Message from the General Chair

Welcome to NAACL-HLT 2015 – at its 14^{th} edition! Computational Linguistics has grown into one of the most exciting and diverse research communities, with an ever increasing number of researchers, many big and small companies, and a vibrant community of learners eager to get prepared to take on some of the fun and exciting challenges in the field. This year's NAACL-HLT conference is a testimony to the vibrancy and vitality of this community.

Some of the highlights of this year's program include two excellent invited speakers – Lillian Lee from Cornell and Fei-fei Li from Stanford – who will talk about the exciting research going on at the intersection of our field with social sciences and computer vision; many interesting paper presentations on cutting-edge research in computational linguistics, culminating with three best paper awards that will be presented in a plenary session during the last day of the conference; several excellent student-authored papers and dissertation proposals as part of the student research workshop; many exciting demos showing the latest in terms of developed systems available in our field; six tutorials on some of the most up-and-coming research topics in computational linguistics; several workshops on diverse topics ranging from multiword expressions and metaphors to clinical psychology and educational applications, including thirteen (!) one-day workshops and SEMEVAL as a two-day workshop; the fourth joint conference on lexical and computational semantics *SEM as a collocated conference; and, last but not least: a country line dance lesson!

As with any event of this scale, it would have not been possible without the hard work of a wonderful group of people. I would like to thank Priscilla Rasmussen for the zillions of bits and pieces that she has been doing on an everyday basis, to make sure that every single logistical detail of the forthcoming NAACL-HLT was ironed out. It is no overstatement to say that the success (and fun!) of this year's conference is in large part due to Priscilla.

I am also grateful to Hal Daumé III for getting us started on this "NAACL-HLT 2015" journey, and being always willing to help with advice and information from his experience from previous years. Lucy Vanderwende and Daniel Marcu have also graciously agreed to "pass the baton" conversations that were very helpful and informative.

I was extremely fortunate to have the chance to work with the best committee ever: Joyce Chai and Anoop Sarkar (program chairs); Cornelia Caragea and Bing Liu (workshop co-chairs); Yang Liu and Thamar Solorio (tutorial co-chairs); Shibamouli Lahiri, Karen Mazidi and Alisa Zhila (student co-chairs) and Diana Inkpen and Smaranda Muresan (faculty advisors) for the student research workshop; Matt Gerber, Catherine Havasi, and Finley Lacatusu (demo co-chairs); Annie Louise (student volunteer coordinator); Kevin Cohen (local sponsorship chair); Saif Mohammad (publicity chair); Matt Post and Adam Lopez (publication co-chairs); Peter Ljunglöf (website chair); Aurelia Bunescu (handbook cover designer); Graeme Hirst and Joel Tetreault (treasurers); Asli Celikyilmaz and Julia Hockenmaier (sponsorship co-chairs).

I am also grateful to our sponsors for their generous contributions, which made the conference possible: A9, Baobab, Bloomberg, Digital Roots, Goldman Sachs, Google, IBM, Information Sciences Institute, National Science Foundation, Nuance, SDL, University of Washington Computational Linguistics, Yahoo Labs.

Finally, my gratitude goes to everyone else who contributed to the success of the conference: area chairs, workshop organizers, tutorial presenters, student mentors, and reviewers. And of course my deepest thanks to you, the attendees: you are the life and spirit of this entire conference.

Here is to an enjoyable NAACL-HLT 2015, and many more exciting conferences to come!

Rada Mihalcea, University of Michigan
NAACL 2015 General Chair

Message from the Program Chairs

Welcome to the 2015 Conference of the North American Chapter of the Association for Computational Linguistics – Human Language Technologies or NAACL HLT 2015 for short.

This year, we received the largest number of submissions in the history of NAACL: a total of 714 submissions with 402 long paper submissions and 312 short papers submissions. From these, 117 long papers (62 oral presentations and 55 poster presentations) and 69 short papers (24 oral presentations and 45 poster presentations) were accepted to appear at the conference.

The submissions to NAACL HLT 2015 were assigned to 18 technical areas including a new topic area called *Language and Vision*. This track was introduced with an intent to broaden research on natural language processing that is situated in a rich visual and perceptual context. We received 16 submissions for this area and seven of them will be presented at the conference.

For NAACL HLT 2015 we initiated a meta review process, where each paper received an analysis of the merits of the paper from the area chair's perspective that was based on the reviewer comments, the reviewer discussion and the author rebuttal. We found the meta reviews very helpful in consolidating the reviews and providing justifications for final decisions. As this was an experiment this year, the meta reviews were not sent to the authors.

Based on comments from reviewers, nominations from area chairs, and rankings from the best paper committee, three papers were selected to receive the best paper awards at the conference.

Continuing the tradition, NAACL HLT 2015 will feature 19 papers which were accepted for publication in the Transactions of the Association for Computational Linguistics (TACL). The TACL papers were split into 10 oral presentations and 9 poster presentatons.

We are very pleased to have two exciting keynote talks: one by Professor Lillian Lee (Cornell University) and the other by Professor Fei-fei Li (Stanford University).

There are many people to thank for who have worked diligently to make NAACL HLT 2015 possible. Thanks to the 32 area chairs for their hard work on recruiting reviewers, managing reviews, leading discussions, and making recommendations. All the area chairs are listed in the Program Committee section of the Front Matter. Thanks to Chris Callison-Burch, David Mimno, Sameer Pradhan, and Philip Resnik for stepping in to serve as area co-chairs at the last minute when we were faced with an unexpectedly large number of submissions in some tracks.

Following what was done in the last NAACL conference, we used the paper assignment tool developed by Mark Dredze to assign papers to reviewers. Thanks to Mark Dredze and Jiang Guo for their hard work on assigning papers to reviewers based on their preferences. We had to especially rely on this tool this year because the distribution of submissions across areas was very different from past trends.

This program certainly would not be possible without the help of the 460 reviewers. Their names are listed in the Program Committee section. In particular, 116 reviewers from this list were recognized by the area chairs as best reviewers who have turned in exceptionally well-written and constructive reviews and who have actively engaged in the post-rebuttal discussions. The names of the best reviewers are

marked with * in the list of reviewers.

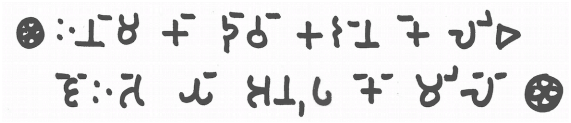
We are also indebted to the best paper award committee which consists of Claire Cardie, Daniel Gildea, Daniel Marcu, and Fernando Pereira. Their time and effort in recommending the best paper awards is much appreciated.

We also would like to thank Hal Daumé III, Kristina Toutanova, and Lucy Vanderwende for generously sharing their experience in organizing prior NAACL/ACL conferences and for their advice. We are grateful for the guidance and the support of the NAACL president Hal Daumé III, and the NAACL board. We also would like to thank the publication co-chairs Matt Post and Adam Lopez for putting together the proceedings and the conference handbook; and Paolo Gai and Rich Gerber from Softconf for always being responsive to our requests.

We would like to thank the ACL Business Manager Priscilla Rasmussen. She was our *go to* person who knew all details of the conference in and out. We are very grateful for her help.

Finally, this conference could not have happened without the efforts of the general chair, Rada Mihalcea. She made sure the various sections of NAACL organization worked well together. Her monthly newsletters informed all the organizers about what was being done by everyone else. We are very thankful for her leadership in the organization of NAACL HLT 2015.

We hope you will enjoy NAACL HLT 2015!



NAACL HLT 2015 Program Co-Chairs
Joyce Chai, Michigan State University
Anoop Sarkar, Simon Fraser University

Organizing Committee

General Chair
Rada Mihalcea, University of Michigan, USA

Local Arrangements Chair
Priscilla Rasmussen, ACL Business Manager

Program Committee Co-chairs
Joyce Chai, Michigan State University, USA
Anoop Sarkar, Simon Fraser University, Canada

Workshop Co-chairs
Cornelia Caragea, University of North Texas, USA
Bing Liu, University of Illinois at Chicago, USA

Tutorial Co-chairs
Yang Liu, University of Texas at Dallas, USA
Thamar Solorio, University of Alabama at Birmingham, USA

Student Research Workshop Co-chairs
Student Co-chairs
Shibamouli Lahiri, University of Michigan, USA
Karen Mazidi, University of North Texas, USA
Alisa Zhila, Instituto Politécnico Nacional (National Polytechnic Institute), Mexico
Faculty Advisors
Diana Inkpen, University of Ottawa, Canada
Smaranda Muresan, Columbia University, USA

Demo Co-chairs
Matt Gerber, University of Virginia, USA
Catherine Havasi, Massachusetts Institute of Technology, USA
Finley Lacatusu, Language Computer Corporation, USA

Student Volunteer Coordinator
Annie Louis, University of Edinburgh, UK

Reviewing Coordinators
Mark Dredze, Johns Hopkins University
Jiang Guo, Harbin Institute of Technology

Local Sponsorship Chair
Kevin B. Cohen, University of Colorado, USA

Publicity Chair
Saif M. Mohammad, National Research Council Canada

Publication Co-chairs
Matt Post, John Hopkins University, USA
Adam Lopez, University of Edinburgh, UK

Conference Handbook Editor
Matt Post, Johns Hopkins University

Website Chair
Peter Ljunglöf, University of Gothenburg and Chalmers University of Technology, Sweden

Business Manager
Priscilla Rasmussen

Program Committee

Program Committee Co-chairs
Joyce Chai, Michigan State University, USA
Anoop Sarkar, Simon Fraser University, Canada

Area Chairs
Dialogue and Interactive Systems
Jason D. Williams, Microsoft Research

Discourse and Pragmatics
Ani Nenkova, University of Pennsylvania
Vincent Ng, University of Texas at Dallas

Generation and Summarization
Chris Callison-Burch, University of Pennsylvania
Fei Liu, Carnegie Mellon University

Information Extraction and Question Answering
Alan Ritter, The Ohio State University
Bowen Zhou, IBM Research

Information Retrieval
David Smith, Northeastern University

Language and Vision
Julia Hockenmaier, University of Illinois at Urbana-Champaign

Language Resources and Evaluation
Will Lewis, Microsoft Research
Sameer Pradhan, Harvard University

Linguistic and Psycholinguistic Aspects of CL
William Schuler, The Ohio State University

Machine Learning for NLP
Amarnag Subramanya, Google Research
Tong Zhang, Baidu Inc. and Rutgers University

Machine Translation
Bill Byrne, Cambridge University
Hany Hassan, Microsoft Research
Kevin Knight, Information Sciences Institute, University of Southern California
Haitao Mi, IBM Research

NLP for Web, Social Media and Social Sciences
Brendan O'Connor, University of Massachusetts
Philip Resnik, University of Maryland

NLP-enabled Technology
Richard Socher, Stanford University

Phonology, Morphology, and Word Segmentation
Sami Virpioja, Lingsoft and Aalto University

Semantics
Dipanjan Das, Google

Luke Zettlemoyer, University of Washington

Sentiment Analysis and Opinion Mining
Saif M. Mohammad, National Research Council Canada
Jerry Zhu, University of Wisconsin-Madison

Spoken Language Processing
Xiaodong He, Microsoft Research

Tagging, Chunking, Syntax, and Parsing
Noah Smith, Carnegie Mellon University
Yue Zhang, Singapore University of Technology and Design

Text Categorization and Topic Models
Jordan Boyd-Graber, University of Colorado at Boulder
David Mimno, Cornell University

Primary Reviewers

The list of all reviewers for NAACL HLT 2015. The area chairs also picked the best reviewers in their track. These best reviewers are marked with an asterisk in the list which is alphabetical on the last name. Multiple asterisks mean that multiple area chairs chose that reviewer to be the best in their track.

