only in the supertagging test phase and our main objective is to improve the performance of the final parser.

6 Conclusions and Future Work

In this paper, based on the observation that supertaggers are commonly trained separately from lexicalized parsers without global grammar constraints, we proposed a forest-guided supertagger training method to integrate supertagging more tightly with deep parsing. We applied this method to HPSG parsing and made further significant improvement for both supertagging (0.28%) and the HPSG parsing (0.68%) compared to the baseline. The improved parser also achieved a competitive result (89.31%) with a faster parsing speed, compared to a state-of-the-art HPSG parser.

For future work, we will try to weight the forest trees for the supertagger training and extend this method to other lexicalized grammars, such as LTAG and CCG.

Abstract

Entity linking refers entity mentions in a document to their representations in a knowledge base (KB). In this paper, we propose to use additional information sources from Wikipedia to find more name variations for entity linking task. In addition, as manually creating a training corpus for entity linking is labor-intensive and costly, we present a novel method to automatically generate a large scale corpus annotation for ambiguous mentions leveraging on their unambiguous synonyms in the document collection. Then, a binary classifier is trained to filter out KB entities that are not similar to current mentions. This classifier not only can effectively reduce the ambiguities to the existing entities in KB, but also be very useful to highlight the new entities to KB for the further population. Furthermore, we also leverage on the Wikipedia documents to provide additional information which is not available in our generated corpus through a domain adaption approach which provides further performance improvements. The experiment results show that our proposed method outperforms the state-of-the-art approaches.

1 Introduction

The named entity (NE) ambiguation has raised serious problems in many areas, including web people search, knowledge base population (KBP), and information extraction, because an entity (such as *Abbott Laboratories*, a diversified pharmaceuticals health care company) can be referred to by multiple mentions (e.g. "*ABT*" and "*Abbott*"), and a mention (e.g. "*Abbott*") can be shared by different entities (e.g. *Abbott Texas*: a city in United States; *Bud Abbott*, an American actor; and *Abbott Laboratories*, a diversified pharmaceutical health care company).

Both Web People Search (WePS) task (Artiles et al. 2007) and Global Entity Detection & Recognition task (GEDR) in Automatic Content Extraction 2008 (ACE08) disambiguate entity mentions by clustering documents with these mentions. Each cluster then represents a unique entity. Recently entity linking has been proposed in this field. However, it is quite different from the previous tasks.

Given a knowledge base, a document collection, entity linking task as defined by KBP-09[1] (McNamee and Dang, 2009) is to determine for each name string and the document it appears, which knowledge base entity is being referred to, or if the entity is a new entity which is not present in the reference KB.

Compared with GEDR and WePS, entity linking has a given entity list (i.e. the reference KB) to which we disambiguate the entity mentions. Moreover, in document collection, there are new entities which are not present in KB and can be used for further population. In fact, new entities with or without the names in KB cover more than half of testing instances.

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 1290–1298,
Beijing, August 2010

Entity linking has been explored by several researchers. Without any training data available, most of the previous work ranks the similarity between ambiguous mention and candidate entities through Vector Space Model (VSM). Since they always choose the entity with the highest rank as the answer, the ranking approaches hardly detect a situation where there may be a new entity that is not present in KB. It is also difficult to combine bag of words (BOW) with other features. For example, to capture the "category" information, the method of Cucerzan (2007) involves a complicated optimization issue and the approach has to be simplified for feasible computation, which compromises the accuracy. Besides unsupervised methods, some supervised approaches (Agirre et al. 2009, Li et al. 2009 and McNamee et al. 2009) also have been proposed recently for entity linking. However, the supervised approaches for this problem require large amount of training instances. But manually creating a corpus is labor-intensive and costly.

In this paper, we explore how to solve the entity linking problem. We present a novel method that can automatically generate a large scale corpus for ambiguous mentions leveraging on their unambiguous synonyms in the document collection. A binary classifier based on Support Vector Machine (SVM) is trained to filter out some candidate entities that are not similar to ambiguous mentions. This classifier can effectively reduce the ambiguities to the existing entities in KB, and it is very useful to highlight the new entities to KB for the further population. We also leverage on the Wikipedia documents to provide additional information which is not available in our generated corpus through a domain adaption approach which provides further performance improvements. Besides, more information sources for finding more variations also contribute to the overall 22.9% accuracy improvements on KBP-09 test data over baseline.

The remainder of the paper is organized as follows. Section 2 reviews related work for entity linking. In Section 3 we detail our algorithm including name variation and entity disambiguation. Section 4 describes the experimental setup and results. Finally, Section 5 concludes the paper.

2 Related Work

The crucial component of entity linking is the disambiguation process. Raphael et al. (2007) report a disambiguation algorithm for geography. The algorithm ranks the candidates based on the manually assigned popularity scores in KB. The class with higher popularity will be assigned higher score. It causes that the rank of entities would never change, such as Lancaster (California) would always have a higher rank than Lancaster (UK) for any mentions. However, as the popularity scores for the classes change over time, it is difficult to accurately assign dynamic popularity scores. Cucerzan (2007) proposes a disambiguation approach based on vector space model for linking ambiguous mention in a document with one entity in Wikipedia. The approach ranks the candidates and chooses the entity with maximum agreement between the contextual information extracted from Wikipedia and the context of a document, as well as the agreement among the category tags associated with the candidate entities. Nguyen and Cao (2008) refer the mentions in a document to KIM (Popov et al. 2004) KB. KIM KB is populated with over 40,000 named entities. They represent a mention and candidates as vectors of their contextual noun phrase and co-occurring NEs, and then the similarity is determined by the common terms of the vectors and their associated weights. For linking mentions in news articles with a Wikipedia-derived KB (KBP-09 data set), Varma et al. (2009) rank the entity candidates using a search engine. Han and Zhao (2009) rank the candidates based on BOW and Wikipedia semantic knowledge similarity.

All the related work above rank the candidates based on the similarity between ambiguous mention and candidate entities. However, the ranking approach hardly detects the new entity which is not present in KB.

Some supervised approaches also have been proposed. Li et al. (2009) and McNamee et al. (2009) train their models on a small manually created data set containing only 1,615 examples. But entity linking requires large training data. Agirre et al. (2009) use Wikipedia to construct their training data by utilizing Inter-Wikipedia links and the surrounding snippets of text. However, their training data is created from a different domain which does not work well in the targeted news article domain.

3 Approach

In this section we describe our two-stage approach for entity linking: name variation and entity disambiguation. The first stage finds variations for every entity in the KB and generates an entity candidate set for a given query. The second stage is entity disambiguation, which links an entity mention with the real world entity it refers to.

3.1 Name Variation

The aim for Name Variation is to build a Knowledge Repository of entities that contains vast amount of world knowledge of entities like name variations, acronyms, confusable names, spelling variations, nick names etc. We use Wikipedia to build our knowledge repository since Wikipedia is the largest encyclopedia in the world and surpasses other knowledge bases in its coverage of concepts and up-to-date content. We obtain useful information from Wikipedia by the tool named Java Wikipedia Library[2] (Zesch et al. 2008), which allows to access all information contained in Wikipedia.

Cucerzan (2007) extracts the name variations of an entity by leveraging four knowledge sources in Wikipedia: "entity pages", "disambiguation pages" "redirect pages" and "anchor text".

Entity page in Wikipedia is uniquely identified by its title – a sequence of words, with the first word always capitalized. The title of Entity Page represents an unambiguous name variation for the entity. A redirect page in Wikipedia is an aid to navigation. When a page in Wikipedia is redirected, it means that those set of pages are referring to the same entity. They often indicate synonym terms, but also can be abbreviations, more scientific or more common terms, frequent misspellings or alternative spellings etc. Disambiguation pages are created only for ambiguous mentions which denote two or more entities in Wikipedia, typically followed by the word "*disambiguation*" and containing a list of references to pages for entities that share the same name. This is more useful in extracting the abbreviations of entities, other possible names for an entity etc. Besides, both outlinks and inlinks in Wikipedia are associated with anchor texts that represent name variations for the entities.

Using these four sources above, we extracted name variations for every entity in KB to form the Knowledge Repository as Cucerzan's (2007) method. For example, the variation set for entity *E0272065* in KB is {*Abbott Laboratories, Abbott Nutrition, Abbott* …}. Finally, we can generate the entity candidate set for a given query using the Knowledge Repository. For example, for the query containing "*Abbott*", the entity candidate set retrieved is {*E0272065, E0064214* …}.

From our observation, for some queries the retrieved candidate set is empty. If the entity for the query is a new entity, not present in KB, empty candidate set is correct. Otherwise, we fail to identify the mention in the query as a variation, commonly because the mention is a misspelling or infrequently used name. So we propose to use two more sources "Did You Mean" and "Wikipedia Search Engine" when Cucerzan (2007) algorithm returns empty candidate set. Our experiment results show that both proposed knowledge sources are effective for entity linking. This contributes to a performance improvement on the final entity linking accuracy.

Did You Mean: The "*did you* mean" feature of Wikipedia can provide one suggestion for misspellings of entities. This feature can help to correct the misspellings. For example, "Abbot Nutrition" can be corrected to "Abbott Nutrition".

Wikipedia Search Engine: This key word based search engine can return a list of relevant entity pages of Wikipedia. This feature is more useful in extracting infrequently used name.

Algorithm 1 below presents the approach to generate the entity candidate set over the created Knowledge Repository. $\boldsymbol{Ref_E(s)}$ is the entity set indexed by mention $\boldsymbol{s}$ retrieved from Knowledge Repository. In Step 8, we use the longest common subsequence algorithm to measure the similarity between strings $\boldsymbol{s}$ and the title of the entity page with highest rank. More details about longest common subsequence algorithm can be found in Cormen et al. (2001).

Algorithm 1 Candidate Set Generation

```
Input: mention $s$;
if $Ref_E(s)$ is empty
    $s'$ $\leftarrow$ Wikipedia“did you mean”Suggestion
    If s’ is not NULL
        s $\leftarrow$ $s'$
    else
        EntityPageList $\leftarrow$ WikipediaSearchEngine(s)
        EntityPage$\leftarrow$FirstPage of EntityPageList
        Sim=Similarity(s,EntityPage.title)
        if Sim > Threshold
            $s \leftarrow EntityPage.title$
        end if
    end if
end if
Output: $Ref_E(s)$;
```

3.2 Entity Disambiguation

The disambiguation component is to link the mention in query with the entity it refers to in candidate set. If the entity to which the mention refers is a new entity which is not present in KB, *nil* will be returned. In this Section, we will describe the method for automatic data creation, domain adaptation from Wikipedia data, and our supervised learning approach as well.

3.2.1 Automatic Data Creation

The basic idea is to take a document with an unambiguous reference to an entity E1 and replacing it with a phrase which may refer to E1, E2 or others.

Observation: Some full names for the entities in the world are unambiguous. This phenomenon also appears in the given document collection of entity linking. The mention “*Abbott Laboratories*” appearing at multiple locations in the document collection refers to the same entity “*a pharmaceuticals health care company*” in KB.

From this observation, our method takes into account the mentions in the Knowledge Repository associated with only one entity and we treat these mentions as unambiguous name. Let us take *Abbott Laboratories*-{*E0272065*} in the Knowledge Repository as an example. We first use an index and search tool to find the documents with unambiguous mentions. Such as, the mention “*Abbott Laboratories” occurs in* document *LDC2009T13* and *LDC2007T07* in the document collection. The chosen text indexing and searching tool is the well-known Apache Lucene information retrieval open-source library[3].

Next, to validate the consistency of NE type between entities in KB and in document, we run the retrieved documents through a Named Entity Recognizer, to tag the named entities in the documents. Then we link the document to the entity in KB if the document contains a named entity whose name exactly matches with the unambiguous mention and type (i.e. Person, Organization and Geo-Political Entity) exactly matches with the type of entity in KB. In this example, after Named Entity Recognition, “Abbott Laboratories” in document *LDC2009T13* is tagged as an Organization which is consistent with the entity type of *E0272065* in KB. We link the *“Abbott Laboratories”* occurring in *LDC2009T13* with entity *E0272065.*

Finally, we replace the mention in the selected documents with the ambiguous synonyms. For example, we replace the mention *“Abbott Laboratories”* in document *LDC2009T13* with *“Abbott”* where *Abbott-{E0064214, E0272065…}* is an entry in Knowledge Repository. *“Abbott”* is ambiguous, because it is referring not only to *E0272065*, but also to *E0064214* in Knowledge Repository. Then, we can get two instances for the created data set as Figure 1, where one is positive and the other is negative.

(Abbott, LDC2009T13) E0272065 +

(Abbott, LDC2009T13) E0064214 -

…

+ refer to - not refer to

Figure 1: An instance of the data set

However, from our studies, we realize some limitations on our training data. For example, as shown in Figure 1, the negative instance for *E0272065* and the positive instance for

[3] http://lucene.apache.org

E0064214 are not in our created data set. However, those instances exist in the current document collection. We do not retrieve them since there is no unambiguous mention for *E0064214* in the document collection.

To reduce the effect of this problem, we propose to use the Wikipedia data as well, since Wikipedia data has training examples for all the entities in KB. Articles in Wikipedia often contain mentions of entities that already have a corresponding article, and at least the first occurrence of the mentions of an entity in a Wikipedia article must be linked to its corresponding Wikipedia article, if such an article exists. Therefore, if the mention is ambiguous, the hyperlink is disambiguating it. Next, we will describe how to incorporate Wikipedia data.

Incorporating Wikipedia Data. The document collection for entity linking is commonly from other domains, but not Wikipedia. To benefit from Wikipedia data, we introduce a domain adaption approach (Daumé III, 2007) which is suitable for this work since we have enough "target" domain data. The approach is to augment the feature vectors of the instances. Denote by X the input space, and by Y the output space, in this case, X is the space of the real vectors $\varphi(\mathrm{x})$ for the instances in data set and $Y=\{+1,-1\}$ is the label. D^s is the Wikipedia domain dataset and D^t is our automatically created data set. Suppose for simplicity that $X=R^F$ for some $F > 0$ (R^F is the space of F-dimensions). The augmented input space will be defined by $\breve{X} = R^{3F}$. Then, define mappings $\varphi^s, \varphi^t : X \rightarrow \breve{X}$ for mapping the Wikipedia and our created data set respectively. These are defined as follows:

$$\varphi^{\mathrm{s}}(\mathrm{x}) =< \varphi(\mathrm{x}), \varphi(\mathrm{x}), 0 >$$

$$\varphi^{\mathrm{t}}(\mathrm{x}) =< \varphi(\mathrm{x}), 0, \varphi(\mathrm{x}) >$$

Where $\mathbf{0}=<0,0,\ldots,0> \in R^F$ is the zero vector. We use the simple linear kernel in our experiments. However, the following kernelized version can help us to gain some insight into the method. K denotes the dot product of two vectors. $K(x,x')=< \varphi\ (x),\ \varphi\ (x')>$. When the domain is the same, we get: $\breve{K}(x,x') =< \varphi\ (x), \varphi\ (x') > +< \varphi\ (x), \varphi\ (x') = 2K(x,x')$. When they are from different domains, we get: $\breve{K}(x,x') =< \varphi\ (x), \varphi\ (x') >= K(x,x')$. Putting this together, we have:

$$\breve{K} = \begin{cases} 2K(x,x') & \text{same domain} \\ K(x,x') & \text{diff. domain} \end{cases}$$

This is an intuitively pleasing result. Loosely speaking, this means that data points from our created data set have twice as much influence as Wikipedia points when making predictions about test data from document collection.

3.2.2 The Disambiguation Framework

To disambiguate a mention in document collection, the ranking method is to rank the entities in candidate set based on the similarity score. In our work, we transform the ranking problem into a classification problem: deciding whether a mention refers to an entity on an SVM classifier. If there are 2 or more than 2 candidate entities that are assigned *positive* label by the binary classifier, we will use the baseline system (explained in Section 4.2) to rank the candidates and the entity with the highest rank will be chosen.

In the learning framework, the training or testing instance is formed by (*query*, *entity*) pair. For Wikipedia data, (*query*, *entity*) is *positive* if there is a hyperlink from the article containing the mention in query to the entity, otherwise (*query*, *entity*) is *negative*. Our automatically created data has been assigned labels in Section 3.2.1. Based on the training instances, a binary classifier is generated by using particular learning algorithm. During disambiguation, (*query*, *entity*) is presented to the classifier which then returns a class label.

Each (*query*, *entity*) pair is represented by the feature vector using different features and similarity metrics. We chose the following three classes of features as they represent a wide range of information - lexical features, word-category pair, NE type - that have been proved to be effective in previous works and tasks. We now discuss the three categories of features used in our framework in details.

Lexical features. For Bag of Words feature in Web People Search, Artiles et al. (2009) illustrated that noun phrase and n-grams longer than 2 were not effective in comparison with token-based features and using bi-grams gives the best results only reaching recall 0.7. Thus, we use token-based features. The similarity metric we choose is cosine (using standard tf.idf weighting). Furthermore, we also take into account the co-occurring NEs and represent it in the form of token-based features. Then, the single cosine similarity feature is based on Co-occurring NEs and Bag of Words.

Word Category Pair. Bunescu (2007) demonstrated that word-category pairs extracted from the document and Wikipedia article are a good signal for disambiguation. Thus we also consider word-category pairs as a feature class, i.e., all *(w,c)* where *w* is a word from Bag of Words of document and *c* is a category to which candidate entity belongs.

NE Type. This feature is a single binary feature to guarantee that the type of entity in document (i.e. Person, Geo-Political Entity and Organization) is consistent with the type of entity in KB.

4 Experiments and Discussions

4.1 Experimental Setup

In our study**,** we use KBP-09 knowledge base and document collection for entity linking. In the current setting of KBP-09 Data, the KB has been generated automatically from Wikipedia. The KB contains 818,741 different entities. The document collection is mainly composed of newswire text from different press agencies. The collection contains 1.3 million documents that span from 1994 to the end of 2008. The test data has 3904 queries across three named entity types: Person, Geo-Political Entity and Organization. Each query contains a document with an ambiguous mention.

Wikipedia data can be obtained easily from the website[4] for free research use. It is available in the form of database dumps that are released periodically. In order to leverage various information mentioned in Section 3.1 to derive name variations, make use of the links in Wikipedia to generate our training corpus and get word category information for the disambiguation, we further get Wikipedia data directly from the website. The version we used in our experiments was released on Sep. 02, 2009. The automatically created corpus (around 10K) was used as the training data, and 30K training instances associated with the entities in our corpus was derived from Wikipedia.

For pre-processing, we perform sentence boundary detection and Chunking derived from Stanford parser (Klein and Manning, 2003), Named Entity Recognition using a SVM based system trained and tested on ACE 2005 with 92.5(P) 84.3(R) 88.2(F), and coreference resolution using a SVM based coreference resolver trained and tested on ACE 2005 with 79.5%(P), 66.7%(R) and 72.5%(F).

We select SVM as the classifier used in this paper since SVM can represent the stat-of-the-art machine learning algorithm. In our implementation, we use the binary SVM^{Light} developed by Joachims (1999). The classifier is trained with default learning parameters.

We adopt the measure used in KBP-09 to evaluate the performance of entity linking. This measure is micro-averaged accuracy: the number of correct link divided by the total number of queries.

4.2 Baseline Systems

We build the baseline using the ranking approach which ranks the candidates based on similarity between mention and candidate entities. The entity with the highest rank is chosen. Bag of words and co-occurring NEs are represented in the form of token-based feature vectors. Then tf.idf is employed to calculate similarity between feature vectors.

To make the baseline system with token-based features state-of-the-art, we conduct a series of experiments. Table 1 lists the performances of our token-based ranking systems. In our experiment, local tokens are text segments generated by a text window centered on the mention. We set the window size to 55, which is the value that was observed to give optimum performance for the disambiguation problem (Gooi and Allan, 2004). Full tokens and NE are all the tokens and named entities co-occurring in the text respectively. We notice that tokens of the full text as well as the co-occurring named entity produce the best baseline performance, which we use for the further experiment.

	Micro-averaged Accuracy
local tokens	60.0
local tokens + NE	60.6
full tokens + NE	61.9

Table 1: Results of the ranking methods

4.3 Experiment and Result

As discussed in Section 3.1, we exploit two more knowledge sources in Wikipedia: “did you mean” (DYM) and “Wikipedia search engine” (SE) for name variation step. We conduct some experiments to compare our name variation method using Algorithm 1 in Section 3.1 with the name variation method of Cucerzan (2007). Table 2 shows the comparison results of different name variation methods for entity linking. The experiments results show that, in entity linking task, our name variation method outperforms the method of Cucerzan (2007) for both entity disambiguation methods.

Name Variation Approaches	Ranking Method	Our Disambiguation Method
Cucerzan (2007)	60.9	82.2
+DYM+SE	61.9	**83.8**

Table 2: Entity Linking Result for two name variation approaches. Column 1 used the baseline method for entity disambiguation step. Column 2 used our proposed entity disambiguation method.

Table 3 compares the performance of different methods for entity linking on the KBP-09 test data. Row 1 is the result for baseline system. Row 2 and Row 3 show the results training on Wikipedia data and our automatically data respectively. Row 4 is the result training on both Wikipedia and our created data using the domain adaptation method mentioned in Section 3.2.1. It shows that our method trained on the automatically generated data alone significantly outperforms baseline. Compared Row 3 with Row 2, our created data set serves better at training the classifier than Wikipedia data. This is due to the reason that Wikipedia is a different domain from newswire domain. By comparing Row 4 with Row 3, we find that by using the domain adaptation method in Section 3.2.1, our method for entity linking can be further improved by 1.5%. Likely, this is because of the limitation of the auto-generated corpus as discussed in Section 3.2.1. In another hand, Wikipedia can complement the missing information with the auto-generated corpus. So combining Wikipedia data with our generated data can achieve better result. Compared with baseline system using Cucerzan (2007) name variation method in Table 2, in total our proposed method achieves a significant 22.9% improvement.

	Micro-averaged Accuracy
Baseline	61.9
Wiki	79.9
Created Data	82.3
Wiki → Created Data	**83.8**

Table 3: Micro-averaged Accuracy for Entity Linking

To test the effectiveness of our method to deal with new entities not present in KB and existing entities in KB respectively, we conduct some experiments to compare with Baseline. Table 4 shows the performances of entity linking systems for existing entities (non-NIL) in KB and new entity (NIL) which is not present in KB. We can see that the binary classifier not only effectively reduces the ambiguities to the existing entities in KB, but also is very useful to highlight the new entities to KB for the further population. Note that, in baseline system, all the new entities are found by the empty candidate set of name variation process, while the disambiguation component has no contribution. However, our approach finds the new entities not only by the empty candidate set, but also leveraging on disambiguation component which also contributes to the performance improvement.

	non-NIL	NIL
Baseline	72.6	52.4
Wiki → Created Data	79.2	87.8

Table 4: Entity Linking on Existing and New Entities

Finally, we also compare our method with the top 5 systems in KBP-09. Among them, *Siel_093* (Varma et al. 2009) and *NLPR_KBP1* (Han and Zhao 2009) use similarity ranking approach; *Stanford_UBC2* (Agirre et al. 2009), *QUANTA1* (Li et al. 2009) and *hltcoe1* (McNamee et al. 2009) use supervised approach. From the results shown in Figure 2, we observe that our method outperforms all the top 5 systems and the baseline system of KBP-09. Specifically, our method achieves better result than both similarity ranking approaches. This is due to the limitations of the ranking approach which have been discussed in Section 2. We also observe that our method gets a 5% improvement over *Stanford_UBC2*. This is because they collect their training data from Wikipedia which is a different domain from document collection of entity linking, news articles in this case; while our automatic data generation method can create a data set from the same domain as the document collection. Our system also outperforms *QUANTA1* and *hltcoe1* because they train their model on a small manually created data set (1,615 examples), while our method can automatically generate a much larger data set.

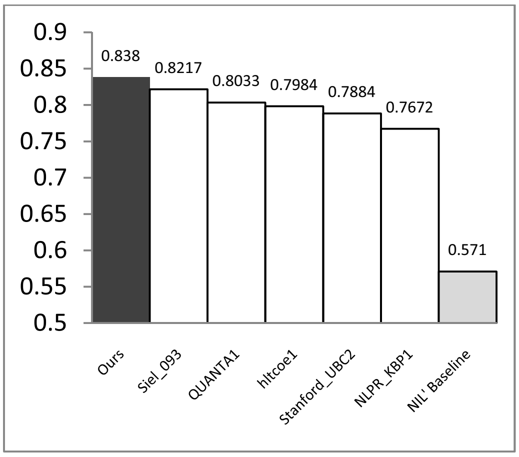

Figure 2: A comparison with KBP09 systems

5 Conclusion

The purpose of this paper is to explore how to leverage the automatically generated large scale annotation for entity linking. Traditionally, without any training data available, the solution is to rank the candidates based on similarity. However, it is difficult for the ranking approach to detect a new entity that is not present in KB, and it is also difficult to combine different features. In this paper, we create a large corpus for entity linking by an automatic method. A binary classifier is then trained to filter out KB entities that are not similar to current mentions. We further leverage on the Wikipedia documents to provide other information which is not available in our generated corpus through a domain adaption approach. Furthermore, new information sources for finding more variations also contribute to the overall 22.9% accuracy improvements on KBP-09 test data over baseline.

A Rhetorical Syntax-Driven Model for Speech Summarization

Jian Zhang and Pascale Fung
Human Language Technology Center
Department of Electronic & Computer Engineering
Hong Kong University of Science & Technology (HKUST)
{zjustin, pascale}@ece.ust.hk

Abstract

We show a novel approach of parsing and reordering rhetorical syntax tree for extractive summarization of presentation speech. Our previous work showed (Fung et al., 2008) that rhetorical structures are embedded in this type of speech and that exploring this structure helps improve summarization quality. We further demonstrate that speakers do not follow the strict order of bullet points in the presentation slides, and that a re-ordering of these points occurs. We therefore propose a method of parsing presentation transcriptions into a rhetorical syntax tree and then re-order the leaf nodes to transform the speech transcriptions into an extractive summary, akin to a process of presentation slide generation. Chunking, parsing, and reordering are carried out by 28-class Hidden Markov Support Vector Machine(HMSVM) classifier trained from reference presentations and presentation slides. Using ROUGE-L F-measure we showed that our rhetorical syntax-driven model gives a 35.8% relative improvement over a binary summarizer with no rhetorical information, a 14.3% improvement over Rhetorical State Hidden Markov Model(RSHMM) (Fung et al., 2008), and a 4.3% improvement over our proposed model with no reordering.

1 Introduction

In this paper, we propose to improve extractive summarization of presentation speech using parsing and reordering of the salient points in the speech. Presentation speech includes classroom lectures, conference talks, business seminars, as well as political debates and parliamentary speech where the speaker gives a presentation according to some prepared slides containing bullet points. Some of the speech are transcribed into text, others might even be accompanied by short abstracts. Nevertheless, for learning and collaboration purposes, transcribed text is too long to read whereas short abstracts do not contain enough information (Teufel and Moens, 2002). Especially, in our conference presentation corpus, on average only about 40% bullet points of each transcription appears in the corresponding conference paper abstract. The accompanying presentation slides, on the other hand, are much better in summarizing the gists.

In recent years, more research has been conducted on exploring the hierarchical structure for better summarization performance (Fung et al., 2003; Murray et al., 2006; Sauper and Regina, 2009; Tatar et al., 2008). Unlike text documents, the structure of a spoken document is not immediately apparent in terms of its layout. However, researchers have shown that structural characteristics of a speech are clearly rendered by not just its linguistic features but also its acoustic features (Fung et al., 2008; Hirschberg and Nakatani, 1996; Nakatani et al., 1995). The hierarchical layout structure of Power Point slides enhances

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 1299–1307,
Beijing, August 2010

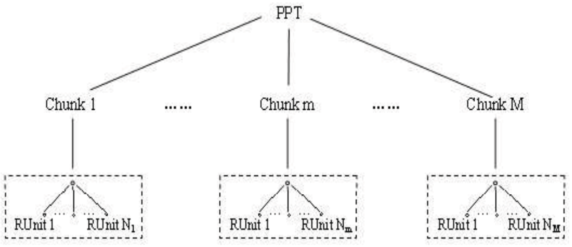

Figure 1: Rhetorical syntax tree

the understanding by the audience. In fact, they even provide a kind of extractive summarization that is superior in terms of informativeness than short abstracts. Unfortunately, presentation slides are not always made available to the audience or for the archive. In some cases, presentation slides consist of mostly figures and graphs, even videos, but without sufficient text bullet points to summarize the content. Meanwhile, there are significant amounts of presentation speech online (e.g. political speech, lectures and seminars) that can be rendered more useful if we can summarize them in a format similar to presentation slides.

Following previous research showing that modeling hierarchical structure indeed helps improve summarization performance, we are interested in going a step further in proposing a rhetorical syntax driven summarization model. Presentation speech is transcribed automatically by an ASR system, then "parsed" into a rhetorical syntax tree. The leaf nodes of the tree, representing actual utterances with rhetorical unit labels, are then "reordered" and organized into a target summary. In this paper, we also propose using a HMSVM (Altun et al., 2003) for the parser and the summarizer. HMSVM has the advantage of considering the interdependence between neighboring sentences. Reordering rules are automatically learned and candidate sequences generated, before they are scored by the final summarizer.

This paper is organized as follows: Section 2 describes our motivation, and the rhetorical structure characteristics in lecture speech. Section 3 details how to parse rhetorical structure of the lecture speech. Section 4 describes the reordering process. Section 5 then describes how to produce extractive summaries. We then describe the corpus, how to create reference summaries, the acoustic/prosodic, linguistic and discourse characteristics of lecture speech, baselines, and our in-house automatic speech recognition system are presented in Section 6. Section 7 presents the experiment results. Section 8 describes related work. We then conclude at the end of this paper.

2 Rhetorical Syntax Tree of Presentation Speech

Unlike conversational speech, lectures and presentations are planned. Lecture speakers follow a relatively rigid rhetorical structure at the document level: s/he starts with an overview of the topic to be presented, followed with the actual content with more detailed descriptions, and then concludes at the end. The speech is given in several coherent "chunks" corresponding to the talk outline. By looking at presentation slides as shown in Figure 1, we can clearly see the chunk boundaries, which always exist at slide transitions, delineate content changes. Each of the chunks, in turn, contains many coherent text spans, namely the rhetorical units. Each rhetorical unit contains one or more slides. We represent the rhetorical structure of presentations by a hierarchical text plan, or a rhetorical tree. Since lecture speeches are mostly based on presentation slides with main bullet points, the structural format of the presentation slides is a faithful representation of the document-level rhetorical structure of the speech. At the top level of the tree are the rhetorical chunks, and at the lower level child nodes are rhetorical units. Each of the chunks contains several rhetorical units, where each unit may contain a number of utterances corresponding to a list of bullet points in the slides.

We propose using the annotation labels commonly shared by most presentation speech for labeling rhetorical chunks as shown in the left column of Table 1. The chunk label definitions are derived from the general structure of presentations in the specific domain of our corpus, namely conference presentations. Note that whereas we chose to use 7 labels for presentation speech, label definitions are fairly obvious and easy to derive for other genres of speech. We use a machine-aided manual annotation method to label the training presentation speech data. Referring to the slides

Table 1: Rhetorical Chunk and Unit Description

Rhetorical Chunk	Rhetorical Unit
c_1 (Title)	title, author of the presentation
c_2 (Outline)	texture structure;
c_3 (Motivation)	aim; problem/phenomenon
c_4 (Related work)	rival/contrast; continuation
c_5 (Methodology)	solution/inventive step
c_6 (Experiment)	corpus description; detailed experimental setup
c_7 (Conclusion)	conclusion; future work

of each presentation, each sentence in the speech transcription is assigned a label corresponding to one of the 7 chunks defined in Table 1. First, all bullet point sentences in the slides are assigned a chunk label according to its section. Referring to our previous work, a Relaxed Dynamic Time Warping program (Zhang et al., 2008) is used to roughly align transcribed sentences to the corresponding slide bullet points. Chunk labels are also included in this alignment. Human inspection quickly corrects any alignment mistakes made by the program. We then label all the sentence of each type "c_i" rhetorical chunk as "c_i". For example, the sentences of a rhetorical chunk which describes "Methodology: solution/inventive step" is labeled as "c_5".

Rhetorical units are described in the right column of Table 1. The rhetorical units, as we explain below, are clustered automatically without explicit labels. These rhetorical units correspond more or less to the definitions in Table 1, without human effort. To obtain the reference rhetorical unit labels of each type of rhetorical chunks in the entire experiment corpus described in Section 6.1, we cluster all utterances that belong to the same chunk in all presentation speech into several rhetorical units by using modified k-means (MKM) clustering algorithm (Wilpon and Rabiner, 1984; Fung et al., 2003). MKM starts from the centroid of all utterances in one rhetorical chunk and splits the clusters top down until the sub-clusters stabilize. Each final cluster represents one rhetorical unit. The clustering algorithm is shown as follows.

Given all utterances within the same type of chunk from all presentation speech:
(1) **Compute** the centroid;
(2) **Assign** sentence feature vectors closest to each centroid to its cluster;
(3) **Update** each centroid feature vector using all sentence feature vectors assigned to each cluster;
(4) **Iterate** step(2) to step (4) until sentence feature vectors stop moving between clusters;
(5) **Stop** if clusters stabilizes, and **get** final clusters, else **goto** step (6);
(6) **Split** the cluster with largest intra-cluster distance into two by finding the pair of vectors as new centroids, and **repeat** steps (2) to step (5).

Using the above algorithm, we find out the following rhetorical unit clusterings of different kinds of rhetorical chunks on our experiment corpus: (1) two rhetorical units in "Title"(c_1) chunk:
"r_i:c_1, $i = 1, 2$";
(2) three rhetorical units in "Outline"(c_2) chunk and "Conclusion"(c_7) chunk:
"r_i:c_j, $i = 1, 2, 3; j = 2, 7$";
(3) five rhetorical units in "Motivation"(c_3) chunk,
"Related work"(c_4) chunk,
"Methodology"(c_5) chunk,
and "Experiment"(c_6) chunk:
"r_i:c_j, $i = 1, 2, 3, 4, 5; j = 3, 4, 5, 6$".

These rhetorical unit clusters correspond roughly to the definitions in the right hand column of Table 1, though no manual labeling is involved.

3 Parsing Presentation Speech

By using our rhetorical syntax-driven model, the process of parsing presentation speech can be described as follows. First we extract acoustic/prosodic features from presentation speech, and linguistic, discourse features from the ASR transcribed text. These features are described in Section 6.1. Next we parse the presentation speech into rhetorical units. Given the ASR transcription of a presentation speech, our task is to parse the transcription sentences into chunks and then into rhetorical units (leaf nodes) that roughly correspond to the rhetorical chunks and units in Table 1 according to their feature vectors. We consider the parsing process as a multi-class classification problem. Each rhetorical unit of each rhetorical chunk is represented by one class.

Considering that HMSVM (Altun et al., 2003) combines the advantages of maximum margin classifier and kernels with the elegance and efficiency of HMMs, and can effectively handle the dependency between neighboring sentences, we train a twenty-eight-class HMSVM classifier for parsing speech, with one class representing each rhetorical unit. As an example, the sentences labeled as "r_2:c_5" belong to the second rhetorical unit of "Methodology"(c_5) chunk. We have found that, by looking at our corpus of conference presentations, speakers indeed follow the "chunk order" of the slides they use. We add some constraints existing between "r_m:c_i" and "r_n:c_j" where "$i \neq j$" according to the "chunk order" of the slides. Function f_1 maps each given speech or transcription **y** to a rhetorical unit label sequence **z**. For example we want to learn a discriminant function $F_1 : \mathcal{Y} \times \mathcal{Z} \rightarrow \mathcal{R}$ over input/output pairs from which we produce a prediction by maximizing F_1 over the output variable for a given input **y**. The general form of our hypotheses f_1 is:

$$\mathbf{z}^* = f_1(\mathbf{y}; \mathbf{w}) = \underset{\mathbf{z} \in \mathcal{Z}}{\operatorname{argmax}} F_1(\mathbf{y}, \mathbf{z}; \mathbf{w}) \quad (1)$$

where **w** denotes a weighting parameter vector to learn.

We assume F_1 to be linear in some combined feature representation of inputs, described in Section 6.1, and outputs $\Psi(\mathbf{y}, \mathbf{z})$. We then get $F_1(\mathbf{y}, \mathbf{z}; \mathbf{w}) = \langle \mathbf{w}, \Psi(\mathbf{y}, \mathbf{z}) \rangle$. Moreover, we apply a kernel function K over the joint input/output space such that:

$$K((\mathbf{y}, \mathbf{z}), (\bar{\mathbf{y}}, \bar{\mathbf{z}})) = \langle \Psi(\mathbf{y}, \mathbf{z}), \Psi(\bar{\mathbf{y}}, \bar{\mathbf{z}}) \rangle \quad (2)$$

Ψ can be written as a sum over the length of the sequence and decomposed as:

$$\Psi(\mathbf{O}, \mathbf{z}) = (\sum_{i=1}^{l(\mathbf{O})} \Psi_{\sigma,\tau}(\upsilon_i, \upsilon_{i+1}, \mathbf{O}, i))_{\sigma,\tau \in \gamma} \quad (3)$$

where γ is the rhetorical unit label set. $l(\mathbf{O})$ is the length of the observation sequence **O** in our case. Ψ is composed by mapping functions that depend only on labels at position i and $i+1$, **O** as well as i (Markov property).

We then rewrite F_1 using $\mathbf{w} = (\mathbf{w}_{\sigma,\tau})_{\sigma,\tau \in \gamma}$ as Equation 4.

$$\begin{aligned} F_1(\mathbf{O}, \mathbf{z}) &= \sum_{\sigma,\tau \in \gamma} \langle \mathbf{w}_{\sigma,\tau}, \sum_{i=1}^{l(\mathbf{O})} \Psi_{\sigma,\tau}(\upsilon_i, \upsilon_{i+1}, \mathbf{O}, i) \rangle \\ &= \sum_{i=1}^{l(\mathbf{O})} \underbrace{\sum_{\sigma,\tau \in \gamma} \langle \mathbf{w}_{\sigma,\tau}, \Psi_{\sigma,\tau}(\upsilon_i, \upsilon_{i+1}, \mathbf{O}, i) \rangle}_{=:g(\upsilon_i, \upsilon_{i+1}, \mathbf{O}, i)} \end{aligned} \quad (4)$$

In decoding process, using this decomposition (Altun et al., 2003) we can define

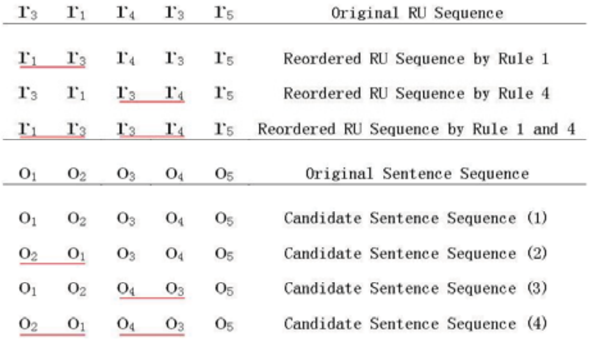
$$\begin{aligned} V(i, \upsilon) := \max_{\upsilon' \in \gamma}(V(i-1, \upsilon')) + g(\upsilon', \upsilon, \mathbf{O}, i-1) \\ when\ i > 1 \\ or\ := 0 \quad otherwise \end{aligned} \quad (5)$$

as the maximal score for all labels with label υ at position i. Using dynamic programming we compute $\max_{\upsilon \in \gamma} V(l(\mathbf{O}), \upsilon)$. The optimal label sequence is recovered by backtracking.

4 Reordering Rhetorical Unit Sequence

4.1 Extracting Reordering Rules

We found that, by looking at our corpus of conference presentations described in Section 6.1, presentation speakers do not always follow the bullet point order within a chunk. When demonstrating a current slide they may be already introducing the next slide. About 11% of the rhetorical units in the transcriptions are out of order vis-a-vis the corresponding bullet points in the presentation slide. As an integral part of our rhetorical syntax-driven summarization model, the rhetorical unit sequence and consequently the sentence sequence are reordered within a chunk. The extraction of reordering rules is based on the alignment between source rhetorical unit sequence in the speech transcription and target rhetorical unit sequence in the Power Point slide sentences. Each sentence is represented by its rhetorical unit label. For example, from the training set and development set in one of our held-out experiment settings described in Section 7, we extracted the following reordering rules: (1)$(r_3, r_1) \rightarrow (r_1, r_3)$;



r_3	r_1	r_4	r_3	r_5	Original RU Sequence
$\underline{r_1}$	$\underline{r_3}$	r_4	r_3	r_5	Reordered RU Sequence by Rule 1
r_3	r_1	$\underline{r_3}$	$\underline{r_4}$	r_5	Reordered RU Sequence by Rule 4
$\underline{r_1}$	$\underline{r_3}$	$\underline{r_3}$	$\underline{r_4}$	r_5	Reordered RU Sequence by Rule 1 and 4
o_1	o_2	o_3	o_4	o_5	Original Sentence Sequence
o_1	o_2	o_3	o_4	o_5	Candidate Sentence Sequence (1)
$\underline{o_2}$	$\underline{o_1}$	o_3	o_4	o_5	Candidate Sentence Sequence (2)
o_1	o_2	$\underline{o_4}$	$\underline{o_3}$	o_5	Candidate Sentence Sequence (3)
$\underline{o_2}$	$\underline{o_1}$	$\underline{o_4}$	$\underline{o_3}$	o_5	Candidate Sentence Sequence (4)

Figure 2: Candidate sentence sequences after applying reordering rules

(2)$(r_3, r_2) \rightarrow (r_2, r_3)$; (3)$(r_4, r_2) \rightarrow (r_2, r_4)$; (4)$(r_4, r_3) \rightarrow (r_3, r_4)$; (5)$(r_5, r_3) \rightarrow (r_3, r_5)$; (6)$(r_5, r_4) \rightarrow (r_4, r_5)$.

In each reordering rule, the left item represents rhetorical unit sequence of the transcription sentences while the right item represents rhetorical unit sequence of bullet points of the corresponding Power Point slides. From these reordering rules, we can see that the speakers in our corpus talk about content described by future bullet points (i.e in the subsequent rhetorical units), but never seem to repeat content from bullet points in the previous unit(s).

4.2 Applying Reordering Rules

Given a sentence sequence and its corresponding rhetorical unit sequence within each chunk, from left to right, with a shifting window of two, we search for the matching reordering rule and adjust the order of the sentences one matched rule at a time, yielding a set of at most 2^L sentence sequence candidates for each chunk where L equals to the length of the sentence. From our data, we found that there are at most 2 matched rules per sentence sequence. So including the original sequence, at most 4 candidate sequences are generated for each chunk.

A reordering example is shown in Figure 2. We apply the reordering rules on a sentence sequence "$(o_1, o_2, o_3, o_4, o_5)$" and the corresponding unit sequence "$(r_3, r_1, r_4, r_3, r_5)$". Four candidate reordered sentence sequence are produced. Without any reordering, we get "Candidate Sentence Sequence (1)". Using reordering Rule 1, we get "Candidate Sentence Sequence (2)".

5 Rhetorical Syntax-driven Summarization

Following sentence reordering, the extractive summarizer selects salient sentences from each chunk using a binary-class classifier. The classifier is run over all candidate sequences from Section 4 and the system selects the best sequence and its summary sentences according to the output probability of the classifier. The best sequence $\{o_1...o_i...o_k\}$ satisfies

$$\text{argmax} \sum_{i=1}^{k} \lg P(o_i \in summary\ sentence\ set | c_j) \qquad (6)$$

where c_j represents the rhetorical chunk c_j which has several candidate sequences, including the sequence $\{o_1...o_i...o_k\}$.
$P(o_i \in summary\ sentence\ set|c_j)$ is output probability of that the sentence o_i in the rhetorical chunk c_j is summary sentence.

Again, an HMSVM classifier is used at this stage. The sentence feature vector **o** now has its rhetorical unit label as an additional feature, to yield a new sentence feature vector $\hat{\mathbf{o}}$. For the sentence vector sequence **z** of each chunk, we label it by using the optimal function $F_2(\mathcal{Z}, \mathcal{V})$. The training stage is similar to that of training the HMSVM parser. The difference is that the HMSVMs for summarization are binary classifiers, while the HMSVM parser is a multi-class classifier.

6 Experimental Setup

6.1 Corpus

We use a lecture speech corpus containing wave files of 71 presentations recorded from different mandarin speakers at two technical conferences, together with well-formatted Power Point slides, manual transcriptions, and their associated audio data. Each presentation lasts about 15 minutes on average. The 71 presentations are split into 391 chunks, and each sentence is assigned a rhetorical chunk label, using the machine-aided human labeling method as described in Section 2. Each chunk has on average 4.3 rhetorical units. The reference rhetorical unit labels are created by using unsupervised MKM algorithm described in Section 2. Since the labeling process also yields an alignment path between transcription sentences and Power Point slide bullet points, we extract those sentences that have the highest alignment scores with the bullet points to form reference summary sentences, then corrected by five human subjects according to the rhetorical chunk descriptions in the right column of Table 1. We use the kappa coefficient (Krippendorff, 1980) for measuring stability of each annotator and reproducibility between each pair of annotators. The average kappa coefficient is higher than 0.85.

6.2 Features and Baselines

We use the discourse feature PossionNoun proposed in our previous work (Zhang et al., 2008) which is based on the following assumptions: first, if a sentence contains new noun words, it probably contains new information. The noun word's Poisson score varies according to its position. We use Poisson distribution to approximate the variation. Second, if a noun word occurs frequently, it is likely to be more important than other noun words, and the sentence with these high frequency noun words should be included in a summary. We also use the following acoustic and linguistic features for representing sentences. The acoustic features are: duration of the sentence, average syllable duration of the sentence, F0 and Energy min/max/mean/slope/range value of the sentence. The linguistic features are: sentence word count, TF/IDF of each word in the sentence, and the word identity in each sentence.

We use three alternate summarization models for comparison. One is a binary classifier without any rhetorical information, one class for summary sentence and the other for non-summary sentence. The second is RSHMM (Fung et al., 2008). The third is our rhetorical syntax tree without reordering. The two above are built by using acoustic, linguistic, and discourse features for representing the sentences. We apply rhetorical unit label as an additional feature for building our proposed models(with/without reordering).

Table 2: Summarization average performance of 6-fold cross validation experiment in ROUGE-L F-measure (F-measure)

Bianry	RSHMM	Without reordering	Syntax tree with reordering
.53(.52)	.63(.56)	.69(.61)	.72(.65)

(1)Binary: binary classifier as baseline
(2)RSHMM: Rhetorical State HMM proposed in our previous work (Fung et al., 2008)
(3)without reordering: rhetorical syntax tree based summarizer without reordering
(4)Syntax tree with reordering: rhetorical syntax tree based summarizer with reordering

6.3 Lecture Speech ASR Transcription System

We apply our rhetorical syntax-driven summarization model for ASR transcriptions. The database for building our in-house ASR system contains 29 hours of audio data from the technical conferences in our corpus. We choose approximately 21 hours of speech as the training data. The test data comprises of 12 presentations with approximately 3 hours of audio data. Our decoding system runs in multiple passes. Automatic segmentation is first performed on the lecture speech audio data. This is followed by bigram decoding with the gender independent (GI) acoustic model (AM) and lattice generation. Trigram and four-gram branches are created for AM adaptation through lattice expansion and rescoring. Re-decoding with both adapted AM and adapted language model (LM) is performed to produce 1-best results. System combination via recognizer output voting error reduction scheme (ROVER) (Fiscus, 1997) is employed by using character based alignment from the trigram and four-gram branch outputs. The final system obtains a recognition performance of 79.2% character accuracy.

7 Experimental Results

For evaluating different summarization systems, we perform 6-fold cross validation experiments, and two held-out experiments. There are many kinds of metrics for evaluating speech summarization performance (Zhu and Penn, 2005; Penn and Zhu, 2008). We choose ROUGE-L F-

Table 3: Summarization performance of held-out experiments in ROUGE-L F-measure (F-measure)

(A) on manual transcription

Binary	RSHMM	Without reordering	Syntax tree with reordering
.50(.48)	.61(.52)	.67(.59)	.69(.61)

(B) on ASR transcription

Binary	RSHMM	Without reordering	Syntax tree with reordering
.46(.43)	.59(.50)	.66(.57)	.68(.61)

(1)Binary: binary classifier as baseline
(2)RSHMM: Rhetorical State HMM proposed in our previous work (Fung et al., 2008)
(3)without reordering: rhetorical syntax tree based summarizer without reordering
(4)Syntax tree with reordering: rhetorical syntax tree based summarizer with reordering

measure (Lin, 2004) and F-measure (Van Rijsbergen, 1979) as evaluation metrics in our experiments. 11 documents from the 71 presentations are excluded as our development set. In the 6-fold cross validation experiments, we divide the remaining 60 presentations into six subsets of equal size. For each experiment, we use five subsets to train all models and the remaining subset for testing. The average performance of these 6-fold cross validation experiments is shown in Table 2.

Among these 60 presentations, 50 are randomly selected as training data for the two held-out experiments, while the remaining ten are used as test data. Table 3-(A) shows the result of the one held-out experiment on manual transcriptions of test data. Table 3-(B) shows the other held-out experiment on ASR transcriptions of test data.

From these results, we can see that the proposed rhetorical syntax-driven summarizer with reordering outperforms all other methods. Table 2 shows that our rhetorical syntax-driven model gives a 35.8% relative improvement over a binary summarizer with no rhetorical information, a 14.3% improvement over RSHMM (Fung et al., 2008), and a 4.3% improvement over our proposed model with no reordering. These findings suggest that our rhetorical syntax-driven summarization model built by using binary HMSVM classifier apply the sequence information of the sentences within the same rhetorical chunk for improving summarization performance because of the Markov property of HMSVM.

In the above experiments, we all use the rhetorical unit labels produced by our rhetorical structure parser for improving summarization performance. The average accuracy of the rhetorical structure parser is about 83.2%. When we use the reference rhetorical unit labels on our cross-validation experiments, the average summarization performance is 0.75 of ROUGE-L F-measure, a 4.2% improvement over that using the rhetorical unit labels produced by the rhetorical structure parser.

Although the overall performance on ASR transcriptions is worse than that of manual transcriptions, the performance is also satisfying. Furthermore, we also find that using only acoustic features our model obtains satisfying result, 0.65 of ROUGE-L F-measure, on 6-fold cross validation experiment.

8 Related Work

(Furui et al., 2008) has shown that feature-based extractive summarization is an approach that is efficient and more effective than MMR-based approach for lecture speech summarization.

(Marcu, 1997) described the first experiment that shows the concepts of rhetorical analysis and nuclearity can be used effectively for text summarization. (Fung et al., 2003) presented a stochastic HMM framework with modified K-means and segmental K-means algorithms for extractive text summarization. (Fung and Ngai, 2006) further presented a stochastic Hidden Markov Story Model for multilingual and multi-document summarization and proposed that monolingual documents recounting the same story (i.e., in the same topic) share a unique story flow (one story, one flow), and such a flow can be modeled by HMMs. (Barzilay and Lee, 2004) presented an unsupervised method for the induction of content models, which capture constraints on topic selection and organization for texts in a particular domain (Branavan et al., 2007) proposed a structured discriminative model for table-of-contents generation on written text that accounts for a wide range of phrase-based and collocation features. (Eisenstein and Barzilay, 2008) describes a novel Bayesian approach to unsupervised lexical cohesion driven topic segmentation.

Many researchers have suggested that rhetorical information also exists in spoken documents and efficient modeling of this information is helpful to the summarization task. (Tatar et al., 2008) and (AKITA and Kawahara, 2007) used the Hearst method (Hearst, 1997) to segment documents and detect topics for text summarization and topic adaptation of speech recognition systems for long speech archives respectively. (Hirohata et al., 2005) consider that humans tend to summarize presentations by extracting important sentences from introduction and conclusion sections, and further propose a summarization method based on this structural characteristic. They estimated the introduction and conclusion section boundaries based on the Hearst method (Hearst, 1997), using sentence cohesiveness which is measured by a cosine value between content word-frequency vectors, before performing summarization. Teufel and Moens (Teufel and Moens, 2002) also proposed "rhetorical status" as summary unit, but without hierarchical structure or reordering. Furthermore, many linguists believe that speech acoustics contribute to rhetorical and discourse structure. (Nakatani et al., 1995) provide empirical evidence that discourses can be segmented reliably, and that acoustic characteristics are used by speakers to convey linguistic structure at the discourse level in the English domain. There is a large amount of previous work seeking to demonstrate that acoustic prosodic profile of speech closely models its discourse or rhetorical structure (Halliday, 1967; Ladd, 1996; Hirschberg and Nakatani, 1996).

Our work described in this paper is closely related to (Marcu, 1997; Teufel and Moens, 2002) in that we propose using rhetorical units for summarization. Our method differs from (Teufel and Moens, 2002) in that we assume the relevance or saliency and function of certain text pieces can be determined by analyzing the full hierarchical structure of the text. Instead of annotating the training data with rhetorical labels manually, we propose using Power Point slides as references. (He et al., 2000; He et al., 1999) also investigate the correlation between Power Point slides and extractive summaries. Our learning method is based on classifiers, while (Marcu, 1997) uses rule-based method for parsing rhetorical structure. We train our rhetorical parser by using those reference rhetorical units of the transcriptions created by aligning Power Point slides. We propose a syntax-driven parsing model with reordering for summarization, and we propose a different classifier, HMSVM, for handling the dependency between neighboring sentences within each chunk, when we accomplish our summarization task.

9 Conclusion and Discussion

In this paper, we have shown a rhetorical syntax-driven summarization method for presentation speech. In view of the fact that rhetorical structure in speech is inherently hierarchical, our method chunks, parses, and reorders the presentation utterance sentences before selecting some of them as summary sentences.

We have proposed to use HMSVM classifiers for the parser and the summarizer, taking into account the dependency between neighboring chunks, rhetorical units and sentences with Markov property. Our rhetorical syntax-driven summarizer with reordering outperforms a binary summarizer without rhetorical information with 35.8% relative improvement and outperforms RSHMM (Fung et al., 2008) with 14.3% relative improvement. It gives a 4.3% relative improvement over the same model without reordering. For future work, we are interested in investigating how to apply our rhetorical syntax-driven method to other genres of speech, such as meetings and parliamentary speech.

Maximum Metric Score Training for Coreference Resolution

Shanheng Zhao and **Hwee Tou Ng**

Abstract

A large body of prior research on coreference resolution recasts the problem as a two-class classification problem. However, standard supervised machine learning algorithms that minimize classification errors on the training instances do not always lead to maximizing the F-measure of the chosen evaluation metric for coreference resolution. In this paper, we propose a novel approach comprising the use of instance weighting and beam search to maximize the evaluation metric score on the training corpus during training. Experimental results show that this approach achieves significant improvement over the state-of-the-art. We report results on standard benchmark corpora (two MUC corpora and three ACE corpora), when evaluated using the link-based MUC metric and the mention-based B-CUBED metric.

1 Introduction

Coreference resolution refers to the process of determining whether two or more noun phrases (NPs) in a text refer to the same entity. Successful coreference resolution benefits many natural language processing tasks. In the literature, most prior work on coreference resolution recasts the problem as a two-class classification problem. Machine learning-based classifiers are applied to determine whether a candidate anaphor and a potential antecedent are coreferential (Soon et al., 2001; Ng and Cardie, 2002b).

A large body of prior research on coreference resolution follows the same process: during training, they apply standard supervised machine learning algorithms to minimize the number of misclassified training instances; during testing, they maximize either the local or the global probability of the coreferential relation assignments according to the specific chosen resolution method.

However, minimizing the number of misclassified training instances during training does not guarantee maximizing the F-measure of the chosen evaluation metric for coreference resolution. First of all, coreference is a rare relation. There are far fewer positive training instances than negative ones. Simply minimizing the number of misclassified training instances is suboptimal and favors negative training instances. Secondly, evaluation metrics for coreference resolution are based on global assignments. Not all errors have the same impact on the metric score. Furthermore, the extracted training instances are not equally easy to be classified.

In this paper, we propose a novel approach comprising the use of instance weighting and beam search to address the above issues. Our proposed maximum metric score training (MMST) approach performs maximization of the chosen evaluation metric score on the training corpus during training. It iteratively assigns higher weights to the hard-to-classify training instances. The output of training is a standard classifier. Hence, during testing, MMST is faster than approaches which optimize the assignment of coreferential relations during testing. Experimental results show that MMST achieves significant improvements over the baselines. Unlike most of the previous work, we report improved results over the state-of-the-art on all five standard benchmark corpora

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 1308–1316,
Beijing, August 2010

(two MUC corpora and three ACE corpora), with both the link-based MUC metric and the mention-based B-CUBED metric.

The rest of this paper is organized as follows. We first review the related work and the evaluation metrics for coreference resolution in Section 2 and 3, respectively. Section 4 describes the proposed MMST algorithm. Experimental results and related discussions are given in Section 5. Finally, we conclude in Section 6.

2 Related Work

Soon *et al.* (2001) proposed a training and testing framework for coreference resolution. During training, a positive training instance is formed by a pair of markables, i.e., the anaphor (a noun phrase) and its closest antecedent (another noun phrase). Each markable (noun phrase) between the two, together with the anaphor, form a negative training instance. A classifier is trained on all training instances, using a standard supervised learning algorithm. During testing, all preceding markables of a candidate anaphor are considered as potential antecedents, and are tested in a back-to-front manner. The process stops if either an antecedent is found or the beginning of the text is reached. This framework has been widely used in the community of coreference resolution.

Recent work boosted the performance of coreference resolution by exploiting fine-tuned feature sets under the above framework, or adopting alternative resolution methods during testing (Ng and Cardie, 2002b; Yang et al., 2003; Denis and Baldridge, 2007; Versley et al., 2008).

Ng (2005) proposed a ranking model to maximize F-measure during testing. In the approach, n different coreference outputs for each test text are generated, by varying four components in a coreference resolution system, i.e., the learning algorithm, the instance creation method, the feature set, and the clustering algorithm. An SVM-based ranker then picks the output that is likely to have the highest F-measure. However, this approach is time-consuming during testing, as F-measure maximization is performed during testing. This limits its usage on a very large corpus.

In the community of machine learning, researchers have proposed approaches for learning a model to optimize a chosen evaluation metric other than classification accuracy on all training instances. Joachims (2005) suggested the use of support vector machines to optimize nonlinear evaluation metrics. However, the approach does not differentiate between the errors in the same category in the contingency table. Furthermore, it does not take into account inter-instance relation (e.g., transitivity), which the evaluation metric for coreference resolution cares about.

Daume III (2006) proposed a structured learning framework for coreference resolution to approximately optimize the ACE metric. Our proposed approach differs in two aspects. First, we directly optimize the evaluation metric itself, and not by approximation. Second, unlike the incremental local loss in Daume III (2006), we evaluate the metric score globally.

In contrast to Ng (2005), Ng and Cardie (2002a) proposed a rule-induction system with rule pruning. However, their approach is specific to rule induction, and is not applicable to other supervised learning classifiers. Ng (2004) varied different components of coreference resolution, choosing the combination of components that results in a classifier with the highest F-measure on a held-out development set during training. In contrast, our proposed approach employs instance weighting and beam search to maximize the F-measure of the evaluation metric during training. Our approach is general and applicable to any supervised learning classifiers.

Recently, Wick and McCallum (2009) proposed a partition-wise model for coreference resolution to maximize a chosen evaluation metric using the Metropolis-Hastings algorithm (Metropolis et al., 1953; Hastings, 1970). However, they found that training on classification accuracy, in most cases, outperformed training on the coreference evaluation metrics. Furthermore, similar to Ng (2005), their approach requires the generation of multiple coreference assignments during testing.

Vemulapalli *et al.* (2009) proposed a document-level boosting technique for coreference resolution by re-weighting the documents that have the lowest F-measures. By combining multiple classifiers generated in multiple iterations, they achieved a CEAF score slightly better than the baseline. Different from them, our approach works at the instance level, and we output a single classifier.

3 Coreference Evaluation Metrics

In this section, we review two commonly used evaluation metrics for coreference resolution.

First, we introduce the terminology. The gold standard annotation and the output by a coreference resolution system are called key and response, respectively. In both the key and the response, a coreference chain is formed by a set of coreferential mentions. A *mention* (or markable) is a noun phrase which satisfies the markable definition in an individual corpus. A *link* refers to a pair of coreferential mentions. If a mention has no links to other mentions, it is called a *singleton*.

3.1 The MUC Evaluation Metric

Vilain *et al.* (1995) introduced the link-based MUC evaluation metric for the MUC-6 and MUC-7 coreference tasks. Let S_i be an equivalence class generated by the key (i.e., S_i is a coreference chain), and $p(S_i)$ be a partition of S_i relative to the response. Recall is the number of correctly identified links over the number of links in the key.

$$Recall = \frac{\sum(|S_i| - |p(S_i)|)}{\sum(|S_i| - 1)}$$

Precision, on the other hand, is defined in the opposite way by switching the role of key and response. F-measure is a trade-off between recall and precision.

$$F = \frac{2 \cdot Recall \cdot Precision}{Recall + Precision}$$

3.2 The B-CUBED Evaluation Metric

Bagga and Baldwin (1998) introduced the mention-based B-CUBED metric. The B-CUBED metric measures the accuracy of coreference resolution based on individual mentions. Hence, it also gives credit to the identification of singletons, which the MUC metric does not. Recall is computed as

$$Recall = \frac{1}{N} \sum_{d \in D} \sum_{m \in d} \frac{|O_m|}{|S_m|}$$

where D, d, and m are the set of documents, a document, and a mention, respectively. S_m is the equivalence class generated by the key that contains m, while O_m is the overlap of S_m and the equivalence class generated by the response that contains m. N is the total number of mentions in D. The precision, again, is computed by switching the role of key and response. F-measure is computed in the same way as the MUC metric.

4 Maximum Metric Score Training

Before explaining the algorithm, we describe our coreference clustering method used during testing. It is the same as most prior work in the literature, including Soon *et al.* (2001) and Ng and Cardie (2002b). The individual classification decisions made by the coreference classifier do not guarantee that transitivity of coreferential NPs is obeyed. So it can happen that the pair A and B, and the pair B and C are both classified as coreferential, but the pair A and C is not classified as coreferential by the classifier. After all coreferential markable pairs are found (no matter by closest-first, best-first, or resolving-all strategies as in different prior work), all coreferential pairs are clustered together to form the coreference output. By doing so, transitivity is kept: a markable is in a coreference chain if and only if it is classified to be coreferential to at least one other markable in the chain.

4.1 Instance Weighting

Suppose there are m_k and m_r coreferential links in the key and the response, respectively, and a coreference resolution system successfully predicts n correct links. The recall and the precision are then $\frac{n}{m_k}$ and $\frac{n}{m_r}$, respectively. The learnt classifier predicts false positive and false negative instances during testing. For a false positive instance, if we could successfully predict it as negative, the recall is unchanged, but the precision will be $\frac{n}{m_r - 1}$, which is higher than the original precision $\frac{n}{m_r}$. For a false negative instance, it is more subtle. If the two markables in the instance are determined to be in the same coreference chain by the clustering algorithm, it does not matter whether we predict this instance as positive or negative, i.e., this false negative does not change the F-measure of the evaluation metric at all. If the two markables are not in the same coreference chain under the clustering, in case that we can predict it as positive, the recall will be $\frac{n+1}{m_k}$, which is higher than the original recall $\frac{n}{m_k}$, and the precision will be $\frac{n+1}{m_r+1}$, which is higher than the original precision $\frac{n}{m_r}$, as $n < m_r$. In both cases, the F-measure improves. If we can instruct the learning algorithm to pay more attention to these false positive and false negative instances and to predict them correctly by assigning them more weight, we should be able to improve the F-measure.

In the literature, besides the training instance extraction methods proposed by Soon *et al.* (2001) and Ng and Cardie (2002b) as discussed in Section 2, McCarthy and Lehnert (1995) used all possible pairs of training instances. We also use all pairs of training instances in our approach to keep as much information as possible. Initially all the pairs are equally weighted. We then iteratively assign more weights to the hard-to-classify pairs. The iterative process is conducted by a beam search algorithm.

4.2 Beam Search

Our proposed MMST algorithm searches for a set of weights to assign to training instances such that the classifier trained on the weighted training instances gives the maximum coreference metric score when evaluated on the training instances. Beam search is used to limit the search. Each search state corresponds to a set of weighted training instances, a classifier trained on the weighted training instances minimizing misclassifications, and the F-measure of the classifier when evaluated on the weighted training instances using the chosen coreference evaluation metric. The root of the search tree is the initial search state where all the training instances have identical weights of one. Each search state s can expand into two different children search states s_l and s_r. s_l (s_r) corresponds to assigning higher weights to the false positive (negative) training instances in s. The search space thus forms a binary search tree.

Figure 1 shows an example of a binary search tree. Initially, the tree has only one node: the root (node 1 in the figure). In each iteration, the algorithm expands all the leaf nodes in the beam. For example, in the first iteration, node 1 is expanded to generate node 2 and 3, which corresponds to adding weights to false positive and false negative training instances, respectively. An expanded node always has two children in the binary search tree. All the nodes are then sorted in descending order of F-measure. Only the top M nodes are kept, and the remaining nodes are discarded. The discarded nodes can either be leaf nodes or non-leaf nodes. For example, if node 5 is discarded because of low F-measure, it will not be expanded to generate children in the binary search tree. The iterative algorithm stops when all the nodes in the beam are non-leaf nodes, i.e., all the nodes in the beam have been expanded.

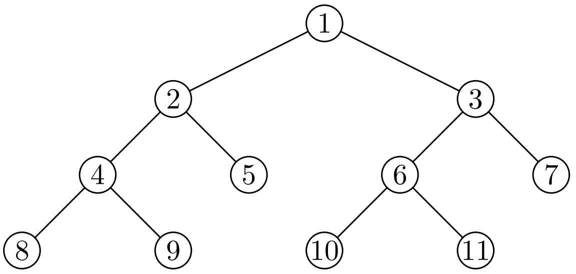

Figure 1: An example of a binary search tree

Figure 2 gives the formal description of the proposed maximum metric score training algorithm. In the algorithm, assume that we have N texts T_1, T_2, ..., T_N in the training data set. m_{ki} and m_{kj} are the ith and jth markable in the text T_k, respectively. Hence, for all $i < j$, $(m_{ki}, m_{kj}, w_{kij})$ is a training instance for the markable pair (m_{ki}, m_{kj}), in which w_{kij} is the weight of the instance. Let L_{kij} and L'_{kij} be the true and predicted label of the pair (m_{ki}, m_{kj}), respectively. Let W, C, F, and E be the set of weights $\{w_{kij} | 1 \leq k \leq N, i < j\}$, the classifier, the F-measure, and a boolean indicator of whether the search state has been expanded, respectively. Finally, M is the beam size, and δ controls how much we update the weights in each iteration.