Amjad Abu-Jbara, Mikhail Ageev, Eneko Agirre, *Gregory Aist, Jan Alexandersson, *James Allan, Jesse Anderton, Jacob Andreas, Nicholas Andrews, Gabor Angeli, *Yoav Artzi, Nicholas Asher, Javed Aslam, Michael Auli, amittai axelrod.

Invited Talk: “Big data pragmatics!”, or, “Putting the ACL in computational social science”, or, if you think these title alternatives could turn people on, turn people off, or otherwise have an effect, this talk might be for you.

Lillian Lee

Cornell University

Abstract

What effect does language have on people?

You might say in response, "Who are you to discuss this problem?" and you would be right to do so; this is a Major Question that science has been tackling for many years. But as a field, I think natural language processing and computational linguistics have much to contribute to the conversation, and I hope to encourage the community to further address these issues.

This talk will focus on the effect of phrasing, emphasizing aspects that go beyond just the selection of one particular word over another. The issues we’ll consider include: Does the way in which something is worded in and of itself have an effect on whether it is remembered or attracts attention, beyond its content or context? Can we characterize how different sides in a debate frame their arguments, in a way that goes beyond specific lexical choice (e.g., "pro-choice" vs. "pro-life")? The settings we’ll explore range from movie quotes that achieve cultural prominence; to posts on Facebook, Wikipedia, Twitter, and the arXiv; to framing in public discourse on the inclusion of genetically-modified organisms in food.

Joint work with Lars Backstrom, Justin Cheng, Eunsol Choi, Cristian Danescu-Niculescu-Mizil, Jon Kleinberg, Bo Pang, Jennifer Spindel, and Chenhao Tan.

Biography

Lillian Lee is a professor of computer science and of information science at Cornell University, and the co-Editor-in-Chief, together with Michael Collins, of Transactions of the ACL. Her research interests include natural language processing and computational social science. She is the recipient of the inaugural Best Paper Award at HLT-NAACL 2004 (joint with Regina Barzilay), a citation in “Top Picks: Technology Research Advances of 2004” by Technology Research News (also joint with Regina Barzilay), and an Alfred P. Sloan Research Fellowship; and in 2013, she was named a Fellow of the Association for the Advancement of Artificial Intelligence (AAAI). Her group’s work has received several mentions in the popular press, including The New York Times, NPR’s All Things Considered, and NBC’s The Today Show, and one of her co-authored papers was publicly called “boring” by Youtubers Rhett and Link, in a video viewed over 1.8 million times.

Invited Talk: A Quest for Visual Intelligence in Computers

Fei-Fei Li

Stanford University

Abstract

More than half of the human brain is involved in visual processing. While it took mother nature billions of years to evolve and deliver us a remarkable human visual system, computer vision is one of the youngest disciplines of AI, born with the goal of achieving one of the loftiest dreams of AI. The central problem of computer vision is to turn millions of pixels of a single image into interpretable and actionable concepts so that computers can understand pictures just as well as humans do, from objects, to scenes, activities, events and beyond. Such technology will have a fundamental impact in almost every aspect of our daily life and the society as a whole, ranging from e-commerce, image search and indexing, assistive technology, autonomous driving, digital health and medicine, surveillance, national security, robotics and beyond. In this talk, I will give an overview of what computer vision technology is about and its brief history. I will then discuss some of the recent work from my lab towards large scale object recognition and visual scene story telling. I will particularly emphasize on what we call the "three pillars" of AI in our quest for visual intelligence: data, learning and knowledge. Each of them is critical towards the final solution, yet dependent on the other. This talk draws upon a number of projects ongoing at the Stanford Vision Lab.

Biography

Dr. Fei-Fei Li is an Associate Professor in the Computer Science Department at Stanford, and the Director of the Stanford Artificial Intelligence Lab and the Stanford Vision Lab. Her research areas are in machine learning, computer vision and cognitive and computational neuroscience, with an emphasis on Big Data analysis. Dr. Fei-Fei Li has published more than 100 scientific articles in top-tier journals and conferences, including Nature, PNAS, Journal of Neuroscience, CVPR, ICCV, NIPS, ECCV, IJCV, IEEE-PAMI, etc. Dr. Fei-Fei Li obtained her B.A. degree in physics from Princeton in 1999 with High Honors, and her PhD degree in electrical engineering from California Institute of Technology (Caltech) in 2005. She joined Stanford in 2009 as an assistant professor, and was promoted to associate professor with tenure in 2012. Prior to that, she was on faculty at Princeton University (2007-2009) and University of Illinois Urbana-Champaign (2005-2006). Dr. Fei-Fei Li is a speaker at TED2015 main conference, a recipient of the 2014 IBM Faculty Fellow Award, 2011 Alfred Sloan Faculty Award, 2012 Yahoo Labs FREP award, 2009 NSF CAREER award, the 2006 Microsoft Research New Faculty Fellowship and a number of Google Research awards. Work from Fei-Fei's lab have been featured in a number of popular press magazines and newspapers including New York Times, Wired Magazine, and New Scientists.

Table of Contents

Conference Program

Monday, June 1, 2015

07:30–08:45 ***Registration and Breakfast***

08:45–09:00 *Welcome to NAACL HLT 2015*
Rada Mihalcea

09:00–10:10 *Invited Talk: "Big data pragmatics!", or, "Putting the ACL in computational social science", or, if you think these title alternatives could turn people on, turn people off, or otherwise have an effect, this talk might be for you*
Lillian Lee

10:10–10:40 ***Break***

10:40–12:20 **Session 1A: Semantics (Long Papers)**

10:40–11:05 *Unsupervised Induction of Semantic Roles within a Reconstruction-Error Minimization Framework*
Ivan Titov and Ehsan Khoddam

11:05–11:30 *Predicate Argument Alignment using a Global Coherence Model*
Travis Wolfe, Mark Dredze and Benjamin Van Durme

11:30–11:55 *Improving unsupervised vector-space thematic fit evaluation via role-filler prototype clustering*
Clayton Greenberg, Asad Sayeed and Vera Demberg

11:55–12:20 *A Compositional and Interpretable Semantic Space*
Alona Fyshe, Leila Wehbe, Partha P. Talukdar, Brian Murphy and Tom M. Mitchell

Monday, June 1, 2015 (continued)

10:40–12:20 Session 1B: Tagging, Chunking, Syntax and Parsing (Long + TACL Papers)

10:40–11:05 *Randomized Greedy Inference for Joint Segmentation, POS Tagging and Dependency Parsing*
Yuan Zhang, Chengtao Li, Regina Barzilay and Kareem Darwish

11:05–11:30 *An Incremental Algorithm for Transition-based CCG Parsing*
Bharat Ram Ambati, Tejaswini Deoskar, Mark Johnson and Mark Steedman

11:30–11:55 *Because Syntax Does Matter: Improving Predicate-Argument Structures Parsing with Syntactic Features*
Corentin Ribeyre, Eric Villemonte de la Clergerie and Djamé Seddah

11:55–12:20 *[TACL] Exploring Compositional Architectures and Word Vector Representations for Prepositional Phrase Attachment*
Yonatan Belinkov, Tao Lei, Regina Barzilay, Amir Globerson

10:40–12:20 Session 1C: Information Retrieval, Text Categorization, Topic Modeling (Long Papers)

10:40–11:05 *A Hybrid Generative/Discriminative Approach To Citation Prediction*
Chris Tanner and Eugene Charniak

11:05–11:30 *Weakly Supervised Slot Tagging with Partially Labeled Sequences from Web Search Click Logs*
Young-Bum Kim, Minwoo Jeong, Karl Stratos and Ruhi Sarikaya

11:30–11:55 *Not All Character N-grams Are Created Equal: A Study in Authorship Attribution*
Upendra Sapkota, Steven Bethard, Manuel Montes and Thamar Solorio

11:55–12:20 *Effective Use of Word Order for Text Categorization with Convolutional Neural Networks*
Rie Johnson and Tong Zhang

12:20–14:00 ***Lunch***

14:00–15:15 Session 2A: Generation and Summarization (Long Papers)

14:00–14:25 *Transition-Based Syntactic Linearization*
Yijia Liu, Yue Zhang, Wanxiang Che and Bing Qin

14:25–14:50 *Extractive Summarisation Based on Keyword Profile and Language Model*
Han Xu, Eric Martin and Ashesh Mahidadia

14:50–15:15 *HEADS: Headline Generation as Sequence Prediction Using an Abstract Feature-Rich Space*
Carlos A. Colmenares, Marina Litvak, Amin Mantrach and Fabrizio Silvestri

14:00–15:15 Session 2B: Language and Vision (Long Papers)

14:00–14:25 *What's Cookin'? Interpreting Cooking Videos using Text, Speech and Vision*
Jonathan Malmaud, Jonathan Huang, Vivek Rathod, Nicholas Johnston, Andrew Rabinovich and Kevin Murphy

14:25–14:50 *Combining Language and Vision with a Multimodal Skip-gram Model*
Angeliki Lazaridou, Nghia The Pham and Marco Baroni

14:50–15:15 *Discriminative Unsupervised Alignment of Natural Language Instructions with Corresponding Video Segments*
Iftekhar Naim, Young C. Song, Qiguang Liu, Liang Huang, Henry Kautz, Jiebo Luo and Daniel Gildea

14:00–15:15 Session 2C: NLP for Web, Social Media and Social Sciences (Long Papers)

14:00–14:25 *TopicCheck: Interactive Alignment for Assessing Topic Model Stability*
Jason Chuang, Margaret E. Roberts, Brandon M. Stewart, Rebecca Weiss, Dustin Tingley, Justin Grimmer and Jeffrey Heer

14:25–14:50 *Inferring latent attributes of Twitter users with label regularization*
Ehsan Mohammady Ardehaly and Aron Culotta

14:50–15:15 *A Neural Network Approach to Context-Sensitive Generation of Conversational Responses*
Alessandro Sordoni, Michel Galley, Michael Auli, Chris Brockett, Yangfeng Ji, Margaret Mitchell, Jian-Yun Nie, Jianfeng Gao and Bill Dolan

15:15–16:00 Session 3A: Generation and Summarization (Short Papers)

15:15–15:30 *How to Make a Frenemy: Multitape FSTs for Portmanteau Generation*
Aliya Deri and Kevin Knight

15:30–15:45 *Aligning Sentences from Standard Wikipedia to Simple Wikipedia*
William Hwang, Hannaneh Hajishirzi, Mari Ostendorf and Wei Wu

15:45–16:00 *Inducing Lexical Style Properties for Paraphrase and Genre Differentiation*
Ellie Pavlick and Ani Nenkova

15:15–16:00 Session 3B: Information Extraction and Question Answering (Short Papers)

15:15–15:30 *Entity Linking for Spoken Language*
Adrian Benton and Mark Dredze

15:30–15:45 *Spinning Straw into Gold: Using Free Text to Train Monolingual Alignment Models for Non-factoid Question Answering*
Rebecca Sharp, Peter Jansen, Mihai Surdeanu and Peter Clark

15:45–16:00 *Personalized Page Rank for Named Entity Disambiguation*
Maria Pershina, Yifan He and Ralph Grishman

15:15–16:00 Session 3C: Machine Learning for NLP (Short Papers)

15:15–15:30 *When and why are log-linear models self-normalizing?*
Jacob Andreas and Dan Klein

15:30–15:45 *Deep Multilingual Correlation for Improved Word Embeddings*
Ang Lu, Weiran Wang, Mohit Bansal, Kevin Gimpel and Karen Livescu

15:45–16:00 *Disfluency Detection with a Semi-Markov Model and Prosodic Features*
James Ferguson, Greg Durrett and Dan Klein

16:00–16:30 ***Break***

Monday, June 1, 2015 (continued)

16:30–18:00 One minute madness (Long + TACL papers)

Session P1A: 18:00–19:30 Poster session 1A: Long + TACL papers

Empty Category Detection With Joint Context-Label Embeddings
Xun Wang, Katsuhito Sudoh and Masaaki Nagata

Incrementally Tracking Reference in Human/Human Dialogue Using Linguistic and Extra-Linguistic Information
Casey Kennington, Ryu Iida, Takenobu Tokunaga and David Schlangen

Digital Leafleting: Extracting Structured Data from Multimedia Online Flyers
Emilia Apostolova, Payam Pourashraf and Jeffrey Sack

Multi-Target Machine Translation with Multi-Synchronous Context-free Grammars
Graham Neubig, Philip Arthur and Kevin Duh

Sign constraints on feature weights improve a joint model of word segmentation and phonology
Mark Johnson, Joe Pater, Robert Staubs and Emmanuel Dupoux

Semi-Supervised Word Sense Disambiguation Using Word Embeddings in General and Specific Domains
Kaveh Taghipour and Hwee Tou Ng

Continuous Space Representations of Linguistic Typology and their Application to Phylogenetic Inference
Yugo Murawaki

Interpreting Compound Noun Phrases Using Web Search Queries
Marius Pasca

Lexicon-Free Conversational Speech Recognition with Neural Networks
Andrew Maas, Ziang Xie, Dan Jurafsky and Andrew Ng

I Can Has Cheezburger? A Nonparanormal Approach to Combining Textual and Visual Information for Predicting and Generating Popular Meme Descriptions
William Yang Wang and Miaomiao Wen

A Transition-based Algorithm for AMR Parsing
Chuan Wang, Nianwen Xue and Sameer Pradhan

Tuesday, June 2, 2015

07:30–09:00 ***Registration and Breakfast***

09:00–10:40 **Session 4A: Dialogue and Spoken Language Processing (Long Papers)**

09:00–09:25 *Semantic Grounding in Dialogue for Complex Problem Solving*
Xiaolong Li and Kristy Boyer

09:25–09:50 *Learning Knowledge Graphs for Question Answering through Conversational Dialog*
Ben Hixon, Peter Clark and Hannaneh Hajishirzi

09:50–10:15 *Sentence segmentation of aphasic speech*
Kathleen C. Fraser, Naama Ben-David, Graeme Hirst, Naida Graham and Elizabeth Rochon

10:15–10:40 *Semantic parsing of speech using grammars learned with weak supervision*
Judith Gaspers, Philipp Cimiano and Britta Wrede

Tuesday, June 2, 2015 (continued)

09:00–10:40 Session 4B: Machine Learning for NLP (Long Papers)

09:00–09:25 *Early Gains Matter: A Case for Preferring Generative over Discriminative Crowdsourcing Models*
Paul Felt, Kevin Black, Eric Ringger, Kevin Seppi and Robbie Haertel

09:25–09:50 *Optimizing Multivariate Performance Measures for Learning Relation Extraction Models*
Gholamreza Haffari, Ajay Nagesh and Ganesh Ramakrishnan

09:50–10:15 *Convolutional Neural Network for Paraphrase Identification*
Wenpeng Yin and Hinrich Schütze

10:15–10:40 *Representation Learning Using Multi-Task Deep Neural Networks for Semantic Classification and Information Retrieval*
Xiaodong Liu, Jianfeng Gao, Xiaodong He, Li Deng, Kevin Duh and Ye-Yi Wang

09:00–10:40 Session 4C: Phonology, Morphology and Word Segmentation (Long Papers)

09:00–09:25 *Inflection Generation as Discriminative String Transduction*
Garrett Nicolai, Colin Cherry and Grzegorz Kondrak

09:25–09:50 *Penalized Expectation Propagation for Graphical Models over Strings*
Ryan Cotterell and Jason Eisner

09:50–10:15 *Joint Generation of Transliterations from Multiple Representations*
Lei Yao and Grzegorz Kondrak

10:15–10:40 *Prosodic boundary information helps unsupervised word segmentation*
Bogdan Ludusan, Gabriel Synnaeve and Emmanuel Dupoux

10:40–11:15 ***Break***

11:15–12:30 Session 5A: Semantics (Short Papers)

11:15–11:30 *So similar and yet incompatible: Toward the automated identification of semantically compatible words*
Germán Kruszewski and Marco Baroni

11:30–11:45 *Do Supervised Distributional Methods Really Learn Lexical Inference Relations?*
Omer Levy, Steffen Remus, Chris Biemann and Ido Dagan

11:45–12:00 *A Word Embedding Approach to Predicting the Compositionality of Multiword Expressions*
Bahar Salehi, Paul Cook and Timothy Baldwin

12:00–12:15 *Word Embedding-based Antonym Detection using Thesauri and Distributional Information*
Masataka Ono, Makoto Miwa and Yutaka Sasaki

12:15–12:30 *A Comparison of Word Similarity Performance Using Explanatory and Non-explanatory Texts*
Lifeng Jin and William Schuler

11:15–12:30 Session 5B: Machine Translation (Short Papers)

11:15–11:30 *Morphological Modeling for Machine Translation of English-Iraqi Arabic Spoken Dialogs*
Katrin Kirchhoff, Yik-Cheung Tam, Colleen Richey and Wen Wang

11:30–11:45 *Continuous Adaptation to User Feedback for Statistical Machine Translation*
Frédéric Blain, Fethi Bougares, Amir Hazem, Loïc Barrault and Holger Schwenk

11:45–12:00 *Normalized Word Embedding and Orthogonal Transform for Bilingual Word Translation*
Chao Xing, Dong Wang, Chao Liu and Yiye Lin

12:00–12:15 *Fast and Accurate Preordering for SMT using Neural Networks*
Adrià de Gispert, Gonzalo Iglesias and Bill Byrne

12:15–12:30 *APRO: All-Pairs Ranking Optimization for MT Tuning*
Markus Dreyer and Yuanzhe Dong

Tuesday, June 2, 2015 (continued)

11:15–12:30 Session 5C: Morphology, Syntax, Multilinguality, and Applications (Short Papers)

11:15–11:30 *Paradigm classification in supervised learning of morphology*
Malin Ahlberg, Markus Forsberg and Mans Hulden

11:30–11:45 *Shift-Reduce Constituency Parsing with Dynamic Programming and POS Tag Lattice*
Haitao Mi and Liang Huang

11:45–12:00 *Unsupervised Code-Switching for Multilingual Historical Document Transcription*
Dan Garrette, Hannah Alpert-Abrams, Taylor Berg-Kirkpatrick and Dan Klein

12:00–12:15 *Matching Citation Text and Cited Spans in Biomedical Literature: a Search-Oriented Approach*
Arman Cohan, Luca Soldaini and Nazli Goharian

12:15–12:30 *Effective Feature Integration for Automated Short Answer Scoring*
Keisuke Sakaguchi, Michael Heilman and Nitin Madnani

12:30–14:00 ***Lunch***

14:00–15:15 Session 6A: Generation and Summarization (Long Papers)

14:00–14:25 *Socially-Informed Timeline Generation for Complex Events*

Unsupervised Induction of Semantic Roles within a Reconstruction-Error Minimization Framework

Ivan Titov **Ehsan Khoddam**
University of Amsterdam
{titov|e.khoddammohammadi}@uva.nl

Abstract

We introduce a new approach to unsupervised estimation of feature-rich semantic role labeling models. Our model consists of two components: (1) an encoding component: a semantic role labeling model which predicts roles given a rich set of syntactic and lexical features; (2) a reconstruction component: a tensor factorization model which relies on roles to predict argument fillers. When the components are estimated jointly to minimize errors in argument reconstruction, the induced roles largely correspond to roles defined in annotated resources. Our method performs on par with most accurate role induction methods on English and German, even though, unlike these previous approaches, we do not incorporate any prior linguistic knowledge about the languages.

1 Introduction

Shallow semantic representations, and semantic role labels in particular, have a long history in linguistics (Fillmore, 1968). More recently, with an emergence of large annotated resources such as PropBank (Palmer et al., 2005) and FrameNet (Baker et al., 1998), automatic semantic role labeling (SRL) has attracted a lot of attention (Gildea and Jurafsky, 2002; Carreras and Màrquez, 2005; Surdeanu et al., 2008; Hajič et al., 2009; Das et al., 2010).

Semantic role representations encode the underlying predicate-argument structure of sentences, or, more specifically, for every predicate in a sentence they identify a set of arguments and associate each argument with an underlying *semantic role*, such as an agent (an initiator or doer of the action) or a patient (an affected entity). Semantic roles have many potential applications in NLP and have been shown to benefit question answering (Shen and Lapata, 2007; Kaisser and Webber, 2007), textual entailment (Sammons et al., 2009), machine translation (Wu and Fung, 2009; Liu and Gildea, 2010; Wu et al., 2011; Gao and Vogel, 2011), and dialogue systems (Basili et al., 2009; van der Plas et al., 2009), among others.

Most current statistical approaches to SRL are supervised, requiring large quantities of human annotated data to estimate model parameters. However, such resources are expensive to create and only available for a small number of languages. Moreover, when moved to a new domain (e.g., from news corpora to blogs or biomedical texts), the performance of these models tends to degrade substantially (Pradhan et al., 2008). The scarcity of annotated data has motivated the research into unsupervised learning of semantic representations (Swier and Stevenson, 2004; Grenager and Manning, 2006; Lang and Lapata, 2010; Lang and Lapata, 2011a; Lang and Lapata, 2011b; Titov and Klementiev, 2012a; Fürstenau and Rambow, 2012; Garg and Henderson, 2012). The existing methods have a number of serious shortcomings. First, they make very strong assumptions, for example, assuming that arguments are conditionally independent of each other given the predicate. Second, unlike state-of-the-art supervised parsers, they rely on a very simplistic set of features of a sentence. These factors lead to models being insufficiently expressive to capture the syntax-semantics interface, inadequate

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 1–10,
Denver, Colorado, May 31 – June 5, 2015.

handling of language ambiguity and, overall, introduces a restrictive upper bound on their performance. Moreover, these approaches are especially problematic for languages with freer word order than English, where richer features are necessary to account for interactions between surface realizations, syntax and semantics. For example, the two most accurate previous models (Titov and Klementiev, 2012a; Lang and Lapata, 2011a) both treat the role induction task as clustering of argument signatures: an argument signature encodes key syntactic properties of an argument realization and consists of a syntactic function of an argument along with additional information such as an argument position with respect to the predicate. Though it is possible to design signatures which mostly map to a single role, this set-up limits oracle performance even for English, and can be quite restrictive for languages with freer word order. These shortcomings are inherent limitations of the modeling frameworks used in previous work (primarily generative modeling or agglomerative clustering), and cannot be addressed by simply incorporating more features or relaxing some of the modeling assumptions.

In this work, we propose a method for effective unsupervised estimation of feature-rich models of semantic roles. We demonstrate that reconstruction-error objectives, which have been shown to be effective primarily for training neural networks, are well suited for inducing feature-rich log-linear models of semantics. Our model consists of two components: a log-linear feature-rich semantic role labeler and a tensor-factorization model which captures interaction between semantic roles and argument fillers. When estimated jointly on unlabeled data, roles induced by the model mostly corresponds to roles defined in existing resources by annotators.

Our method rivals the most accurate semantic role induction methods on English and German (Titov and Klementiev, 2012a; Lang and Lapata, 2011a). Importantly, no prior knowledge about the languages was incorporated in our feature-rich model, whereas the clustering counterparts relied on language-specific argument signatures. These languages-specific priors were crucial for their success. For example, using English-specific argument signatures for German with the Bayesian model of Titov and Klementiev (2012a) results in a drop of performance from clustering F1 of 80.9% to considerably lower 78.3% (our model yields 81.4%). This confirms the intuition that using richer features helps to capture the syntax-semantics interface in multilingual settings, reducing the need for language-specific model engineering, as is highly desirable in unsupervised learning.