Since we train the model on all possible pairs, during testing we also test if a potential anaphor is coreferential to each preceding antecedent.

```
INPUT: $T_1, T_2, \ldots, T_N$
OUTPUT: classifier $C$
$w_{kij} \leftarrow 1$, for all $1 \leq k \leq N$ and $i < j$
$C \leftarrow$ train($\{(m_{ki}, m_{kj}, w_{kij}) | 1 \leq k \leq N, i < j\}$)
$F \leftarrow$ resolve and evaluate $T_1, \ldots, T_N$ with $C$
$E \leftarrow false$
BEAM$\leftarrow \{(W, C, F, E)\}$
repeat
  BEAM$' \leftarrow \{\}$
  for all $(W, C, F, E)$ in BEAM do
    BEAM$' \leftarrow$ BEAM$' \bigcup \{(W, C, F, true)\}$
    if E=false then

5 Experiments

5.1 Experimental Setup

In the experiments, we used all the five commonly used evaluation corpora for coreference resolution, namely the two MUC corpora (MUC6 and MUC7) and the three ACE corpora (BNEWS, NPAPER, and NWIRE). The MUC6 and the MUC7 corpora were defined in the DARPA Message Understanding Conference (MUC-6, 1995; MUC-7, 1998). The dry-run texts were used as the training data sets. In both corpora, each training data set contains 30 texts. The test data sets for MUC6 and MUC7 consist of the 30 and 20 formal evaluation texts, respectively. The ACE corpora were defined in NIST Automatic Content Extraction phase 2 (ACE-2) (NIST, 2002). The three data sets are from different news sources: broadcast news (BNEWS), newspaper (NPAPER), and newswire (NWIRE). Each of the three data sets contains two portions: training and development test. They were used as our training set and test set, respectively. The BNEWS, NPAPER, and NWIRE data sets contain 216, 76, and 130 training texts, and 51, 17, and 29 test texts, respectively.

Unlike some previous work on coreference resolution that assumes that the gold standard markables are known, we work directly on raw text input. Versley *et al.* (2008) presented the BART package[1], an open source coreference resolution toolkit, that accepts raw text input and reported state-of-the-art MUC F-measures on the three ACE corpora. BART uses an extended feature set and tree kernel support vector machines (SVM) under the Soon *et al.* (2001) training and testing framework. We used the BART package in our experiments, and implemented the proposed MMST algorithm on top of it. In our experiments reported in this paper, the features we used are *identical* to the features output by the preprocessing code of BART reported in Versley *et al.* (2008), except that we did not use their tree-valued and string-valued features (see the next subsection for details).

Since we use automatically extracted markables, it is possible that some extracted markables and the gold standard markables are unmatched, or *twinless* as defined in Stoyanov *et al.* (2009). How to use the B-CUBED metric for evaluating twinless markables has been explored recently. In this paper, we adopt the $B^3 all$ variation proposed by Stoyanov *et al.* (2009), which retains all twinless markables. We also experimented with their $B^3 0$ variation, which gave similar results. Note that no matter which variant of the B-CUBED metric is used, it is a fair comparison as long as the baseline and our proposed MMST algorithm are compared against each other using the same B-CUBED variant.

5.2 The Baseline Systems

We include state-of-the-art coreference resolution systems in the literature for comparison. Since we use the BART package in our experiments,

[1] `http://www.sfs.uni-tuebingen.de/~versley/BART/`

we include the results of the original BART system (with its extended feature set and SVM-light-TK (Moschitti, 2006), as reported in Versley *et al.* (2008)) as the first system for comparison. Versley *et al.* (2008) reported only the results on the three ACE data sets with the MUC evaluation metric. Since we used all the five data sets in our experiments, for fair comparison, we also include the MUC results reported in Ng (2004). To the best of our knowledge, Ng (2004) was the only prior work which reported MUC metric scores on all the five data sets. The MUC metric scores of Versley *et al.* (2008) and Ng (2004) are listed in the row "Versley *et al.* 08" and "Ng 04", respectively, in Table 1. For the B-CUBED metric, we include Ng (2005) for comparison, although it is unclear how Ng (2005) interpreted the B-CUBED metric. The scores are listed in the row "Ng 05" in Table 2.

Tree kernel SVM learning is time-consuming. To reduce the training time needed, instead of using SVM-light-TK, we used a much faster learning algorithm, J48, which is the WEKA implementation of the C4.5 decision tree learning algorithm. (Quinlan, 1993; Witten and Frank, 2005). As tree-valued features and string-valued features cannot be used with J48, in our experiments we excluded them from the extended feature set that BART used to produce state-of-the-art MUC F-measures on the three ACE corpora. All our results in this paper were obtained using this reduced feature set and J48 decision tree learning. However, given sufficient computational resources, our proposed approach is able to apply to any supervised machine learning algorithms.

Our baselines that follow the Soon *et al.* (2001) framework, using the reduced feature set and J48 decision tree learning, are shown in the row "*SNL*-Style Baseline" in Table 1 and 2. The results suggest that our baseline system is comparable to the state of the art. Although in Table 1, the performance of the *SNL*-style baseline is slightly lower than Versley *et al.* (2008) on the three ACE corpora, the computational time needed has been greatly reduced.

Our MMST algorithm trains and tests on all pairs of markables. To show the effectiveness of weight updating of MMST, we built another baseline which trains and tests on all pairs. The performance of this system is shown in the row "*All*-Style Baseline" in Table 1 and 2.

5.3 Results Using Maximum Metric Score Training

Next, we show the results of using the proposed maximum metric score training algorithm. From the description of the algorithm, it can be seen that there are two parameters in the algorithm. One parameter is M, the size of the beam. The other parameter is δ, which controls how much we increase the weight of a training instance in each iteration.

Since the best M and δ for the MUC evaluation metric were not known, we used held-out development sets to tune the parameters. Specifically, we trained classifiers with different combinations of M and δ on a development training set, and evaluated their performances on a development test set. In our experiments, the development training set contained 2/3 of the texts in the training set of each individual corpus, while the development test set contained the remaining 1/3 of the texts. After having picked the best M and δ values, we trained a classifier on the entire training set with the chosen parameters. The learnt classifier was then applied to the test set.

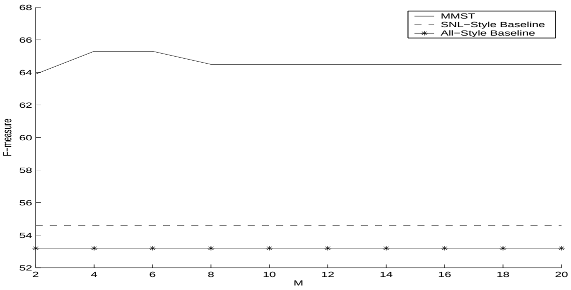

Figure 3: Tuning M on the held-out development set

To limit the search space, we tuned the two parameters sequentially. First, we fixed $\delta = 1$, which is equivalent to duplicating each training instance once in J48, and evaluated $M = 2, 4, 6, \ldots, 20$. After having chosen the best M that corresponded to the maximum F-measure, we fixed the value of M, and evaluated $\delta = 0.1, 0.2, 0.3, \ldots, 2.0$. Take MUC6 as an exam-

Table 2: Results for the two MUC and three ACE corpora with B^3 evaluation metric

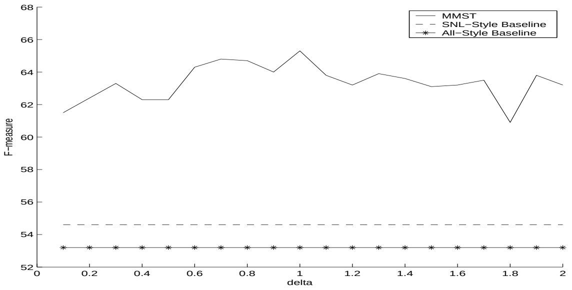

Figure 4: Tuning δ on the held-out development set

ple. The results of tuning M on MUC6 are shown in Figure 3. The maximum F-measure is obtained when $M = 4$ and $M = 6$. On all the different M values we have tried, MMST outperforms both the *SNL*-style baseline and the *All*-style baseline on the development test set. We then fixed $M = 6$, and evaluated different δ values. The results are shown in Figure 4. The best F-measure was obtained when $\delta = 1.0$. Again, on all the different δ values we have tried, MMST outperforms both baselines on the development test set.

The rows "MMST" in Table 1 and 2 show the performance of MMST on the test sets, with the tuned parameters indicated. In our experiments, the statistical significance test was conducted as in Chinchor (1995). * and ** stand for $p < 0.05$ and $p < 0.01$ over the *SNL*-style baseline, respectively. † and †† stand for $p < 0.05$ and $p < 0.01$ over the *All*-style baseline, respectively.

For the MUC metric, when compared to the *All*-style baseline, MMST gains 3.4, 2.5, 3.2, 2.4, and 2.8 improvement in F-measure on MUC6, MUC7, BNEWS, NPAPER, and NWIRE, respectively. The experimental results clearly show that MMST gains not only consistent, but also statistically significant improvement over both the *SNL*-style baseline and the *All*-style baseline in all combinations (five data sets and two baselines) on the MUC metric, except that it is not significant ($p = 0.06$) over the *SNL*-style baseline in NPAPER. As for the B-CUBED metric, MMST gains significant improvement in F-measure on MUC6 and MUC7 data sets, while its performance on the three ACE data sets are comparable to the *All*-style baseline.

5.4 Discussion

To see how MMST actually updates the weight, we use the MUC metric as an example. Under the experimental settings, it takes 6 – 9 iterations for MMST to stop on the five data sets. The number of explored states in the binary search tree, including the root, is 33, 39, 25, 29, and 75 on MUC6, MUC7, BNEWS, NPAPER, and NWIRE, respectively. It is instructive to find out the final weight of each instance. Take MUC6 as an example, the number of positive instances with weight 1, 2, 3, and 4 are 5,204, 1,568, 1,379, and 1,844, respectively, while the number of negative instances with weight 1 and 2 are 503,141 and 1,755, respectively. Counting the weighted number of instances (e.g., an instance with weight 2 is equivalent to 2 instances), we have 19,853 positive and 506,651 negative training instances. This changes the ratio of the positive instances from 1.9% to 3.8%. As a by-product, MMST reduces data skewness, while using all possible NP pairs for training to keep as much information as possible.

The change of weights of the training instances is equivalent to the change of distribution of the training instances. This effectively changes the classification hypothesis to the one that tends to yield higher evaluation metric score. Take the following sentence in the MUC6 data set as an example:

> In a news release, ***the company*** said the new name more accurately reflects ***its*** focus on high-technology communications, including business and entertainment software, interactive media and wireless data and voice transmission.

In the above example, the pronoun *its* is coreferential to the antecedent NP *the company*. The baseline classifier gives a probability of 0.02 that the two NPs are coreferential. The pair is classified wrongly and none of the other pairs in the article can link the two NPs together through clustering. However, with MMST, this probability increases to 0.54, which leads to the correct classification. This is because the baseline classifier is not good at predicting in the case when the second markable is a pronoun. In the above example, *its* can have another candidate antecedent *the new name*. There are far more negative training instances than positive ones for this case. In fact, in the induced decision tree by the baseline, the leaf node corresponding to the pair *the company* – *its* has 7,782 training instances, out of which only 175 are positive. With MMST, however, these numbers decrease to 83 and 45, respectively. MMST also promotes the Anaphor_Is_Pronoun feature to a higher level in the decision tree. Although we use decision tree to illustrate the working of the algorithm, MMST is not limited to tree learning, and can make use of any learning algorithms that are able to take advantage of instance weighting.

It can also be seen that with the B-CUBED metric, MMST gains improvement on MUC6 and MUC7, but not on the three ACE corpora. However, the results of MMST on the three ACE corpora with the B-CUBED evaluation metric are at least comparable with the *All*-style baseline. This is because we always pick the classifier which corresponds to the maximum evaluation metric score on the training set and the classifier corresponding to the *All*-style baseline is one of the candidates. In addition, our MMST approach improves upon state-of-the-art results (Ng, 2004; Ng, 2005; Versley et al., 2008) on most of the five standard benchmark corpora (two MUC corpora and three ACE corpora), with both the link-based MUC metric and the mention-based B-CUBED metric.

Finally, our approach performs all the F-measure maximization during training, and is very fast during testing, since the output of the MMST algorithm is a standard classifier. For example, on the MUC6 data set with the MUC evaluation metric, it took 1.6 hours and 31 seconds for training and testing, respectively, on an Intel Xeon 2.33GHz machine.

6 Conclusion

In this paper, we present a novel maximum metric score training approach comprising the use of instance weighting and beam search to maximize the chosen coreference metric score on the training corpus during training. Experimental results show that the approach achieves significant improvement over the baseline systems. The proposed approach improves upon state-of-the-art results on most of the five standard benchmark corpora (two MUC corpora and three ACE corpora), with both the link-based MUC metric and the mention-based B-CUBED metric.

Paraphrasing with Search Engine Query Logs

Shiqi Zhao[†‡], **Haifeng Wang**[†], **and Ting Liu**[‡]

Abstract

This paper proposes a method that extracts paraphrases from search engine query logs. The method first extracts paraphrase query-title pairs based on an assumption that a search query and its corresponding clicked document titles may mean the same thing. It then extracts paraphrase query-query and title-title pairs from the query-title paraphrases with a pivot approach. Paraphrases extracted in each step are validated with a binary classifier. We evaluate the method using a query log from Baidu[1], a Chinese search engine. Experimental results show that the proposed method is effective, which extracts more than 3.5 million pairs of paraphrases with a precision of over 70%. The results also show that the extracted paraphrases can be used to generate high-quality paraphrase patterns.

1 Introduction

The use of paraphrases is ubiquitous in human languages, which also presents a challenge for natural language processing (NLP). Previous studies have shown that paraphrasing can play important roles in plenty of areas, such as machine translation (MT) (Callison-Burch et al., 2006; Kauchak and Barzilay, 2006), question answering (QA) (Duboue and Chu-Carroll, 2006; Riezler et al., 2007), natural language generation (NLG) (Iordanskaja et al., 1991), and so on. As a result, the research on paraphrasing and its applications have attracted significant interest.

This paper proposes a method that uses search engine query logs for extracting paraphrases, which is illustrated in Figure 1. Specifically, three kinds of paraphrases can be extracted with our method, which include (1) query-title (Q-T): a query and a document title that users clicked on; (2) query-query (Q-Q): two queries, for which users clicked on the same document title; (3) title-title (T-T): two titles that users clicked on for the same query. We train a classifier for each kind to filter incorrect pairs and refine the paraphrases.

Extracting paraphrases using query logs has many advantages. First, query logs keep growing, which have no scale limitation. Second, query logs reflect web users' real needs, hence the extracted paraphrases may be more useful than that from other kinds of corpora. Third, paraphrases extracted from query logs can be directed applied in search engines for query suggestion and document reranking. In addition, we find that both queries and titles contain a good many question sentences, which can be useful in developing QA systems.

We conduct experiments using a query log of a commercial Chinese search engine Baidu, from which we extracted about 2.7 million pairs of paraphrase Q-T, 0.4 million pairs of paraphrase Q-Q, and 0.4 million pairs of paraphrase T-T. The precision of the paraphrases is above 70%. In addition, we generate paraphrase patterns using the extracted paraphrases. The results show that 73,484 pairs of paraphrase patterns have been generated, with a precision of over 78%.

In the rest of the paper, we first review related work in Section 2. Section 3 describes our method in detail. Section 4 presents the evaluation and re-

2 Related Work

In this section, we briefly review previous studies on paraphrase extraction and query log mining in information retrieval (IR).

2.1 Paraphrase Extraction

A variety of data resources have been exploited for paraphrase extraction. For example, some researchers extract paraphrases from multiple translations of the same foreign novel (Barzilay and McKeown, 2001; Ibrahim et al., 2003), while some others make use of comparable news articles that report on the same event within a small time interval (Shinyama et al., 2002; Barzilay and Lee, 2003; Dolan et al., 2004). Besides the monolingual corpora, bilingual parallel corpora have also been used for extracting paraphrases (Bannard and Callison-Burch, 2005; Callison-Burch, 2008; Zhao et al., 2008). Their basic assumption is that phrases that align with the same foreign phrase may have the same meaning.

The above methods have achieved promising results. However, their performances are usually constrained due to the scale and domain limitation. As an alternative, researchers have tried to acquire paraphrases from large-scale web corpora (Lin and Pantel, 2001; Paşca and Dienes, 2005; Bhagat and Ravichandran, 2008) or directly based on web mining (Ravichandran and Hovy, 2002). These methods are guided by an extended version of distributional hypothesis, namely, if two phrases often occur in similar contexts, their meanings tend to be similar. The disadvantage of these methods is that the underlying assumption does not always hold. Phrases with opposite meanings can also occur in similar contexts, such as “X solves Y” and “X worsens Y” (Lin and Pantel, 2001). In addition, the extracted paraphrases are generally short fragments with two slots (variables) at both ends.

2.2 Query Log Mining in IR

Query logs are widely used in the IR community, especially for mining similar queries. For example, Wen et al. (2002) clustered queries based on user click information. Their basic idea is that if some queries result in similar user clicks, the meanings of these queries should be similar. Such methods have also been investigated in (Gao et al., 2007) for cross-lingual query suggestion and (Zhao et al., 2007) for synonymous questions identification. This paper is partly inspired by their studies. However, we do not simply use click information as clues for mining similar queries. Instead, we mine paraphrases across queries and clicked document titles.

In addition, query logs can be used for query expansion. For instance, Cui et al. (2002) extract probabilistic correlations between query terms and document terms by analyzing query logs, which are then used to select high-quality

H1: If a query q hits a title t, then q and t are likely to be paraphrases.

H2: If queries q_1 and q_2 hit the same title t, q_1 and q_2 are likely to be paraphrases.

H3: If a query q hits titles t_1 and t_2, then t_1 and t_2 are likely to be paraphrases.

Table 1: Hypotheses for extracting paraphrases.

expansion terms for new queries. Note that the expansion terms are merely related terms of the queries, not necessarily paraphrases.

There are other studies that use query logs for constructing ontologies (Sekine and Suzuki, 2007), learning named entities (Paşca, 2007), building user profiles (Richardson, 2008), correcting spelling errors (Ahmad and Kondrak, 2005), and so forth.

3 The Proposed Method

3.1 Basic Idea

Nowadays, more and more users tend to search long queries with search engines. Many users even directly search questions to get exact answers. By analyzing our query log that records rich information including user queries, clicked urls, titles, etc., we find that most titles of clicked documents are highly related with search queries. Especially, paraphrases can be easily found from long queries and the corresponding clicked titles. This motivates us to extract paraphrases from query-title pairs. Here we introduce a concept *hit* that will be frequently used: given a query q, a web document d, and d's title t, if there exist some users that click on d when searching q, then we say *q hits t*.

The hypothesis for extracting paraphrase Q-T is shown in Table 1 (H1). In addition, we find that when several queries hit the same title, the queries are likely to be paraphrases of each other. The other way round, when a query hits several titles, paraphrases can also be found among the titles. We therefore further extract paraphrase Q-Q and T-T from the paraphrase Q-T. The underlying hypotheses can be found in Table 1 (H2 and H3). Note that, based on H2 and H3, paraphrase Q-Q and T-T can be directly extracted from raw Q-T pairs. However, in consideration of precision, we extract them from paraphrase Q-T. We call our paraphrase Q-Q and T-T extraction approach as a pivot approach, since we use titles as *pivots* (queries as *targets*) when extracting paraphrase Q-Q and use queries as *pivots* (titles as *targets*) when extracting paraphrase T-T.

```
INPUT: $\mathcal{Q}$: query space, $\mathcal{T}$: title space
OUTPUT: $P_{qt}$: the set of paraphrase Q-T,
        $P_{qq}$: the set of paraphrase Q-Q,
        $P_{tt}$: the set of paraphrase T-T,
        $ParaSet$: the set of paraphrases

 1. FOR any $q \in \mathcal{Q}$ and $t \in \mathcal{T}$
 2.     IF $q$ hits $t$
 3.         IF $IsParaphrase(q, t)$
 4.             Add $\langle q, t \rangle$ to $P_{qt}$
 5.         END IF
 6.     END IF
 7. END FOR

 8. FOR any $q_1, q_2 \in \mathcal{Q}$ and $t \in \mathcal{T}$
 9.     IF $\langle q_1, t \rangle \in P_{qt}$ and $\langle q_2, t \rangle \in P_{qt}$
10.         IF $IsParaphrase(q_1, q_2)$
11.             Add $\langle q_1, q_2 \rangle$ to $P_{qq}$
12.         END IF
13.     END IF
14. END FOR

15. FOR any $t_1, t_2 \in \mathcal{T}$ and $q \in \mathcal{Q}$
16.     IF $\langle q, t_1 \rangle \in P_{qt}$ and $\langle q, t_2 \rangle \in P_{qt}$
17.         IF $IsParaphrase(t_1, t_2)$
18.             Add $\langle t_1, t_2 \rangle$ to $P_{tt}$
19.         END IF
20.     END IF
21. END FOR