The rest of the paper is structured as follows. Section 2 begins with a definition of the semantic role labeling task and discusses some specifics of the unsupervised setting. In Section 3, we describe our approach, starting with a general motivation and proceeding to technical details of the model (Section 3.3) and the learning procedure (Section 3.4). Section 4 provides both evaluation and analysis. Finally, additional related work is presented in Section 5.

2 Task Definition

The SRL task involves prediction of predicate argument structure, i.e. both identification of arguments and assignment of labels according to their underlying semantic role. For example, in the following sentences:

(a) $[_{Agent}$ Mary] opened $[_{Patient}$ the door].

(b) $[_{Patient}$ The door] opened.

(c) $[_{Patient}$ The door] was opened $[_{Agent}$ by Mary].

Mary always takes an agent role for the predicate *open*, and *door* is always a patient.

In this work we focus on the labeling stage of semantic role labeling. Identification, though an important problem, can be tackled with heuristics (Lang and Lapata, 2011a; Grenager and Manning, 2006; de Marneffe et al., 2006), with unsupervised techniques (Abend et al., 2009) or potentially by using a supervised classifier trained on a small amount of data.

3 Approach

At the core of our approach is a statistical model encoding an interdependence between a semantic role structure and its realization in a sentence. In the unsupervised learning setting, sentences, their syntactic representations and argument positions (denoted by x) are observable whereas the associated semantic roles $\boldsymbol{r}$ are latent and need to be induced by the

model. The idea which underlines much of latent variable modeling is that a good latent representation is the one which helps us to reconstruct x. In practice, we are not interested in predicting x, as x is observable, but rather interested in inducing appropriate latent representations (i.e. $\boldsymbol{r}$). Thus, it is crucial to design the model in such a way that the good $\boldsymbol{r}$ (the one predictive of x) indeed encodes roles, rather than some other form of abstraction.

In what follows, we will refer to roles using their names, though, in the unsupervised setting, our method, as any other latent variable model, will not yield human-interpretable labels for them. We will use the following sentence as a motivating example in our discussion of the model:

[$_{Agent}$ The police] charged [$_{Patient}$ the demonstrators] [$_{Instrument}$ with batons].

The model consists of two components. The first component is responsible for prediction of argument tuples based on roles and the predicate. In our experiments, in this component, we represent arguments as lemmas of their lexical heads (e.g., *baton* instead of *with batons*). We also restrict ourselves to only verbal predicates. Intuitively, we can think of predicting one argument at a time (see Figure 1(b)): an argument (e.g., *demonstrator* in our example) is predicted based on the predicate lemma (*charge*), the role assigned to this argument (i.e. `Patient`) and other role-argument pairs ((`Agent`, *police*) and (`Instrument`, *baton*)). While learning to predict arguments, the inference algorithm will search for role assignments which simplify this prediction task as much as possible. Our hypothesis is that these assignments will correspond to roles accepted in linguistic theories (or, more importantly, useful in practical applications). Why is this hypothesis plausible? Primarily because these semantic representations were introduced as an abstraction capturing the essence of a situation (or a event). And the underlying situation and participant roles in this situation (rather than surface linguistic details like argument order or syntactic functions) are precisely what impose constraints on admissible argument tuples.

The reconstruction component is not the only part of the model. Crucially, what we referred to above as 'searching for role assignments to simplify argument prediction' would actually correspond to learning another component: a semantic role labeler which predicts roles relying on a rich set of sentence features. These two components will be estimated jointly in such a way as to minimize errors in recovering arguments. The role labeler will be the end-product of learning: it will be used to process new sentences, and it will be compared to existing methods in our evaluation.

3.1 Shortcomings of generative modeling

The above paragraph can be regarded as our desiderata; now we discuss how to achieve them. The standard way to approach latent variable modeling is to use the generative framework: that is to define a family of joint models $p(x, y|\theta)$ and estimate the parameters θ by, for example, maximizing the likelihood. Generative models of semantics (Titov and Klementiev, 2012a; Titov and Klementiev, 2011; Modi et al., 2012; O'Connor, 2013; Kawahara et al., 2014) necessarily make very strong independence assumptions (e.g., arguments are conditionally independent of each other given the predicate) and use simplistic features of x and y. Thus, they cannot meet the desiderata stated above. Importantly, they are also much more simplistic in their assumptions than state-of-the-art supervised role labelers (Erk and Pado, 2006; Johansson and Nugues, 2008; Das et al., 2010).

3.2 Reconstruction error minimization

Generative modeling is not the only way to learn latent representations. One alternative, popular in the neural network community, is to instead use autoencoders and optimize the reconstruction error (Hinton, 1989; Vincent et al., 2008). In autoencoders, a latent representation y (their hidden layer) is predicted from x by an encoding model and then this y is used to recover $\tilde{x}$ with a reconstruction model (see Figure 1(a)). Parameters of the encoding and reconstruction components are chosen so as to minimize some form of the reconstruction error, for example, the Euclidean distance $\Delta(x, \tilde{x}) = ||x - \tilde{x}||_2$. Though currently popular only within the deep learning community, latent variable models other than neural networks can also be trained this way, moreover:

- the encoding and reconstruction models can belong to different model families;

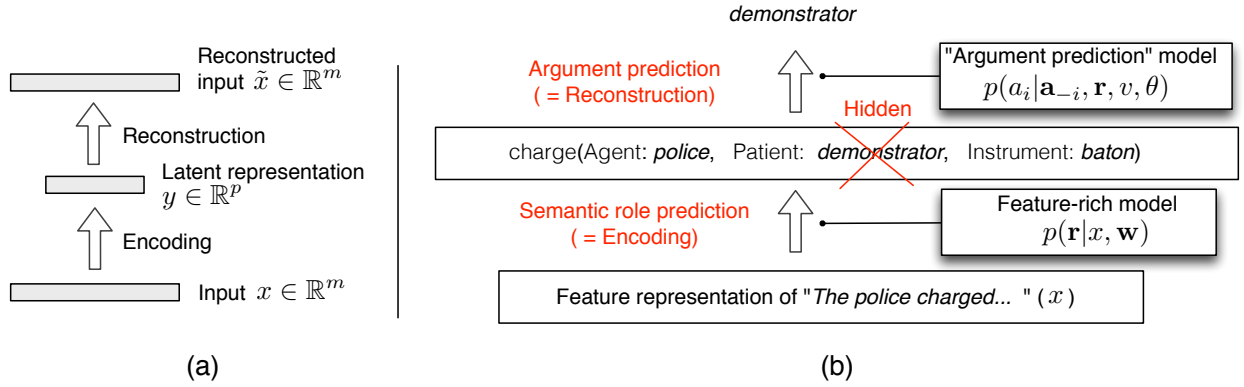

Figure 1: (a) An autoencoder from $\mathbb{R}^m$ to $\mathbb{R}^p$ (typically $p < m$). (b) Modeling roles within the reconstruction-error minimization framework.

- the reconstruction component may be focused on recovering a part of x rather than the entire x, and, in doing so, can rely not only on y but on the remaining part of x.

These observations are crucial as they allow us to implement our desiderata. More specifically, the encoding model will be a feature-rich classifier which predicts semantic roles for a sentence, and the reconstruction model is the model which predicts an argument given its role, and given the rest of the arguments and their roles. The idea of training linear models by minimizing the reconstruction error was previously explored by Daumé (2009) and very recently by Ammar et al. (2014).

3.3 Modeling semantics within the reconstruction-error framework

There are several possible ways to translate the ideas above into a specific method, and we consider one of the simplest instantiations. For simplicity, in the discussion (but not in our experiments), we assume that exactly one predicate is realized in each sentence x. As we mentioned above, we focus only on argument labeling: we assume that arguments $\boldsymbol{a} = (a_1, \ldots, a_N)$, $a_i \in \mathcal{A}$, are known, and only their roles $\boldsymbol{r} = (r_1, \ldots, r_N)$, $r_i \in \mathcal{R}$ need to be induced. For the encoder (i.e. the semantic role labeler), we use a log-linear model:

$$p(\boldsymbol{r}|x, \boldsymbol{w}) \propto \exp(\boldsymbol{w}^T \boldsymbol{g}(x, \boldsymbol{r})),$$

where $\boldsymbol{g}(x, \boldsymbol{r})$ is a feature vector encoding interactions between sentence x and the semantic role representation $\boldsymbol{r}$. Any model can be used here as long as the posterior distributions of roles r_i can be efficiently computed or approximated (we will see why in Section 3.4). In our experiments, we used a model which factorizes over individual arguments (i.e. a set of independent logistic regression classifiers).

The reconstruction component predicts an argument (e.g., the ith argument a_i) given the semantic roles $\boldsymbol{r}$, the predicate v and other arguments $\boldsymbol{a}_{-i} = (a_1, \ldots, a_{i-1}, a_{i+1}, \ldots, a_N)$ with a bilinear softmax model:

$$p(a_i|\boldsymbol{a}_{-i}, \boldsymbol{r}, v, C, \boldsymbol{u}) = \frac{\exp(\boldsymbol{u}_{a_i}^T C_{v,r_i}^T \sum_{j \neq i} C_{v,r_j} \boldsymbol{u}_{a_j})}{Z(\boldsymbol{r}, v, i)}, \quad (1)$$

$\boldsymbol{u}_a \in \mathbb{R}^d$ (for every $a \in \mathcal{A}$) and $C_{v,r} \in \mathbb{R}^{k \times d}$ (for every verb v and every role $r \in \mathcal{R}$) are model parameters, $Z(\boldsymbol{r}, v, i)$ is the partition function ensuring that the probabilities sum to one. Intuitively, embeddings $\boldsymbol{u}_a$, when learned from data, will encode semantic properties of an argument: for example, embeddings for the words *demonstrator* and *protestor* should be somewhere near each other in $\mathbb{R}^d$ space, and further away from that for the word *cat*. The product $C_{v,r}\boldsymbol{u}_a$ is a k-dimensional vector encoding beliefs about other arguments based on the argument-role pair (a, r). For example, seeing the argument *demonstrator* in the `Patient` position for the predicate *charge*, one would predict that the `Agent` is perhaps the word *police*, and the role `Instrument` is filled by the word *baton* or perhaps

(a water) *cannon*. On the contrary, if the `Patient` is *cat* then the `Agent` is more likely to be *dog* than *police*. In turn, the dot product $(C_{v,r_i}\boldsymbol{u}_{a_i})^T C_{v,r_j}\boldsymbol{u}_{a_j}$ is large if these expectations are met for the argument pair (a_i, a_j), and small otherwise. Intuitively, this objective corresponds to scoring argument tuples according to

$$h(\boldsymbol{a}, \boldsymbol{r}, v, C, \boldsymbol{u}) = \sum_{i \neq j} \boldsymbol{u}_{a_i}^T C_{v,r_i}^T C_{v,r_j} \boldsymbol{u}_{a_j}, \quad (2)$$

hinting at connections to (coupled) tensor and matrix factorization methods (Nickel et al., 2011; Yılmaz et al., 2011; Bordes et al., 2011; Riedel et al., 2013) and distributional semantics (Mikolov et al., 2013; Pennington et al., 2014). Note also that the reconstruction model does not have access to any features of the sentence (e.g., argument order or syntax), forcing the roles to convey all the necessary information.