22. RETURN $ParaSet = P_{qt} \cup P_{qq} \cup P_{tt}$
```

Table 2: Algorithm for extracting paraphrases.

3.2 Algorithm

Our paraphrase extraction algorithm is shown in Table 2. In particular, lines 1$\sim$7 extract paraphrase Q-T from the query log. Lines 8∼14 and 15∼21 extract paraphrase Q-Q and T-T, respectively. Line 22 combines the paraphrase Q-T, Q-Q, and T-T together. To filter noise, the extracted Q-T, Q-Q, and T-T pairs are all validated using a function $IsParaphrase(s_1, s_2)$. In this work, we recast paraphrase validation as a binary classification problem. Any pair of $\langle s_1, s_2\rangle$ is classified as 1 (paraphrase) or 0 (non-paraphrase) with a support vector machine (SVM) classifier. The features used for classification will be detailed in Section 3.3.

In practice, we exploit a query log that contains 287 million Q-T pairs, which are then filtered using the following constraints: (1) exclude Q-T pairs that are too short, i.e., either query q or tittle t contains less than three terms; (2) exclude Q-T pairs where q subsumes t or vice versa, e.g., "牛肉 (beef)" and "牛肉 的 做法 (cooking method of beef)"; (3) exclude Q-T pairs in which the similarity between q and t is below a predefined threshold T[2]; (4) exclude Q-T pairs whose t contains frequent internet terms, such as "主页 (home page)", "网站 (web site)", "在线 (online)", since such titles are mostly organization home pages, online videos, downloadable resources, etc., which are useless for our purpose of paraphrase extraction.

3.3 Features for Paraphrase Validation

Given a pair of candidate paraphrases $\langle s_1, s_2\rangle$, in which s_1 and s_2 can be either a query or a title, we exploit the following features in the classification-based paraphrase validation.

• **Frequency Feature** F_F. F_F is defined based on each $\langle s_1, s_2\rangle$'s frequency. We expect that more frequent $\langle s_1, s_2\rangle$ should be more reliable.

$$F_F(s_1, s_2) = \{ \begin{array}{ll} \frac{c(s_1,s_2)}{C} & if \;\; c(s_1, s_2) < C \\ 1 & if \;\; c(s_1, s_2) \geq C \end{array} \quad (1)$$

where $c(s_1, s_2)$ denotes the number of times that the $\langle s_1, s_2\rangle$ pair occurs in the corpus. C is a normalizing factor ($C = 10$ in our experiments).

• **Length Rate Feature** F_{LR}:

$$F_{LR}(s_1, s_2) = \frac{min\{c_w(s_1), c_w(s_2)\}}{max\{c_w(s_1), c_w(s_2)\}} \quad (2)$$

where $c_w(s)$ denotes the number of words in s.

• **Word Overlap Rate Feature** F_{WOR}:

$$F_{WOR}(s_1, s_2) = \frac{c_w(s_1 \cap s_2)}{max\{c_w(s_1), c_w(s_2)\}} \quad (3)$$

where "$s_1 \cap s_2$" is the intersection of s_1 and s_2.

• **Character Overlap Rate Feature** F_{COR}. Chinese words are composed of characters. It is quite often that words with similar characters share similar meanings, such as "爽快 (comfortable)" and "痛快 (comfortable)", "出售 (sell)" and "销售 (sell)". Here we use F_{COR} to measure the similarity between s_1 and s_2 at the character level. Detailedly, we segment s_1 and s_2 into sets of characters and compute the overlap rate based on Equation (3)[3].

• **Cosine Similarity Feature** F_{CS}. In F_{CS}, both s_1 and s_2 are represented as vectors and their cosine similarity is computed as:

$$F_{CS}(s_1, s_2) = \frac{vec_w(s_1) \cdot vec_w(s_2)}{\|vec_w(s_1)\| \times \|vec_w(s_2)\|} \quad (4)$$

where $vec_w(s)$ is the vector of words in s, "$\cdot$" denotes the dot product of two vectors, $\|vec_w(s)\|$ is the norm of a vector. Here, the weight of each word w in a vector is computed using a heuristic similar to tf-idf:

$$W(w) = tf(w) \times log(\frac{N}{c(w)} + 0.1) \quad (5)$$

where $tf(w)$ is the frequency of w in the given s, $c(w)$ is the number of times that w occurs in the corpus, $N = \max_w c(w)$.

• **Edit Distance Feature** F_{ED}. Let $ED(s_1, s_2)$ be the edit distance at the word level between s_1 and s_2, we compute F_{ED} as follows:

$$F_{ED}(s_1, s_2) = 1 - \frac{ED(s_1, s_2)}{max\{c_w(s_1), c_w(s_2)\}} \quad (6)$$

[2] The similarity is computed based on word overlap rate, which will be described in detail in section 3.3. We set $T = 0.6$ in the experiments.

[3] In F_{COR}, $c_w(s)$ of Equation (3) denotes the number of characters in s.

• **Named Entity (NE) Similarity Feature** F_{NE}. NE information is critical in paraphrase identification (Shinyama et al., 2002). We therefore compute the NE similarity between s_1 and s_2 and take it as a feature. We employ a Chinese NE recognition tool that can recognize *person names*, *locations*, *organizations*, and *numerals*. The NE similarity is computed as:

$$F_{NE}(s_1, s_2) = \frac{c_{ne}(s_1 \cap s_2) + 1}{max\{c_{ne}(s_1), c_{ne}(s_2)\} + 1} \quad (7)$$

where $c_{ne}(s)$ denotes the number of NEs in s. Equation (7) guarantees $F_{NE} = 1$ if there are no NEs in either s_1 or s_2.

• **Pivot Fertility Feature** F_{PF}**:** F_{PF} is a feature specially designed for paraphrase Q-Q and T-T extraction, which are based on the pivot approach[4]. Specifically, we define *fertility* of a pivot as the number of targets it corresponds to. Our observation indicates that the larger the fertility of a pivot is, the more noisy the targets are. Hence we define F_{PF} as:

$$F_{PF}(s_1, s_2) = \max_p \frac{1}{f(p)} \quad (8)$$

where $s_1 = q_1$, $s_2 = q_2$, $p = t$ when classifying Q-Q, while $s_1 = t_1$, $s_2 = t_2$, $p = q$ when classifying T-T. $f(p)$ denotes the fertility of the pivot p. The value is maximized over p if s_1 and s_2 can be extracted with multiple pivots.

3.4 Generating Paraphrase Patterns

A key feature of our method is that the extracted paraphrases are particularly suitable for generating paraphrase patterns, especially for the hot domains that are frequently searched. For example, there are quite a few paraphrases concerning the therapy of various diseases, from which we can easily induce patterns expressing the meaning of "How to treat [X] disease", such as "[X] 病 如何 治疗", "怎么 治疗 [X] 病", and "[X] 病 的 治疗 方法". Therefore, in this work, we try to generate paraphrase patterns using the extracted paraphrases.

In our preliminary experiments, we only induce paraphrase patterns from paraphrases that contain no more than 6 words. In addition, only one slot is allowed in each pair of paraphrase patterns. Let s_1 and s_2 be a pair of paraphrases extracted above. If there exist words $w \in s_1$ and $v \in s_2$ that satisfy (1) $w = v$, (2) w and v are not stop words, then we can induce a pair of paraphrase patterns by replacing w in s_1 and v in s_2 with a slot "[X]". It is obvious that several pairs of paraphrase patterns may be induced from one pair of paraphrases.

	SAME	**RELA**	**DIFF**
percent (%)	55.92	44.08	-

Table 3: Human labeling of candidate Q-T.

4 Experiments

We experiment with a query log that contains a total of 284,316,659 queries. Statistics reveal that 170,315,807 queries (59.90%) lead to at least one user click, each having 1.69 clicks on average. We extract 287,129,850 raw Q-T pairs using the query log, from which 4,448,347 pairs of candidate Q-T are left after filtering as described in Section 3.2. Almost all queries and titles are written in Chinese, though some of them contain English or Japanese words. The preprocessing of candidate Q-T includes Chinese word segmentation (WSeg) and NE recognition (NER). Our WSeg tool is implemented based on forward maximum matching, while the NER tool is based on a NE dictionary mined from the web.

4.1 Evaluation of Candidate Q-T

We first evaluate candidate Q-T without validation. To this end, we randomly sampled 5000 pairs of candidate Q-T and labeled them manually. Each pair is labeled into one of the 3 classes: SAME - q and t have the same meaning; RELA - q and t have related meanings; DIFF - q and t have clearly different meanings. The labeling results are listed in Table 3. We can see that no candidate Q-T is in the DIFF class. This is not surprising, since users are unlikely to click on web pages unrelated to their queries.

To gain a better insight into the data, we analyzed the subtle types of candidate Q-T in both SAME and RELA classes. In detail, we sampled

[4] F_{PF} is not used in paraphrase Q-T validation.

1000 pairs of candidate Q-T from the 5000 pairs labeled above, in which 563 are in the SAME class, while the other 437 are in the RELA class. Our analysis suggests that candidate Q-T in the SAME class can be divided into 4 subtle types:

- Trivial change (12.61%): changes of punctuation or stop words, such as “考研 失败 怎么 办” and “考研 失败 怎么 办？”.
- Word or phrase replacement (68.38%): replacements of synonymous words or phrases, such as “咖啡 斑 的 治疗 多少 钱 (how mach is ...)” and “咖啡 斑 的 治疗 费用 是 多少 (what is the price of ...)”.
- Structure change (7.10%): changes of both words and word orders, such as “减肥 中 水果 可以 吃 什么 (what fruit can I eat on a diet)” and “吃 什么 水果 可以 瘦身 (what fruit can help loss weight)”.
- Others (11.90%): candidate Q-T that cannot be classified into the 3 types above.

The above analysis reveals that more than two thirds of candidate Q-T in the SAME class are in the “word or phrase replacement” type, while the ones with structure changes are slightly more than 7%. We believe this is mainly because queries and titles are relatively short and their structures are simple. Thus structure rewriting can hardly be conducted. This distribution is in line with that reported in (Zhao et al., 2008).

As for the RELA class, we find that 42.33% of such candidate Q-T share a problem of named entity mismatch, such as “美国 (US) 大型 水利 工程” and “中国 (China) 急需 大型 水利 工程”. This indicates that the NE similarity feature is necessary in paraphrase validation.

4.2 Evaluation of Paraphrase Q-T

The candidate Q-T extracted above are classified with a SVM classifier[5] under its default setting. To evaluate the classifier, we run 5-fold cross validation with the 5000 human annotated data, in which we use 4000 for training and the rest 1000 for testing in each run. The evaluation criteria are precision (P), recall (R), and f-measure (F), which are defined as follows:

$$P = \frac{\|S_a \cap S_m\|}{\|S_a\|} \tag{9}$$

$$R = \frac{\|S_a \cap S_m\|}{\|S_m\|} \tag{10}$$

$$F = \frac{2 \times P \times R}{P + R} \tag{11}$$

where S_a is the set of paraphrases automatically recognized with the classifier, S_m is the set of paraphrases manually annotated. Precision, recall, and f-measure are averaged over 5 runs in the 5-fold cross validation.

Figure 2 (a) shows the classification results (dark bars). For comparison, we also show the precision, recall[6], and f-measure of the candidate Q-T (light bars). As can be seen, the precision is improved from 0.5592 to 0.7444 after classification. F-measure is also evidently enhanced. This result indicates that the classification-based paraphrase validation is effective. We then use all of the 5000 annotated data to train a classifier and classify all the candidate Q-T. Results show that 2,762,291 out of 4,448,347 pairs of candidate Q-T are classified as paraphrases.

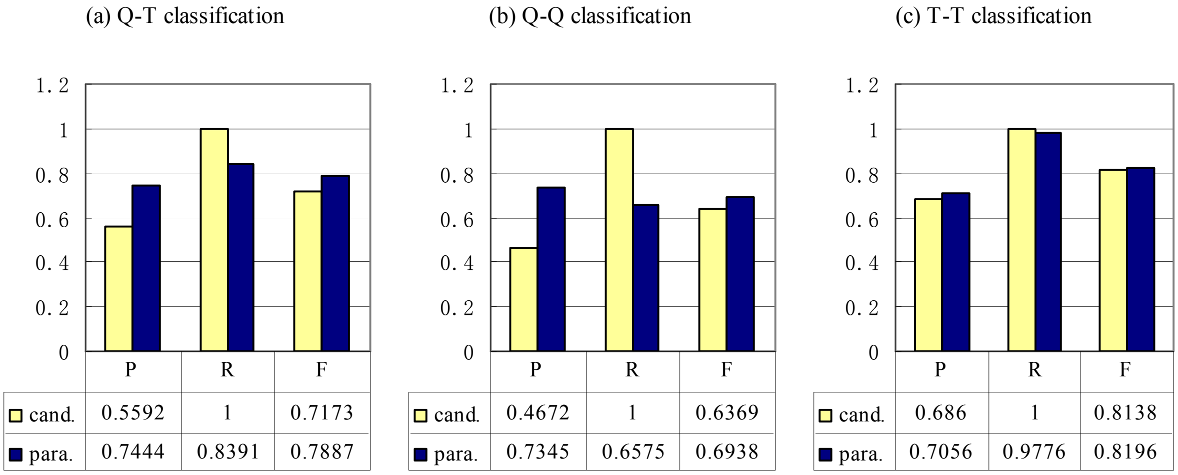
4.3 Evaluation of Paraphrase Q-Q and T-T

From the paraphrase Q-T, we further extracted 934,758 pairs of candidate Q-Q and 438,954 pairs of candidate T-T (without validation). We randomly sampled 5000 from each for human annotation. The results show that the precisions of candidate Q-Q and T-T are 0.4672 and 0.6860, respectively. As can be seen, the precision of candidate Q-Q is much lower than that of candidate T-T. Our analysis reveals that it is mainly because candidate Q-Q are more noisy, since user queries contain quite a lot of spelling mistakes and informal expressions.

The candidate Q-Q and T-T are also refined based on classification. We first evaluate the classification performance using the 5000 human labeled data. The experimental setups for Q-Q and

[5] We use libsvm-2.82 toolkit, which can be downloaded from http://www.csie.ntu.edu.tw/ cjlin/libsvm/

[6] We assume all possible paraphrases are included in the candidates, thus its recall is 100%.



(a)	P	R	F
□ cand.	0.5592	1	0.7173
■ para.	0.7444	0.8391	0.7887

(b)	P	R	F
□ cand.	0.4672	1	0.6369
■ para.	0.7345	0.6575	0.6938

(c)	P	R	F
□ cand.	0.686	1	0.8138
■ para.	0.7056	0.9776	0.8196

Figure 2: Classification precision (P), recall (R), and f-measure (F).

T-T classification are the same as that of Q-T classification, in which we run 5-fold cross validation with a SVM classifier using its default parameters. Figure 2 (b) and (c) give the classification results (dark bars) as well as the precision, recall, and f-measure of the candidates (light bars).

We can see that the precision of Q-Q is significantly enhanced from 0.4672 to 0.7345 after classification, which suggests that a substantial part of errors and noise are removed. The increase of f-measure demonstrates the effectiveness of classification despite the decrease of recall. Meanwhile, the quality of candidate T-T is not clearly improved after classification. The reason should be that the precision of candidate T-T is already pretty high. We then use all 5000 human labeled data to train a classifier for Q-Q and T-T respectively and classify all candidate Q-Q and T-T. Results show that 390,920 pairs of paraphrase Q-Q and 415,539 pairs of paraphrase T-T are extracted after classification.

4.4 Evaluation of Paraphrase Patterns

Using the method introduced in Section 3.4, we have generated 73,484 pairs of paraphrase patterns that appear at least two times in the corpus. We randomly selected 500 pairs and labeled them manually. The results show that the precision is 78.4%. Two examples are shown in Table 4, in which p_1 and p_2 are paraphrase patterns. Some slot fillers are also listed below. We realize that the method currently used for inducing paraphrase patterns is simple. Hence we will improve the method in our following experiments. Specifically, multiple slots will be allowed in a pair of patterns. In addition, we will try to apply the alignment techniques in the generation of paraphrase patterns, as Zhao et al. (2008) did.

p_1	[X] 文件 怎么 打开
p_2	如何 打开 [X] 文件
	(how to open [X] file)
slot	7z; ashx; aspx; bib; cda; cdfs; cmp; cpi; csf; csv; cur; dat; dek...
p_1	关于 [X] 的 诗词
p_2	有关 [X] 的 诗歌
	(poems about [X])
slot	草原 (prairies); 长江 (Yangtze River); 泰山 (Mount Tai); 乡愁 (nostalgia)...

Table 4: Examples of paraphrase patterns.

4.5 Analysis

Feature Contribution. To investigate the contributions of different features used in classification, we tried different feature combinations for each of our three classifiers. The results are shown in Table 5, in which "+" means the feature has contribution to the corresponding classifier. As can be seen, the character overlap rate feature (F_{COR}), cosine similarity feature (F_{CS}), and NE similarity

Feature	Q-T	Q-Q	T-T
F_F	+		
F_{LR}		+	
F_{WOR}			
F_{COR}	+	+	+
F_{CS}	+	+	+
F_{ED}		+	
F_{NE}	+	+	+
F_{PF}		+	

Table 5: Feature contribution.

feature (F_{NE}) are the most useful, which play important roles in all the three classifiers. The other features are useful in some of the classifiers except the word overlap rate feature (F_{WOR}). The classification results reported in prior sections are all achieved with the optimal feature combination.

Analysis of the Paraphrases. We combine the extracted paraphrase Q-T, Q-Q and T-T and get a total of 3,560,257 pairs of unique paraphrases. Statistics show that only 8380 pairs (0.24%) are from more than one source, which indicates that the intersection among the three sets is very small. Further statistics show that the average length of the queries and titles in the paraphrases is 6.69 (words).

To have a detailed analysis of the extracted paraphrases, we randomly selected 1000 pairs and manually labeled the precision, types, and domains. It is found that more than 43% of the paraphrases are paraphrase questions, in which *how* (36%), *what* (19%), and *yes/no* (14%) questions are the most common. In addition, we find that the precision of paraphrase questions (84.26%) is evidently higher than non-question paraphrases (65.14%). Those paraphrase questions are useful in question analysis and expansion in QA, which can hardly be extracted from other kinds of corpora.

As expected, the paraphrases we extract cover a variety of domains. However, around 50% of them are in the 7 most popular domains[7], including: (1) health and medicine, (2) documentary download, (3) entertainment, (4) software, (5) education and study, (6) computer game, (7) economy and finance. This analysis reflects what web users are most concerned about. These domains, especially (4) and (6), are not well covered by the parallel and comparable corpora previously used for paraphrase extraction.

5 Conclusions and Future Directions

In this paper, we put forward a novel method that extracts paraphrases from search engine query logs. Our contribution is that we, for the first time, propose to extract paraphrases from user queries and the corresponding clicked document titles. Specifically, three kinds of paraphrases are extracted, which can be (1) a query and a hit title, (2) two queries that hit the same title, and (3) two titles hit by the same query. The extracted paraphrases are refined based on classification. Using the proposed method, we extracted over 3.5 million pairs of paraphrases from a query log of Baidu. Human evaluation results show that the precision of the paraphrases is above 70%. The results also show that we can generate high-quality paraphrase patterns from the extracted paraphrases.

Our future research will be conducted along the following directions. Firstly, we will use a much larger query log for paraphrase extraction, so as to enhance the coverage of paraphrases. Secondly, we plan to have a deeper study of the transitivity of paraphrasing. Simply speaking, we want to find out whether we can extract $\langle s_1, s_3 \rangle$ as paraphrases given that $\langle s_1, s_2 \rangle$ and $\langle s_2, s_3 \rangle$ are paraphrases.

Abstract

This paper proposes a method that leverages multiple machine translation (MT) engines for paraphrase generation (PG). The method includes two stages. Firstly, we use a multi-pivot approach to acquire a set of candidate paraphrases for a source sentence S. Then, we employ two kinds of techniques, namely the selection-based technique and the decoding-based technique, to produce a best paraphrase T for S using the candidates acquired in the first stage. Experimental results show that: (1) The multi-pivot approach is effective for obtaining plenty of valuable candidate paraphrases. (2) Both the selection-based and decoding-based techniques can make good use of the candidates and produce high-quality paraphrases. Moreover, these two techniques are complementary. (3) The proposed method outperforms a state-of-the-art paraphrase generation approach.

1 Introduction

This paper addresses the problem of paraphrase generation (PG), which seeks to generate paraphrases for sentences. PG is important in many natural language processing (NLP) applications. For example, in machine translation (MT), a sentence can be paraphrased so as to make it more translatable (Zhang and Yamamoto, 2002; Callison-Burch et al., 2006). In question answering (QA), a question can be paraphrased to improve the coverage of answer extraction (Duboue and Chu-Carroll, 2006; Riezler et al., 2007). In natural language generation (NLG), paraphrasing can help to increase the expressive power of the NLG systems (Iordanskaja et al., 1991).

In this paper, we propose a novel PG method. For an English sentence S, the method first acquires a set of candidate paraphrases with a multi-pivot approach, which uses MT engines to automatically translate S into multiple pivot languages and then translate them back into English. Furthermore, the method employs two kinds of techniques to produce a best paraphrase T for S using the candidates, i.e., the selection-based and decoding-based techniques. The former selects a best paraphrase from the candidates based on Minimum Bayes Risk (MBR), while the latter trains a MT model using the candidates and generates paraphrases with a MT decoder.

We evaluate our method on a set of 1182 English sentences. The results show that: (1) although the candidate paraphrases acquired by MT engines are noisy, they provide good raw materials for further paraphrase generation; (2) the selection-based technique is effective, which results in the best performance; (3) the decoding-based technique is promising, which can generate paraphrases that are different from the candidates; (4) both the selection-based and decoding-based techniques outperform a state-of-the-art approach SPG (Zhao et al., 2009).

2 Related Work

2.1 Methods for Paraphrase Generation

MT-based method is the mainstream method on PG. It regards PG as a monolingual machine translation problem, i.e., "translating" a sentence S into another sentence T in the same language.

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 1326–1334,
Beijing, August 2010

Quirk et al. (2004) first presented the MT-based method. They trained a statistical MT (SMT) model on a monolingual parallel corpus extracted from comparable news articles and applied the model to generate paraphrases. Their work shows that SMT techniques can be extended to PG. However, its usefulness is limited by the scarcity of monolingual parallel data.

To overcome the data sparseness problem, Zhao et al. (2008a) improved the MT-based PG method by training the paraphrase model using multiple resources, including monolingual parallel corpora, monolingual comparable corpora, bilingual parallel corpora, etc. Their results show that bilingual parallel corpora are the most useful among the exploited resources. Zhao et al. (2009) further improved the method by introducing a *usability sub-model* into the paraphrase model so as to generate varied paraphrases for different applications.

The main disadvantage of the MT-based method is that its performance heavily depends on the fine-grained paraphrases, such as paraphrase phrases and patterns, which provide paraphrase options in decoding. Hence one has to first extract fine-grained paraphrases from various corpora with different methods (Zhao et al., 2008a; Zhao et al., 2009), which is difficult and time-consuming.

In addition to the MT-based method, researchers have also investigated other methods for paraphrase generation, such as the pattern-based methods (Barzilay and Lee, 2003; Pang et al., 2003), thesaurus-based methods (Bolshakov and Gelbukh, 2004; Kauchak and Barzilay, 2006), and NLG-based methods (Kozlowski et al., 2003; Power and Scott, 2005).

2.2 Pivot Approach for Paraphrasing

Bannard and Callison-Burch (2005) introduced the pivot approach to extracting paraphrase phrases from bilingual parallel corpora. Their basic assumption is that two English phrases aligned with the same phrase in a foreign language (also called a pivot language) are potential paraphrases. Zhao et al. (2008b) extended the approach and used it to extract paraphrase patterns. Both of the above works have proved the effectiveness of the pivot approach in paraphrase extraction.

Pivot approach can also be used in paraphrase generation. It generates paraphrases by translating sentences from a source language to one (single-pivot) or more (multi-pivot) pivot languages and then translating them back to the source language. Duboue et al. (2006) first proposed the multi-pivot approach for paraphrase generation, which was specially designed for question expansion in QA. In addition, Max (2009) presented a single-pivot approach for generating sub-sentential paraphrases. A clear difference between our method and the above works is that we propose selection-based and decoding-based techniques to generate high-quality paraphrases using the candidates yielded from the pivot approach.

3 Multi-pivot Approach for Acquiring Candidate Paraphrases

A single-pivot PG approach paraphrases a sentence S by translating it into a pivot language PL with a MT engine MT_1 and then translating it back into the source language with MT_2. In this paper, a single-pivot PG system is represented as a triple (MT_1, PL, MT_2). A multi-pivot PG system is made up of a set of single-pivot systems with various pivot languages and MT engines. Given m pivot languages and n MT engines, we can build a multi-pivot PG system consisting of N ($N \leq n * m * n$) single-pivot ones, where $N = n * m * n$ iff all the n MT engines can perform bidirectional translation between the source and each pivot language.

In this work, we experiment with 6 pivot languages (Table 1) and 3 MT engines (Table 2) in the multi-pivot approach. All the 3 MT engines are off-the-shelf systems, in which Google and Microsoft translators are SMT engines, while Systran translator is a rule-based MT engine. Each MT engine can translate English to all the 6 pivot languages and back to English. We thereby construct a multi-pivot PG system consisting of 54 (3*6*3) single-pivot systems.

The advantages of the multi-pivot PG approach lie in two aspects. First, it effectively makes use of the vast bilingual data and translation rules underlying the MT engines. Second, the approach is simple, which just sends sentences to the online MT engines and gets the translations back.

4 Producing High-quality Paraphrases using the Candidates

Table 3 shows some examples of candidate paraphrases for a sentence. As can be seen, the candidates do provide some correct and useful paraphrase substitutes (in bold) for the source sentence. However, they also contain quite a few errors (in italic) due to the limited translation quality of the MT engines. The problem is even worse when the source sentences get longer and more complicated. Therefore, we need to combine the outputs of the multiple single-pivot PG systems and produce high-quality paraphrases out of them. To this end, we investigate two techniques, namely, the selection-based and decoding-based techniques.

4.1 Selection-based Technique

Given a source sentence S along with a set D of candidate paraphrases $\{T_1, T_2, ..., T_i, ...T_N\}$, the goal of the selection-based technique is to select the best paraphrase $\hat{T_i}$ for S from D. The paraphrase selection technique we propose is based on Minimum Bayes Risk (MBR). In detail, the MBR based technique first measures the quality of each candidate paraphrase $T_i \in D$ in terms of Bayes risk (BR), and then selects the one with the minimum BR as the best paraphrase. In detail, given S, a candidate $T_i \in D$, a reference paraphrase T[1], and a loss function $L(T, T_i)$ that measures the quality of T_i relative to T, we define the Bayes risk as follows:

$$BR(T_i) = E_{P(T,S)}[L(T, T_i)], \qquad (1)$$

where the expectation is taken under the true distribution $P(T, S)$ of the paraphrases. According to (Bickel and Doksum, 1977), the candidate paraphrase that minimizes the Bayes risk can be found as follows:

$$\hat{T_i} = \arg\min_{T_i \in D} \sum_{T \in \mathcal{T}} L(T, T_i) P(T|S), \qquad (2)$$

where $\mathcal{T}$ represents the space of reference paraphrases. In practice, however, the collection of reference paraphrases is not available. We thus construct a set $D' = D \bigcup \{S\}$ to approximate $\mathcal{T}$[2]. In addition, we cannot estimate $P(T|S)$ in Equation (2), either. Therefore, we make a simplification by assigning a constant c to $P(T|S)$ for each $T \in D'$, which can then be removed:

$$\hat{T_i} = \arg\min_{T_i \in D} \sum_{T \in D'} L(T, T_i). \qquad (3)$$

Equation (3) can be further rewritten using a gain function $G(T, T_i)$ instead of the loss function:

[1] Here we assume that we have the collection of all possible paraphrases of S, which are used as references.

[2] The source sentence S is included in D' based on the consideration that a sentence is allowed to keep unchanged during paraphrasing.

$$\hat{T}_i = \arg\max_{T_i \in D} \sum_{T \in D'} G(T, T_i). \qquad (4)$$

We define the gain function based on BLEU: $G(T, T_i) = BLEU(T, T_i)$. BLEU is a widely used metric in the automatic evaluation of MT (Papineni et al., 2002). It measures the similarity of two sentences by counting the overlapping n-grams (n=1,2,3,4 in our experiments):

$$BLEU(T, T_i) = BP \cdot \exp(\sum_{n=1}^{4} w_n \log p_n(T, T_i)),$$

where $p_n(T, T_i)$ is the n-gram precision of T_i and $w_n = 1/4$. BP (≤ 1) is a brevity penalty that penalizes T_i if it is shorter than T.

In summary, for each sentence S, the MBR based technique selects a paraphrase that is the most similar to all candidates and the source sentence. The underlying assumption is that correct paraphrase substitutes should be common among the candidates, while errors committed by the single-pivot PG systems should be all different. We denote this approach as **S-1** hereafter.

Approaches for comparison. In the experiments, we also design another two paraphrase selection approaches S-2 and S-3 for comparison with S-1.

S-2: S-2 selects the best single-pivot PG system from all the 54 ones. The selection is also based on MBR and BLEU. For each single-pivot PG system, we sum up its gain function values over a set of source sentences (i.e., $\sum_S \sum_{T_S \in D'_S} G(T_S, T_{Si})$). Then we select the one with the maximum gain value as the best single-pivot system. In our experiments, the selected best single-pivot PG system is (ST, P, GG), the candidate paraphrases acquired by which are then returned as the best paraphrases in S-2.

S-3: S-3 is a simple baseline, which just randomly selects a paraphrase from the 54 candidates for each source sentence S.

4.2 Decoding-based Technique

The selection-based technique introduced above has an inherent limitation that it can only select a paraphrase from the candidates. That is to say, it can never produce a perfect paraphrase if all the candidates have some tiny flaws. To solve this problem, we propose the decoding-based technique, which trains a MT model using the candidate paraphrases of each source sentence S and generates a new paraphrase T for S with a MT decoder.

major cuts	high-level civil servants
significant cuts	senior officials
major cuts*	high-level officials
important cuts	senior civil servants
big cuts	
great cuts	

Table 4: Extracted phrase pairs. (*This is called a *self-paraphrase* of the source phrase, which is generated when a phrase keeps unchanged in some of the candidate paraphrases.)

In this work, we implement the decoding-based technique using Giza++ (Och and Ney, 2000) and Moses (Hoang and Koehn, 2008), both of which are commonly used SMT tools. For a sentence S, we first construct a set of parallel sentences by pairing S with each of its candidate paraphrases: $\{(S,T_1),(S,T_2),...,(S,T_N)\}$ ($N = 54$). We then run word alignment on the set using Giza++ and extract aligned phrase pairs as described in (Koehn, 2004). Here we only keep the phrase pairs that are aligned $\geq$3 times on the set, so as to filter errors brought by the noisy sentence pairs. The extracted phrase pairs are stored in a phrase table. Table 4 shows some extracted phrase pairs.

Note that Giza++ is sensitive to the data size. Hence it is interesting to examine if the alignment can be improved by augmenting the parallel sentence pairs. To this end, we have tried augmenting the parallel set for each sentence S by pairing any two candidate paraphrases. In this manner, C_N^2 sentence pairs are augmented for each S. We conduct word alignment using the $(N + C_N^2)$ sentence pairs and extract aligned phrases from the original N pairs. However, we have not found clear improvement after observing the results. Therefore, we do not adopt the augmentation strategy in our experiments.

Using the extracted phrasal paraphrases, we conduct decoding for the sentence S with Moses, which is based on a log-linear model. The default setting of Moses is used, except that the distortion model for phrase reordering is turned off[3]. The language model in Moses is trained using a 9 GB English corpus. We denote the above approach as **D-1** in what follows.

Approach for comparison. The main advantage of the decoding-based technique is that it allows us to customize the paraphrases for different requirements through tailoring the phrase table or tuning the model parameters. As a case study, this paper shows how to generate paraphrases with varied *paraphrase rates*[4].

D-2: The extracted phrasal paraphrases (including self-paraphrases) are stored in a phrase table, in which each phrase pair has 4 scores measuring their alignment confidence (Koehn et al., 2003). Our basic idea is to control the paraphrase rate by tuning the scores of the self-paraphrases. We thus extend D-1 to D-2, which assigns a weight λ ($\lambda > 0$) to the scores of the self-paraphrase pairs. Obviously, if we set $\lambda < 1$, the self-paraphrases will be penalized and the decoder will prefer to generate a paraphrase with more changes. If we set $\lambda > 1$, the decoder will tend to generate a paraphrase that is more similar to the source sentence. In our experiments, we set $\lambda = 0.1$ in D-2.

5 Experimental Setup

Our test sentences are extracted from the parallel reference translations of a Chinese-to-English MT evaluation[5], in which each Chinese sentence c has 4 English reference translations, namely e_1, e_2, e_3, and e_4. We use e_1 as a test sentence to paraphrase and e_2, e_3, e_4 as human paraphrases of e_1 for comparison with the automatically generated paraphrases. We process the test set by manually filtering ill-formed sentences, such as the ungrammatical or incomplete ones. 1182 out of 1357 test sentences are retained after filtering. Statistics show that about half of the test sentences are from news and the other half are from essays. The average length of the test sentences is 34.12 (words).

Score	Adequacy	Fluency
5	All	Flawless English
4	Most	Good English
3	Much	Non-native English
2	Little	Disfluent English
1	None	Incomprehensible

Table 5: Five point scale for human evaluation.

Manual evaluation is used in this work. A paraphrase T of a sentence S is manually scored based on a five point scale, which measures both the "adequacy" (i.e., how much of the meaning of S is preserved in T) and "fluency" of T (See Table 5). The five point scale used here is similar to that in the human evaluation of MT (Callison-Burch et al., 2007). In MT, adequacy and fluency are evaluated separately. However, we find that there is a high correlation between the two aspects, which makes it difficult to separate them. Thus we combine them in this paper.

We compare our method with a state-of-the-art approach SPG[6] (Zhao et al., 2009), which is a statistical approach specially designed for PG. The approach first collects a large volume of fine-grained paraphrase resources, including paraphrase phrases, patterns, and collocations, from various corpora using different methods. Then it generates paraphrases using these resources with a statistical model[7].

6 Experimental Results

We evaluate six approaches, i.e., S-1, S-2, S-3, D-1, D-2 and SPG, in the experiments. Each approach generates a 1-best paraphrase for a test sentence S. We randomize the order of the 6 paraphrases of each S to avoid bias of the raters.

[3] We conduct monotone decoding as previous work (Quirk et al., 2004; Zhao et al., 2008a, Zhao et al., 2009).

[4] The paraphrase rate reflects how different a paraphrase is from the source sentence.

[6] SPG: Statistical Paraphrase Generation.

[7] We ran SPG under the setting of baseline-2 as described in (Zhao et al., 2009).

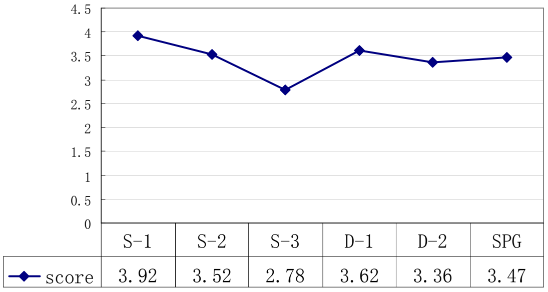

Figure 1: Evaluation results of the approaches.

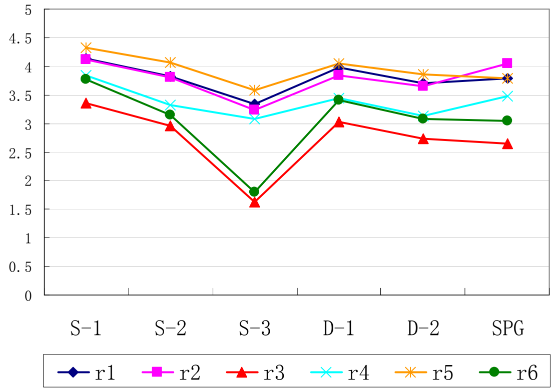

Figure 2: Evaluation results from each rater.

6.1 Human Evaluation Results

We have 6 raters in the evaluation, all of whom are postgraduate students. In particular, 3 raters major in English, while the other 3 major in computer science. Each rater scores the paraphrases of 1/6 test sentences, whose results are then combined to form the final scoring result. The average scores of the six approaches are shown in Figure 1. We can find that among the selection-based approaches, the performance of S-3 is the worst, which indicates that randomly selecting a paraphrase from the candidates works badly. S-2 performs much better than S-3, suggesting that the quality of the paraphrases acquired with the best single-pivot PG system are much higher than the randomly selected ones. S-1 performs the best in all the six approaches, which demonstrates the effectiveness of the MBR-based selection technique. Additionally, the fact that S-1 evidently outperforms S-2 suggests that it is necessary to extend a single-pivot approach to a multi-pivot one.

To get a deeper insight of S-1, we randomly sample 100 test sentences and manually score all of their candidates. We find that S-1 successfully picks out a paraphrase with the highest score for 72 test sentences. We further analyze the remaining 28 sentences for which S-1 fails and find that the failures are mainly due to the BLEU-based gain function. For example, S-1 sometimes selects paraphrases that have correct phrases but incorrect phrase orders, since BLEU is weak in evaluating phrase orders and sentence structures. In the next step we shall improve the gain function by investigating other features besides BLEU.

In the decoding-based approaches, D-1 ranks the second in the six approaches only behind S-1. We will further improve D-1 in the future rather than simply use Moses in decoding with the default setting. However, the value of D-1 lies in that it enables us to break down the candidates and generate new paraphrases flexibly. The performance decreases when we extend D-1 to D-2 to achieve a larger paraphrase rate. This is mainly because more errors are brought in when more parts of a sentence are paraphrased.

We can also find from Figure 1 that S-1, S-2, and D-1 all get higher scores than SPG, which shows that our method outperforms this state-of-the-art approach. This is more important if we consider that our method is lightweight, which makes no effort to collect fine-grained paraphrase resources beforehand. After observing the results, we believe that the outperformance of our method can be mainly ascribed to the selection-based and decoding-based techniques, since we avoid many errors by voting among the candidates. For instance, an ambiguous phrase may be incorrectly paraphrased by some of the single-pivot PG systems or the SPG approach. However, our method may obtain the correct paraphrase through statistics over all candidates and selecting the most credible one.

The human evaluation of paraphrases is subjective. Hence it is necessary to examine the coherence among the raters. The scoring results from the six raters are depicted in Figure 2. As it can be seen, they show similar trends though the raters have different degrees of strictness.

	S-1	S-2	S-3	D-1	D-2	SPG	HP1	HP2	HP3
🟨 PR1	0.116	0.138	0.232	0.149	0.206	0.139	0.366	0.379	0.386
🟦 PR2	0.211	0.272	0.427	0.22	0.3	0.234	0.607	0.602	0.694

Figure 3: Paraphrase rates of the approaches.

6.2 Paraphrase Rate

Human evaluation assesses the quality of paraphrases. However, the paraphrase rates cannot be reflected. A paraphrase that is totally transformed from the source sentence and another that is almost unchanged may get the same score. Therefore, we propose two strategies, i.e., PR1 and PR2, to compute the paraphrase rate:

$$PR1(T) = 1 - \frac{OL(S,T)}{L(S)}; \;\; PR2(T) = \frac{ED(S,T)}{L(S)}.$$

Here, PR1 is defined based on word overlapping rate, in which $OL(S,T)$ denotes the number of overlapping words between a paraphrase T and its source sentence S, $L(S)$ denotes the number of words in S. PR2 is defined based on edit distance, in which $ED(S,T)$ denotes the edit distance between T and S. Obviously, PR1 only measures the percentage of words that are changed from S to T, whereas PR2 further takes word order changes into consideration. It should be noted that PR1 and PR2 not only count the correct changes between S and T, but also count the incorrect ones. We compute the paraphrase rate for each of the six approaches by averaging the paraphrase rates over the whole test set. The results are shown in the left part of Figure 3.

On the whole, the paraphrase rates of the approaches are not high. In particular, we can see that the paraphrase rate of D-2 is clearly higher than D-1, which is in line with our intention of designing D-2. We can also see that the paraphrase rate of S-3 is the highest among the approaches. We find it is mainly because the paraphrases generated with S-3 contain quite a lot of errors, which contribute most of the changes.

7 Analysis

7.1 Effectiveness of the Proposed Method

Our analysis starts from the candidate paraphrases acquired with the multi-pivot approach. Actually, the results of S-3 reflect the average quality of the candidate paraphrases. A score of 2.78 (See Figure 1) indicates that the candidates are unacceptable according to the human evaluation metrics. This is in line with our expectation that the automatically acquired paraphrases through a two-way translation are noisy. However, the results of S-1 and D-1 demonstrate that, using the selection-based and decoding-based techniques, we can produce paraphrases of good quality. Especially, S-1 gets a score of nearly 4, which suggests that the paraphrases are pretty good according to our metrics. Moreover, our method outperforms SPG built on pre-extracted fine-grained paraphrases. It shows that our method makes good use of the paraphrase knowledge from the large volume of bilingual data underlying the multiple MT engines.

7.2 How to Choose Pivot Languages and MT Engines in the Multi-pivot Approach

In our experiments, besides the six pivot languages used in the multi-pivot system, we have also tried another five pivot languages, including Arabic, Japanese, Korean, Russian, and Dutch. They are finally abandoned since we find that they perform badly. Our experience on choosing pivot languages is that: (1) a pivot language should be a language whose translation quality can be well guaranteed by the MT engines; (2) it is better to choose a pivot language similar to the source language (e.g., French - English), which is easier to translate; (3) the translation quality of a pivot language should not vary a lot among the MT engines. On the other hand, it is better to choose MT engines built on diverse models and corpora, which can provide different paraphrase options. We plan to employ a syntax-based MT engine in our further experiments besides the currently used phrase-based SMT and rule-based MT engines.

Table 6: Comparing the automatically generated paraphrases with the human paraphrases.

7.3 Comparing the Selection-based and Decoding-based Techniques

It is necessary to compare the paraphrases generated via the selection-based and decoding-based techniques. As stated above, the selection-based technique can only select a paraphrase from the candidates, while the decoding-based technique can generate a paraphrase different from all candidates. In our experiments, we find that for about 90% test sentences, the paraphrases generated by the decoding-based approach D-1 are outside the candidates. In particular, we compare the paraphrases generated by S-1 and D-1 and find that, for about 40% test sentences, S-1 gets higher scores than D-1, while for another 21% test sentences, D-1 gets higher scores than S-1[8]. This indicates that the selection-based and decoding-based techniques are complementary. In addition, we find examples in which the decoding-based technique can generate a perfect paraphrase for the source sentence, even if all the candidate paraphrases have obvious errors. This also shows that the decoding-based technique is promising.

7.4 Comparing Automatically Generated Paraphrases with Human Paraphrases

We also analyze the characteristics of the generated paraphrases and compare them with the human paraphrases (i.e., the other 3 reference translations in the MT evaluation, see Section 5, which are denoted as HP1, HP2, and HP3). We find that, compared with the automatically generated paraphrases, the human paraphrases are more complicated, which involve not only phrase replacements, but also structure reformulations and even inferences. Their paraphrase rates are also much higher, which can be seen in the right part of Figure 3. We show the automatic and human paraphrases for the example sentence of this paper in Table 6. To narrow the gap between the automatic and human paraphrases, it is necessary to learn structural paraphrase knowledge from the candidates in the future work.

8 Conclusions and Future Work

We put forward an effective method for paraphrase generation, which has the following contributions. First, it acquires a rich fund of paraphrase knowledge through the use of multiple MT engines and pivot languages. Second, it presents a MBR-based technique that effectively selects high-quality paraphrases from the noisy candidates. Third, it proposes a decoding-based technique, which can generate paraphrases that are different from the candidates. Experimental results show that the proposed method outperforms a state-of-the-art approach SPG.

In the future work, we plan to improve the selection-based and decoding-based techniques. We will try some standard system combination strategies, like confusion networks and consensus decoding. In addition, we will refine our evaluation metrics. In the current experiments, paraphrase correctness (adequacy and fluency) and paraphrase rate are evaluated separately, which seem to be incompatible. We plan to combine them together and propose a uniform metric.

[8] For the rest 39%, S-1 and D-1 get identical scores.

Abstract

Ambiguity of entity mentions and concept references is a challenge to mining text beyond surface-level keywords. We describe an effective method of disambiguating surface forms and resolving them to Wikipedia entities and concepts. Our method employs an extensive set of features mined from Wikipedia and other large data sources, and combines the features using a machine learning approach with automatically generated training data. Based on a manually labeled evaluation set containing over 1000 news articles, our resolution model has 85% precision and 87.8% recall. The performance is significantly better than three baselines based on traditional context similarities or sense commonness measurements. Our method can be applied to other languages and scales well to new entities and concepts.

1 Introduction

Ambiguity in natural language is prevalent and, as such, it can be a difficult challenge for information retrieval systems and other text mining applications. For example, a search for "*Ford*" in Yahoo! News retrieves about 40 thousand articles containing *Ford* referring to a company (Ford Motors), an athlete (Tommy Ford), a place (Ford City), etc. Due to reference ambiguity, even if we knew the user was only interested in the company, they would still have to contend with articles referring to the other concepts as well.

In this paper we focus on the problem of resolving references of named-entities and concepts in natural language through their textual *surface forms*. Specifically, we present a method of resolving surface forms in general text documents to Wikipedia entries. The tasks of resolution and disambiguation are nearly identical; we make the distinction that resolution specifically applies when a known set of referent concepts are given a priori. Our approach differs from others in multiple aspects including the following.

1) We employ a rich set of disambiguation features leveraging mining results from large-scale data sources. We calculate context-sensitive features by extensively mining the categories, links and contents of the entire Wikipedia corpus. Additionally we make use of context-independent data mined from various data sources including Web user-behavioral data and Wikipedia. Our features also capture the one-to-one relationship between a surface form and its referent.

2) We use machine learning methods to train resolution models with a large automatically labeled training set. Both ranking-based and classification-based resolution approaches are explored.

3) Our method disambiguates both entities and word senses. It scales well to new entities and concepts, and it can be easily applied to other languages.

We propose an extensive set of metrics to evaluate not only overall resolution performance but also out-of-Wikipedia prediction. Our systems for English language are evaluated using real-world test sets and compared with a number of baselines. Evaluation results show that our systems consistently and significantly outperform others across all test sets.

The paper is organized as follows. We first describe related research in Section 2, followed by an introduction of Wikipedia in Section 3. We then introduce our learning method in Section 4 and our features in Section 5. We show our experimental results in Section 6, and finally close with a discussion of future work.

Beijing, August 2010

2 Related Work

Named entity disambiguation research can be divided into two categories: some works (Bagga and Baldwin, 1998; Mann and Yarowsky, 2003; Pedersen et al., 2005; Fleischman and Hovy, 2004; Ravin and Kazi, 1999) aim to cluster ambiguous surface forms to different groups, with each representing a unique entity; others (Cucerzan, 2007; Bunescu and Paşca, 2006; Han and Zhao, 2009; Milne and Witten, 2008a; Milne and Witten, 2008b) resolve a surface form to an entity or concept extracted from existing knowledge bases. Our work falls into the second category.

Looking specifically at resolution, Bunescu and Pasca (2006) built a taxonomy SVM kernel to enrich a surface form's representation with words from Wikipedia articles in the same category. Cucerzan (2007) employed context vectors consisting of phrases and categories extracted from Wikipedia. The system also attempted to disambiguate all surface forms in a context simultaneously, with the constraint that their resolved entities should be globally consistent on the category level as much as possible. Milne and Witten (2008a, 2008b) proposed to use Wikipedia's link structure to capture the *relatedness* between Wikipedia entities so that a surface form is resolved to an entity based on its relatedness to the surface form's surrounding entities. Besides relatedness, they also define a *commonness* feature that captures how common it is that a surface form links to a particular entity in general. Han and Zhao (2009) defined a novel alignment strategy to calculate similarity between surface forms based on semantic relatedness in the context.

Milne and Witten's work is most related to what we propose here in that we also employ features similar to their relatedness and commonness features. However, we add to this a much richer set of features which are extracted from Web-scale data sources beyond Wikipedia, and we develop a machine learning approach to automatically blend our features using completely automatically generated training data.

3 Wikipedia

Wikipedia has more than 200 language editions, and the English edition has more than 3 million articles as of March 2009. Newsworthy events are often added to Wikipedia within days of occurrence; Wikipedia has bi-weekly snapshots available for download.

Each article in Wikipedia is uniquely identified by its title which is usually the most common surface form of an entity or concept. Each article includes body text, outgoing links and categories. Here is a sample sentence in the article titled "Aristotle" in wikitext format. "*Together with Plato and [[Socrates]] (Plato's teacher), Aristotle is one of the most important founding figures in [[Western philosophy]].*" Near the end of the article, there are category links such as "*[[Category:Ancient Greek mathematicians]]*". The double brackets annotate outgoing links to other Wikipedia articles with the specified titles. The category names are created by authors. Articles and category names have many-to-many relationships.

In addition to normal articles, Wikipedia also has special types of articles such as redirect articles and disambiguation articles. A redirect article's title is an alternative surface form for a Wikipedia entry. A disambiguation article lists links to similarly named articles, and usually its title is a commonly used surface form for multiple entities and concepts.

4 Method of Learning

Our goal is to resolve surface forms to entities or concepts described in Wikipedia. To this end, we first need a recognizer to detect surface forms to be resolved. Then we need a resolver to map a surface form to the most probable entry in Wikipedia (or to *out-of-wiki*) based on the context.

Recognizer: We first create a set of Wikipedia (article) entries $E = \{e_1, e_2, ...\}$ to which we want to resolve surface forms. Each entry's surface forms are mined from multiple data sources. Then we use simple string match to recognize surface forms from text documents.

Among all Wikipedia entries, we exclude those with low importance. In our experiments, we removed the entries that would not interest general Web users, such as stop words and punctuations. Second, we collect surface forms for entries in E using Wikipedia and Web search query click logs based on the following assumptions:

- Each Wikipedia article title is a surface form for the entry. Redirect titles are taken as alternative surface forms for the target entry.
- The anchor text of a link from one article to another is taken as an alternative surface form for the linked-to entry.
- Web search engine queries resulting in user clicks on a Wikipedia article are taken as alternative surface forms for the entry.

As a result, we get a number of surface forms for each entry e_i. If we let s_{ij} denote the j-th surface form for entry i, then we can represent our entry dictionary as $EntSfDict = \{<e_1, (s_{11}, s_{12}, ...)>, <e_2, (s_{21}, s_{22}, ...)>, ...\}$.

Resolver: We first build a labeled training set automatically, and then use supervised learning methods to learn models to resolve among Wikipedia entries. In the rest of this section we describe the resolver in details.

4.1 Automatically Labeled Data

To learn accurate models, supervised learning methods require training data with both large quantity and high quality, which often takes lots of human labeling effort. However, in Wikipedia, links provide a *supervised* mapping from surface forms to article entries. We use these links to automatically generate training data. If a link's anchor text is a surface form in *EntSfDict*, we extract the anchor text as surface form *s* and the link's destination article as Wikipedia entry *e*, then add the pair *(s, e)* with a positive judgment to our labeled example set. Continuing, we use *EntSfDict* to find other Wikipedia entries for which *s* is a surface form and create negative examples for these and add them to our labeled example set. If *e* does not exist in *EntSfDict* (for example, if the link points to a Wikipedia article about a stop word), then a negative training example is created for every Wikipedia entry to which *s* may resolve. We use *oow* (out-of-wiki) to denote this case.

Instead of article level coreference resolution, we only match partial names with full names based on the observation that surface forms for named entities are usually capitalized word sequences in English language and a named entity is often mentioned by a long surface form followed by mentions of short forms in the same article. For each pair *(s, e)* in the labeled example set, if *s* is a partial name of a full name *s'* occurring earlier in the same document, we replace *(s, e)* with *(s', e)* in the labeled example set.

Using this methodology we created 2.4 million labeled examples from only 1% of English Wikipedia articles. The abundance of data made it possible for us to experiment on the impact of training set size on model accuracy.

4.2 Learning Algorithms

In our experiments we explored both Gradient Boosted Decision Trees (GBDT) and Gradient Boosted Ranking (GBRank) to learn resolution models. They both can easily combine features of different scale and with missing values. Other supervised learning methods are to be explored in the future.

GBDT: We use the stochastic variant of GBDTs (Friedman, 2001) to learn a binary logistic regression model with the judgments as the target. GBDTs compute a function approximation by performing a numerical optimization in the function space. It is done in multiple stages, with each stage modeling residuals from the model of the last stage using a small decision tree. A brief summary is given in Algorithm 1. In the stochastic version of GBDT, one sub-samples the training data instead of using the entire training set to compute the loss function.

Algorithm 1 GBDTs

```
Input: training data $\{(x_i, y_i)\}_{i=1}^{N}$, loss function
$L[y, f(x)]$, the number of nodes for each tree $J$
, the number of trees $M$.
1:    Initialize $f(x)=f^0$
2:    For $m = 1$ to $M$
2.1:     For $i = 1$ to $N$, compute the negative
         gradient by taking the derivative of the
         loss with respect to $f(x)$ and substitute
         with $y_i$ and $f_i^{m-1}(x_i)$.
2.2:     Fit a $J$-node regression tree to the
         components of the negative gradient.
2.3:     Find the within-node updates $a_j^m$ for $j$
         $= 1$ to $J$ by performing $J$ univariate op-
         timizations of the node contributions to
         the estimated loss.
2.4:     Do the update $f_i^m(x_i) = f_i^{m-1}(x_i) + r \times a_j^m$,
         where $j$ is the node that $x_i$ belongs to, $r$
         is learning rate.
3:    End for
4:    Return $f^M$
```

In our setting, the loss function is a negative binomial log-likelihood, x_i is the feature vector for a surface-form and Wikipedia-entry pair *(s_i, e_i)*, and y_i is +1 for positive judgments and -1 is for negative judgments.

GBRank: From a given surface form's judgments we can infer that the correct Wikipedia entry is preferred over other entries. This allows us to derive pair-wise preference judgments from absolute judgments and train a model to rank all the Wikipedia candidate entries for each surface form. Let $S=\{(x_i,x_i^{'})\,|\,l(x_i)\geq l(x_i^{'}),i=1,...,N\}$ be the set of preference judgments, where x_i and x_i' are the feature vectors for two pairs of surface-forms and Wikipedia-entry, $l(x_i)$ and $l(x_i')$ are their absolute judgments respectively. GBRank (Zheng et al., 2007) tries to learn a function h such that $h(x_i)\geq h(x_i^{'})$ for $(x_i,x_i^{'})\in S$. A sketch of the algorithm is given in Algorithm 2.

Algorithm 2 GBRank

```
1:    Initialize $h=h_0$
2:    For $k=1$ to $K$
2.1:    Use $h_{k-1}$ as an approximation of $h$ and
        compute
        $S^{+}=\{(x_i,x_i^{'})\in S\,|\,h_{k-1}(x_i)\geq h_{k-1}(x_i^{'})+\tau\}$
        $S^{-}=\{(x_i,x_i^{'})\in S\,|\,h_{k-1}(x_i)< h_{k-1}(x_i^{'})+\tau\}$
        where $\tau=\alpha(l(x_i)-l(x_i^{'}))$
2.2:    Fit a regression function $g_k$ using
        GBDT and the incorrectly predicted
        examples
        $\{(x_i,h_{k-1}(x_i^{'})+\tau),(x_i^{'},h_{k-1}(x_i)-\tau)\,|\,(x_i,x_i^{'})\in S^{-}\}$
2.3:    Do the update
        $h_k(x)=(kh_{k-1}(x)+\eta g_k(x))/(k+1)$, where $\eta$ is
        learning rate.
3:    End for
4:    Return $h_K$
```

We use a tuning set independent from the training set to select the optimal parameters for GBDT and GBRank. This includes the number of trees M, the number of nodes J, the learning rate r, and the sampling rate for GBDT; and for GBRank we select K, α and η.

The feature importance measurement given by GBDT and GBRank is computed by keeping track of the reduction in the loss function at each feature variable split and then computing the total reduction of loss along each explanatory feature variable. We use it to analyze feature effectiveness.

4.3 Prediction

After applying a resolution model on the given test data, we obtain a score for each surface-form and Wikipedia-entry pair *(s, e)*. Among all the pairs containing s, we find the pair with the highest score, denoted by *(s, $\tilde{e}$)*.

It's very common that a surface form refers to an entity or concept not defined in Wikipedia. So it's important to correctly predict whether the given surface form cannot be mapped to any Wikipedia entry in *EntSfDict*.

We apply a threshold to the scores from resolution models. If the score for *(s, $\tilde{e}$)* is lower than the threshold, then the prediction is *oow* (see Section 4.1), otherwise $\tilde{e}$ is predicted to be the entry referred by s. We select thresholds based on F1 (see Section 6.2) on a tuning set that is independent from our training set and test set.

5 Features

For each surface-form and Wikipedia-entry pair *(s, e)*, we create a feature vector including features capturing the context surrounding s and features independent of the context. They are context-dependent and context-independent features respectively. Various data sources are mined to extract these features, including Wikipedia articles, Web search query-click logs, and Web-user browsing logs. In addition, *(s, e)* is compared to all pairs containing s based on above features and the derived features are called differentiation features.

5.1 Context-dependent Features

These features measure whether the given surface form s resolving to the given Wikipedia entry e would make the given document more coherent. They are based on 1) the vector representation of e, and 2) the vector representation of the context of s in a document d.

Representation of *e*: By thoroughly mining Wikipedia and other large data sources we extract contextual clues for each Wikipedia entry e and formulate its representation in the following ways.

1) *Background representation*. The overall background description of e is given in the corresponding Wikipedia article, denoted as A_e. Naturally, a bag of terms and surface forms in A_e can represent e. So we represent e by a back-

ground word vector E_{bw} and a background surface form vector E_{bs}, in which each element is the occurrence count of a word or a surface form in A_e's first paragraph.

2) *Co-occurrence representation.* The terms and surface forms frequently co-occurring with *e* capture its contextual characteristics. We first identify all the Wikipedia articles linking to A_e. Then, for each link pointing to A_e we extract the surrounding words and surface forms within a window centered on the anchor text. The window size is set to 10 words in our experiment. Finally, we select the words and surface forms with the top co-occurrence frequency, and represent *e* by a co-occurring word vector E_{cw} and a co-occurring surface form vector E_{cs}, in which each element is the co-occurrence frequency of a selected word or surface form.

3) *Relatedness representation.* We analyzed the relatedness between Wikipedia entries from different data sources using various measurements, and we computed over 20 types of relatedness scores in our experiments. In the following we discuss three types as examples. The first type is computed based on the overlap between two Wikipedia entries' categories. The second type is mined from Wikipedia inter-article links. (In our experiments, two Wikipedia entries are considered to be related if the two articles are mutually linked to each other or co-cited by many Wikipedia articles.) The third type is mined from Web-user browsing data based on the assumption that two Wikipedia articles co-occurring in the same browsing session are related. We used approximately one year of Yahoo! user data in our experiments. A number of different metrics are used to measure the relatedness. For example, we apply the algorithm of Google distance (Milne and Witten, 2008b) on Wikipedia links to calculate the Wikipedia link-based relatedness, and use mutual information for the browsing-session-based relatedness. In summary, we represent *e* by a related entry vector E_r for each type of relatedness, in which each element is the relatedness score between *e* and a related entry.

Representation of *s*: We represent a surface form's context as a vector, then calculate a context-dependent feature for a pair <*s,e*> by a similarity function *Sim* from two vectors. Here are examples of context representation.

1) *s* is represented by a word vector S_w and a surface form vector S_s, in which each element is the occurrence count of a word or a surface form surrounding *s.* We calculate each vector's similarity with the background and co-occurrence representation of *e*, and it results in $Sim(S_w, E_{bw})$, $Sim(S_w, E_{cw})$, $Sim(S_s, E_{bs})$ and $Sim(S_s, E_{cs})$.

2) *s* is represented by a Wikipedia entry vector S_e, in which each element is a Wikipedia entry to which a surrounding surface form *s* could resolve. We calculate its similarity with the relatedness representation of *e*, and it results in $Sim(S_e, E_r)$.

In the above description, similarity is calculated by dot product or in a summation-of-maximum fashion. In our experiments we extracted surrounding words and surface forms for *s* from the whole document or from the text window of 55 tokens centered on *s*, which resulted in 2 sets of features. We created around 50 context-dependent features in total.

5.2 Context-independent Features

These features are extracted from data beyond the document containing s. Here are examples.

- During the process of building the dictionary *EntSfDict* as described in Section 4, we count how often *s* maps to *e* and estimate the probability of *s* mapping to *e* for each data source. These are the commonness features.
- The number of Wikipedia entries that *s* could map to is a feature about the ambiguity of *s*.
- The string similarity between *s* and the title of A_e is used as a feature. In our experiments string similarity was based on word overlap.

5.3 Differentiation Features

Among all surface-form and Wikipedia-entry pairs that contain *s*, at most one pair gets the positive judgment. Based on this observation we created differentiation features to represent how *(s, e)* is compared to other pairs for *s*. They are derived from the context-dependent and context-independent features described above. For example, we compute the difference between the string similarity for *(s, e)* and the maximum string similarity for all pairs containing *s*. The derived feature value would be zero if *(s, e)* has larger string similarity than other pairs containing *s*.

6 Experimental Results

In our experiments we used the Wikipedia snapshot for March 6th, 2009. Our dictionary *EntSfDict* contains 3.5 million Wikipedia entries and 6.5 million surface forms.

A training set was created from randomly selected Wikipedia articles using the process described in Section 4.1. We varied the number of Wikipedia articles from 500 to 40,000, but the performance did not increase much after 5000. The experimental results reported in this paper are based on the training set generated from 5000 articles. It contains around 1.4 million training examples. There are approximately 300,000 surface forms, out of which 28,000 are the *oow* case.

Around 400 features were created in total, and 200 of them were selected by GBDT and GBRank to be used in our resolution models.

6.1 Evaluation Datasets

Three datasets from different data sources are used in evaluation.

1) *Wikipedia hold-out set*. Using the same process for generating training data and excluding the surface forms appearing in the training data, we built the hold-out set from approximately 15,000 Wikipedia articles, containing around 600,000 labeled instances. There are 400,000 surface forms, out of which 46,000 do not resolve to any Wikipedia entry.

2) *MSNBC News test set*. This entity disambiguation data set was introduced by Cucerzan (2007). It contains 200 news articles collected from ten MSNBC news categories as of January 2, 2007. Surface forms were manually identified and mapped to Wikipedia entities. The data set contains 756 surface forms. Only 589 of them are contained in our dictionary *EntSfDict*, mainly because *EntSfDict* excludes surface forms of out-of-Wikipedia entities and concepts. Since the evaluation task is focused on resolution performance rather than recognition, we exclude the missing surface forms from the labeled example set. The final dataset contains 4,151 labeled instances. There are 589 surface forms and 40 of them do not resolve to any Wikipedia entry.

3) *Yahoo! News set*. One limitation of the MSNBC test set is the small size. We built a much larger data set by randomly sampling around 1,000 news articles from Yahoo! News over 2008 and had them manually annotated. The experts first identified *person*, *location* and *organization* names, then mapped each name to a Wikipedia article if the article is about the entity referred to by the name. We didn't include more general concepts in this data set to make the manual effort easier. This data set contains around 100,000 labeled instances. The data set includes 15,387 surface forms and 3,532 of them cannot be resolved to any Wikipedia entity. We randomly split the data set to 2 parts of equal size. One part is used to tune parameters of GBDT and GBRank and select thresholds based on F1 value. The evaluation results presented in this paper is based on the remaining part of the Yahoo! News set.

6.2 Metrics

The possible outcomes from comparing a resolution system's prediction with ground truth can be categorized into the following types.

- True Positive (TP), the predicted *e* was correctly referred to by *s*.
- True Negative (TN), *s* was correctly predicted as resolving to *oow*.
- Mismatch (MM), the predicted *e* was not correctly referred to by *s* and should have been *e'* from *EntSfDict*.
- False Positive (FP), the predicted *e* was not correctly referred to by *s* and should have been *oow*.
- False Negative (FN), the predicted *oow* is not correct and should have been *e'* from *EntSfDict*.

Similar to the widely used metrics for classification systems, we use following metrics to evaluate disambiguation performance.

$$precision = \frac{TP}{TP+FP+MM} \qquad recall = \frac{TP}{TP+FN+MM}$$

$$F1 = \frac{2\times precision \times recall}{precision + recall} \qquad accuracy = \frac{TP+TN}{TP+FP+TN+FN+MM}$$

In the Yahoo! News test set, 23.5% of the surface forms do not resolve to any Wikipedia entries, and in the other two test sets the percentages of *oow* are between 10% and 20%. This demonstrates it is necessary in real-world applications to explicitly measure *oow* prediction. We propose following metrics.

$$precision\_oow = \frac{TN}{TN+FN} \qquad recall\_oow = \frac{TN}{TN+FP}$$

$$F1\_oow = \frac{2\times precision\_oow \times recall\_oow}{precision\_oow + recall\_oow}$$

6.3 Evaluation Results

With our training set we trained one resolution model using GBDT (named as *WikiRes-c*) and another resolution model using GBRank (named as *WikiRes-r*). The models were evaluated along with the following systems.

1) *Baseline-r*: each surface form *s* is randomly mapped to *oow* or a candidate entry for *s* in *EntSfDict*.

2) *Baseline-p*: each surface form *s* is mapped to the candidate entry *e* for *s* with the highest commonness score. The commonness score is linear combination of the probability of *s* being mapped to *e* estimated from different data sources. The commonness score is among the features used in *WikiRes-c* and *WikiRes-r*.

3) *Baseline-m*: we implemented the approach brought by Cucerzan (2007) based on our best understanding. Since we use a different version of Wikipedia and a different entity recognition approach, the evaluation result differs from the result presented in their paper. But we believe our implementation follows the algorithm described in their paper.

In Table 1 we present the performance for each system on the Yahoo! News test set and the MSNBC test set. The performance of *WikiRes-c* and *WikiRes-r* are computed after we apply the thresholds selected on the tuning set described in Section 6.1. In the upper half of Table 1, the three baselines use the thresholds that lead to the best F1 on the Yahoo! News test set. In the lower half of Table 1, the three baselines use the thresholds that lead to the best F1 on the MSNBC test set.

Among the three baselines, *Baseline-r* has the lowest performance. *Baseline-m* uses a few context-sensitive features and *Baseline-p* uses a context-independent feature. These two types of features are both useful, but *Baseline-p* shows better performance, probably because the surface forms in our test sets are dominated by common senses. In our resolution models, these features are combined together with many other features calculated from different large-scale data sources and on different granularity levels. As shown in Table 1, both of our resolution solutions substantially outperform other systems. Furthermore, *WikiRes-c* and *WikiRes-r* have similar performance.

	Precision	**Recall**	**F1**	**Accuracy**	**p-value**
Yahoo! News Test Set					
Baseline-r	47.023	60.831	53.043	47.023	0
Baseline-p	73.869	88.157	80.383	73.175	5.2e-78
Baseline-m	62.240	80.517	70.208	62.240	1.3e-160
WikiRes-r	83.406	**88.858**	86.046	80.717	0.012
WikiRes-c	**85.038**	87.831	**86.412**	**81.463**	---
MSNBC Test Set					
Baseline-r	60.272	64.545	62.335	60.272	8.9e-19
Baseline-p	82.292	86.182	84.192	82.003	0.306
Baseline-m	78.947	84.545	81.651	78.947	0.05
WikiRes-r	**88.785**	**86.364**	**87.558**	**84.550**	0.102
WikiRes-c	88.658	85.273	86.932	83.192	---

Table 1. Performance on the Yahoo! News Test Set and the MSNBC Test set

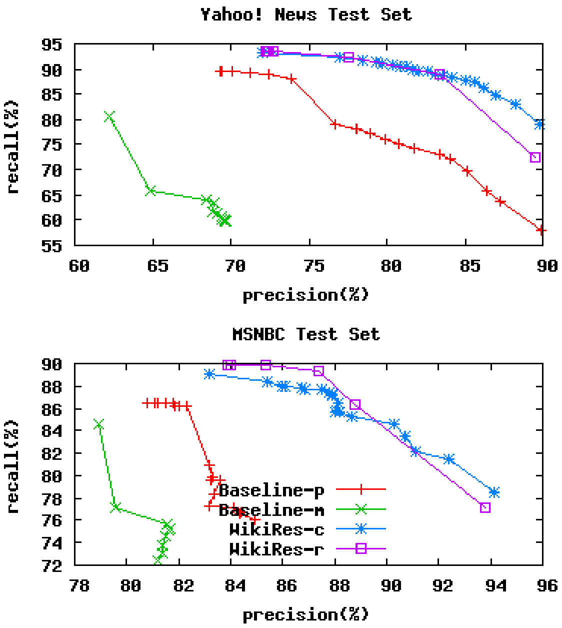

Figure 1. Precision-recall on the Yahoo! News Test Set and the MSNBC Test Set

We compared *WikiRes-c* with each competitor and from the statistical significance test results in the last column of Table 1 we see that on the Yahoo! News test set *WikiRes-c* significantly outperforms others. The p-values for the MSNBC test set are much higher than for the Yahoo! News test set because the MSNBC test set is much smaller.

Attempting to address this point, we see that the F1 values of *WikiRes* on the MSNBC test set and on the Yahoo! News test set only differs by a couple percentage points, although, these test sets were created independently. This suggests the objectivity of our method for creating the Yahoo! News test set and provides a way to measure resolution model performance on what would occur in a general news corpus in a statistically significant manner.

In Figure 1 we present the precision-recall curves on the Yahoo! News and the MSNBC test sets. We see that our resolution models are substantially better than the other two baselines at any particular precision or recall value on both test sets. *Baseline-r* is not included in the comparison since it does not have the tradeoff between precision and recall. We find the precision-recall curve of *WikiRes-r* is very similar to *WikiRes-c* at the lower precision area, but its recall is much lower than other systems after precision reaches around 90%. So, in Figure 1 the curves of *WikiRes-r* are truncated at the high precision area.

In Table 2 we compare the performance of out-of-Wikipedia prediction. The comparison is done on the Yahoo! News test set only, since there are only 40 surface forms of *oow* case in the MSNBC test set. Each system's threshold is the same as that used for the upper half of Table 1. The results show our models have substantially higher precision and recall than *Baseline-p* and *Baseline-m*. From the statistical significance test results in the last column, we can see that *WikiRes-c* significantly outperforms *Baseline-p* and *Baseline-m*. Also, our current approaches still have room to improve in the area of out-of-Wikipedia prediction.

We also evaluated our models on a Wikipedia hold-out set. The model performance is greater than that obtained from the previous two test sets because the hold-out set is more similar to the training data source itself. Again, our models perform better than others.

From the feature importance lists of our GBDT model and GBRank model, we find that the commonness features, the features based on Wikipedia entries' co-occurrence representation and the corresponding differentiation features are the most important.

	Precision	Recall	F1	p-value
Baseline-p	64.907	22.152	33.03	1.6e-20
Baseline-m	47.207	44.78	45.961	1.3e-34
WikiRes-r	**68.166**	52.994	59.630	0.084
WikiRes-c	67.303	**59.777**	**63.317**	---

Table 2. Performance of Out-of-Wikipedia Prediction on the Yahoo! News Test Set

7 Conclusions

We have described a method of learning to resolve surface forms to Wikipedia entries. Using this method we can enrich the unstructured documents with structured knowledge from Wikipedia, the largest knowledge base in existence. The enrichment makes it possible to represent a document as a machine-readable network of senses instead of just a bag of words. This can supply critical semantic information useful for next-generation information retrieval systems and other text mining applications.

Our resolution models use an extensive set of novel features and are leveraged by a machine learned approach that depends only on a purely automated training data generation facility. Our methodology can be applied to any other language that has Wikipedia and Web data available (after modifying the simple capitalization rules in Section 4.1). Our resolution models can be easily and quickly retrained with updated data when Wikipedia and the relevant Web data are changed.

For future work, it will be important to investigate other approaches to better predict *oow*. Adding global constraints on resolutions of the same term at multiple locations in the same document may also be important. Of course, developing new features (such as part-of-speech, named entity type, etc) and improving training data quality is always critical, especially for social content sources such as those from Twitter. Finally, directly demonstrating the degree of applicability to other languages is interesting when accounting for the fact that the quality of Wikipedia is variable across languages.

Heterogeneous Parsing via Collaborative Decoding

Abstract

There often exist multiple corpora for the same natural language processing (NLP) tasks. However, such corpora are generally used independently due to distinctions in annotation standards. For the purpose of full use of readily available human annotations, it is significant to simultaneously utilize multiple corpora of different annotation standards. In this paper, we focus on the challenge of constituent syntactic parsing with treebanks of different annotations and propose a collaborative decoding (or co-decoding) approach to improve parsing accuracy by leveraging bracket structure consensus between multiple parsing decoders trained on individual treebanks. Experimental results show the effectiveness of the proposed approach, which outperforms state-of-the-art baselines, especially on long sentences.

1 Introduction

Recent years have seen extensive applications of machine learning methods to natural language processing problems. Typically, increase in the scale of training data boosts the performance of machine learning methods, which in turn enhances the quality of learning-based NLP systems (Banko and Brill, 2001). However, annotating data by human is expensive in time and labor. For this reason, human-annotated corpora are considered as the most valuable resource for NLP.

In practice, there often exist more than one corpus for the same NLP tasks. For example, for constituent syntactic parsing (Collins, 1999; Charniak, 2000; Petrov et al., 2006) in Chinese, in addition to the most popular treebank Chinese Treebank (CTB) (Xue et al., 2002), there are also other treebanks such as Tsinghua Chinese Treebank (TCT) (Zhou, 1996). For the purpose of full use of readily available human annotations for the same tasks, it is significant if such corpora can be used jointly. At first sight, a direct combination of multiple corpora is a way to this end. However, corpora created for the same NLP tasks are generally built by different organizations. Thus such corpora often follow different annotation standards and/or even different linguistic theories. We take CTB and TCT as a case study. Although both CTB and TCT are Chomskian-style treebanks, they have annotation divergences in at least two dimensions: a) CTB and TCT have dramatically different tag sets, including parts-of-speech and grammar labels, and the tags cannot be mapped one to one; b) CTB and TCT have distinct hierarchical structures. For example, the words "中国 (Chinese) 传统 (traditional) 文化 (culture)" are grouped as a flat noun phrase according to the CTB standard (right side in Fig. 1), but in TCT, the last two words are instead grouped together beforehand (left side in Fig. 1). The differences cause such treebanks of different annotations to be generally used independently. This paper is dedicated to solving the problem of how to use jointly multiple disparate treebanks for constituent syntactic parsing. Hereafter, treebanks of different annotations are

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 1344–1352,
Beijing, August 2010

called *heterogeneous treebanks*, and correspondingly, the problem of syntactic parsing with heterogeneous treebanks is referred to as *heterogeneous parsing*.

Previous work on heterogeneous parsing is often based on treebank transformation (or treebank conversion) (Wang et al., 1994; Niu et al., 2009). The basic idea is to transform annotations of one treebank (source treebank) to fit the standard of another treebank (target treebank). Due to divergences of treebank annotations, such transformation is generally achieved in an indirect way by selecting transformation results from the output of a parser trained on the target treebank. A common property of all the work mentioned above is that transformation accuracy is heavily dependent on the performance of parsers trained on the target treebank. Sometimes transformation accuracy is not so satisfactory that techniques like instance pruning are needed in order to refine transformation results (Niu et al., 2009).

We claim there exists another way, interesting but less studied for heterogeneous parsing. The basic idea is that, although there are annotation divergences between heterogenous treebanks, actually we can also find consensus in annotations of bracket structures. Thus we would like to train parsers on individual heterogeneous treebanks and guide the parsers to gain output with consensus in bracket structures as much as possible when they are parsing the same sentences.

To realize this idea, we propose a generic collaborative decoding (or co-decoding) framework where decoders trained on heterogeneous treebanks can exchange consensus information between each other during the decoding phase. Theoretically the framework is able to incorporate a large number of treebanks and various functions that formalize consensus statistics.

Our contributions can be summarized: 1) we propose a co-decoding approach to directly utilizing heterogeneous treebanks; 2) we propose a novel function to measure parsing consensus between multiple decoders. We also conduct experiments on two Chinese treebanks: CTB and TCT. The results show that our approach achieves promising improvements over baseline systems which make no use of consensus information.

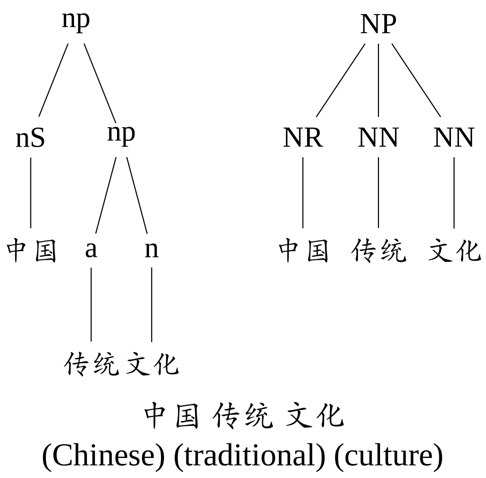

Figure 1: Example tree fragments with TCT (left) and CTB (right) annotations

2 Collaborative Decoding-based Heterogeneous Parsing

2.1 Motivation

This section describes the motivation to use co-decoding for heterogeneous parsing. We first use the example in Fig. 1 to illustrate what consensus information exists between heterogenous treebanks and why such information might help to improve parsing accuracy. This figure contains two partial parse trees corresponding to the words “中国 (Chinese) 传统 (traditional) 文化 (culture)”, annotated according to the TCT (left side) and CTB (right side) standards respectively. Despite the distinctions in tag sets and bracket structures, these parse trees actually have partial agreements in bracket structures. That is, not all bracket structures in the parse trees are different. Specifically put, although the internal structures of the parse trees are different, both CTB and TCT agree to take “中国 传统 文化” as a noun phrase. Motivated by this observation, we would like to guide parsers that are trained on CTB and TCT respectively to verify their output interactively by using consensus information implicitly contained in these treebanks. Better performance is expected when such information is considered.

A feasible framework to make use of consensus information is n-best combination (Henderson and Brill, 1999; Sagae and Lavie, 2006; Zhang et al., 2009; Fossum and Knight, 2009). In contrast to previous work on n-best combination where multiple parsers, say, Collins parser (Collins, 1999) and Berkeley parser (Petrov et al., 2006) are trained on the same training data, n-best combination for heterogeneous parsing is instead allowed to use either a single parser or multiple parsers which are trained on heterogeneous treebanks. Consensus information can be incorporated during the combination of the output (n-best list of full parse trees following distinct annotation standards) of individual parsers. However, despite the success of n-best combination methods, they suffer from the limited scope of n-best list. Taking this into account, we prefer to apply the co-decoding approach such that consensus information is expected to affect the entire procedure of searching hypothesis space.

2.2 System Overview

The idea of co-decoding is recently extensively studied in the literature of SMT (Li et al., 2009; Liu et al., 2009). As the name shows, co-decoding requires multiple decoders be combined and proceed collaboratively. As with n-best combination, there are at least two ways to build multiple decoders: we can either use multiple parsers trained on the same training data (use of diversity of models), or use a single parser on different training data (use of diversity of datasets) [1]. Both ways can build multiple decoders which are to be integrated into co-decoding. For the latter case, one method to get diverse training data is to use different portions of the same training set. In this study we extend the case to an extreme situation where heterogeneous treebanks are used to build multiple decoders.

Fig. 2 represents a basic flow chart of heterogeneous parsing via co-decoding. Note that here we discuss the case of co-decoding with only two decoders, but the framework is generic enough to integrate more than two decoders. For convenience of reference, we call a decoder without incorporating consensus information as *baseline decoder* and correspondingly refer to a decoder augmented with consensus information as *member decoder*. So the basic steps of co-decoding for heterogeneous parsing is to first build baseline decoders on heterogeneous treebanks and then use the baseline decoders to parse sentences with consensus information exchanged between each other.

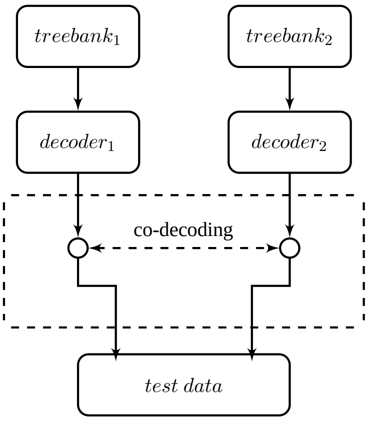

Figure 2: Basic flow chart of co-decoding

To complete co-decoding for heterogeneous parsing, three key components should be considered in the system:

- Co-decoding model. A co-decoder consists of multiple member decoders which are baseline decoders augmented with consensus information. Co-decoding model defines how baseline decoders and consensus information are correlated to get member decoders.

- Decoder coordination. Decoders in the co-decoding model cannot proceed independently but should have interactions between each other in order to exchange consensus information. A decoder coordination strategy decides on when, where, and how the interactions happen.

- Consensus-based score function. Consensus-based score functions formalize consensus information between member decoders. Taking time complexity into consideration, consensus statistics should be able to be computed efficiently.

[1] To make terminologies clear, we use *parser* as its regular sense, including training models (ex. Collins model 2) and parsing algorithms (ex. the CKY algorithm used in Collins parser), and we use *decoder* to represent parsing algorithms with specified parameter values

In the following subsections, we first present the generic co-decoding model and then describe in detail how member decoders collaborate. Finally we introduce a novel consensus-based score function which is used to quantify consensus information exchanged between member decoders.

2.3 Generic Co-decoding Model

The generic co-decoding model described here is also used in (Li et al., 2009) for co-decoding of machine translators. For a given sentence S, a parsing algorithm (decoder) seeks a parse tree T^* which is optimal in the sense that it maximizes some score function $F(T)$, as shown in Eq. 1.

$$T^* = \underset{Ts.t.S=yield(T)}{\arg\max} \quad F(T) \qquad (1)$$

where $Ts.t.S = yield(T)$ represents the set of parse trees that yield the input sentence S. For baseline decoders, the score function $F(T)$ is generally just the inside probability $P(T)$ [2] of a tree T, defined as the product of probabilities of grammar rules appearing in parse tree T: $\prod_{r \in R(T)} P(r)$. In the co-decoding framework, $F(T)$ is extended so as to integrate consensus-based score functions which measure consensus information between member decoders, as shown in Eq. 2.

$$F_m(T) = P_m(T) + \sum_{k,k \neq m}^{n} \Psi_k(H_k(S), T) \qquad (2)$$

We use d_k to denote the k_{th} decoder and use $H_k(S)$ to denote corresponding parsing hypothesis space of decoder d_k. Moreover, $P_m(T)$ is referred to as *baseline score* given by baseline decoders and $\Psi_k(H_k(S), T)$ is *consensus score* between decoders d_m and d_k, which is defined as a linear combination of consensus-based score functions, as shown in Eq. 3.

$$\Psi_k(H_k(S), T) = \sum_l \lambda_{k,l} f_{k,l}(H_k(S), T) \qquad (3)$$

where $f_{k,l}(H_k(S), T)$ represents a consensus-based score function between T and $H_k(S)$, and $\lambda_{k,l}$ is the corresponding weight. Index l ranges over all consensus-based score functions in Eq. 3. Theoretically we can define a variety of consensus-based score functions.

For the simplest case where there are only two member decoders and one consensus-based score function, Eq. 2 and Eq. 3 can be combined and simplified into the equation

$$F_i(T) = P_i(T) + \lambda_{1-i} f(H_{1-i}(S), T) \qquad (4)$$

where index i is set to the value of either 1 or 0. This simplified version is used in the experiments of this study.

2.4 Decoder Coordination

This subsection discusses the problem of decoder coordination. Note that although Eq. 2 is defined at sentence level, the co-decoding model actually should be applied to the parsing procedure of any subsequence (word span) of sentence S. So it is natural to render member decoders collaborate when they are processing the same word spans. To this end, we would like to adopt best-first CKY-style parsing algorithms as baseline decoders, since CKY-style decoders have the property that they process word spans in the ascending order of span sizes. Moreover, the hypotheses [3] spanning the same range of words are readily stacked together in a chart cell before CKY-style decoders move on to process other spans. Thus, member decoders can process the same word spans collaboratively from small ones to big ones until they finally complete parsing the entire sentence.

A second issue in Eq. 2 is that consensus-based score functions are dependent on hypothesis space $H_k(S)$. Unfortunately, the whole hypothesis space is not available most of the time. To address this issue, one practical method is to approximate $H_k(S)$ with a n-best hypothesis list. For best-first CKY parsing, we actually retain all unpruned partial hypotheses over the same span as the approximation. Hereafter, the approximation is denoted as $\hat{H}_k(S)$

Finally, we notice in Eq. 2 that consensus score

[2] Actually, the joint probability P(S,T) of sentence S and parse tree T is used, but we can prove that $P(S,T) = P(T)$.

[3] In the literature of syntactic parsing, especially in chart parsing, hypotheses is often called *edges*. This paper will continue to use the terminology *hypothesis* when no ambiguity exists.

$\Psi_k(H_k(S), T)$ and $H_k(S)$ form a circular dependency: searching for $H_k(S)$ requires both baseline score and consensus score; on the other hand, calculating consensus score needs $H_k(S)$ (its approximation in practice) to be known beforehand. Li et al. (2009) solves this dilemma with a bootstrapping method. It starts with seedy n-best lists generated by baseline decoders and then alternates between calculating consensus scores and updating n-best hypothesis lists. Such bootstrapping method is a natural choice to break down the circular dependency, but multi-pass re-decoding might dramatically reduce decoding efficiency. Actually, Li et al. (2009) restricts the iteration number to two in their experiments. In this paper, we instead use an alternative to the bootstrapping method. The process is described as follows.

1. In traditional best-first CKY-style parsing algorithms, hypotheses over the same word spans are grouped according to some criterion of hypothesis equivalence [4]. Among equivalent hypotheses, only a single optimal hypothesis is retained. In this paper, we instead keep top k of equivalent hypotheses in a data structure called *best-first cache*.

2. Use hypotheses in best-first caches to approximate $H_k(S)$, and calculate consensus score $\Psi_k(H_k(S), T)$ between decoders.

3. Use baseline score and consensus score to locally rerank hypotheses in best-first caches. Then remove hypotheses in caches except the top one hypothesis.

In this study, we choose the best-first CKY-style parsing algorithm used in Collins parser (Collins, 1999). Algorithm 1 extends this algorithm for co-decoding. The first two steps initialize baseline decoders and assign appropriate POS tags to sentence S^t. Since baseline decoders are built on heterogeneous treebanks, POS taggers corresponding to each baseline decoder are demanded, unless gold POS tags are provided. The third step is the core of the co-decoding algorithm. Here the *complete* procedure invokes baseline decoders to complete parsing on the span $[start, end]$ and generates $\hat{H}_k(s)$. The *co-decoding* procedure calculates consensus score and locally reranks hypotheses in best-first caches.

Algorithm 1 CKY-style Co-decoding

```
Argument: $d_k${the set of baseline decoders}
          $S^t${a sentence to be parsed}

Begin
Steps:
1. assign POS tags to sentence $S^t$
2. initialize baseline decoders $d_k$
3. for span from 2 to sentence_length do
       for start from 1 to (sentence_length-span+1) do
           end := (start + span - 1)
           for each base decoder $d_k$ do
               complete($d_k$, start, end)
           do co-decoding(start, end)
End