This factorization can be thought of as a generalization of the notion of selection preferences. Selectional preferences characterize the set of arguments licensed for a given role of a given predicate: for example, `Agent` for the predicate *charge* can be *police* or *dog* but not *table* or *idea*. In our generalization, we model soft restrictions imposed not only by the role itself but also by other arguments and their assignment to roles.

In practice, we extend the model slightly: (1) we introduce a word-specific bias (a scalar b_a for every $a \in \mathcal{A}$) in the argument prediction model (equation (1)); (2) we smooth the model by using a sum of predicate-specific and cross-predicate projection matrices $(C_{v,r} + C_r)$ instead of just $C_{v,r}$.

3.4 Learning

Parameters of both model components ($\boldsymbol{w}$, $\boldsymbol{u}$ and C) are learned jointly: the natural objective associated with every sentence would be the following:

$$\sum_{i=1}^{N} \log \sum_{\boldsymbol{r}} p(a_i | \boldsymbol{a}_{-i}, \boldsymbol{r}, v, C, \boldsymbol{u}) p(\boldsymbol{r} | x, \boldsymbol{w}). \quad (3)$$

However optimizing this objective is not practical in its exact form for two reasons: (1) marginalization over $\boldsymbol{r}$ is exponential in the number of arguments; (2) the partition function $Z(\boldsymbol{r}, v, i)$ requires summation over the entire set of potential argument lemmas. We use existing techniques to address both challenges.

In order to deal with the first challenge, we use a basic mean-field approximation. Namely, instead of computing an expectation of $p(a_i|\boldsymbol{a}_{-i}, \boldsymbol{r}, v, C, \boldsymbol{u})$ under $p(\boldsymbol{r}|x, \boldsymbol{w})$, as in (3), we use the posterior distributions $\mu_{is} = p(\boldsymbol{r_i} = s|x, \boldsymbol{w})$ and score the argument predictions as

$$p(a_i|\boldsymbol{a}_{-i}, \boldsymbol{\mu}, v, C, \boldsymbol{u}) = \frac{\exp\left(\phi_i(a_i, \boldsymbol{a}_{-i})\right)}{Z(\boldsymbol{\mu}, v, i)} \quad (4)$$

$$\phi_i(a_i, \boldsymbol{a}_{-i}) = \boldsymbol{u}_{a_i}^T \Big(\sum_s \mu_{is} C_{v,s}\Big)^T \times \sum_{j \neq i} \Big(\sum_s \mu_{js} C_{v,s}\Big) \boldsymbol{u}_{a_j},$$

where $\boldsymbol{\mu}$ are the posteriors for all the arguments, and $\phi_i(a, \boldsymbol{a}_{-i})$ is the score associated with predicting lemma a for the argument i.

In order to address the second problem, the computation of $Z(\boldsymbol{\mu}, v, i)$, we use a negative sampling technique (see, e.g., Mikolov et al. (2013)). More specfically, we get rid of the softmax in equation (4) and optimize the following sentence-level objective:

$$\sum_{i=1}^{N} \Big[\log \sigma(\phi_i(a_i, \boldsymbol{a}_{-i})) - \sum_{a' \in S} \log \sigma(\phi_i(a', \boldsymbol{a}_{-i}))\Big], \quad (5)$$

where S is a random sample of n elements from the unigram distribution of lemmas, and σ is the logistic sigmoid function.

Assuming that the posteriors $\boldsymbol{\mu}$ can be derived in a closed form, the gradients of the objective (5) with respect to parameters of both the encoding component ($\boldsymbol{w}$) and the reconstruction component (C, $\boldsymbol{u}$ and $\boldsymbol{b}$) can be computed using back propagation. In our experiments, we used the AdaGrad algorithm (Duchi et al., 2011) to perform the optimization.

The learning algorithm is quite efficient, as the reconstruction computation is bilinear, whereas the computation of the posteriors $\boldsymbol{\mu}$ (and the computation of their gradients) from the semantic roler labeling component (encoder) is not much more expensive than discriminative supervised learning of

the role labeler. Moreover, the computations can be sped up substantially by observing that the sum $\sum_s \mu_{is} C_{v,s}$ in expression (4) can be precomputed for all i, and reused across predictions of different arguments of the same predicate. At test time, only the linear semantic role labeler is used, so the inference is straightforward.

4 Experiments

4.1 Data and evaluation metrics

We considered English and German in our experiments. For each language, we replicated experimental set-ups used in previous work.

For English, we followed Lang and Lapata (2010) and used the dependency version of PropBank (Palmer et al., 2005) released for the CoNLL 2008 shared task (Surdeanu et al., 2008). The dataset is divided into three segments. As in the previous work on unsupervised role labeling, we used the largest segment (the original CoNLL training set, sections 2-21) both for evaluation and learning. This is permissible as unsupervised models do not use gold labels in training. The two small segments (sections 22 and 23) were used for model development. In our experiments, we relied on gold standard syntax and gold standard argument identification, as this set-up allows us to evaluate against much of the previous work. We refer the reader to Lang and Lapata (2010) for details of the experimental set-up.

There has not been much work on unsupervised induction of roles for languages other than English, perhaps primarily because of the above-mentioned model limitations. For German, we replicate the set-up considered in Titov and Klementiev (2012b). They used the CoNLL 2009 version (Hajič et al., 2009) of the SALSA corpus (Burchardt et al., 2006). Instead of using syntactic parses provided in the CoNLL dataset, they re-parsed it with the MALT dependency parser (Nivre et al., 2004). Similarly, rather than relying on gold standard annotations for argument identification, they used a supervised classifier to predict argument positions. Details of the preprocessing can be found in Titov and Klementiev (2012b).

As in most previous work on unsupervised SRL, we evaluate our model using purity, collocation and their harmonic mean F1. *Purity* (PU) measures the average number of arguments with the same gold role label in each cluster, *collocation* (CO) measures to what extent a specific gold role is represented by a single cluster. More formally:

$$PU = \frac{1}{N} \sum_i \max_j |G_j \cap C_i|$$

where if C_i is the set of arguments in the i-th induced cluster, G_j is the set of arguments in the jth gold cluster, and N is the total number of arguments. Similarly, for collocation:

$$CO = \frac{1}{N} \sum_j \max_i |G_j \cap C_i|$$

We compute the aggregate PU, CO, and F1 scores over all predicates in the same way as Lang and Lapata (2010): we weight the scores for each predicate by the number of times its arguments occur and compute the weighted average.

4.2 Parameters and features

For the semantic role labeling (encoding) component, we relied on 14 feature patterns used for argument labeling in a popular supervised role labeler (Johansson and Nugues, 2008). These patterns include non-trivial syntactic features, such as a dependency path between the target predicate and the considered argument. The resulting feature space is quite large (49,474 feature instantiations for our English dataset) and arguably sufficient to accurately capture syntax-semantics interface for most languages. We refer the reader to the original publication for details (Johansson and Nugues, 2008: Table 2). Importantly, the dimensionality of the feature space is very different from the one used typically in unsupervised SRL. In principle, any features could be used here but we chose these 14 feature patterns, as they all are fairly simple and generic. They can also be easily extracted from any treebank. We used the same feature patterns both for English and German. However, there is little doubt that some language-specific feature engineering and the use of language-specific priors or constraints (e.g., posterior regularization (Ganchev et al., 2010)) would benefit the performance. Faithful to our goal of constructing the simplest possible feature-rich model,

we use logistic classifiers independently predicting role distribution for every argument.

For the reconstruction component, both for English and German, we set the embedding dimensionality d, the projection dimensionality k and the number of negative samples n to 30, 15 and 20, respectively. The model was not sensitive to the parameter $|\mathcal{R}|$, defining the number of roles as long it was large enough (see Section 4.3 for more discussion). For training, we used uniform random initialization and AdaGrad (Duchi et al., 2011). Any model selections (e.g., choosing the number of epochs) was done on the basis of the respective held-out set.

4.3 Results

4.3.1 English

Table 1 summarizes the results of our method, as well as those of alternative approaches and baselines.

Following (Lang and Lapata, 2010), we use a baseline (*SyntF*) which simply clusters predicate arguments according to the dependency relation to their head. A separate cluster is allocated for each of 20 most frequent relations in the dataset and an additional cluster is used for all other relations. As observed in the previous work (Lang and Lapata, 2011a), this is a hard baseline to beat.

We also compare with previous approaches: the latent logistic classification model (Lang and Lapata, 2010) (labeled *LLogistic*), the agglomerative clustering method (Lang and Lapata, 2011a) (*Agglom*), the graph partitioning approach (Lang and Lapata, 2011b) (*GraphPart*), the global role ordering model (Garg and Henderson, 2012) (*RoleOrdering*). We also report results of an improved version of *Agglom*, recently reported by Lang and Lapata (2014) (*Agglom+*). The strongest previous model is *Bayes*: *Bayes* is the most accurate ('coupled') version of the Bayesian model of Titov and Klementiev (2012a), estimated from the CoNLL dataset without relying on any external data. Titov and Klementiev (2012a) also showed that using Brown clusters induced from a large external corpus resulted in an 0.5% improvement in F1 but that version is not entirely comparable to other systems induced solely from the CoNLL text.

Our model outperforms or performs on par with best previous models in terms of F1. Interestingly, the purity and collocation balance is very different for our model and for the rest of the systems. In fact, our model induces at most 4-6 roles (even if $|\mathcal{R}|$ is much larger). On the contrary, *Bayes* predicts more than 30 roles for the majority of frequent predicates (e.g., 43 roles for the predicate *include* or 35 for *say*). Though this tendency reduces the purity scores for our model, this also means that our roles are more human interpretable. For example, agents and patients are clearly identifiable in the model predictions. Our model has similar purity to the syntactic baseline but outperforms it vastly according to the collocation metric, suggesting that we go substantially beyond recovering syntactic relations.

	PU	CO	F1
Our Model	79.7	86.2	**82.8**
Bayes	89.3	76.6	82.5
Agglom+	87.9	75.6	81.3
RoleOrdering	83.5	78.5	80.9
Agglom	88.7	73.0	80.1
GraphPart	88.6	70.7	78.6
LLogistic	79.5	76.5	78.0
SyntF	81.6	77.5	79.5

Table 1: Results on English (PropBank / CoNLL 2008).

In additional experiments, we observed that our model, in some regimes, starts to induce roles specific to individual verb senses or specific to groups of semantically similar predicates. This suggests that adding a latent variable capturing predicate senses and conditioning the reconstruction component on this variable may not only result in a more informative semantic representation (i.e. include verb senses) but also improve the role induction performance. We leave this exploration for future work.

4.3.2 German

For German, we replicate the experimental set-up previously used by Titov and Klementiev (2012b). As for English, we report results of the syntactic baseline (*SyntF*). The results for all approaches are presented in Table 2. We compare against *Bayes (De)* – the *Bayes* model with argument signatures specialized for German (as reported in Titov and Klementiev (2012b)). We also consider the original

	PU	CO	F1
Our Model	76.4	87.0	**81.4**
Bayes (De)	86.8	75.7	80.9
Bayes (En)	80.6	76.0	78.3
SyntF	83.1	79.3	81.2

Table 2: Results on German (SALSA / CoNLL 2009).

version of the *Bayes* model (denoted as *Bayes (En)*).

Recently, Lang and Lapata (2014) evaluated their *Agglom+* on a version of the same German SALSA dataset. Their best result is F1 of 79.2%, however, this score and our results are not directly comparable. Instead of using the CoNLL dataset, they processed the corpus themselves. They also relied on syntactic features from a constituent parser whereas we used dependency representations.

The overall picture for German closely resembles the one for English. Our method achieves results comparable to the best method evaluated in this setting. Importantly, parameters and features of our model for German and English are identical. On the contrary, one can see that specialization of argument signatures was crucial for the Bayesian model. Also, similarly to English, our method induces less fine-grain sets of semantic roles but achieves much higher collocation scores.