Subroutine:
    complete($d_k$, start, end): base decoder $d_k$ generates hypotheses over the span (begin.end), and fills in best-first caches.
    co-decoding(start, end): calculate consensus score and rerank hypotheses in best-first caches. The top 1 is chosen to be the best-first hypothesis.
```

2.5 Consensus-based Score Function

There are at least two feasible ways to measure consensus between constituency parse trees. By viewing parse trees from diverse perspectives, we can either use functions on bracket structures of parse trees, as in (Wang et al., 1994), or use functions on head-dependent relations by first transforming constituency trees into dependency trees, as in (Niu et al., 2009). Although the co-decoding model is generic enough to integrate various consensus-based score functions in a uniform way, this paper only uses a bracket structure-based function.

As mentioned above, the function proposed in (Wang et al., 1994) is based on bracket structures. Unfortunately, that function is not applicable in the situation of this paper. The reason is that, the function in (Wang et al., 1994) is defined to work on two parse trees, but this paper instead needs a function on a tree T and a set of trees (the approximation $\hat{H}_k(S)$). To this end, we first introduce the concept of *constituent set (CS)* of a parse tree. Conceptually, CS of a parse tree is a set of word spans corresponding to all the sub-

[4] the simplest criterion of equivalence is whether hypotheses have the same grammar labels.

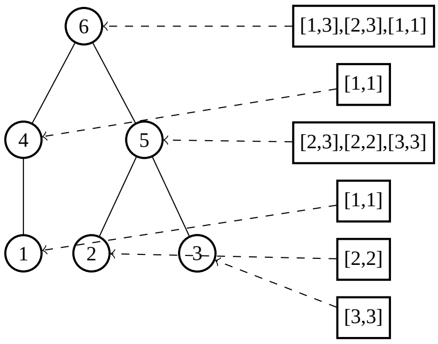

Figure 3: Constituent set of a synthetic parse tree

trees of the tree, as illustrated in Fig. 3. For example, the constituent set of the tree rooted at node 6 has three elements: $[1, 1]$, $[1, 3]$, and $[1, 2]$. For $\hat{H}_k(S)$, the constituent set is defined as the union of constituent sets of all elements it contains.

$$CS(\hat{H}_k(S)) = \bigcup_{T\in\hat{H}_k(S)} CS(T)$$

In practice, we need to cut off elements in $CS(\hat{H}_k(S))$ in order to retain most confident word spans.

With the concept of constituent set, a consensus-based score function on T and $\hat{H}_k(S)$ can be defined as follows.

$$f(\hat{H}_k(S), T) = \frac{\sum_{c\in CS(T)} I(c, CS(\hat{H}_k(S)))}{|CS(T)|} \qquad (5)$$

where $I(c, CS(\hat{H}_k(S)))$ is an indicator function which returns one if $c \in CS(T)$ is compatible with all the elements in $CS(\hat{H}_k(S))$, zero otherwise. Two spans, $[a, b]$ and $[i, j]$ are said to be compatible if they satisfy one of the following conditions: 1) $i > b$; 2) $a > j$; 3) $a \leq i \leq b$ and $j \leq b$; 4) $i \leq a \leq j$ and $b \leq j$. Fig 4 uses two example to illustrate the concept of compatibility.

3 Experiments

3.1 Data and Performance Metric

The most recent version of the CTB corpus, CTB 6.0 and the CIPS ParsEval data are used as heterogeneous treebanks in the experiments. Following the split utilized in (Huang et al., 2007), we divided the dataset into blocks of 10 files. For each block, the first file was added to the CTB development data, the second file was added to the CTB testing data, and the remaining 8 files were added to the CTB training data. For the sake of parsing efficiency, we randomly sampled 1,000 sentences of no more than 40 words from the CTB test set.

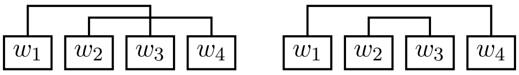

Figure 4: left) two spans conflict; right) two spans are compatible

CTB-Partitions	Train	Dev	Test
#Sentences	22,724	2,855	1,000
#Words	627,833	78,653	25,100
Ave-Length	30.1	30.0	20.3
TCT-Partitions	Train	Dev	Test
#Sentences	32,771	N/A	1,000
#Words	354,767	N/A	10,400
Ave-Length	10.6	N/A	10.4

Table 1: Basic statistics on the CTB and TCT data

CIPS-ParsEval data is publicly available for the first Chinese syntactic parsing competition, CIPS-ParsEval 2009. Compared to CTB, sentences in CIPS-ParsEval data are much shorter in length. We removed sentences which have words less than three. CIPS-ParsEval test set has 7,995 sentences after sentence pruning. As with the CTB test set, we randomly sampled 1,000 sentences for evaluating co-decoding performance. Since CIPS-ParsEval data is actually a portion of the TCT corpus, for convenience of reference, we will refer to CIPS-ParsEval data as TCT in the following sections. Table 1 contains statistics on CTB and TCT.

The two training sets are used individually to build baseline decoders. With regard to the test sets, each sentence in the test sets should have two kinds of POS tags, according to the CTB and TCT standards respectively. To this end, we applied a HMM-based method for POS annotation transformation (Zhu and Zhu, 2009). During the POS transformation, the divergences of word segmentation are omitted.

For all experiments, *bracketing F1* is used as the performance metric, provided by *EVALB* [5].

[5] http://nlp.cs.nyu.edu/evalb

3.2 Baseline Decoders

As already mentioned above, we apply Collins parser in this paper. Specifically speaking, two CKY-style baseline decoders to participate co-decoding are built on CTB and TCT respectively with Collins model two. For the CTB-based decoder, we use the CTB training data with slight modifications: we replaced POS tags of punctuations with specific punctuation symbols.

To get the TCT-based decoder, we made following modifications. Firstly, TCT is available with manually annotated head indices for all the constituents in parse trees. For example, a grammar label, say, np-1, means that the constituent is a noun phrase with the second child being its head child. In order to relax context independence assumptions made in PCFG, we appended head indices to grammar labels to get new labels, for example $np1$. Secondly, since Collins parser is a lexicalized parser, head rules specific to the TCT corpus were manually created, which are used together with readily available head indices. Such adaptation is also used in (Chen et al., 2009);

3.3 Parsing Results

We conduct experiments on both CTB and TCT test sets. Two parameters need to be set: the cutoff threshold for constructing constituent set of $\hat{H}_k(S)$ and the weight λ [6] of consensus score in Eq. 4. We tuned the parameters on the CTB development set and finally set them to 5 and 20 respectively in the experiments. Table 2 presents bracketing F1 scores of baseline systems and the co-decoding approach. Here, the row of *baseline* represents the performance of individual baseline decoders, and the comparison of baseline and co-decoding on a test set, say CTB, demonstrates how much boosting the other side, say TCT, can supply. For the co-decoding approach, the size of best-first cache is set to 5 which achieves the best result among the cache sizes we have experimented.

As the results show, co-decoding achieves promising improvements over baseline systems on both test sets. Interestingly, we see that the improvement on the TCT test set is larger than that on the CTB test set. In general, a relatively strong decoder can improve co-decoding performance more than a relatively weak decoder does. At the first sight, the TCT-based decoder seems to have better performance than the CTB-based decoder. But if taking sentence length into consideration, we can find that the TCT-based decoder is actually relatively weak. Table 3 shows the performance of the CTB-based decoder on short sentences.

Test Set	CTB	TCT
Baseline	79.82	81.02
Co-decoding	80.33	81.77

Table 2: Baseline and Co-decoding on the CTB and TCT test sets

3.4 Analysis

Fig. 5 shows the bracketing F1 on the CTB test set at different settings of the best-first cache size C. F1 scores reach the peak before C increases to 6. As a result, we set C to 5 in all our experiments.

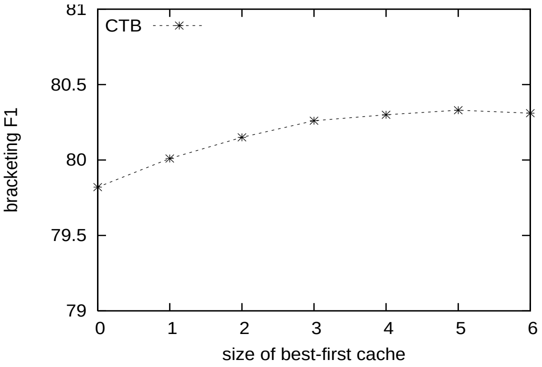

Figure 5: Bracketing F1 with varying best-first cache size

To evaluate the effect of sentence length on co-decoding, Table 3 presents F1 scores on portions of the CTB test set, partitioned according to sentence length. From the results we can see that co-decoding performs better on long sentences. One possible reason is that member decoders have more consensus on big spans. Taking this observation into consideration, one enhancement to the co-decoding approach is to enable co-decoding only on long sentences. This way, parsing ef-

[6] We use the same λ for both member decoders.

Partitions	[0,10]	(10,20]	(20,30]	(30,40]
# Sentence	276	254	266	204
Ave-Length	6.07	15.64	25.43	35.20
Baseline	92.83	84.34	78.98	76.69
Co-decoding	92.84	84.36	79.43	77.65

Table 3: Effect of sentence length on co-decoding performance

ficiency of co-decoding can be improved. It is worth emphasizing that co-decoding is still helpful for parsers whose performance on short sentences is not satisfactory, as shown in Table 2.

Another interesting analysis is to check how many parsing results are affected by co-decoding, compared to baseline decoders. Table 4 shows the statistics.

Test Set	# All	# Improved	# Decreased
CTB	1000	225	109
TCT	1000	263	92

Table 4: Statistics on sentences of test data

As the table shows, although overall accuracy is increased, we find that on some sentences, co-decoding instead worsens parsing accuracy. In order to get insights on error sources, we manually analyzed 20 sentences on which co-decoding achieves negative results. We find a large portion (14 of 20) of sentences are short sentences (of words less than 20). Actually, due to high accuracy of the CTB-based decoder on short sentences, co-decoding is indifferent when this decoder is processing short sentences. And we also find that some errors are derived from differences in annotation standards. Fortunately, the divergence of annotations mainly exists in relatively small spans. So one solution to the problem is to enable co-decoding on relatively big spans. These will be done in our future work.

4 Related Work

4.1 System Combination

In the literature of syntactic parsing, n-best combination methods include parse selection, constituent recombination, production recombination, and n-best reranking. Henderson and Brill (1999) performs parse selection by maximizing the expected precision of selected parse with respect to the set of parses to be combined. Sagae and Lavie (2006) proposes to recombine constituents from the output of individual parsers. More recently, Fossum and Knight (2009) studies a combination method at production level. Zhang et al. (2009) reranks n-best list of one parser with scores derived from another parser.

Compared to n-best combination, co-decoding (Li et al., 2009; Liu et al., 2009) combines systems during decoding phase. Theoretically, system combination during decoding phase helps decoders to select better approximation to hypothesis space, since pruning is practically unavoidable. To the best of our knowledge, co-decoding methods have not been applied to syntactic parsing.

4.2 Treebank Transformation

The focus of this study is heterogeneous parsing. Previous work on this challenge is generally based on treebank transformation. Wang et al. (1994) describes a method for transformation between constituency treebanks. The basic idea is to train a parser on a target treebank and generate a n-best list for each sentence in source treebank(s). Then, a matching metric which is a function on the number of the same word spans between two trees is defined to select a best parse from each n-best list. Niu et al. (2009) applies a closely similar framework as with (Wang et al., 1994) to transform a dependency treebank to a constituency one.

5 Conclusions

This paper proposed a co-decoding approach to the challenge of heterogeneous parsing. Compared to previous work on this challenge, co-decoding is able to directly utilize heterogeneous treebanks by incorporating consensus information between partial output of individual parsers during the decoding phase. Experiments demonstrate the effectiveness of the co-decoding approach, especially the effectiveness on long sentences.

Abstract

In this paper, we consider sentence simplification as a special form of translation with the complex sentence as the source and the simple sentence as the target. We propose a Tree-based Simplification Model (TSM), which, to our knowledge, is the first statistical simplification model covering splitting, dropping, reordering and substitution integrally. We also describe an efficient method to train our model with a large-scale parallel dataset obtained from the Wikipedia and Simple Wikipedia. The evaluation shows that our model achieves better readability scores than a set of baseline systems.

1 Introduction

Sentence simplification transforms long and difficult sentences into shorter and more readable ones. This helps humans read texts more easily and faster. Reading assistance is thus an important application of sentence simplification, especially for people with reading disabilities (Carroll et al., 1999; Inui et al., 2003), low-literacy readers (Watanabe et al., 2009), or non-native speakers (Siddharthan, 2002).

Not only human readers but also NLP applications can benefit from sentence simplification. The original motivation for sentence simplification is using it as a preprocessor to facilitate parsing or translation tasks (Chandrasekar et al., 1996). Complex sentences are considered as stumbling blocks for such systems. More recently, sentence simplification has also been shown helpful for summarization (Knight and Marcu, 2000), sentence fusion (Filippova and Strube, 2008b), semantic role labeling (Vickrey and Koller, 2008), question generation (Heilman and Smith, 2009), paraphrase generation (Zhao et al., 2009) and biomedical information extraction (Jonnalagadda and Gonzalez, 2009).

At sentence level, reading difficulty stems either from lexical or syntactic complexity. Sentence simplification can therefore be classified into two types: *lexical simplification* and *syntactic simplification* (Carroll et al., 1999). These two types of simplification can be further implemented by a set of simplification operations. *Splitting*, *dropping*, *reordering*, and *substitution* are widely accepted as important simplification operations. The splitting operation splits a long sentence into several shorter sentences to decrease the complexity of the long sentence. The dropping operation further removes unimportant parts of a sentence to make it more concise. The reordering operation interchanges the order of the split sentences (Siddharthan, 2006) or parts in a sentence (Watanabe et al., 2009). Finally, the substitution operation replaces difficult phrases or words with their simpler synonyms.

In most cases, different simplification operations happen simultaneously. It is therefore necessary to consider the simplification process as a combination of different operations and treat them as a whole. However, most of the existing models only consider one of these operations. Siddharthan (2006) and Petersen and Ostendorf (2007) focus on sentence splitting, while sentence compression systems (Filippova and Strube, 2008a) mainly use the dropping operation. As far as lexical simplification is concerned, word substitution is usually done by selecting simpler synonyms from Wordnet based on word frequency (Carroll et al., 1999).

In this paper, we propose a sentence simplification model by tree transformation which is based

Beijing, August 2010

on techniques from statistical machine translation (SMT) (Yamada and Knight, 2001; Yamada and Knight, 2002; Graehl et al., 2008). Our model integrally covers splitting, dropping, reordering and phrase/word substitution. The parameters of our model can be efficiently learned from complex-simple parallel datasets. The transformation from a complex sentence to a simple sentence is conducted by applying a sequence of simplification operations. An expectation maximization (EM) algorithm is used to iteratively train our model. We also propose a method based on monolingual word mapping which speeds up the training process significantly. Finally, a decoder is designed to generate the simplified sentences using a greedy strategy and integrates language models.

In order to train our model, we further compile a large-scale complex-simple parallel dataset (PWKP) from Simple English Wikipedia[1] and English Wikipedia[2], as such datasets are rare.

We organize the remainder of the paper as follows: Section 2 describes the PWKP dataset. Section 3 presents our TSM model. Sections 4 and 5 are devoted to training and decoding, respectively. Section 6 details the evaluation. The conclusions follow in the final section.

2 Wikipedia Dataset: PWKP

We collected a paired dataset from the English Wikipedia and Simple English Wikipedia. The targeted audience of Simple Wikipedia includes "children and adults who are learning English language". The authors are requested to "use easy words and short sentences" to compose articles. We processed the dataset as follows:

Article Pairing 65,133 articles from Simple Wikipedia[3] and Wikipedia[4] were paired by following the "language link" using the dump files in Wikimedia.[5] Administration articles were further removed.

Plain Text Extraction We use JWPL (Zesch et al., 2008) to extract plain texts from Wikipedia articles by removing specific Wiki tags.

Pre-processing including sentence boundary detection and tokenization with the Stanford Parser package (Klein and Manning, 2003), and lemmatization with the TreeTagger (Schmid, 1994).

Monolingual Sentence Alignment As we need a parallel dataset aligned at the sentence level, we further applied monolingual sentence alignment on the article pairs. In order to achieve the best sentence alignment on our dataset, we tested three similarity measures: (i) sentence-level TF*IDF (Nelken and Shieber, 2006), (ii) word overlap (Barzilay and Elhadad, 2003) and (iii) word-based maximum edit distance (MED) (Levenshtein, 1966) with costs of insertion, deletion and substitution set to 1. To evaluate their performance we manually annotated 120 sentence pairs from the article pairs. Tab. 1 reports the precision and recall of these three measures. We manually adjusted the similarity threshold to obtain a recall value as close as possible to 55.8% which was previously adopted by Nelken and Shieber (2006).

Similarity	Precision	Recall
TF*IDF	91.3%	55.4%
Word Overlap	50.5%	55.1%
MED	13.9%	54.7%

Table 1: Monolingual Sentence Alignment

The results in Tab. 1 show that sentence-level TF*IDF clearly outperforms the other two measures, which is consistent with the results reported by Nelken and Shieber (2006). We henceforth chose sentence-level TF*IDF to align our dataset.

As shown in Tab. 2, PWKP contains more than 108k sentence pairs. The sentences from Wikipedia and Simple Wikipedia are considered as "complex" and "simple" respectively. Both the average sentence length and average token length in Simple Wikipedia are shorter than those in Wikipedia, which is in compliance with the purpose of Simple Wikipedia.

Avg. Sen. Len		Avg. Tok. Len		#Sen.Pairs
complex	simple	complex	simple	-
25.01	20.87	5.06	4.89	108,016

Table 2: Statistics for the PWKP dataset

In order to account for sentence splitting, we allow 1 to n sentence alignment to map one complex sentence to several simple sentences. We first perform 1 to 1 mapping with sentence-level TF*IDF and then combine the pairs with the same complex sentence and adjacent simple sentences.

3 The Simplification Model: TSM

We apply the following simplification operations to the parse tree of a complex sentence: splitting,

[1] http://simple.wikipedia.org

[2] http://en.wikipedia.org

[3] As of Aug 17th, 2009

[4] As of Aug 22nd, 2009

[5] http://download.wikimedia.org

dropping, reordering and substitution. In this section, we use a running example to illustrate this process. c is the complex sentence to be simplified in our example. Fig. 1 shows the parse tree of c (we skip the POS level).

c: ***August was the sixth month in the ancient Roman calendar which started in 735BC.***

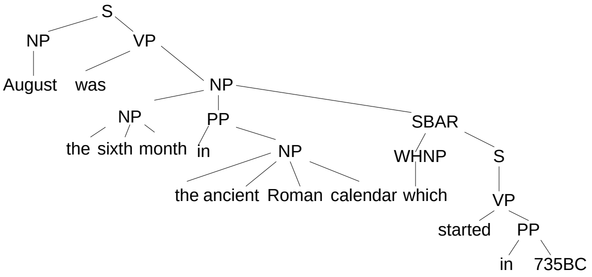

Figure 1: Parse Tree of c

3.1 Splitting

The first operation is sentence splitting, which we further decompose into two subtasks: (i) *segmentation*, which decides where and whether to split a sentence and (ii) *completion*, which makes the new split sentences complete.

First, we decide where we can split a sentence. In our model, the splitting point is judged by the syntactic constituent of the split boundary word in the complex sentence. The decision whether a sentence should be split is based on the length of the complex sentence. The features used in the *segmentation* step are shown in Tab. 3.

Word	Constituent	iLength	isSplit	Prob.
"which"	SBAR	1	true	0.0016
"which"	SBAR	1	false	0.9984
"which"	SBAR	2	true	0.0835
"which"	SBAR	2	false	0.9165

Table 3: Segmentation Feature Table (SFT)

Actually, we do not use the direct constituent of a word in the parse tree. In our example, the direct constituent of the word "which" is "WHNP". Instead, we use Alg. 1 to calculate the constituent of a word. Alg. 1 returns "SBAR" as the adjusted constituent for "which". Moreover, directly using the length of the complex sentence is affected by the data sparseness problem. Instead, we use $\mathrm{iLength}$ as the feature which is calculated as $\mathrm{iLength} = \mathrm{ceiling}(\frac{\mathrm{comLength}}{\mathrm{avgSimLength}})$, where $\mathrm{comLength}$ is the length of the complex sentence and $\mathrm{avgSimLength}$ is the average length of simple sentences in the training dataset. The "Prob." column shows the probabilities obtained after training on our dataset.

Algorithm 1 adjustConstituent($word$, $tree$)

```
$constituent \leftarrow word.father$;
$father \leftarrow constituent.father$;
**while** $father \neq NULL$ AND $constituent$ is the most left child of $father$ **do**
    $constituent \leftarrow father$;
    $father \leftarrow father.father$;
**end while**
**return** $constituent$;
```

In our model, one complex sentence can be split into two or more sentences. Since many splitting operations are possible, we need to select the most likely one. The probability of a segmentation operation is calculated as:

$$P(seg|c) = \prod_{w:c} SFT(w|c) \tag{1}$$

where w is a word in the complex sentence c and $SFT(w|c)$ is the probability of the word w in the Segmentation Feature Table (SFT); Fig. 2 shows a possible segmentation result of our example.

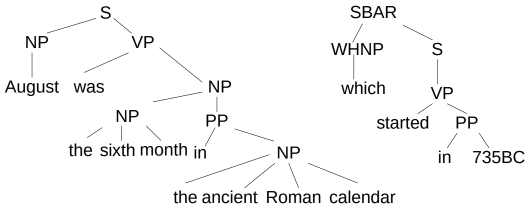

Figure 2: Segmentation

The second step is *completion*. In this step, we try to make the split sentences complete and grammatical. In our example, to make the second sentence "which started in 735BC" complete and grammatical we should first drop the border word "which" and then copy the dependent NP "the ancient Roman calendar" to the left of "started" to obtain the complete sentence "the ancient Roman calendar started in 735BC". In our model, whether the border word should be dropped or retained depends on two features of the border word: the direct constituent of the word and the word itself, as shown in Tab. 4.

Const.	Word	isDropped	Prob.
WHNP	which	True	1.0
WHNP	which	False	Prob.Min

Table 4: Border Drop Feature Table (BDFT)

In order to copy the necessary parts to complete the new sentences, we must decide which parts should be copied and where to put these parts in the new sentences. In our model, this is judged by two features: the dependency relation and the constituent. We use the Stanford Parser for parsing the dependencies. In our example, the dependency relation between “calendar” in the complex sentence and the verb “started” in the second split sentence is “gov_nsubj”.[6] The direct constituent of “started” is “VP” and the word “calendar” should be put on the “left” of “started”, see Tab. 5.

Dep.	Const.	isCopied	Pos.	Prob.
gov_nsubj	VP(VBD)	True	left	0.9000
gov_nsubj	VP(VBD)	True	right	0.0994
gov_nsubj	VP(VBD)	False	-	0.0006

Table 5: Copy Feature Table (CFT)

For dependent NPs, we copy the whole NP phrase rather than only the head noun.[7] In our example, we copy the whole NP phrase “the ancient Roman calendar” to the new position rather than only the word “calendar”. The probability of a completion operation can be calculated as

$$P(com|seg) = \prod_{bw:s} BDFT(bw|s) \prod_{w:s} \prod_{dep:w} CFT(dep).$$

where s are the split sentences, bw is a border word in s, w is a word in s, dep is a dependency of w which is out of the scope of s. Fig. 3 shows the most likely result of the completion operation for our example.

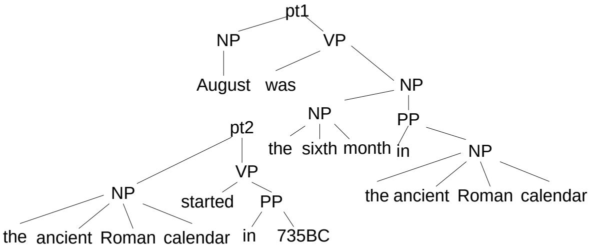

Figure 3: Completion

3.2 Dropping and Reordering

We first apply dropping and then reordering to each non-terminal node in the parse tree from top to bottom. We use the same features for both dropping and reordering: the node’s direct constituent and its children’s constituents pattern, see Tab. 6 and Tab. 7.

Constituent	Children	Drop	Prob.
NP	DT_JJ_NNP_NN	1101	7.66E-4
NP	DT_JJ_NNP_NN	0001	1.26E-7

Table 6: Dropping Feature Table (DFT)

Constituent	Children	Reorder	Prob.
NP	DT_JJ_NN	012	0.8303
NP	DT_JJ_NN	210	0.0039

Table 7: Reordering Feature Table (RFT)

The bits ‘1’ and ‘0’ in the “Drop” column indicate whether the corresponding constituent is retained or dropped. The number in the “Reorder” column represents the new order for the children. The probabilities of the dropping and reordering operations can be calculated as Equ. 2 and Equ. 3.

$$P(dp|node) = DFT(node) \qquad (2)$$

$$P(ro|node) = RFT(node) \qquad (3)$$

In our example, one of the possible results is dropping the NNP “Roman”, as shown in Fig. 4.

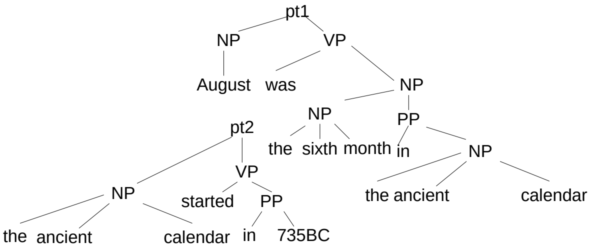

Figure 4: Dropping & Reordering

3.3 Substitution

3.3.1 Word Substitution

Word substitution only happens on the terminal nodes of the parse tree. In our model, the conditioning features include the original word and the substitution. The substitution for a word can be another word or a multi-word expression (see Tab. 8). The probability of a word substitution operation can be calculated as $P(sub|w) = SubFT(Substitution|Origin)$.

Origin	Substitution	Prob.
ancient	ancient	0.963
ancient	old	0.0183
ancient	than transport	1.83E-102
old	ancient	0.005

Table 8: Substitution Feature Table (SubFT)

3.3.2 Phrase Substitution

Phrase substitution happens on the non-terminal nodes and uses the same conditioning features as word substitution. The “Origin” consists of the leaves of the subtree rooted at the node. When we apply phrase substitution on a non-terminal node, then any simplification operation (including dropping, reordering and substitution) cannot happen on its descendants any more

[6] With Stanford Parser, “which” is a referent of “calender” and the nsubj of “started”. “calender” thus can be considered to be the nsubj of “started” with “started” as the governor.

[7] The copied NP phrase can be further simplified in the following steps.

because when a node has been replaced then its descendants are no longer existing. Therefore, for each non-terminal node we must decide whether a substitution should take place at this node or at its descendants. We perform substitution for a non-terminal $node$ if the following constraint is met:

$$Max(SubFT(*|node)) \geq \prod_{ch:node} Max(SubFT(*|ch)).$$

where ch is a child of the $node$. "$*$" can be any substitution in the SubFT. The probability of the phrase substitution is calculated as $P(sub|node) = SubFT(Substitution|Origin)$. Fig. 5 shows one of the possible substitution results for our example where "ancient" is replaced by "old".

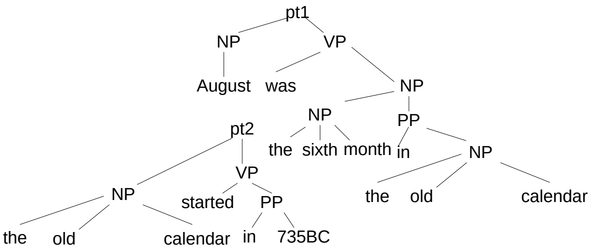

Figure 5: Substitution

As a result of all the simplification operations, we obtain the following two sentences: $s1 = Str(pt1)$=*"August was the sixth month in the old calendar."* and $s2 = Str(pt2)$=*"The old calendar started in 735BC."*

3.4 The Probabilistic Model

Our model can be formalized as a direct translation model from complex to simple $P(s|c)$ multiplied by a language model $P(s)$ as shown in Equ. 4.

$$s = \underset{s}{\operatorname{argmax}}\, P(s|c)P(s) \tag{4}$$

We combine the parts described in the previous sections to get the direct translation model:

$$P(s|c) = \sum_{\theta:Str(\theta(c))=s} (P(seg|c)P(com|seg) \tag{5}$$

$$\prod_{node} P(dp|node)P(ro|node)P(sub|node)$$

$$\prod_{w} (sub|w)).$$

where θ is a sequence of simplification operations and $Str(\theta(c))$ corresponds to the leaves of a simplified tree. There can be many sequences of operations that result in the same simplified sentence and we sum up all of their probabilities.

4 Training

In this section, we describe how we train the probabilities in the tables. Following the work of Yamada and Knight (2001), we train our model by maximizing $P(s|c)$ over the training corpus with the EM algorithm described in Alg. 2, using a constructed graph structure. We develop the Training Tree (Fig. 6) to calculate $P(s|c)$. $P(s|c)$ is equal to the inside probability of the root in the Training Tree. Alg. 3 and Alg. 4 are used to calculate the inside and outside probabilities. We refer readers to Yamada and Knight (2001) for more details.

Algorithm 2 EM Training ($dataset$)

```
Initialize all probability tables using the uniform distribution;
for several iterations do
    reset all $cnt$ = 0;
    for each sentence pair $< c, s >$ in $dataset$ do
        $tt$ = buildTrainingTree($< c, s >$);
        calcInsideProb($tt$);
        calcOutsideProb($tt$);
        update $cnt$ for each conditioning $feature$ in each $node$ of $tt$: $cnt = cnt + node.insideProb * node.outsideProb/root.insideProb$;
    end for
    updateProbability();
end for
```

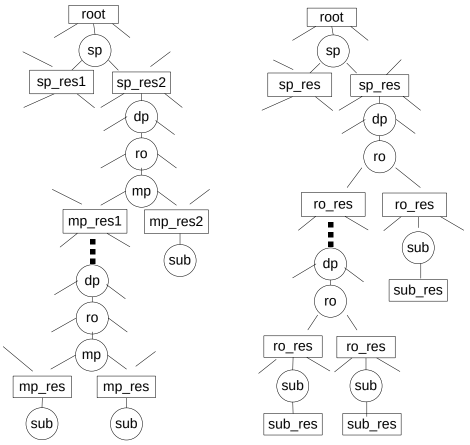

Figure 6: Training Tree (Left) and Decoding Tree (Right)

We illustrate the construction of the training tree with our running example. There are two kinds of nodes in the training tree: data nodes in rectangles and operation nodes in circles. Data nodes contain data and operation nodes execute operations. The training is a supervised learning process with the parse tree of c as input and the two strings $s1$ and $s2$ as the desired output. $root$ stores the parse tree of c and also $s1$ and $s2$. sp, ro, mp and sub are splitting, reordering, mapping and substitution operations. sp_res and mp_res store the results of sp and mp. In our example, sp splits the parse tree into two parse trees $pt1$ and $pt2$ (Fig. 3). sp_res1 contains $pt1$ and $s1$. sp_res2 contains $pt2$ and $s2$. Then dp, ro and mp are iteratively applied to each non-terminal node at each level of $pt1$ and $pt2$ from top to down. This process continues until the terminal nodes are reached or is stopped by a sub node. The function of mp operation is similar to the word mapping operation in the string-based machine translation. It maps substrings in the complex sentence which are dominated by the children of the current node to proper substrings in the simple sentences.

Speeding Up The example above is only one of the possible paths. We try all of the promising paths in training. Promising paths are the paths which are likely to succeed in transforming the parse tree of c into $s1$ and $s2$. We select the promising candidates using monolingual word mapping as shown in Fig. 7. In this example, only the word "which" can be a promising candidate for splitting. We can select the promising candidates for the dropping, reordering and mapping operations similarly. With this improvement, we can train on the PWKP dataset within 1 hour excluding the parsing time taken by the Stanford Parser.

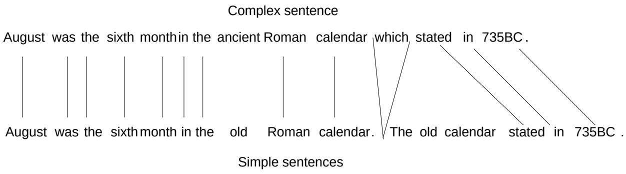
We initialize the probabilities with the uniform distribution. The binary features, such as SFT and BDFT, are assigned the initial value of 0.5. For DFT and RFT, the initial probability is $\frac{1}{N!}$, where N is the number of the children. CFT is initialized as 0.25. SubFT is initialized as 1.0 for any substitution at the first iteration. After each iteration, the $updateProbability$ function recalculates these probabilities based on the cnt for each feature.

Algorithm 3 calcInsideProb (TrainingTree tt)

```
for each $node$ from $level = N$ to $root$ of $tt$ do
    if $node$ is a $sub$ node then
        $node.insideProb$ = $P(sub|node)$;
    else if $node$ is a $mp$ OR $sp$ node then
        $node.insideProb$ = $\prod_{child} child.insideProb$;
    else
        $node.insideProb$ = $\sum_{child} child.insideProb$;
    end if
end for
```

Algorithm 4 calcOutsideProb (TrainingTree tt)