5 Additional Related Work

In recent years, unsupervised approaches to semantic role induction have attracted considerable attention. However, there exist other ways to address lack of coverage provided by existing semantically-annotated resources.

One natural direction is semi-supervised role labeling, where both annotated and unannotated data is used to estimate a model. Previous semi-supervised approaches to SRL can be mostly regarded as extensions to supervised learning by either incorporating word features induced from unnannoted texts (Collobert and Weston, 2008; Deschacht and Moens, 2009) or creating some form of 'surrogate' supervision (He and Gildea, 2006; Fürstenau and Lapata, 2009). Benefits from using unlabeled data were moderate, and more significant for the harder SRL version, frame-semantic parsing (Das and Smith, 2011).

Another important direction includes cross-lingual approaches (Pado and Lapata, 2009; van der Plas et al., 2011; Kozhevnikov and Titov, 2013) which leverage resources from resource-rich languages, as well as parallel data, to produce annotation or models for resource-poor languages. However, both translation shifts and noise in word alignments harm the performance of cross-lingual methods. Nevertheless, even joint unsupervised induction across languages appears to be beneficial (Titov and Klementiev, 2012b).

Unsupervised learning has also been one of the central paradigms for the closely-related area of relation extraction (RE), where several techniques have been proposed to cluster semantically similar verbalizations of relations (Lin and Pantel, 2001; Banko et al., 2007; Yao et al., 2011). Similarly to SRL, unsupervised methods for RE mostly rely on generative modeling and agglomerative clustering.

From the learning perspective, methods which use the reconstruction-error objective to estimate linear models (Ammar et al., 2014; Daumé III, 2009) are certainly related. However, they do not consider learning factorization models, and they also do not deal with semantics. Tensor factorization methods used in the context of modeling knoweldge bases (e.g., (Bordes et al., 2011)) are also close in spirit. However, they do not deal with inducing semantics but rather factorize existing relations (i.e. rely on semantics).

6 Conclusions and Discussion

This work introduces a method for inducing feature-rich semantic role labelers from unannoated text. In our approach, we view a semantic role representation as an encoding of a latent relation between a predicate and a tuple of its arguments. We capture this relation with a probabilistic tensor factorization model. The factorization model (relying on semantic roles) and a feature-rich model (predicting the roles) are jointly estimated by optimizing an objective which favours accurate reconstruction of arguments given the latent semantic representation (and other arguments). Our estimation method yields a semantic role labeler which achieves state-of-the-art results both on English and German.

Unlike previous work on role induction, in our

approach, virtually any computationally tractable structured model can be used as a role labeler, including almost any semantic role labeler introduced in the context of supervised SRL (see, e.g., CoNLL shared tasks (Carreras and Màrquez, 2005; Surdeanu et al., 2008; Hajič et al., 2009)). This opens interesting possibilities to extend our approach to the semi-supervised setting. Previous unsupervised SRL models make too strong assumption and use too limited features to effectively exploit labeled data. For our model, the reconstruction objective can be easily combined with the likelihood objective, yielding a potentially powerful semi-supervised method. We leave this direction for future work.

Predicate Argument Alignment using a Global Coherence Model

Travis Wolfe, Mark Dredze, and Benjamin Van Durme
Johns Hopkins University
Baltimore, MD, USA

Abstract

We present a joint model for predicate argument alignment. We leverage multiple sources of semantic information, including temporal ordering constraints between events. These are combined in a max-margin framework to find a globally consistent view of entities and events across multiple documents, which leads to improvements over a very strong local baseline.

1 Introduction

Natural language understanding (NLU) requires analysis beyond the sentence-level. For example, an *entity* may be mentioned multiple times in a discourse, participating in various events, where each event may itself be referenced elsewhere in the text. Traditionally the task of *coreference resolution* has been defined as finding those entity mentions within a single document that co-refer, while *cross-document coreference resolution* considers a wider discourse context across many documents, yet still pertains strictly to entities.

Predicate argument alignment, or entity-event cross-document coreference resolution, enlarges the set of possible co-referent elements to include the mentions of situations in which entities participate. This expanded definition drives practitioners towards a more complete model of NLU, where systems must not only consider who is mentioned, but also what happened. However, despite the drive towards an expanded notion of discourse, models typically are formulated with strong notions of local-independence: viewing a multi-document task as one limited to individual pairs of sentences. This creates a mis-match between the goals of such work – considering entire documents – with the systems – consider individual sentences.

In this work, we consider a system that takes a document level view in considering coreference for entities and predictions: the task of predicate argument linking. We treat this task as a global inference problem, leveraging multiple sources of semantic information identified at the document level. Global inference for this problem is mostly unexplored, with the exception of Lee et al. (2012) (discussed in § 8). Especially novel here is the use of document-level temporal constraints on events, representing a next step forward on the path to full understanding.

Our approach avoids the pitfalls of local inference while still remaining fast and exact. We use the pairwise features of a very strong predicate argument aligner (Wolfe et al., 2013) (competitive with the state-of-the-art (Roth, 2014)), and add quadratic factors that constrain local decisions based on global document information. These global factors lead to superior performance compared to the previous state-of-the-art. We release both our code and data.[1]

2 Model

Consider the two sentences from the document pair shown in Figure 1. These sentences describe the same event, although with different details. The source sentence has four predicates and four arguments, while the target has three predicates and three arguments. In this case, one of the predicates from each sentence aligns, as do three of the arguments. We also show additional information potentially helpful to determining alignments: temporal relations between the predicates. The goal of predicate argument alignment is to assign these links indicating coreferent predicates and arguments across a document pair (Roth and Frank, 2012).

Previous work by Wolfe et al. (2013) formulated

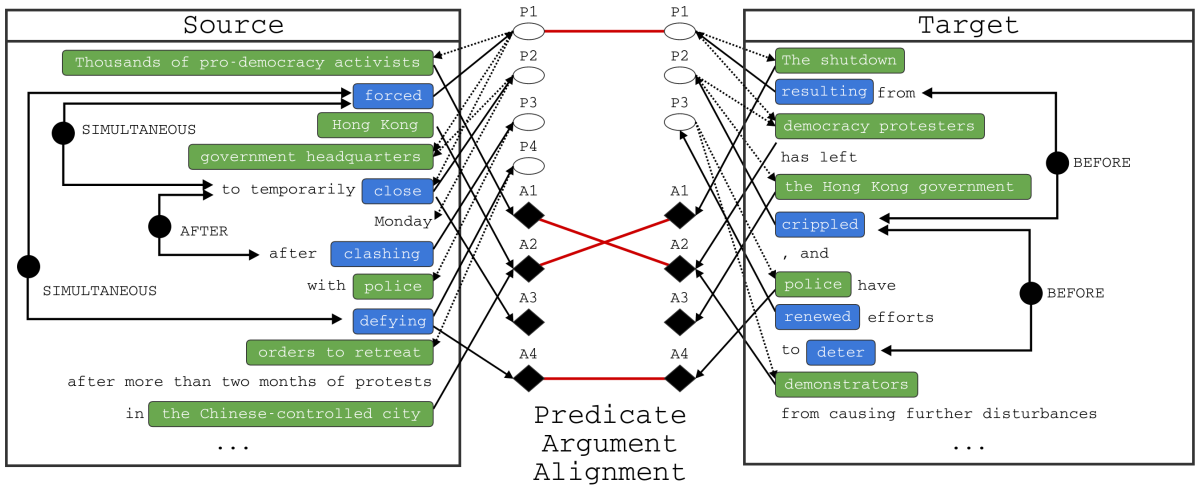

Figure 1: An example analysis and predicate argument alignment task between a source and target document. Predicates appear as hollow ovals, have blue mentions, and are aligned considering their arguments (dashed lines). Arguments, in black diamonds with green mentions, represent a document-level entity (coreference chain), and are aligned using their predicate structure and mention-level features. The alignment choices appear in the middle in red. Temporal relation information is lifted into the global inference over alignments.

this as a binary classification problem: given a pair of arguments or predicates, construct features and score the pair, where scores above threshold indicate links. A binary classification framework has advantages: it's fast since individual decisions can be made quickly, but it comes at the cost of global information across links. The result may be links that conflict in their interpretation of the document. Figure 1 makes clear that jointly considering all links at once can aid individual decisions, for example, by including temporal ordering of predicates.

The global nature of this task is similar to word alignment for machine translation (MT). Many systems consider alignment links between words individually, selecting the best link for each word independently of the other words in the sentence. Just as with an independent linking strategy in predicate argument alignment, this can lead to inconsistencies in the output. Lacoste-Julien et al. (2006) introduced a model that jointly resolved word alignments based on the introduction of quadratic variables, factors that depend on two alignment decisions which characterize patterns that span word-word links. Their approach achieved improved results even in the presence of little training data.

We present a global predicate argument alignment model based on considering quadratic interactions between alignment variables to captures patterns we expect in coherent discourse. We introduce factors which are comprised of a binary variable, multiple quadratic constraints on that variable, and features that determine the cost associated with that variable in order to characterize the dependence between alignment decisions.

While the mathematical framework we use is similar to Lacoste-Julien et al. (2006), predicate argument alignment greatly differs from word alignment; thus our joint factors are based on different sources of regularity. Word alignment favors monotonicity in word order, but this effect is very weak in predicate argument alignment: aligned items can be spread throughout a document, and are often nested, gapped, or shuffled. Instead, we encode assumptions about consistency of temporal relations between coreferent events, coherence between predicates and arguments that appear in both documents, and fertility (to prevent over-alignment). We also note that our setting has much less data than typical word alignment tasks, as well as richer features that utilize semantic resources.

Notation An alignment between an item indexed by i in the source document and j in the target document is represented by variable $z_{ij} \in \{0, 1\}$, where $z_{ij} = 1$ indicates that items i and j are aligned. In some cases, we will explicitly indicate when the two items are predicates as z^p_{ij}; an argument alignment will be z^a_{ij}. We represent all alignments for a document pair as matrix $\mathbf{z}$.

For clarity, we omit any variable representing observed data when discussing feature functions; alignment variables are endowed with this information. For each pair of items we use "local" feature functions $\mathbf{f}(\cdot)$ and corresponding parameters w, which capture the similarity between two items without the context of other alignments.

$$s_{ij} = w \cdot \mathbf{f}(z_{ij}) \tag{1}$$

where s_{ij} is the score of linking items i and j.

Using only local features, our system would greedily select alignments. To capture global aspects we add joint factors that capture effects between alignment variables. Each joint factor ϕ is comprised of a constrained binary variable z_ϕ associated with features $\mathbf{f}(\phi)$ that indicates when the factor is active. Together with parameters w these form additional scores s_ϕ for the objective:

$$s_\phi = w \cdot \mathbf{f}(\phi) \tag{2}$$

The full linear scoring function on alignments sums over both local similarity and joint factors:

$$\sum_{ij} s_{ij} z_{ij} + \sum_{\phi \in \Phi} s_\phi z_\phi. \tag{3}$$

Lastly, it is convenient to describe the local feature functions and their corresponding alignment variable as factors with no constraints, and we will do so when describing the full score function.

3 Local Factors

Local factors encode features based on the mention pair, which include a wide variety of similarity measures, e.g. whether two headwords appear as synonyms in WordNet, gender agreement based on possessive pronouns. We adopt the features of Wolfe et al. (2013), a strong baseline system which doesn't use global inference.[2] These features are built on top of a variety of semantic resources (PPDB (Ganitkevitch et al., 2013), WordNet (Miller, 1995), FrameNet (Baker et al., 1998)) and methods for comparing mentions (tree edit distance (Yao et al., 2013), string transducer (Andrews et al., 2012)).

4 Joint Factors

Our goal is to develop joint factors that improve over the feature rich local factors baseline by considering global information.

Fertility A common mistake when making independent classification decisions is to align many source items to a single target item. While each link looks promising on its own, they clearly cannot all be right. Empirically, the training set reveals that many to one alignments are uncommon; thus many to one predictions are likely errors. We add a fertility factor for predicates and arguments, where fertility is defined as the number of links to an item. Higher fertilities are undesired and are thus penalized. Formally, for matrix $\mathbf{z}$, the fertility of a row i or column j is the sum of that row or column. We discuss fertility in terms of rows below.

We include two types of fertility factors. First, factor ϕ_{fert1} distinguishes between rows with at least one link from those with none. For row i, we add one instance of the linear factor ϕ_{fert1} with constraints

$$z_{\phi_{\text{fert1}}} \geq z_{ij} \; \forall j \tag{4}$$

The cost associated with $z_{\phi_{\text{fert1}}}$, which we will refer to as s_{fert1}, will be incurred any time an item is mentioned in both documents. For data sets with many singletons, s_{fert1} more strongly penalizes non-singleton rows, reflecting this pattern in the training data. We make s_{fert1} parametric, where the features of the ϕ_{fert1} factor allow us to learn different weights for predicates and arguments, as well as the size of the row, i.e. number of items in the pairing.

The second fertility factory ϕ_{fert2} considers items with a fertility greater than one, penalizing items for having too many links. Its binary variable has the

[2] Some features inspect the apparent predicate argument structure, based on things like dependency parses, but the model may not inspect more than one of its own decisions (joint factors) while scoring an alignment.

quadratic constraints:

$$z_{\phi_{\text{fert2}}} \geq z_{ij} z_{ik} \; \forall j < k \tag{5}$$

This factor penalizes rows that have fertility of at least two, but does not distinguish beyond that. An alternative would be to introduce a factor for every pair of variables in a row, each with one constraint. This would heavily penalize fertilities greater than two. We found that the resulting quadratic program took longer to solve and gave worse results.

Since documents have been processed to identify in-document coreference chains, we do not expect multiple arguments from a source document to align to a single target item. For this reason, we expect ϕ_{fert2} for arguments to have a large negative weight. In contrast, since predicates do not form chains, we may have multiple source predicates for one target.

We note an important difference between our fertility factor compared with Lacoste-Julien et al. (2006). We parameterize fertility for only two cases (1 and 2) whereas they consider fertility factors from 2 to D. We do not parameterize fertilities higher than two because they are not common in our dataset and come at a high computational cost.

The features $\mathbf{f}(\phi)$ for both ϕ_{fert1} and ϕ_{fert2} are an intercept feature (which always fires), indicator features for whether this row corresponds to an argument or a predicate, and a discretized feature for how many alignments are in this row.

Predicate Argument Structure We expect structure among links that involve a predicate and its associated arguments. Therefore, we add joint factors that consider a predicate and its associated alignments: the predicate argument structure. We determine this structure from a dependency parse, though the idea is general to any semantic binding, e.g. FrameNet or Propbank style parses. Given a coherent discourse, there are several expected types of patterns in the PAS; we add factors for these.

Predicate-centric We begin with a predicate-centric factor, which views scores an alignment between predicates based on their arguments, i.e. the two predicates share the same arguments. Ideally, two predicates can only align when their arguments are coreferent. However, in practice we may incorrectly resolve argument links, or there may be implicit arguments that do not appear as syntactic dependencies of the predicate trigger. Therefore, we settle for a weaker condition, that there should be *some* overlap in the arguments of two coreferent predicates.

For every predicate alignment z^p_{ij}, we add a factor ϕ_{psa} whose score s_{psa} is a penalty for having no argument overlap; predicates share arguments (`psa`). To constrain the variable of ϕ_{psa}, we add a quadratic constraint that considers every possible pair of argument alignments that might overlap:

$$z_{\phi_{\text{psa}}} \geq z^p_{ij}\big(1 - \max_{\substack{k \in \text{args}(p_i) \\ l \in \text{args}(p_j)}} z^a_{kl}\big) \tag{6}$$

where $\text{args}(p_i)$ finds the indices of all arguments governed by the predicate p_i.

Entity-centric We expect similar behavior from arguments (entities). If an entity appears in two documents, it is likely that this entity will be mentioned in the context of a common predicate, i.e. arguments share predicates (`asp`). For a given argument alignment z^a_{ij} we add quadratic constraints so that $z_{\phi_{\text{asp}}}$ represents a penalty for two arguments not sharing a single predicate:

$$z_{\phi_{\text{asp}}} \geq z^a_{ij}\big(1 - \max_{\substack{k \in \text{preds}(a_i) \\ l \in \text{preds}(a_j)}} z^p_{kl}\big) \tag{7}$$

where $\text{preds}(a_i)$ finds the indices of all predicates that govern any mention of argument a_i.

The features $\mathbf{f}(\phi)$ for both `psa` and `asp` are an intercept feature and a bucketed count of the size of $\text{args}(p_i) \times \text{args}(p_j)$ or $\text{preds}(a_i) \times \text{preds}(a_j)$ respectively.

Temporal Information Temporal ordering, in contrast to textual ordering, can indicate when predicates cannot align: we expect aligned predicates in both documents to share the same temporal relations. SemEval 2013 included a task on predicting temporal relations between events (UzZaman et al., 2013). Many systems produced partial relations of events in a document based on lexical aspect and tense, as well as discourse connectives like "during" or "after". We obtain temporal relations with CAEVO, a state-of-the-art sieve-based system (Chambers et al., 2014).

TimeML (Pustejovsky et al., 2003), the format for specifying temporal relations, defines relations between predicates (e.g. *immediately before* and *simultaneous*), each with an inverse (e.g. *immediately after* and *simultaneous* respectively). We will refer to a relation as R and its inverse as R^{-1}. Suppose we had p_a and p_b in the source document, p_x and p_y in the target document, and $p_a R_1 p_b$, $p_x R_2 p_y$. Given this configuration the following alignments conflict with the in-doc relations:

z_{ax}	z_{by}	z_{ay}	z_{bx}	In-Doc Relations
*	*	1	1	$R_1 = R_2$
1	1	*	*	$R_1 = R_2^{-1}$

where 1 means there is a link and * means there is a link or no link (wildcard). The simplest example that fits this pattern is: 'a before b', 'x before y', 'a corefers with y', and 'b corefers with x' implies a conflict.

We introduce a factor that penalizes these conflicting configurations. In every instance where the predicted temporal relation for a pair of predicate alignments matches one of the conflict patterns above, we add a factor using $z_{\phi_{\text{temp}}}$:

$$\begin{aligned} z_{\phi_{\text{temp}}} &\geq z_{ay} z_{bx} \\ &\quad \text{if } p_a R_1 p_b, p_x R_2 p_y, R_1 = R_2 \\ z_{\phi_{\text{temp}}} &\geq z_{ax} z_{by} \\ &\quad \text{if } p_a R_1 p_b, p_x R_2 p_y, R_1 = R_2^{-1} \end{aligned} \tag{8}$$

Thus $s_{\phi_{\text{temp}}}$ is the cost of disagreeing with the in-doc temporal relations. This is a general technique for incorporating relational information into coreference decisions. It only requires specifying when two relations are incompatible, e.g. `spouseOf` and `siblingOf` are incompatible relations (in most states). We leave this for future work.

Since CAEVO gives each relation prediction a probability, we incorporate this into the feature by indicating the probability of a conflict *not* arising:

$$\mathbf{f}(\phi_{\text{temp}}) = \log\left(1 - p(R_1)p(R_2) + \epsilon\right) \tag{9}$$

ϵ avoids large negative values since CAEVO probabilities are not perfectly calibrated. We use $\epsilon = 0.1$, allowing feature values of at most -2.3.

Summary The objective is a linear function over binary variables. There is a local similarity score coefficient on every alignment variable, and a joint factor similarity score on every quadratic variable. These quadratic variables are constrained by products of the original alignment variables. Decoding an alignment requires solving this quadratically constrained integer program; in practice is can be solved quickly without relations.

```
def train(alignments):
  w = init_weights()
  working_set = set()
  while True:
    xi = solve_ILP(w, working_set)
    c = most_violated_constraint(w, alignments)
    working_set.add(c)
    if hinge(c, w) < xi:
      break

def most_violated_constraint(w, alignments):
  delta_features = vector()

```

Figure 2: Learning algorithm (caching and ILP solver not shown). The sum in each constraint is performed once when finding the constraint, and implicitly thereafter.

5 Inference

Learning We use the supervised structured SVM formulation of Joachims et al. (2009). As is common in structure prediction we use margin rescaling and 1 slack variable, with the structural SVM objective:

$$\begin{gathered} \min_w ||w||_2^2 + C\xi \\ \text{s.t. } \xi \geq 0 \\ \xi + \sum_{i=1}^{N} w \cdot f(z_i) \geq \sum_{i=1}^{N} w \cdot f(\hat{z}_i) + \Delta(z_i, \hat{z}_i) \\ \forall \hat{z}_i \in \mathcal{Z}_i \end{gathered} \tag{10}$$

where $\mathcal{Z}_i$ is the set of all possible alignments that have the same shape as z_i.

The score function for an alignment uses three types of terms: weights, features, and alignment variables. When we decode, we take the product of the weights and the features to get the costs for the ILP (e.g. $s_\phi = w \cdot \mathbf{f}(\phi)$). When we optimize our SVM objective, we take the product of the alignment variables and the features to get modified features for the SVM:

$$f(z) = \sum_{ij} z_{ij} \mathbf{f}(z_{ij}) + \sum_{\phi \in \Phi} z_\phi \mathbf{f}(\phi) \qquad (11)$$

Since we cannot iterate over the exponentially many margin constraints, we solve for this optimization using the cutting-plane learning algorithm. This algorithm repeatedly asks the "separation oracle" for the most violated SVM constraint, which finds this constraint by solving:

$$\arg \max_{\hat{z_1} \ldots \hat{z_N}} \sum_i w \cdot f(\hat{z}_i) + \Delta(z_i, \hat{z}_i) \qquad (12)$$

subject to the constraints defined by the joint factors. When the separation oracle returns a constraint that is not violated or is already in the working set, then we have a guarantee that we solved the original SVM problem with exponentially many constraints. This is the most time-consuming aspect of learning, but since the problem decomposes over document alignments, we cache solutions on a per document alignment basis. With caching, we only call the separation oracle around 100-300 times.

We implement the separation oracle using an ILP solver, CPLEX,[3] due to complexity of the discrete optimization problem: there are 2^{m^n} possible alignments for and $m \times n$ alignment grid. In practice this is solved very efficiently, taking less than a third of a second per document alignment on average. We would like Δ to be F1, but we need a decomposable loss to include it in a linear objective (Taskar et al., 2003). Instead, we use Hamming loss as a surrogate, as in Lacoste-Julien et al. (2006).

Our training data is heavily biased towards negative examples, performing poorly on F1 since precision and recall are unbalanced. We use an asymmetric version of Hamming loss that incurs c_{FP} cost for predicting an alignment for two unaligned items and c_{FN} for predicting no alignment for two aligned items. We fixed $c_{FP} = 1$ and tuned $c_{FN} \in \{1, 2, 3, 4\}$ on dev data. Additionally we found it useful to tune the scale of the loss function across $\{\frac{1}{2}, 1, 2, 4\}$. Previous work, such as Joachims et al. (2009), use a hand-chosen constant for the scale of the Hamming loss, but we observe some sensitivity in this parameter and choose to optimize it.