```
for each $node$ from $root$ to $level = N$ of $tt$ do
    if $node$ is the $root$ then
        $node.outsideProb$ = 1.0;
    else if $node$ is a $sp\_res$ OR $mp\_res$ node then
        {COMMENT: $father$ are the fathers of the current $node$, $sibling$ are the children of $father$ excluding the current $node$}
        $node.outsideProb = \sum_{father} father.outsideProb * \prod_{sibling} sibling.insideProb$;
    else if $node$ is a $mp$ node then
        $node.outsideProb = father.outsideProb * 1.0$;
    else if $node$ is a $sp$, $ro$, $dp$ or $sub$ node then
        $node.outsideProb = father.outsideProb * P(sp$ or $ro$ or $dp$ or $sub|node)$;
    end if
end for
```



Complex sentence
August was the sixth month in the ancient Roman calendar which stated in 735BC .
August was the sixth month in the old Roman calendar. The old calendar stated in 735BC .
Simple sentences

Figure 7: Monolingual Word Mapping

5 Decoding

For decoding, we construct the decoding tree (Fig. 6) similarly to the construction of the training tree. The decoding tree does not have mp operations and there can be more than one sub nodes attached to a single ro_res. The $root$ contains the parse tree of the complex sentence. Due to space limitations, we cannot provide all the details of the decoder.

We calculate the inside probability and outside probability for each node in the decoding tree. When we simplify a complex sentence, we start from the root and greedily select the branch with the highest outside probability. For the substitution operation, we also integrate a trigram language model to make the generated sentences more fluent. We train the language model with SRILM (Stolcke, 2002). All the articles from the Simple Wikipedia are used as the training corpus, amounting to about 54 MB.

6 Evaluation

Our evaluation dataset consists of 100 complex sentences and 131 parallel simple sentences from PWKP. They have not been used for training. Four baseline systems are compared in our evaluation. The first is Moses which is a state of the art SMT system widely used as a baseline in MT community. Obviously, the purpose of Moses is cross-lingual translation rather than monolingual simplification. The goal of our comparison is therefore to assess how well a standard SMT system may perform simplification when fed with a proper training dataset. We train Moses with the same part of PWKP as our model. The second baseline system is a sentence compression system (Filippova and Strube, 2008a) whose demo system is available online.[8] As the compression system can only perform dropping, we further extend it to our third and fourth baseline systems, in order to make a reasonable comparison. In our third baseline system, we substitute the words in the output of the compression system with their simpler synonyms. This is done by looking up the synonyms in Wordnet and selecting the most frequent synonym for replacement. The word frequency is counted using the articles from Simple Wikipedia. The fourth system performs sentence splitting on the output of the third system. This is simply done by splitting the sentences at "and", "or", "but", "which", "who" and "that", and discarding the border words. In total, there are 5 systems in our evaluation: *Moses*, the MT system; *C*, the compression system; *CS*, the compression+substitution system; *CSS*, the compression+substitution+split system; *TSM*, our model. We also provide evaluation measures for the sentences in the evaluation dataset: *CW*: complex sentences from Normal Wikipedia and *SW*: parallel simple sentences from Simple Wikipedia.

6.1 Basic Statistics and Examples

The first three columns in Tab. 9 present the basic statistics for the evaluation sentences and the output of the five systems. $tokenLen$ is the average length of tokens which may roughly reflect the lexical difficulty. TSM achieves an average token length which is the same as the Simple Wikipedia (SW). $senLen$ is the average number of tokens in one sentence, which may roughly reflect the syntactic complexity. Both TSM and CSS produce shorter sentences than SW. Moses is very close to CW. $\#sen$ gives the number of sentences. Moses, C and CS cannot split sentences and thus produce about the same number of sentences as available in CW.

Here are two example results obtained with our TSM system.

Example 1. *CW*: "Genetic engineering has expanded the genes available to breeders to utilize in creating desired germlines for new crops." *SW*: "New plants were created with genetic engineering." *TSM*: "Engineering has expanded the genes available to breeders to use in making germlines for new crops."

Example 2. *CW*: "An umbrella term is a word that provides a superset or grouping of related concepts, also called a hypernym." *SW*: "An umbrella term is a word that provides a superset or grouping of related concepts." *TSM*: "An umbrella term is a word. A word provides a superset of related concepts, called a hypernym."

In the first example, both substitution and dropping happen. TSM replaces "utilize" and "creating" with "use" and "making". "Genetic" is dropped. In the second example, the complex sentence is split and "also" is dropped.

6.2 Translation Assessment

In this part of the evaluation, we use traditional measures used for evaluating MT systems. Tab. 9 shows the BLEU and NIST scores. We use "mteval-v11b.pl"[9] as the evaluation tool. CW and SW are used respectively as source and reference sentences. TSM obtains a very high BLEU score (0.38) but not as high as Moses (0.55). However, the original complex sentences (CW) from Normal Wikipedia get a rather high BLEU (0.50), when compared to the simple sentences. We also find that most of the sentences generated by Moses are exactly the same as those in CW: this shows that Moses only performs few modifications to the original complex sentences. This is confirmed by MT evaluation measures: if we set CW as both source and reference, the BLEU score obtained by Moses is 0.78. TSM gets 0.55 in the same setting which is significantly smaller than Moses and demonstrates that TSM is able to generate simplifications with a greater amount of variation from the original sentence. As shown in the "#Same" column of Tab. 9, 25 sentences generated by Moses are exactly identical to the complex sentences, while the number for TSM is 2 which is closer to SW. It is however not clear how well BLEU and NIST discriminate simplification systems. As discussed in Jurafsky and Martin (2008), "BLEU does poorly at comparing systems with radically different architectures and is most appropriate when evaluating incremental changes with similar architectures." In our case, TSM and CSS can be considered as having similar architectures as both of them can do splitting, dropping

[9] `http://www.statmt.org/moses/`

	TokLen	SenLen	#Sen	BLEU	NIST	#Same	Flesch	Lix(Grade)	OOV%	PPL
CW	4.95	27.81	100	0.50	6.89	100	49.1	53.0 (10)	52.9	384
SW	4.76	17.86	131	1.00	10.98	3	60.4 (PE)	44.1 (8)	50.7	179
Moses	4.81	26.08	100	**0.55**	**7.47**	25	54.8	48.1 (9)	52.0	363
C	4.98	18.02	103	0.28	5.37	1	56.2	45.9 (8)	51.7	481
CS	4.90	18.11	103	0.19	4.51	0	59.1	45.1 (8)	**49.5**	616
CSS	4.98	**10.20**	**182**	0.18	4.42	0	65.5 (PE)	38.3 (6)	53.4	581
TSM	**4.76**	13.57	180	0.38	6.21	**2**	**67.4 (PE)**	**36.7 (5)**	50.8	**353**

Table 9: Evaluation

and substitution. But Moses mostly cannot split and drop. We may conclude that TSM and Moses have different architectures and BLEU or NIST is not suitable for comparing them. Here is an example to illustrate this: *(CW):* "Almost as soon as he leaves, Annius and the guard Publius arrive to **escort** Vitellia to Titus, who has now chosen her as his empress." *(SW):* "Almost as soon as he leaves, Annius and the guard Publius arrive to **take** Vitellia to Titus, who has now chosen her as his empress." *(Moses):* The same as (SW). *(TSM):* "Annius and the guard Publius arrive to **take** Vitellia to Titus. Titus has now chosen her as his empress." In this example, *Moses* generates an exactly identical sentence to *SW*, thus the BLUE and NIST scores of *Moses* is the highest. *TSM* simplifies the complex sentence by dropping, splitting and substitution, which results in two sentences that are quite different from the *SW* sentence and thus gets lower BLUE and NIST scores. Nevertheless, the sentences generated by *TSM* seem better than *Moses* in terms of simplification.

6.3 Readability Assessment

Intuitively, readability scores should be suitable metrics for simplification systems. We use the Linux "style" command to calculate the Flesch and Lix readability scores. The results are presented in Tab. 9. "PE" in the Flesch column stands for "Plain English" and the "Grade" in Lix represents the school year. TSM achieves significantly better scores than Moses which has the best BLEU score. This implies that good monolingual translation is not necessarily good simplification. OOV is the percentage of words that are not in the Basic English BE850 list.[10] TSM is ranked as the second best system for this criterion.

The perplexity (PPL) is a score of text probability measured by a language model and normalized by the number of words in the text (Equ. 6). PPL can be used to measure how tight the language model fits the text. Language models constitute an important feature for assessing readability (Schwarm and Ostendorf, 2005). We train a trigram LM using the simple sentences in PWKP and calculate the PPL with SRILM. TSM gets the best PPL score. From this table, we can conclude that TSM achieves better overall readability than the baseline systems.

$$PPL(text) = P(w_1 w_2 ... w_N)^{-\frac{1}{N}} \tag{6}$$

There are still some important issues to be considered in future. Based on our observations, the current model performs well for word substitution and segmentation. But the completion of the new sentences is still problematic. For example, we copy the dependent NP to the new sentences. This may break the coherence between sentences. A better solution would be to use a pronoun to replace the NP. Sometimes, excessive droppings occur, e.g., "older" and "twin" are dropped in "She has an older brother and a twin brother...". This results in a problematic sentence: "She has an brother and a brother...". There are also some errors which stem from the dependency parser. In Example 2, "An umbrella term" should be a dependency of "called". But the parser returns "superset" as the dependency. In the future, we will investigate more sophisticated features and rules to enhance TSM.

7 Conclusions

In this paper, we presented a novel large-scale parallel dataset PWKP for sentence simplification. We proposed TSM, a tree-based translation model for sentence simplification which covers splitting, dropping, reordering and word/phrase substitution integrally for the first time. We also described an efficient training method with speeding up techniques for TSM. The evaluation shows that TSM can achieve better overall readability scores than a set of baseline systems.

A Minimum Error Weighting Combination Strategy for Chinese Semantic Role Labeling

Tao Zhuang and **Chengqing Zong**
National Laboratory of Pattern Recognition
Institute of Automation, Chinese Academy of Sciences
{tzhuang, cqzong}@nlpr.ia.ac.cn

Abstract

Many Semantic Role Labeling (SRL) combination strategies have been proposed and tested on English SRL task. But little is known about how much Chinese SRL can benefit from system combination. And existing combination strategies trust each individual system's output with the same confidence when merging them into a pool of candidates. In our approach, we assign different weights to different system outputs, and add a weighted merging stage to the conventional SRL combination architecture. We also propose a method to obtain an appropriate weight for each system's output by minimizing some error function on the development set. We have evaluated our strategy on Chinese Proposition Bank data set. With our minimum error weighting strategy, the F_1 score of the combined result achieves 80.45%, which is 1.12% higher than baseline combination method's result, and 4.90% higher than the best individual system's result.

1 Introduction

In recent years, Chinese Semantic Role Labeling has received much research effort (Sun and Jurafsky, 2004; Xue, 2008; Che et al., 2008; Ding and Chang, 2008; Sun et al., 2009; Li et al., 2009). And Chinese SRL is also included in CoNLL-2009 shared task (Hajič et al., 2009). On the data set used in (Xue, 2008), the F_1 score of the SRL results using automatic syntactic analysis is still in low 70s (Xue, 2008; Che et al., 2008; Sun et al., 2009). As pointed out by Xue (Xue, 2008), the SRL errors are mainly caused by the errors in automatic syntactic analysis. In fact, Chinese SRL suffers from parsing errors even more than English SRL, because the state-of-the-art parser for Chinese is still not as good as that for English. And previous research on English SRL shows that combination is a robust and effective method to alleviate SRL's dependency on parsing results (Màrquez et al., 2005; Koomen et al., 2005; Pradhan et al., 2005; Surdeanu et al., 2007; Toutanova et al., 2008). However, the effect of combination for Chinese SRL task is still unknown. This raises two questions at least: (1) How much can Chinese SRL benefit from combination? (2) Can existing combination strategies be improved? All existing combination strategies trust each individual system's output with the same confidence when putting them into a pool of candidates. But according to our intuition, different systems have different performance. And the system that have better performance should be trusted with more confidence. We can use our prior knowledge about the combined systems to do a better combination.

The observations above motivated the work in this paper. Instead of directly merging outputs with equal weights, different outputs are assigned different weights in our approach. An output's weight stands for the confidence we have in that output. We acquire these weights by minimizing an error function on the development set. And we use these weights to merge the outputs. In this paper, outputs are generated by a full parsing based Chinese SRL system and a shallow parsing based SRL system. The full parsing based system

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 1362–1370,
Beijing, August 2010

use multiple parse trees to generate multiple SRL outputs. Whereas the shallow parsing based system only produce one SRL output. After merging all SRL outputs, we use greedy and integer linear programming combination methods to combine the merged outputs.

We have evaluated our combination strategy on Chinese Propbank data set used in (Xue, 2008) and get encouraging results. With our minimum error weighting (MEW) strategy, the F_1 score of the combined result achieves 80.45%. This is a significant improvement over the best reported SRL performance on this data set, which is 74.12% in the literature (Sun et al., 2009).

2 Related work

A lot of research has been done on SRL combination. Most of them focused on English SRL task. But the combination methods are general. And they are closely related to the work in this paper.

Punyakanok et al. (2004) formulated an Integer Linear Programming (ILP) model for SRL. Based on that work, Koomen et al. (2005) combined several SRL outputs using ILP method. Màrquez et al. (2005) proposed a combination strategy that does not require the individual system to give a score for each argument. They used a binary classifier to filter different systems' outputs. Then they used a greedy method to combine the candidates that pass the filtering process. Pradhan et al. (2005) combined systems that are based on phrase-structure parsing, dependency parsing, and shallow parsing. They also used greedy method when combining different outputs. Surdeanu et al. (2007) did a complete research on a variety of combination strategies. All these research shows that combination can improve English SRL performance by 2$\sim$5 points on F_1 score. However, little is known about how much Chinese SRL can benefit from combination. And, as we will show, existing combination strategies can still be improved.

3 Individual SRL Systems

3.1 Full Parsing Based System

The full parsing based system utilize full syntactic analysis to perform semantic role labeling. We implemented a Chinese semantic role labeling system similar to the one described in (Xue, 2008). Our system consists of an argument identification stage and an argument classification stage. In the argument identification stage, a number of argument locations are identified in a sentence. In the argument classification stage, each location identified in the first stage is assigned a semantic role label. The features used in this paper are the same with those used in (Xue, 2008).

Maximum entropy classifier is employed for both the argument identification and classification tasks. And Zhang Le's MaxEnt toolkit[1] is used for implementation.

3.2 Shallow Parsing Based System

The shallow parsing based system utilize shallow syntactic information at the level of phrase chunks to perform semantic role labeling. Sun et al. (2009) proposed such a system on Chinese SRL and reported encouraging results. The system used in this paper is based on their approach. For Chinese chunking, we adopted the method used in (Chen et al., 2006), in which chunking is regarded as a sequence labeling task with IBO2 representation. The features used for chunking are the uni-gram and bi-gram word/POS tags with a window of size 2. The SRL task is also regarded as a sequence labeling problem. For an argument with label ARG*, we assign the label B-ARG* to its first chunk, and the label I-ARG* to its rest chunks. The chunks outside of any argument are assigned the label O. The features used for SRL are the same with those used in the one-stage method in (Sun et al., 2009).

In this paper, we employ Tiny SVM along with Yamcha (Kudo and Matsumoto, 2001) for Chinese chunking, and CRF++[2] for SRL.

3.3 Individual systems' outputs

The maximum entropy classifier used in full parsing based system and the CRF model used in shallow paring based system can both output classification probabilities. For the full parsing based system, the classification probability of the ar-

[1] http://homepages.inf.ed.ac.uk/lzhang10/maxent_toolkit .html

[2] http://crfpp.sourceforge.net/

gument classification stage is used as the argument's probability. Whereas for the shallow parsing based system, an argument is usually comprised of multiple chunks. For example, an argument with label ARG0 may contain three chunks labeled as: B-ARG0, I-ARG0, I-ARG0. And each chunk has a label probability. Thus we have three probabilities p_1, p_2, p_3 for one argument. In this case, we use the geometric mean of individual chunks' probabilities $(p_1 \cdot p_2 \cdot p_3)^{1/3}$ as the argument's probability.

As illustrated in Figure 1, in an individual system's output, each argument has three attributes: its location in sentence loc, represented by the number of its first word and last word; its semantic role label l; and its probability p.

Sent:	外商 投资 企业	成为	中国 外贸 重要 增长点
Args:	[ARG0]	[pred]	[ARG1]
loc:	(0, 2)		(4, 7)
l:	ARG0		ARG1
p:	0.94		0.92

Figure 1: Three attributes of an output argument: location loc, label l, and probability p.

So each argument outputted by a system is a triple (loc, l, p). For example, the ARG0 in Figure 1 is $((0, 2), \text{ARG0}, 0.94)$. Because the outputs of baseline systems are to be combined, we call such triple a **candidate** for combination.

4 Approach Overview

As illustrated in Figure 2, the architecture of our system consists of a candidates generation stage, a weighted merging stage, and a combination stage. In the candidates generation stage, the baseline systems are run individually and their outputs are collected. We use 2-best parse trees of Berkeley parser (Petrov and Klein, 2007) and 1-best parse tree of Bikel parser (Bikel, 2004) and Stanford parser (Klein and Manning, 2003) as inputs to the full parsing based system. The second best parse tree of Berkeley parser is used here for its good quality. So together we have four different outputs from the full parsing based system. From the shallow parsing based system, we have only one output.

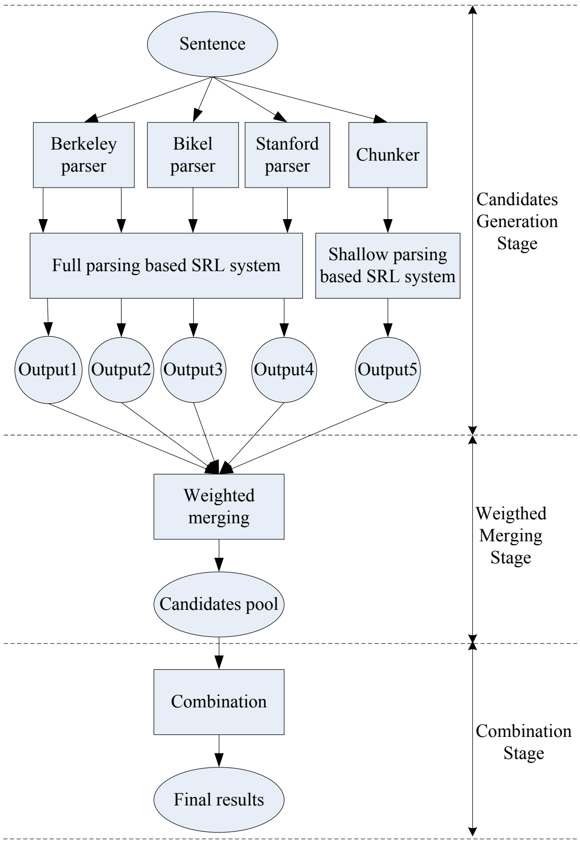

Figure 2: The overall architecture of our system.

In the weighted merging stage, each system output is assigned a weight according to our prior knowledge obtained on the development set. Details about how to obtain appropriate weights will be explained in Section 6. Then all candidates with the same loc and l are merged to one by weighted summing their probabilities. Specifically, suppose that there are n system outputs to be combined, with the i-th output's weight to be w_i. And the candidate in the i-th output with loc and l is (loc, l, p_i) (If there is no candidate with loc and l in the i-th output, p_i is 0.). Then the merged candidate is (loc, l, p), where $p = \sum_{i=1}^{n} w_i p_i$.

After the merging stage, a pool of merged candidates is obtained. In the combination stage, candidates in the pool are combined to form a consistent SRL result. Greedy and integer linear programming combination methods are experimented in this paper.

5 Combination Methods

5.1 Global constraints

When combining the outputs, two global constraints are enforced to resolve the conflict between outputs. These two constraints are:

1. *No duplication*: There is no duplication for key arguments: ARG0 $\sim$ ARG5.

2. *No overlapping*: Arguments cannot overlap with each other.

We say two argument candidates **conflict** with each other if they do not satisfy the two constraints above.

5.2 Two combination methods

Under these constraints, two methods are explored to combine the outputs. The first one is a greedy method. In this method, candidates with probability below a threshold are deleted at first. Then the remaining candidates are inspected in descending order according to their probabilities. And each candidate will be put into a solution set if it does not conflict with candidates already in the set. This greedy combination method is very simple and has been adopted in previous research (Pradhan et al., 2005; Màrquez et al., 2005).

The second combination method is integer linear programming (ILP) method. ILP method was first applied to SRL in (Punyakanok et al., 2004). Here we formulate an ILP model whose form is different from the model in (Punyakanok et al., 2004; Koomen et al., 2005). For convenience, we denote the whole label set as $\{l_1, l_2, \dots, l_n\}$. And let $l_1 \sim l_6$ stand for the key argument labels ARG0 $\sim$ ARG5 respectively. Suppose there are m different locations, denoted as $loc_1, \dots, loc_m$, among all candidates in the pool. And the probability of assigning l_j to loc_i is p_{ij}. A binary variable x_{ij} is defined as:

$$x_{ij} = \begin{cases} 1 & \text{if } loc_i \text{ is assigned label } l_j, \\ 0 & \text{otherwise.} \end{cases}$$

The objective of the ILP model is to maximize the sum of arguments' probabilities:

$$\max \sum_{i=1}^{m} \sum_{j=1}^{n} (p_{ij} - T) x_{ij} \qquad (1)$$

where T is a threshold to prevent including too many candidates in solution. T is similar to the threshold in greedy combination method. In this paper, both thresholds are empirically tuned on development data, and both are set to be 0.2.

The inequalities in equation (2) make sure that each loc is assigned at most one label.

$$\forall 1 \le i \le m : \sum_{j=1}^{n} x_{ij} \le 1 \qquad (2)$$

The inequalities in equation (3) satisfy the *No duplication* constraint.

$$\forall 1 \le j \le 6 : \sum_{i=1}^{m} x_{ij} \le 1 \qquad (3)$$

For any location loc_i, let C_i denote the index set of the locations that overlap with it. Then the *No overlapping* constraint means that if loc_i is assigned a label, i.e., $\sum_{j=1}^{n} x_{ij} = 1$, then for any $k \in C_i$, loc_k cannot be assigned any label, i.e., $\sum_{j=1}^{n} x_{kj} = 0$. A common technique in ILP modeling to form such a constraint is to use a sufficiently large auxiliary constant M. And the constraint is formulated as:

$$\forall 1 \le i \le m : \sum_{k \in C_i} \sum_{j=1}^{n} x_{kj} \le (1 - \sum_{j=1}^{n} x_{ij}) M \qquad (4)$$

In this case, M only needs to be larger than the number of candidates to be combined. In this paper, $M = 500$ is large enough. And we employ lpsolve[3] to solve the ILP model.

Note that the form of the ILP model in this paper is different from that in (Punyakanok et al., 2004; Koomen et al., 2005) in three aspects: (1) A special label class *null*, which means no label is assigned, was added to the label set in (Punyakanok et al., 2004; Koomen et al., 2005). Whereas no such special class is needed in our model, because if no label is assigned to loc_i, $\sum_{j=1}^{n} x_{ij} = 0$ would simply indicate this case. This makes our model contain fewer variables. (2) Without *null* class in our model, we need to use a different technique to formulate the *No-overlapping* constraint. (3) In order to compare

[3] http://lpsolve.sourceforge.net/

with the greedy combination method, the ILP model in this paper conforms to exactly the same constraints as the greedy method. Whereas many more global constraints were taken into account in (Punyakanok et al., 2004; Koomen et al., 2005).

6 Train Minimum Error Weights

The idea of minimum error weighting is straightforward. Individual outputs $O_1, O_2, \ldots, O_n$ are assigned weights $w_1, w_2, \ldots, w_n$ respectively. These weights are normalized, i.e., $\sum_{i=1}^{n} w_i = 1$. An output's weight can be seen as the confidence we have in that output. It is a kind of prior knowledge we have about that output. We can gain this prior knowledge on the development set. As long as the data of the development set and the test set are similar, this prior knowledge should be able to help to guide SRL combination on test set. In this section, we discuss how to obtain appropriate weights.

6.1 Training model

Suppose the golden answer and SRL result on development set are d and r respectively. An **error function** $Er(r, d)$ is a function that measures the error contained in r in reference to d. An error function can be defined as the number of wrong arguments in r. It can also be defined using precision, recall, or F_1 score. For example, $Er(r, d) = 1 - Precision(r, d)$, or $Er(r, d) = 1 - F_1(r, d)$. Smaller value of error function means less error in r.

The combination process can also be seen as a function, which maps the outputs and weights to the combined result r: $r = Comb(O_1^n, w_1^n)$. Therefore, the error function of our system on development set is:

$$Er(r, d) = Er(Comb(O_1^n, w_1^n), d) \qquad (5)$$

From equation (5), it can be seen that: Given development set d, if the outputs to be combined O_1^n and the combination method $Comb$ are fixed, the error function is just a function of the weights. So we can obtain appropriate weights by minimizing the error function:

$$\hat{w_1^n} = \arg\min_{w_1^n} Er(Comb(O_1^n, w_1^n), d) \qquad (6)$$

6.2 Training algorithm

Algorithm 1 Powell Training Algorithm.

```
 1: Input : Error function $Er(\boldsymbol{w})$.
 2: Initialize $n$ directions $\boldsymbol{d}_1, \ldots, \boldsymbol{d}_n$, and
    a start point $\boldsymbol{w}$ in $R^n$.
 3: Set termination threshold $\delta$.
 4: do:
 5:     $\boldsymbol{w}_1 \leftarrow \boldsymbol{w}$
 6:     for $i \leftarrow 1, \ldots, n$:
 7:         $\alpha_i \leftarrow \arg\min_{\alpha} f(\boldsymbol{w}_i + \alpha \boldsymbol{d}_i)$
 8:         $\boldsymbol{w}_{i+1} \leftarrow \boldsymbol{w}_i + \alpha_i \boldsymbol{d}_i$
 9:     $\boldsymbol{d}_{n+1} \leftarrow \boldsymbol{w}_{n+1} - \boldsymbol{w}$
10:     $\alpha^* \leftarrow \arg\min_{\alpha} f(\boldsymbol{w} + \alpha \boldsymbol{d}_{n+1})$
11:     $\boldsymbol{w}' \leftarrow \boldsymbol{w} + \alpha^* \boldsymbol{d}_{n+1}$
12:     $\Delta Er \leftarrow Er(\boldsymbol{w}) - Er(\boldsymbol{w}')$
13:     $i \leftarrow \arg\max_{1 \leq j \leq n} Er(\boldsymbol{w}_j) - Er(\boldsymbol{w}_{j+1})$
14:     if $(\alpha^*)^2 \geq \frac{\Delta Er}{Er(\boldsymbol{w}_i) - Er(\boldsymbol{w}_{i+1})}$:

17:     $\boldsymbol{w} \leftarrow \boldsymbol{w}'$
18: while $\Delta Er > \delta$
19: Output: The minimum error weights $\boldsymbol{w}$.
```

There are two difficulties to solve the optimization problem in equation 6. The first one is that the error function cannot be written to an analytical form. This is because the $Comb$ function, which stands for the combination process, cannot be written as an analytical formula. So the problem cannot be solved using canonical gradient-based optimization algorithms, because the gradient function cannot be derived. The second difficulty is that, according to our experience, the error function has many local optima, which makes it difficult to find a global optima.

To resolve the first difficulty, Modified Powell's method (Yuan, 1993) is employed to solve the optimization problem. Powell's method is a heuristic search method that does not require the objective function to have an explicit analytical form. The training algorithm is presented in Algorithm 1. In Algorithm 1, the line search problem in steps 7 and 10 is solved using Brent's method (Yuan, 1993). And the temination threshold δ is empirically set to be 0.001 in this paper.

To resolve the second difficulty, we perform multiple searches using different start points, and then choose the best solution found.

7 Experiments

7.1 Experimental setup

We use Chinese Proposition Bank (CPB) 1.0 and Chinese Tree Bank (CTB) 5.0 of Linguistic Data Consortium corpus in our experiments. The training set is comprised of 648 files(chtb_081.fid to chtb_885.fid). The development set is comprised of 40 files(chtb_041.fid to chtb_080.fid). The test set is comprised of 72 files(chtb_001.fid to chtb_040.fid and chtb_900.fid to chtb_931.fid).

The same data setting has been used in (Xue, 2008; Ding and Chang, 2008; Sun et al., 2009). Sun et al. (2009) used sentences with golden segmentation and POS tags as input to their SRL system. However, we use sentences with only golden segmentation as input. Then we perform automatic POS tagging using Stanford POS tagger (Toutanova et al., 2003). In (Xue, 2008), the parser used by the SRL system is trained on the training and development set plus 275K words of broadcast news. In this paper, all parsers used by the full parsing based system are trained on the training set plus the broadcast news portion of CTB6.0. And the chunker used in the shallow parsing based system is trained just on the training set.

7.2 Individual outputs' performance

In this paper the four outputs of the full parsing based system are represented by FO1 $\sim$ FO4 respectively. Among them, FO1 and FO2 are the outputs using the first and second best parse trees of Berkeley parser, FO3 and FO4 are the outputs using the best parse trees of Stanford parser and Bikel parser respectively. The output of the shallow parsing based system is represented by SO. The individual outputs' performance on development and test set are listed in Table 1.

From Table 1 we can see that the performance of individual outputs are similar on development set and test set. On both sets, the F_1 scores of individual outputs are in the same order: FO1 $>$ FO2 $>$ SO $>$ FO3 $>$ FO4.

Data set	Outputs	$P(\%)$	$R(\%)$	F_1
development	FO1	**79.17**	**72.09**	**75.47**
	FO2	77.89	70.56	74.04
	FO3	72.57	67.02	69.68
	FO4	75.60	63.45	69.00
	SO	73.72	67.35	70.39
test	FO1	**80.75**	**70.98**	**75.55**
	FO2	79.44	69.37	74.06
	FO3	73.95	66.37	70.00
	FO4	75.89	63.26	69.00
	SO	75.69	67.90	71.59

Table 1: The results of individual systems on development and test set.

7.3 Combining outputs of full parsing based system

In order to investigate the benefit that the full parsing based system can get from using multiple parsers, we combine the four outputs FO1 $\sim$ FO4. The combination results are listed in Table 2. In tables of this paper, "Grd" and "ILP" stand for greedy and ILP combination methods respectively, and "+MEW" means the combination is performed with MEW strategy.

	$P(\%)$	$R(\%)$	F_1
Grd	**82.68**	73.36	77.74
ILP	82.21	73.93	77.85
Grd+MEW	81.30	75.38	78.23
ILP+MEW	81.27	**75.74**	**78.41**

Table 2: The results of combining outputs of full parsing based system on test set.

	Er	FO1	FO2	FO3	FO4
Grd	$1 - F_1$	0.31	0.16	0.30	0.23
ILP	$1 - F_1$	0.33	0.10	0.27	0.30

Table 3: The minimum error weights for the results in Table 2.

From Table 2 and Table 1, we can see that, without MEW strategy, the F_1 score of combination result is about 2.3% higher than the best individual output. With MEW strategy, the F_1 score is improved about 0.5% further. That is to say, with MEW strategy, the benefit of combination is improved by about 20%. Therefore, the effect of MEW is very encouraging.

Here the error function for MEW training is chosen to be $1 - F_1$. And the trained weights for greedy and ILP methods are listed in Table 3 separately. In tables of this paper, the column Er corresponds to the error function used for MEW strategy.

7.4 Combining all outputs

We have also combined all five outputs. The results are listed in Table 4. Compared with the results in Table 2, we can see that the combination results is largely improved, especially the recall.

	P(%)	R(%)	F_1
Grd	**83.64**	75.32	79.26
ILP	83.31	75.71	79.33
Grd+MEW	83.34	77.47	80.30
ILP+MEW	83.02	**78.03**	**80.45**

Table 4: The results of combining all outputs on test set.

From Table 4 and Table 1 we can see that without MEW strategy, the F_1 score of combination result is about 3.8% higher than the best individual output. With MEW, the F_1 score is improved further by more than 1%. That means the benefit of combination is improved by over 25% with MEW strategy.

Here the error function for MEW training is still $1 - F_1$, and the trained weights are listed in Table 5.

	Er	FO1	FO2	FO3	FO4	SO
Grd	$1 - F_1$	0.23	0.12	0.23	0.20	0.22
ILP	$1 - F_1$	0.24	0.08	0.22	0.21	0.25

Table 5: The minimum error weights for the results in Table 4.

7.5 Using alternative error functions for minimum error weights training

In previous experiments, we use $1 - F_1$ as error function. As pointed out in Section 6, the definition of error function is very general. So we have experimented with two other error functions, which are $1 - Precision$, and $1 - Recall$. Obviously, these two error functions favor precision and recall separately. The results of combining all five outputs using these two error functions are listed in Table 6, and the trained weights are listed in Table 7.

	Er	P(%)	R(%)	F_1
Grd+MEW	$1 - P$	85.31	73.42	78.92
ILP+MEW	$1 - P$	**85.62**	72.76	78.67
Grd+MEW	$1 - R$	81.94	77.55	79.68
ILP+MEW	$1 - R$	79.74	**78.34**	79.03

Table 6: The results of combining all outputs with alternative error functions.

	Er	FO1	FO2	FO3	FO4	SO
Grd	$1 - P$	0.25	0.24	0.22	0.22	0.07
ILP	$1 - P$	0.30	0.26	0.20	0.15	0.09
Grd	$1 - R$	0.21	0.10	0.17	0.15	0.37
ILP	$1 - R$	0.24	0.04	0.10	0.22	0.39

Table 7: The minimum error weights for the results in Table 6.

From Table 6 and Table 4, we can see that when $1 - Precison$ is used as error function, the precision of combination result is largely improved. But the recall decreases a lot. Similar effect of the error function $1 - Recall$ is also observed.

The results of this subsection reflect the flexibility of MEW strategy. This flexibility comes from the generality of the definition of error function. The choice of error function gives us some control over the results we want to get. We can define different error functions to favor precision, or recall, or some error counts such as the number of misclassified arguments.

7.6 Discussion

In this paper, the greedy and ILP combination methods conform to the same simple constraints specified in Section 5. From the experiment results, we can see that ILP method generates slightly better results than greedy method.

In Subsection 7.4, we see that combining all outputs using ILP method with MEW strategy yields 4.90% improvement on F_1 score over the best individual output FO1. In order to understand each output's contribution to the improvement over FO1. We compare the differences between outputs.

Let C_O denote the set of correct arguments in an output O. Then we get the following statistics when comparing two outputs A and B: (1) the number of common correct arguments in A and B, i.e., $|C_A \cap C_B|$; (2) the number of correct arguments in A and not in B, i.e., $|C_A \setminus C_B|$; (3) the number of correct arguments in B and not in A, i.e., $|C_B \setminus C_A|$. The comparison results between some outputs on test set are listed in Table 8. In this table, UF stands for the union of the 4 outputs FO1 $\sim$ FO4.

A	B	$\lvert C_A \cap C_B \rvert$	$\lvert C_A \setminus C_B \rvert$	$\lvert C_B \setminus C_A \rvert$
FO1	FO2	5498	508	372
	FO3	5044	962	552
	FO4	4815	1191	512
	SO	4826	1180	920
UF	SO	5311	1550	435

Table 8: Comparison between outputs on test set.

From Table 8 we can see that the output SO has 4826 common correct arguments with FO1, which is relatively small. And, more importantly, SO contains 920 correct arguments not in FO1, which is much more than any other output contains. Therefore, SO is more complementary to FO1 than other outputs. On the contrary, FO2 is least complementary to FO1. Even compared with the union of FO1 $\sim$ FO4, SO still contains 435 correct arguments not in the union. This shows that the output of shallow parsing based system is a good complement to the outputs of full parsing based system. This explains why recall is largely improved when SO is combined in Subsection 7.4. From the analysis above we can also see that the weights in Table 5 are quite reasonable. In Table 5, SO is assigned the largest weight and FO2 is assigned the smallest weight.

In Subsection 7.3, the MEW strategy improves the benefit of combination by about 20%. And in Subsection 7.4, the MEW strategy improves the benefit of combination by over 25%. This shows that the MEW strategy is very effective for Chinese SRL combination.

To our best knowledge, no results on Chinese SRL combination has been reported in the literature. Therefore, to compare with previous results, the top two results of single SRL system in the literature and the result of our combination system on this data set are listed in Table 9. For the results in Table 9, the system of Sun et al. uses sentences with golden POS tags as input. Xue's system and our system both use sentences with automatic POS tags as input. The result of Sun et al. (2009) is the best reported result on this data set in the literature.

	POS	P(%)	R(%)	F_1
(Xue, 2008)	auto	76.8	62.5	68.9
(Sun et al., 2009)	gold	79.25	69.61	74.12
Ours	auto	**83.02**	**78.03**	**80.45**

Table 9: Previous best single system's results and our combination system's result on this data set.

8 Conclusions

In this paper, we propose a minimum error weighting strategy for SRL combination and investigate the benefit that Chinese SRL can get from combination. We assign different weights to different system outputs and add a weighted merging stage to conventional SRL combination system architecture. And we also propose a method to train these weights on development set. We evaluate the MEW strategy on Chinese Propbank data set with greedy and ILP combination methods.

Our experiments have shown that the MEW strategy is very effective for Chinese SRL combination, and the benefit of combination can be improved over 25% with this strategy. And also, the MEW strategy is very flexible. With different definitions of error function, this strategy can favor precision, or recall, or F_1 score. The experiments have also shown that Chinese SRL can benefit a lot from combination, especially when systems based on different syntactic views are combined. The SRL result with the highest F_1 score in this paper is generated by ILP combination together with MEW strategy. In fact, the MEW strategy is easy to incorporate with other combination methods, just like incorporating with the greedy and ILP combination methods in this paper.

Detecting Speech Repairs Incrementally Using a Noisy Channel Approach

Simon Zwarts, Mark Johnson and Robert Dale
Centre for Language Technology
Macquarie University
{simon.zwarts|mark.johnson|robert.dale}@mq.edu.au

Abstract

Unrehearsed spoken language often contains disfluencies. In order to correctly interpret a spoken utterance, any such disfluencies must be identified and removed or otherwise dealt with. Operating on transcripts of speech which contain disfluencies, our particular focus here is the identification and correction of speech repairs using a noisy channel model. Our aim is to develop a high-accuracy mechanism that can identify speech repairs in an incremental fashion, as the utterance is processed word-by-word.

We also address the issue of the evaluation of such incremental systems. We propose a novel approach to evaluation, which evaluates performance in detecting and correcting disfluencies incrementally, rather than only assessing performance once the processing of an utterance is complete. This demonstrates some shortcomings in our basic incremental model, and so we then demonstrate a technique that improves performance on the detection of disfluencies as they happen.

1 Introduction

One of the most obvious differences between written language and spoken language is the fact that the latter presents itself incrementally over some time period. Most natural language processing applications operate on complete sentences; but for real time spontaneous speech, there are potential benefits to incrementally processing the input so that a system can stay responsive and interact directly before a speaker's utterance is complete. Work in psycholinguistics supports the view that the human parsing mechanism works incrementally, with partial semantic interpretations being produced before the complete utterance has been heard (Marslen-Wilson, 1973). Our interest is in developing similarly incremental processing techniques for natural language interpretation, so that, for example, a speech recognizer might be able to interject during a long utterance to object, cut the speaker short, or correct a mistaken assumption; such a mechanism is even required for the appropriate timing of backchannel signals. Additionally the incremental nature of the model allows potential application of this model in speech recognition models.

Another feature of unrehearsed spoken language that has no obvious correlate in written language is the presence of disfluencies.[1] Disfluencies are of different types, ranging from simple filled pauses (such as *um* and *uh*) to more complicated structures where the sequence of words that make up the utterance is 'repaired' while it is being produced. Whereas simpler disfluencies may be handled by simply deleting them from the sequence of words under consideration, the editing terms in a speech repair are part of the utterance, and therefore require more sophisticated processing.

There are three innovations in the present paper. First, we demonstrate that a noisy channel model of speech repairs can work accurately in an incremental fashion. Second, we provide an approach to the evaluation of

[1] Although some disfluencies can be considered grammatical errors, they are generally quite distinct in both cause and nature from the kinds of grammatical errors found in written text.

Proceedings of the 23rd International Conference on Computational Linguistics (Coling 2010), pages 1371–1378,
Beijing, August 2010

such an incremental model. Third, we tackle the problem of the early detection of speech repairs, and demonstrate a technique that decreases the latency (as measured in tokens) involved in spotting that a disfluency has occurred.

The rest of the paper is structured as follows. Section 2 provides some background on speech repairs and existing approaches to handling them, including Johnson and Charniak's (2004) model, which we use as a starting point for our incremental model. Section 3 describes our model in detail, focusing on the noisy channel model and the incremental component of this model. Section 4 introduces some considerations that arise in the development of techniques for the evaluation of incremental disfluency detection; we then provide a quantitative assessment of our performance using these techniques. Our evaluation reveals that our basic incremental model does not perform very well at detecting disfluencies close to where they happen, so in Section 5 we present a novel approach to optimise detection of these disfluencies as early as possible. Finally Section 6 concludes and discusses future work.

2 Speech Repairs

We adopt the terminology and definitions introduced by Shriberg (1994) to discuss disfluency. We are particularly interested in what are called **repairs**. These are the hardest types of disfluency to identify since they are not marked by a characteristic vocabulary. Shriberg (1994) identifies and defines three distinct parts of a repair, referred to as the **reparandum**, the **interregnum** and the **repair**. Consider the following utterance:

$$\begin{array}{c} \textit{I want a flight } \overbrace{\textit{to Boston,}}^{\text{reparandum}} \\ \underbrace{\textit{uh, I mean}}_{\text{interregnum}}\underbrace{\textit{to Denver}}_{\text{repair}} \textit{ on Friday} \end{array} \qquad (1)$$

The reparandum *to Boston* is the part of the utterance that is being edited out; the interregnum *uh* is a filler, which may not always be present; and the repair *to Denver* replaces the reparandum.

Given an utterance that contains such a repair, we want to be able to correctly detect the start and end positions of each of these three components. We can think of each word in an utterance as belonging to one of four categories: fluent material, reparandum, interregnum, or repair. We can then assess the accuracy of techniques that attempt to detect disfluencies by computing precision and recall values for the assignment of the correct categories to each of the words in the utterance, as compared to the gold standard as indicated by annotations in the corpus.

An alternative means of evaluation would be to simply generate a new signal with the reparandum and filler removed, and compare this against a 'cleaned-up' version of the utterance; however, Core and Schubert (1999) argue that, especially in the case of speech repairs, it is important not to simply throw away the disfluent elements of an utterance, since they can carry meaning that needs to be recovered for proper interpretation of the utterance. We are therefore interested in the first instance in a model of speech error *detection*, rather than a model of *correction*.

Johnson and Charniak (2004) describe such a model, using a noisy-channel based approach to the detection of the start and end points of reparanda, interregna and repairs. Since we use this model as our starting point, we provide a more detailed explanation in Section 3.

The idea of using a noisy channel model to identify speech repairs has been explored for languages other than English. Honal and Schultz (2003) use such a model, comparing speech disfluency detection in spontaneous spoken Mandarin against that in English. The approach performs well in Mandarin, although better still in English.

Both the models just described operate on transcripts of completed utterances. Ideally, however, when we deal with speech we would like to process the input word by word as it is received. Being able to do this would enable tighter integration in both speech recognition and interpretation, which might in turn improve overall accuracy.

The requirement for incrementality is recognised by Schuler et al. (2010), who employ an incremental Hierarchical Hidden Markov Model (HHMM) to detect speech disfluencies. The HHMM is trained on manually annotated parse trees which are transformed by a right corner transformation; the HHMM is then used in an incremental fashion on unseen data, growing the parse structure each time a new token comes in. Special subtrees in this parse can carry a marker indicating that the span of the subtree consists of tokens corresponding to a speech disfluency. Schuler et al.'s approach thus provides scope for detecting disfluencies in an incremental fashion. However, their reported accuracy scores are not as good as those of Johnson and Charniak (2004): they report an F-score of 0.690 for their HHMM+RCT model, as compared to 0.797 for Johnson and Charniak's parser model.

Our aim in this paper, then, is to investigate whether it is possible to adapt Johnson and Charniak's model to process utterances incrementally, without any loss of accuracy. To define the incremental component more precisely, we investigate the possibility of marking the disfluencies as soon as possible during the processing of the input. Given two models that provide comparable accuracy measured on utterance completion, we would prefer a model which detects disfluencies earlier.

3 The Model

In this section, we describe Johnson and Charniak's (2004) noisy channel model, and show how this model can be made incremental.

As a data set to work with, we use the Switchboard part of the Penn Treebank 3 corpus. The Switchboard corpus is a corpus of spontaneous conversations between two parties. In Penn Treebank 3, the disfluencies are manually annotated. Following Johnson and Charniak (2004), we use all of sections 2 and 3 for training; we use conversations 4[5-9]* for a held-out training set; and conversations 40*, 41[0-4]* and 415[0-3]* as the held-out test set.

3.1 The Noisy Channel Model

To find the repair disfluencies a noisy channel model is used. For an observed utterance with disfluencies, y, we wish to find the most likely source utterance, $\hat{x}$, where:

$$\begin{aligned} \hat{x} &= argmax_x \; p(x \mid y) \qquad (2) \\ &= argmax_x \; p(y \mid x) \, p(x) \end{aligned}$$

Here we have a channel model $p(y|x)$ which generates an utterance y given a source x and a language model $p(x)$. We assume that x is a substring of y, i.e., the source utterance can be obtained by marking words in y as a disfluency and effectively removing them from this utterance.

Johnson and Charniak (2004) experiment with variations on the language model; they report results for a bigram model, a trigram model, and a language model using the Charniak Parser (Charniak, 2001). Their parser model outperforms the bigram model by 5%. The channel model is based on the intuition that a reparandum and a repair are generally very alike: a repair is often almost a copy of the reparandum. In the training data, over 60% of the words in a reparandum are lexically identical to the words in the repair. Example 1 provides an example of this: half of the repair is lexically identical to the reparandum. The channel model therefore gives the highest probability when the reparandum and repair are lexically equivalent. When the potential reparandum and potential repair are not identical, the channel model performs deletion, insertion or substitution. The probabilities for these operations are defined on a lexical level and are derived from the training data. This channel model is formalised using a Synchronous Tree Adjoining Grammar (STAG) (Shieber and Schabes, 1990), which matches words from the reparandum to the repair. The weights for these STAG rules are learnt from the training text, where reparanda and repairs are aligned to each other using a minimum edit-distance string aligner.

For a given utterance, every possible utterance position might be the start of a reparandum, and every given utterance position thereafter might be the start of a repair (to limit complexity, a maximum distance between these two points is imposed). Every disfluency in turn can have an arbitrary length (again up to some maximum to limit complexity). After every possible disfluency other new reparanda and repairs might occur; the model does not attempt to generate crossing or nested disfluencies, although they do very occasionally occur in practice. To find the optimal selection for reparanda and repairs, all possibilities are calculated and the one with the highest probability is selected. A chart is filled with all the possible start and end positions of reparanda, interregna and repairs; each entry consists of a tuple $\langle rm_{\text{begin}}, ir_{\text{begin}}, rr_{\text{begin}}, rr_{\text{end}}\rangle$, where rm is the reparandum, ir is the interregnum and rr is the repair. A Viterbi algorithm is used to find the optimal path through the utterance, ranking each chart entry using the language model and channel model. The language model, a bigram model, can be easily calculated given the start and end positions of all disfluency components. The channel model is slightly more complicated because an optimal alignment between reparandum and repair needs to be calculated. This is done by extending each partial analysis by adding a word to the reparandum, the repair or both. The start position and end position of the reparandum and repair are given for this particular entry. The task of the channel model is to calculate the highest probable alignment between reparandum and repair. This is done by initialising with an empty reparandum and repair, and 'growing' the analysis one word at a time. Using a similar approach to that used in calculating the edit-distance between reparandum and repair, the reparandum and repair can both be extended with one of four operations: deletion (only the reparandum grows), insertion (only the repair grows), substitution (both grow), or copy (both grow). When the reparandum and the repair have their length corresponding to the current entry in the chart, the channel probability can be calculated. Since there are multiple alignment possibilities, we use dynamic programming to select the most probable solutions. The probabilities for insertion, deletion or substitution are estimated from the training corpus. We use a beam-search strategy to find the final optimum when combining the channel model and the language model.

3.2 Incrementality

Taking Johnson and Charniak's model as a starting point, we would like to develop an incremental version of that algorithm. We simulate incrementality by maintaining for each utterance to be processed an **end-of-prefix boundary**; tokens after this boundary are not available for the model to use. At each step in our incremental model, we advance this boundary by one token (the **increment**), until finally the entire utterance is available. We make use of the notion of a **prefix**, which is a substring of the utterance consisting of all tokens up to this boundary marker.

Just as in the non-incremental model, we keep track of all the possible reparanda and repairs in a chart. Every time the end-of-prefix boundary advances, we update the chart: we add all possible disfluencies which have the end position of the repair located one token before the end-of-prefix boundary, and we add all possible start points for the reparandum, interregna and repair, and end points for the reparandum and interregna, given the ordering constraints of these components.

In our basic incremental model, we leave the remainder of the algorithm untouched. When the end-of-prefix boundary reaches the end of the utterance, and thus the entire utterance is available, this model results in an identical analysis to that provided by the non-incremental model, since the chart contains identical entries, although calculated in a different order. Intuitively, this model should perform well when the current prefix is very close to being a complete utterance; and it should perform less well when a potential disfluency is still under construction, since these situations are not typically found in the training data. We will return to this point further below.

We do not change the training phase of the model and we assume that the optimal values found for the non-incremental model are also optimal for the incremental model, since most weights which need to be learned are based on lexical values. Other weights are bigram based values, and values dealing with unknown tokens (i.e., tokens which occur in the test data, but not in the training data); it is not unreasonable to assume these weights are identical or very similar in both the incremental and the non-incremental model.

4 Evaluation Models and Their Application

As well as evaluating the accuracy of the analysis returned at the end of the utterance, it seems reasonable to also evaluate how quickly and accurately an incremental algorithm detects disfluencies on a word-by-word basis as the utterance is processed. In this section, we provide the methodological background to our approach, and in Section 5.2 we discuss the performance of our model when evaluated in this way.

Incremental systems are often judged solely on the basis of their output when the utterance being processed is completed. Although this does give an insight into how well a system performs overall, it does not indicate how well the incremental aspects of the mechanism perform. In this section we present an approach to the evaluation of a model of speech repair detection which measures the performance of the incremental component.

One might calculate the accuracy over all prefixes using a simple word accuracy score. However, because each prefix is a superstring of each previous prefix, such a calculation would not be fair: tokens that appear in early in the utterance will be counted more often than tokens that appear later in the utterance. In theory, the analysis of the early tokens can change at each prefix, so arguably it would make sense to reevaluate the complete analysis so far at every step. In practice, however, these changes do not happen, and so this measurement would not reflect the performance of the system correctly.

Our approach is to define a measure of **responsiveness**: that is, how soon is a disfluency detected? We propose to measure responsiveness in two ways. The **time-to-detection** score indicates how many tokens following a disfluency are read before the given disfluency is marked as one; the **delayed accuracy** score looks n tokens back from the boundary of the available utterance and, when there is a gold standard disfluency-marked token at that distance, counts how often these tokens are marked correctly.

We measure the time-to-detection score by two numbers, corresponding to the number of tokens from the start of the reparandum and the number of tokens from the start of the repair. We do this because disfluencies can be of different lengths. We assume it is unlikely that a disfluency will be found before the reparandum is completed, since the reparandum itself is often fluent. We measure the time-to-detection by the first time a given disfluency appears as one.

Since the model is a statistical model, it is possible that the most probable analysis marks a given word at position j as a disfluency, while in the next prefix the word in the same position is now no longer marked as being disfluent. A prefix later this word might be marked as disfluent again. This presents us with a problem. How do we measure when this word was correctly identified as disfluent: the first time it was marked as such or the second time? Because of the possibility of such oscillations, we take the first marking of the disfluency as the measure point. Disfluencies which are never correctly detected are not part of the time-to-detection score.

Since the evaluation starts with disfluencies found by the model, this measurement has precision-like properties only. Consequently, there are easy ways to inflate the score artificially at the cost of recall. We address this by also calculating the delayed accuracy. This is calculated at each prefix by looking back n tokens from the prefix boundary, where $n = 0$ for the prefix boundary. For each n we calculate the accuracy score at that point over all prefixes. Each token is only assessed once given a set value of n, so we do not suffer from early prefixes being assessed more often. However, larger values of n do not take all tokens into account, since the last y tokens of an utterance will not play a part in the accuracy when $y < n$. Since we evaluate given a gold standard disfluency, this measurement has recall-like properties.

Together with the final accuracy score over the entire utterance, the time-to-detection and delayed accuracy scores provide different insights and together give a good measurement of the responsiveness and performance of the model.

Our incremental model has the same final accuracy as the original non-incremental model; this corresponds to an F-score (harmonic mean) of 0.778 on a word basis.

We found the average time to detection, measured in tokens for this model to be 8.3 measured from the start of reparandum and 5.1 from the start of repair. There are situations where disfluencies can be detected before the end of the repair; by counting from the start rather than the end of the disfluency components, we provide a way of scoring in such cases. To provide a better insight into what is happening, we also report the average distance since the start of the reparandum. We find that the time to detect is larger than the average repair length; this implies that, under this particular model, most disfluencies are only detected after the repair is finished. In fact the difference is greater than 1, which means that in most cases it takes one more token after the repair before the model identifies the disfluency.

Table 1 shows the delayed accuracy. We can see that the score first rises quickly after which the increases become much smaller. As mentioned above, a given disfluency detection in theory might oscillate. In practice, however, oscillating disfluencies are very rare, possibly because a bigram model operates on a very local level. Given that oscillation is rare, a quick stabilisation of the score indicates that, when we correctly detect a disfluency, this happens rather quickly after the disfluency has completed, since the accuracy for the large n is calculated over the same tokens as the accuracy for the smaller n (although not in the same prefix).

5 Disfluencies around Prefix Boundaries

5.1 Early detection algorithm

Our model uses a language model and a channel model to locate disfluencies. It calculates a language model probability for the utterance with the disfluency taken out, and it calculates the probability of the disfluency itself with the STAG channel model.

Consider the following example utterance fragment where a repair disfluency occurs:

$$\dots w_i \ \overbrace{rn_{i+1}\ rn_{i+2}}^{\text{reparandum}}\ \overbrace{rr_{i+3}\ rr_{i+4}}^{\text{repair}}\ w_{i+5} \dots \tag{3}$$

Here, the subscripts indicate token position in sequence; w is a token outside the disfluency; and rn is a reparandum being repaired by the repair rr. The language model estimates the continuation of the utterance without the disfluency. The model considers whether the utterance continuation after the disfluency is probable given the language model; the relevant bigram here is $p(rr_{i+3}|w_i)$, continuing with $p(rr_{i+4}|rr_{i+3})$. However, under the incremental model, it is possible the utterance has only been read as far as token $i + 3$, in which case the probability $p(w_{i+4}|w_{i+3})$ is undefined.

We would like to address the issue of looking beyond a disfluency under construction. We assume the issue of not being able to look for an utterance continuation after the repair component of the disfluency can be found back in the incremental model scores. A disfluency is usually only detected after the disfluency is completely uttered, and always requires one

n tokens back	**1**	**2**	**3**	**4**	**5**	**6**
accuracy	0.500	0.558	0.631	0.665	0.701	0.714

Table 1: delayed accuracy, n tokens back from the end of prefixes

n tokens back	**1**	**2**	**3**	**4**	**5**	**6**
accuracy	0.578	0.633	0.697	0.725	0.758	0.770

Table 2: delayed accuracy under the updated model

more token in the basic model. In the given instance this means it is unlikely that we will detect the disfluency before $i + 5$.

In order to make our model more responsive, we propose a change which makes it possible for the model to calculate channel probabilities and language model probabilities before the repair is completed. Assuming we have not yet reached the end of utterance, we would like to estimate the continuation of the utterance with the relevant bigram $p(rr_{i+4}|rr_{i+3})$. Since rr_{i+4} is not yet available we cannot calculate this probability. The correct thing to do is to sum over all possible continuations, including the end of utterance token (for the complete utterance, as opposed to the current prefix). This results in the following bigram estimation:

$$\sum_{t \in \text{vocabulary}} p(t|w_i) \tag{4}$$

This estimation is not one we need to derive from our data set, since p is a true probability. In this case, the sum over all possible continuations (this might include an end of utterance marker, in which case the utterance is already complete) equals 1. We therefore modify the algorithm so that it takes this into account. This solves the problem of the language model assessing the utterance with the disfluency cut out, when nothing from the utterance continuation after a disfluency is available.

The other issue which needs to be addressed is the alignment of the reparandum with the repair when the repair is not yet fully available. Currently the model is encouraged to align the individual tokens of the reparandum with those of the repair. The algorithm has lower estimations when the reparandum cannot be fully aligned with the repair because the reparandum and repair differ considerably in length.

We note that most disfluencies are very short: reparanda and repairs are often only one or two tokens each in length, and the interregnum is often empty. To remove the penalty for an incomplete repair, we allow the repair to grow one token beyond the prefix boundary; given the relative shortness of the disfluencies, this seems reasonable. Since this token is not available, we cannot calculate the lexical substitution value. Instead we define a new operation in the channel model: in addition to deletion, insertion, copy, and substitution, we add an additional substitution operation, the **incremental completion substitution**. This operation does not compete with the copy operation or the normal substitution operation, since it is only defined when the last token of the repair falls at the prefix boundary.

5.2 Results for the Early detection algorithm

The results of these changes are reflected in new time-to-detection and delayed accuracy scores. Again we calculated the time-to-detection, and found this to be 7.5 from the start of reparandum and 4.6 from the start of repair. Table 2 shows the results under the new early completion model using the delayed accuracy method. We see that the updated model has lower time-to-detection scores (close to a full token earlier); for delayed accuracy, we note that the scores stabilise in a similar fashion, but the scores for the updated model rise slightly more quickly.

6 Conclusions and Future Work

We have demonstrated an incremental model for finding speech disfluencies in spoken language transcripts. When we consider complete utterances, the incremental model provides identical results to those of a non-incremental model that delivers state-of-the-art accuracy in speech repair detection. We have investigated a number of measures which allow us to evaluate the model on an incremental level. Most disfluencies are identified very quickly, typically one or two tokens after the disfluency has been completed. We addressed the problems of the model around the end of prefix boundaries. These are repairs which are either still in the process of being uttered or have just been completed. We have addressed this issue by making some changes to how the model deals with prefix boundaries, and we have shown that this improves the responsiveness of the model.

The work reported in this paper uses a n-gram model as a language model and a STAG based model for the repair. We would like to replace the n-gram language model with a better language model. Previous work (Johnson and Charniak, 2004) has shown that disfluency detection can be improved by replacing the n-gram language model with a statistical parser. Besides a reported 5% accuracy improvement, this also provides a structural analysis, something which an n-gram model does not. We would like to investigate a similar extension in our incremental approach, which will require the integration of an incremental statistical parser with our noisy channel model. While transcripts of spoken texts come with manually annotated sentence boundaries, real time spoken language does not. The language model in particular takes these sentence boundaries into account. We therefore propose to investigate the properties of this model when sentence boundaries are removed.

Syntactic Scope Resolution in Uncertainty Analysis

Abstract

We show how the use of syntactic structure enables the resolution of hedge scope in a hybrid, two-stage approach to uncertainty analysis. In the first stage, a Maximum Entropy classifier, combining surface-oriented and syntactic features, identifies cue words. With a small set of hand-crafted rules operating over dependency representations in stage two, we attain the best overall result (in terms of both combined ranks and average F_1) in the 2010 CoNLL Shared Task.

1 Background—Motivation

Recent years have witnessed an increased interest in the analysis of various aspects of sentiment in natural language (Pang & Lee, 2008). The subtask of *hedge resolution* deals with the analysis of uncertainty as expressed in natural language, and the linguistic means (so-called hedges) by which speculation or uncertainty are expressed. Information of this kind is of importance for various mining tasks which aim at extracting factual data. Example (1), taken from the BioScope corpus (Vincze, Szarvas, Farkas, Móra, & Csirik, 2008), shows a sentence where uncertainty is signaled by the modal verb *may*.[1]

(1) {The unknown amino acid ⟨may⟩ be used by these species}.

The topic of the Shared Task at the 2010 Conference for Natural Language Learning (CoNLL) is hedge detection in biomedical literature—in a sense 'zooming in' on one particular aspect of the broader BioNLP Shared Task in 2009 (Kim, Ohta, Pyysalo, Kano, & Tsujii, 2009). It involves two subtasks: Task 1 is described as *learning to detect sentences containing uncertainty*; the objective of Task 2 is *learning to resolve the in-sentence scope of hedge cues* (Farkas, Vincze, Mora, Csirik, & Szarvas, 2010). The organizers further suggest: *This task falls within the scope of semantic analysis of sentences exploiting syntactic patterns [...].*

The utility of syntactic information within various approaches to sentiment analysis in natural language has been an issue of some debate (Wilson, Wiebe, & Hwa, 2006; Ng, Dasgupta, & Arifin, 2006), and the potential contribution of syntax clearly varies with the specifics of the task. Previous work in the hedging realm has largely been concerned with cue detection, i.e. identifying uncertainty cues such as *may* in (1), which are predominantly individual tokens (Medlock & Briscoe, 2007; Kilicoglu & Bergler, 2008). There has been little previous work aimed at actually resolving the scope of such hedge cues, which presumably constitutes a somewhat different and likely more difficult problem. Morante and Daelemans (2009) present a machine-learning approach to this task, using token-level, lexical information only. To this end, CoNLL 2010 enters largely uncharted territory, and it remains to be seen (a) whether syntactic analysis indeed is a necessary component in approaching this task and, more generally, (b) to what degree the specific task setup can inform us about the strong and weak points in current approaches and technology.

In this article, we investigate the contribution of syntax to hedge resolution, by reflecting on our experience in the CoNLL 2010 task.[2] Our CoNLL system submission ranked fourth (of 24) on Task 1 and third (of 15) on Task 2, for an overall best average result (there appears to be very limited overlap among top performers for the two subtasks).

[1] In examples throughout this paper, angle brackets highlight hedge cues, and curly braces indicate the scope of a given cue, as annotated in BioScope.

[2] It turns out, in fact, that all the top-performing systems in Task 2 of the CoNLLShared Task rely on syntactic information provided by parsers, either in features for machine learning or as input to manually crafted rules (Morante, Asch, & Daelemans, 2010; Rei & Briscoe, 2010).

Table 1: Summary statistics for the Shared Task training data.

This article transcends our CoNLL system description (Velldal, Øvrelid, & Oepen, 2010) in several respects, presenting updated and improved cue detection results (§ 3 and § 4), focusing on the role of syntactic information rather than on machine learning specifics (§ 5 and § 6), providing an analysis and discussion of Task 2 errors (§ 7), and generally aiming to gauge the value of available annotated data and processing tools (§ 8). We present a hybrid, two-level approach for hedge resolution, where a statistical classifier detects cue words, and a small set of manually crafted rules operating over syntactic structures resolve scope. We show how syntactic information—produced by a data-driven dependency parser complemented with information from a 'deep', hand-crafted grammar—contributes to the resolution of in-sentence scope of hedge cues, discussing various types of syntactic constructions and associated scope detection rules in considerable detail. We furthermore present a manual error analysis, which reveals remaining challenges in our scope resolution rules as well as several relevant idiosyncrasies of the preexisting BioScope annotation.

2 Task, Data, and System Basics

Task Definition and Evaluation Metrics Task 1 is a binary sentence classification task: identifying utterances as being *certain* or *uncertain*. Following common practice, this subtask is evaluated in terms of precision, recall, and F_1 for the 'positive' class, i.e. *uncertain*. In our work, we approach Task 1 as a byproduct of the full hedge resolution problem, labeling a sentence as *uncertain* if it contains at least one token classified as a hedge cue. In addition to the sentence-level evaluation for Task 1, we also present precision, recall, and F_1 for the cue-level.

Task 2 comprises two subtasks: cue detection and scope resolution. The official CoNLL evaluation does not tease apart these two aspects of the problem, however: Only an exact match of both the cue and scope bracketing (in terms of substring positions) will be counted as a success, again quantified in terms of precision, recall, and F_1. Discussing our results below, we report cue detection and scope resolution performance separately, and further put scope results into perspective against an upper bound based on the gold-standard cue annotation.

Besides the primary biomedical domain data, some annotated Wikipedia data was provided for Task 1, and participating systems are classified as *in-domain* (using exclusively the domain-specific data), *cross-domain* (combining both types of training data), or *open* (utilizing additional uncertainty-related resources). In our work, we focus on the interplay of syntax and the more challenging Task 2; we ignored the Wikipedia track in Task 1. Despite our using general NLP tools (see below), our system falls into the most restrictive, *in-domain* category.

Training and Evaluation Data The training data for the CoNLL 2010 Shared Task is taken from the BioScope corpus (Vincze et al., 2008) and consists of 14,541 'sentences' (or other root-level utterances) from biomedical abstracts and articles (see Table 1).[3] The BioScope corpus provides annotation for hedge cues as well as their scope. According to the annotation guidelines (Vincze et al., 2008), the annotation adheres to a principle of minimalism when it comes to hedge cues, i.e. the minimal unit expressing hedging is annotated. The inverse is true of scope annotations, which adhere to a principle of maximal scope—meaning that scope should be set to the largest syntactic

[3] As it was known beforehand that evaluation would draw on full articles only, we put more emphasis on the article subset of the training data, for example in cross validation testing and manual diagnosis of errors.

Table 2: Stacked dependency representation of example (1), with MaltParser and XLE annotations.

unit possible.

For evaluation purposes, the task organizers provided newly annotated biomedical articles, following the same general BioScope principles. The CoNLL 2010 evaluation data comprises 5,003 additional utterances (138,276 tokens), of which 790 are annotated as hedged. The data contains a total of 1033 cues, of which 87 are so-called multiword cues (i.e. cues spanning multiple tokens), comprising 1148 cue tokens altogether.

Stacked Dependency Parsing For syntactic analysis we employ the open-source MaltParser (Nivre, Hall, & Nilsson, 2006), a platform for data-driven dependency parsing. For improved accuracy and portability across domains and genres, we make our parser incorporate the predictions of a large-scale, general-purpose LFG parser—following the work of Øvrelid, Kuhn, and Spreyer (2009). A technique dubbed *parser stacking* enables the data-driven parser to learn, not only from gold standard treebank annotations, but from the output of another parser (Nivre & McDonald, 2008). This technique has been shown to provide significant improvements in accuracy for both English and German (Øvrelid et al., 2009), and a similar setup employing an HPSG grammar has been shown to increase domain independence in data-driven dependency parsing (Zhang & Wang, 2009). The stacked parser combines two quite different approaches—data-driven dependency parsing and 'deep' parsing with a handcrafted grammar—and thus provides us with a broad range of different types of linguistic information for the hedge resolution task.

MaltParser is based on a deterministic parsing strategy in combination with treebank-induced classifiers for predicting parse transitions. It supports a rich feature representation of the parse history in order to guide parsing and may easily be extended to take additional features into account. The procedure to enable the data-driven parser to learn from the grammar-driven parser is quite simple. We parse a treebank with the XLE platform (Crouch et al., 2008) and the English grammar developed within the ParGram project (Butt, Dyvik, King, Masuichi, & Rohrer, 2002). We then convert the LFG output to dependency structures, so that we have two parallel versions of the treebank—one gold standard and one with LFG annotation. We extend the gold standard treebank with additional information from the corresponding LFG analysis and train MaltParser on the enhanced data set.

Table 2 shows the enhanced dependency representation of example (1) above, taken from the training data. For each token, the parsed data contains information on the word form, lemma, and part of speech (PoS), as well as on the head and dependency relation in columns 6 and 7. The added XLE information resides in the FEATS column, and in the XLE-specific head and dependency columns 8 and 9. Parser outputs, which in turn form the basis for our scope resolution rules discussed in Section 5, also take this same form. The parser employed in this work is trained on the Wall Street Journal sections 2 – 24 of the Penn Treebank (PTB), converted to dependency format (Johansson & Nugues, 2007) and extended with XLE features, as described above. Parsing uses the arc-eager mode of MaltParser and an SVM with a polynomial kernel. When tested using 10-fold cross validation on the enhanced PTB, the parser achieves a labeled accuracy score of 89.8.

PoS Tagging and Domain Variation Our parser is trained on financial news, and although stacking with a general-purpose LFG parser is expected to aid domain portability, substantial differences in domain and genre are bound to negatively affect syntactic analysis (Gildea, 2001). MaltParser presupposes that inputs have been PoS tagged, leaving room for variation in preprocessing. On the one hand, we aim to make parser inputs maximally similar to its training data (i.e. the conventions established in the PTB); on the other hand we wish to benefit from specialized resources for the biomedical domain.

The GENIA tagger (Tsuruoka et al., 2005) is particularly relevant in this respect (as could be the GENIA Treebank proper[4]). However, we found that GENIA tokenization does not match the PTB conventions in about one out of five sentences (for example wrongly splitting tokens like '`390,926`' or '`Ca(2+)`'); also in tagging proper nouns, GENIA systematically deviates from the PTB. Hence, we adapted an in-house tokenizer (using cascaded finite-state rules) to the CoNLL task, run two PoS taggers in parallel, and eclectically combine annotations across the various preprocessing components—predominantly giving precedence to GENIA lemmatization and PoS hypotheses.

To assess the impact of improved, domain-adapted inputs on our hedge resolution system, we contrast two configurations: first, running the parser in the exact same manner as Øvrelid, Kuhn, and Spreyer (2010), we use TreeTagger (Schmid, 1994) and its standard model for English (trained on the PTB) for preprocessing; second, we give as inputs to the parser our refined tokenization and merged PoS tags, as described above. When evaluating the two modes of preprocessing on the articles subset of the training data, and using gold-standard cues, our system for resolving cue scopes (presented in § 5) achieves an F_1 of 66.31 with TreeTagger inputs, and 72.30 using our refined tokenization and tagger combination. These results underline the importance of domain adaptation for accurate syntactic analysis, and in the following we assume our hybrid in-house setup.

3 Stage 1: Identifying Hedge Cues

For the task of identifying hedge cues, we developed a binary maximum entropy (MaxEnt) classifier. The identification of cue words is used for (a) classifying sentences as certain/uncertain (Task 1), and (b) providing input to the syntactic rules that we later apply for resolving the in-sentence scope of the cues (Task 2). We also report evaluation scores for the sub-task of cue detection in isolation.

As annotated in the training data, it is possible for a hedge cue to span multiple tokens, e.g. as in *whether or not*. The majority of the multi-word cues in the training data are very infrequent, however, most occurring only once, and the classifier itself is not sensitive to the notion of multi-word cues. Instead, the task of determining whether a cue word forms part of a larger multi-word cue, is performed in a separate post-processing step (applying a heuristic rule targeted at only the most frequently occurring patterns of multi-word cues in the training data).

During development, we trained cue classifiers using a wide variety of feature types, both syntactic and surface-oriented. In the end, however, we found n-gram-based lexical features to have the greatest contribution to classifier performance. Our best-performing classifier so far (see 'Final' in Table 3) includes the following feature types: n-grams over forms (up to 2 tokens to the right), n-grams over base forms (up to 3 tokens left and right), PoS (from GENIA), subcategorization frames (from XLE), and phrase-structural coordination level (from XLE). Our CoNLL system description includes more details of the various other feature types that we experimented with (Velldal et al., 2010).

4 Cue Detection Evaluation

Table 3 summarizes the performance of our MaxEnt hedge cue classifier in terms of precision, recall and F_1, computed using the official Shared Task scorer script. The sentence-level scores correspond to Task 1 of the Shared Task, and the cue-level scores are based on the exact-match counts for full hedge cues (possibly spanning multiple tokens).

[4] Although the GENIA Treebank provides syntactic annotation in a form inspired by the PTB, it does not provide function labels. Therefore, our procedure for converting from constituency to dependency requires non-trivial adaptation before we can investigate the effects of retraining the parser against GENIA.

	Sentence Level			Cue Level		
Configuration	**Prec**	**Rec**	$\mathbf{F}_1$	**Prec**	**Rec**	$\mathbf{F}_1$
Baseline, Development	79.25	79.45	79.20	77.37	71.70	74.43
Final, Development	91.39	86.78	89.00	90.18	79.47	84.49
Final, Held-Out	85.61	85.06	85.33	81.97	76.41	79.10

Table 3: Isolated evaluation of the hedge cue classifier.

As the CoNLL test data was known beforehand to consist of articles only, in 10-fold cross validation for classifier development we tested exclusively against the articles segment, while always including all sentences from the abstracts in the training set. This corresponds to the development results in Table 3, while the held-out results are for the official Shared Task evaluation data (training on all the available training data). A model using only unigram features serves as a baseline.

5 Stage 2: Resolving Scope

Hedge scope may vary quite a lot depending on linguistic properties of the cue in question. In our approach to scope resolution we rely heavily on syntactic information, taken from the dependency structures proposed by both MaltParser and XLE, as well as on various additional features relating to specific syntactic constructions.

We constructed a small set of heuristic rules which define the scope for each cue detected in Stage 1. In developing these rules, we made use of the information provided by the guidelines for scope annotation in the BioScope corpus (Vincze et al., 2008), combined with manual inspection of the training data in order to further generalize over the phenomena discussed by Vincze et al. (2008) and work out interactions of constructions for various types of cues.

The rules take as input a parsed sentence which has been further tagged with hedge cues. They operate over the dependency structures and additional features provided by the parser. Default scope is set to start at the cue word and span to the end of the sentence (modulo punctuation), and this scope also provides the baseline for the evaluation of our rules. In the following, we discuss broad classes of rules, organized by categories of hedge cues. As there is no explicit representation of phrase or clause boundaries in our dependency universe, we assume a set of functions over dependency graphs, for example finding the left- or rightmost (direct) *dependent* of a given node, or transitively selecting left- or rightmost *descendants*.

Coordination The dependency analysis of coordination provided by our parser makes the first conjunct the head of the coordination. For cues that are coordinating conjunctions (PoS tag CC), such as *or*, we define the scope as spanning the whole coordinate structure, i.e. start scope is set to the leftmost dependent of the head of the coordination, e.g., *roX* in (2), and end scope is set to its rightmost dependent (conjunct), e.g., *RNAs* in (2). This analysis provides us with coordinations at various syntactic levels, such as NP and $\overline{\text{N}}$ (2), AP and AdvP, or VP (3):

(2) [...] the {roX genes ⟨or⟩ RNAs} recruit the entire set of MSL proteins [...]

(3) [...] the binding interfaces are more often {kept ⟨or⟩ even reused} rather than lost in the course of evolution.

Adjectives We distinguish between adjectives (JJ) in *attributive* (NMOD) function and adjectives in *predicative* (PRD) function. Attributive adjectives take scope over their (nominal) head, with all its dependents, as in (4) and (5):

(4) The {⟨possible⟩ selenocysteine residues} are shown in red, [...]

(5) Extensive analysis of the flanks failed to show any hallmarks of {⟨putative⟩ transposons that might be associated with this RAG1-like protein}, [...]

For adjectives in a predicative function the scope includes the subject argument of the head verb (the copula), as well as a (possible) clausal argument, as in (6). The scope does not, however, include expletive subjects, as in (7).

(6) Therefore, {the unknown amino acid, if it is encoded by a stop codon, is ⟨unlikely⟩ to exist in the current databases of microbial genomes}.

(7) For example, it is quite {⟨likely⟩ that there exists an extremely long sequence that is entirely unique to U}.

Verbs The scope of verbal cues is a bit more complex and depends on several factors. In our rules, we distinguish *passive* usages from active usages, *raising* verbs from non-raising verbs, and the presence or absence of a subject-control embedding context. The scopes of both passive and raising verbs include the subject argument of their head verb, as in (8) and (9), unless it is an expletive pronoun, as in (10).

(8) {Interactions determined by high-throughput methods are generally ⟨considered⟩ to be less reliable than those obtained by low-throughput studies} 1314 and as a consequence [...]

(9) {Genomes of plants and vertebrates ⟨seem⟩ to be free of any recognizable Transib transposons} (Figure 1).

(10) It has been {⟨suggested⟩ that unstructured regions of proteins are often involved in binding interactions, particularly in the case of transient interactions} 77.

In the case of subject control involving a hedge cue, specifically modals, subject arguments are included in scopes where the controller heads a passive construction or a raising verb, as in example (1) above, repeated here for convenience:

(11) {The unknown amino acid ⟨may⟩ be used by these species}.

In general, the end scope of verbs should extend over the minimal clause that contains the verb in question. In terms of dependency structures, we define the clause boundary as comprising the chain of descendants of a verb which is not intervened by a token with a higher attachment in the graph than the verb in question. In example (8) for instance, the sentence-level conjunction *and* marks the end of the clause following the cue *considered*.

Prepositions and Adverbs Cues that are tagged as prepositions (including some complementizers) take scope over their argument, with all its descendants, (12). Adverbs take scope over their head with all its (non-subject) syntactic descendants (13).

	Configuration	**F$_1$**
BSP	Default, Gold Cues	45.21
	Rules, Gold Cues	72.31
	Rules, System Cues	64.77
BSE	Rules, Gold Cues	66.73
	Rules, System Cues	55.75

Table 4: Evaluation of scope resolution rules.

(12) {⟨Whether⟩ the codon aligned to the inframe stop codon is a nonsense codon or not} was neglected at this stage.

(13) These effects are {⟨probably⟩ mediated through the 1,25(OH)2D3 receptor}.

Multi-Word Cues In the case of multi-word cues, such as *indicate that* or *either ... or*, we need to determine the head of the multi-word unit. We then set the scope of the whole unit to the scope of the head token.

As an illustration of rule processing, consider our running example (11), with its syntactic analysis as shown in Table 2 above. This example invokes a variety of syntactic properties, including parts of speech, argumenthood, voice etc. Initially, the scope of the hedge cue is set to default scope. Then the subject control rule is applied, which checks the properties of the verbal argument *used*, going through a chain of verbal dependents from the modal verb. Since it is marked as passive in the LFG analysis, the start scope is set to include the subject of the cue word (the leftmost descendant in its `SBJ` dependent).

6 Rule Evaluation

Table 4 summarizes scope resolution performance (viewed as a an isolated subtask) for various configurations, both against the articles section of the CoNLL training data (dubbed BSP) and against the held-out evaluation data (BSE). First of all, we note that the ‘default scope’ baseline is quite strong: unconditionally extending the scope of a cue to the end of the sentence yields an F$_1$ of 45.21. Given gold standard cue information, our scope rules improve on the baseline by 27 points on the articles section of the data set, for an F$_1$ of 72.31; with system-assigned hedge cues, our rules still achieve an F_1 of 64.77. Note that scope resolution scores based on classified cues also yield the end-to-end system evaluation for Task 2.

The bottom rows of Table 4 show the evaluation of scope rules on the CoNLL held-out test data. Using system cues, scope resolution on the held-out data scores at 55.75 F_1. Comparing to the result on the (articles portion of the) training data, we observe a substantial drop in performance (of six points with gold-standard cues, nine points with system cues). There are several possible explanations for this effect. First of all, there may well be a certain degree of overfitting of our rules to the training data. The held-out data may contain hedging constructions that are not covered by our current set of scope rules, or annotation of parallel constructions may in some cases differ in subtle ways (see § 7 below). Moreover, scope resolution performance is of course influenced by cue detection (see Table 3). The cue-level F_1 of our system on the held-out data set is 79.10, compared to 84.49 (using cross validation) on the training data. This drop in cue-level performance appears to affect classification precision far more than recall. Of course, given that our heuristics for identifying multi-word cues were based on patterns extracted from the training data, some loss in the cue-level score was expected.

7 Error Analysis

To start shedding some light on the significance of our results, we performed a manual error analysis on the article portion of the training material (BSP), with two of the authors (trained linguists) working in tandem. Using gold-standard cues, our scope resolution rules fail to exactly replicate the target annotation in 185 (of 668) cases, corresponding to 72.31 F_1 in Table 4 above. Our evaluators reviewed and discussed these 185 cases, classifying 156 (84 %) as genuine system errors, 22 (12 %) as likely[5] annotation errors, and a remaining seven cases as involving controversial or seemingly arbitrary decisions.

The two most frequent classes of system errors pertain (a) to the recognition of phrase and clause boundaries and (b) to not dealing successfully with relatively superficial properties of the text. Examples (14) and (15) illustrate the first class of errors, where in addition to the gold-standard annotation we use vertical bars (‘|’) to indicate scope predictions of our system.

(14) [...] {the reverse complement |mR of m will be ⟨considered⟩ to be [...]|}

(15) This |{⟨might⟩ affect the results} if there is a systematic bias on the composition of a protein interaction set|.

In our syntax-driven approach to scope resolution, system errors will almost always correspond to a failure in determining constituent boundaries, in a very general sense. However, specifically example (15) is indicative of a key challenge in this task, where adverbials of condition, reason, or contrast frequently attach within the dependency domain of a hedge cue, yet are rarely included in the scope annotation.

Example (16) demonstrates our second frequent class of system errors. One in six items in the BSP training data contains a sentence-final parenthesized element or trailing number, as for example (2), (9), or (10) above; most of these are bibliographic or other in-text references, which are never included in scope annotation. Hence, our system includes a rule to ‘back out’ from trailing parentheticals; in examples like (16), however, syntax does not make explicit the contrast between an in-text reference vs. another type of parenthetical.

(16) More specifically, {|the bristle and leg phenotypes are ⟨likely⟩ to result from reduced signaling by Dl| (and not by Ser)}.

Moving on to apparent annotation errors, the rules for inclusion (or not) of the subject in the scope of verbal hedge cues and decisions on boundaries (or internal structure) of nominals

[5] In some cases, there is no doubt that annotation is erroneous, i.e. in violation of the available annotation guidelines (Vincze et al., 2008) or in conflict with otherwise unambiguous patterns. In other cases, however, judgments are necessarily based on generalizations made by the evaluators, i.e. assumptions about the underlying system and syntactic analyses implicit in the BioScope annotations. Furthermore, selecting items for manual analysis that do not align with the predictions made by our scope resolution rules is likely to bias our sample, such that our estimated proportion of 12 % annotation errors cannot be used to project an overall error rate.

seem problematic—as illustrated in examples (17) to (22).[6]

(17) [...] and |this is also {⟨thought⟩ to be true for the full protein interaction networks we are modeling}|.

(18) [...] {Neur |⟨can⟩ promote Ser signaling|}.

(19) |Some of the domain pairs {⟨seem⟩ to mediate a large number of protein interactions, thus acting as reusable connectors}|.

(20) One {|⟨possible⟩ explanation| is functional redundancy with the mouse Neur2 gene}.

(21) [...] |redefinition of {one of them is ⟨feasible⟩}|.

(22) |The {Bcl-2 family ⟨appears⟩ to function [...]}|.

Finally, the difficult corner cases invoke non-constituent coordination, ellipsis, or NP-initial focus adverbs—and of course interactions of the phenomena discussed above. Without making the syntactic structures assumed explicit, it is often very difficult to judge such items.

8 Reflections — Outlook

Our combination of stacked dependency parsing and hand-crafted scope resolution rules proved adequate for the CoNLL 2010 competition, confirming the central role of syntax in this task. With a comparatively small set of rules (implemented in a few hundred lines of code), constructed through roughly two full weeks of effort (studying BioScope annotations and developing rules), our CoNLL system achieved an end-to-end F_1 of 55.33 on Task 2.[7] The two submissions with better results (at 57.32 and 55.65 F_1) represent groups who have pioneered the hedge analysis task in previous years (Morante et al., 2010; Rei & Briscoe, 2010). Scores for other 'in-domain' participants range from 52.24 to 2.15 F_1. Doubtless there is room for straightforward extension: for example retraining our parser on the GENIA Treebank, further improving the cue classifier, and refining scope resolution rules in the light of the error analysis above.

At the same time, we remain mildly ambivalent about the long-term impact of some of the specifics of the 2010 CoNLL task. Shared tasks (i.e. system bake-offs) have become increasingly popular in past years, and in some subfields (e.g. IE, SMT, or dependency parsing) high-visibility competitions can shape community research agendas. Hence, even at this early stage, it seems appropriate to reflect on the possible conclusions to be drawn from the 2010 hedge resolution task. First, we believe the harsh 'exact substring match' evaluation metric underestimates the degree to which current technology can solve this problem; furthermore, idiosyncratic, string-level properties (e.g. the exact treatment of punctuation or parentheticals) may partly obscure the interpretation of methods used and corresponding system performance.

These effects are compounded by some concerns about the quality of available annotation. Even though we tried fine-tuning our cross validation testing to the nature of the evaluation data (comprising only articles), our system performs substantially worse on the newly annotated CoNLL test data, in both stages.[8] In our view, the annotation of hedge cues and scopes ideally would be overtly related to at least some level of syntactic annotation—as would in principle be possible for the segment of BioScope drawing on the abstracts of the GENIA Treebank.

Acknowledgements

We are grateful to the organizers of the 2010 CoNLL Shared Task and creators of the BioScope resource; first, for engaging in these kinds of community service, and second for many in-depth discussions of annotation and task details. We thank our colleagues at the Universities of Oslo and Potsdam for their comments and support.

[6] Like in the presentation of system errors, we include scope predictions of our own rules here too, which we believe to be correct in these cases. Also in this class of errors, we find the occasional 'uninteresting' mismatch, for example related to punctuation marks and inconsistencies around parentheses.

[7] In § 4 and § 6 above, we report scores for a slightly improved version of our system, where (after the official CoNLL submission date) we eliminated a bug related to the treatment of sentence-initial whitespace in the XML annotations. At an end-to-end F_1 of 55.75, this system would outrank the second best performer in Task 2.

[8] We are leaving open the possibility to further refine our system; we have therefore abstained from an error analysis on the evaluation data so far.