Decoding Following Wolfe et al. (2013), we tune the threshold for classification τ on dev data to maximize F1 (via linesearch). For SVMs τ is typically fixed at 0: this is not necessarily good practice when your training loss differs from test loss (Hamming vs F1). In our case this extra parameter is worth allocating a portion of training data to enable tuning. Tuning τ addresses the same problem as using an asymmetric Hamming loss, but we found that doing both led to better results.[4] Since we are using a global scoring function rather than a set of classifications, τ is implemented as a test-time unary factor on every alignment.

6 Experiments

Data We consider two datasets for evaluation. The first is a cross-document entity and event coreference resolution dataset called the Extended Event Coref Bank (EECB) created by Lee et al. (2012) and based on a corpus from Bejan and Harabagiu (2010). The dataset contains clusters of news articles taken from Google News with annotations about coreference over entities and events. Following the procedure of Wolfe et al. (2013), we select the first document in every cluster and pair it with every other document in the cluster.

The second dataset (RF) comes from Roth and Frank (2012). The dataset contains pairs of news articles that describe the same news story, and are annotated for predicate links between the document pairs. Due to the lack of annotated arguments, we can only report predicate linking performance and the `psa` and `asp` factors do not apply. Lastly, the size of the RF data should be noted as it is much smaller than EECB: the test set has 60 document pairs and the dev set has 10 document pairs.

[3] `http://www-01.ibm.com/software/commerce/optimization/cplex-optimizer/`

[4] Only tuning τ performed almost as well as tuning τ and the Hamming loss, but not tuning τ performed much worse than only tuning the Hamming loss at train time.

Both datasets are annotated with parses and in-document coreference labels provided by the toolset of Napoles et al. (2012)[5] and are available with our code release. Due to the small data size, we use k-fold cross validation for both datasets. We choose $k = 10$ for RF due to its very small size (more folds give more training examples) and $k = 5$ on EECB to save computation time (amount of training data in EECB is less of a concern). Hyperparameters were chosen by hand using using cross validation on the EECB dataset using F1 as the criteria (rather than Hamming). Figures report averages across these folds.

Systems Following Roth and Frank (2012) and Wolfe et al. (2013) we include a *Lemma* baseline for identifying alignments which will align any two predicates or arguments that have the same lemmatized head word.[6] The *Local* baseline uses the same features as Wolfe et al., but none of our joint factors. In addition to running our joint model with all factors, we measure the efficacy of each individual factor by evaluating each with the local features.

For evaluation we use a generous version of F1 that is defined for alignment labels composed of sure, G_s, and possible links, G_p and the system's proposed links H (following Cohn et al. (2008), Roth and Frank (2012) and Wolfe et al. (2013)).

$$P = \frac{|H \cap G_p|}{|H|} \quad R = \frac{|H \cap G_s|}{|G_s|} F = \frac{2PR}{P+R}$$

Note that the EECB data does not have a sure and possible distinction, so $G_s = G_p$, resulting in standard F1. In addition to F1, we separately measure predicate and argument F1 to demonstrate where our model makes the largest improvements.

We performed a one-sided paired-bootstrap test where the null hypothesis was that the joint model was no better than the *Local* baseline (described in Koehn (2004)). Cases where $p < 0.05$ are bolded.

[5] https://github.com/cnap/anno-pipeline

[6] The lemma baseline is obviously sensitive to the lemmatizer used. We used the Stanford CoreNLP lemmatizer (Manning et al., 2014) and found it yielded slightly better results than previously reported as the lemma baseline (Roth and Frank, 2012), so we used it for all systems to ensure fairness and that the baseline is as strong as it could be.

7 Results

Results for EECB and RF are reported in Table 7. As previously reported, using just local factors (features on pairs) improves over lemma baselines (Wolfe et al., 2013). The joint factors make statistically significant gains over local factors in almost all experiments. Fertility factors provide the largest improvements from any single constraint. A fertility penalty actually allows the pairwise weights to be more optimistic in that they can predict more alignments for reasonable pairs, allowing the fertility penalty to ensure only the best is chosen. This penalty also prevents the "garbage collecting" effect that arises for instances that have rare features (Brown et al., 1993).

Temporal constraints are relatively sparse, appearing just 2.8 times on average. Nevertheless, it was very helpful across all experiments, though only statistically significantly on the RF dataset. This is one of the first results to demonstrate benefits of temporal relations affecting an downstream task. Perhaps surprisingly, these improvements result from a a temporal relation system that has relatively poor absolute performance. Despite this, improvements are possibly due to the orthogonal nature of temporal information; no other feature captures this signal. This suggests that future work on temporal relation prediction may yield further improvements and deserves more attention as a useful feature for semantic tasks in NLP.

The predicate-centric factors improved performance significantly on both datasets. For the predicate-centric factor, when a predicate was aligned there is a 72.3% chance that there was at least one argument aligned as well, compared to only 14.1% of case of non-aligned predicates. As mentioned before, the reason the former number isn't 100% is primarily due to implicit arguments and errors in argument identification. The argument-centric features helped almost as much as the predicate-centric version, but the improvements were not significant on the EECB dataset. Running the same diagnostic as the predicate-centric feature reveals similar support: in 57.1% of the cases where an argument was aligned, at least one predicate it partook in was aligned too, compared to 7.6% of cases for non-aligned arguments. Both the

Figure 3: Cross validation results for EECB (above) (Lee et al., 2012) and RF (left) (Roth and Frank, 2012). Statistically significant improvements from Local marked * ($p < 0.05$ using a one-sided paired-bootstrap test) and best results are bolded.

predicate- and argument-centric improve similarly across both predicates and arguments on EECB.

While each of the joint factors all improve over the baselines on RF, the full model with all the joint factors does not perform as well as with some factors excluded. Specifically, the fertility model performs the best. We attribute this small gap to lack of training data (RF only contains 64 training document pairs in our experiments), as this is not a problem on the larger EECB dataset.

Additionally, the joint models seem to trade precision for recall on the RF dataset compared to the *Local* baseline. Note that both models are tuned to maximize F1, so this tells you more about the shape of the ROC curve as opposed to either models' ability to achieve either high precision or recall. Since we don't see this behavior on the EECB corpus, it is more likely that this is a property of the data than the model.

8 Related Work

The task of predicate argument linking was introduced by Roth and Frank (2012), who used a graph parameterized by a small number of semantic features to express similarities between predicates and used min-cuts to produce an alignment. This was followed by Wolfe et al. (2013), who gave a locally-independent, feature-rich log-linear model that utilized many lexical semantic resources, similar to the sort employed in RTE challenges.

Lee et al. (2012) considered a similar problem but sought to produce *clusters* of entities and events rather than an alignment between two documents with the goal of improving coreference resolution. They used features which consider previous event and entity coreference decisions to make future coreference decisions in a greedy manner. This differs from our model which is built on non-greedy joint inference, but much of the signal indicating when two mentions corefer or are aligned is similar.

In the context of in-document coreference resolution, Recasens et al. (2013) sought to overcome the problem of opaque mentions[7] by finding high-precision paraphrases of entities by pivoting off verbs mentioned in similar documents. We address the issue of opaque mentions not by building a paraphrase table, but by jointly reasoning about entities that participate in coreferent events (c.f. §4); the approaches are complementary.

In this work we incorporate ordering information of events. Though we consider it an upstream task, there is a line of work trying to predict temporal relations between events (Pustejovsky et al., 2003; Mani et al., 2006; Chambers et al., 2014). Our results indicate this is a useful source of information, one of the first results to show an improvement from this

[7] A lexically disparate description of an entity.

type of system (Glavaš and Šnajder, 2013).

We utilize an ILP to improve upon a pipelined system, similar to Roth and Yih (2004), but our work differs in that we do not use piecewise-trained classifiers. Our local similarity scores are calibrated according to a global objective by propagating the gradient back from the loss to every parameter in the model. When using piecewise training, local classifiers must focus more on recall (in the spirit of Weiss and Taskar (2010)) than they would for an ordinary classification task with no global objective. Our method trains classifiers jointly with a global convex objective. While our training procedure requires decoding an integer program, the parameters we learn are globally optimal.

9 Conclusion

We presented a max-margin quadratic cost model for predicate argument alignment, seeking to exploit discourse level semantic features to improve on previous, locally independent approaches. Our model includes factors that consider fertility of predicates and arguments, the predicate argument structure present in coherent discourses, and soft constraints on predicate coreference determined by a temporal relation classifier. We have shown that this model significantly improves upon prior work which uses extensive lexical resources but without the benefit of joint inference. Additionally, this is one of the first demonstrations of the benefits of temporal relation identification. Overall, this work demonstrates the benefits of considering global document information as part of natural language understanding.

Future work should extend the problem formulation of predicate argument alignment to consider *incremental* linking: starting with a pair of documents, perform linking, and then continue to add in documents over time. This problem formulation would capture the evolution of a breaking news story, which closely matches the type of data (news articles) considered in this work (EECB and RF datasets). This formulation ties into existing work on news summarization, topic detection and tracking, an multi-document NLU. This goes hand with work on better intra-document relation prediction methods, such as the temporal relation model used in this work, to lead to better joint linking decisions.

Improving unsupervised vector-space thematic fit evaluation via role-filler prototype clustering

Clayton Greenberg, Asad Sayeed and Vera Demberg

Abstract

Most recent unsupervised methods in vector space semantics for assessing thematic fit (e.g. Erk, 2007; Baroni and Lenci, 2010; Sayeed and Demberg, 2014) create prototypical role-fillers without performing word sense disambiguation. This leads to a kind of sparsity problem: candidate role-fillers for different senses of the verb end up being measured by the same "yardstick", the single prototypical role-filler.

In this work, we use three different feature spaces to construct robust unsupervised models of distributional semantics. We show that correlation with human judgements on thematic fit estimates can be improved consistently by clustering typical role-fillers and then calculating similarities of candidate role-fillers with these cluster centroids. The suggested methods can be used in any vector space model that constructs a prototype vector from a non-trivial set of typical vectors.

1 Introduction

Thematic fit estimations can be quite useful for many NLP applications and also for cognitive models of human language processing difficulty, since human processing difficulty is highly sensitive to semantic plausibilities (Ehrlich and Rayner, 1981). For example, we expect that after the word *mash*, *banana* would be easier to process because it fits well as the patient, or direct object, of *mash*, but *milk* would be harder to process because it does not fit well.

A common method for estimating the thematic fit between a verb and a proposed role filler involves computing a centroid, or vector average, over the most typical role fillers for that verb, and then calculating the cosine similarity between this centroid and the proposed role filler (Baroni and Lenci, 2010; Blacoe and Lapata, 2012; Erk, 2012). For instance, we use the cosine of the angle between the *banana* vector and a vector average of the 20 nouns that, according to training data, are most likely to be mashed as a score for how well *banana* fits as the patient of *mash*. Hopefully, the *banana* vector will be closer to the centroid than *milk*, so *banana* will have a higher cosine similarity to the centroid, and thus a higher thematic fit score, than *milk*.

This conceptualization assumes that the most typical fillers for a verb-role will all be variants of a single prototype, i.e. distributionally similar to each other. However, such an assumption may not be true for ambiguous verbs. A verb with many different senses may have typical fillers for each sense, which fit relatively equally well, but are distributionally very different from one another. This means that the calculated prototypical filler will be a mixture of the arguments that are typical role fillers for the main senses of the verb. For example, consider the verb *serve*, for which the 24 most typical prepositional arguments related via the preposition *with* fall into three different senses, as illustrated in Figure 1.

Supposing that the centroid occupies a part of the vector space between two typical role fillers, but is relatively far from any one of the typical role fillers from which it was composed, as in Figure 1, none of the original typical role fillers will achieve high the-

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 21–31,
Denver, Colorado, May 31 – June 5, 2015.

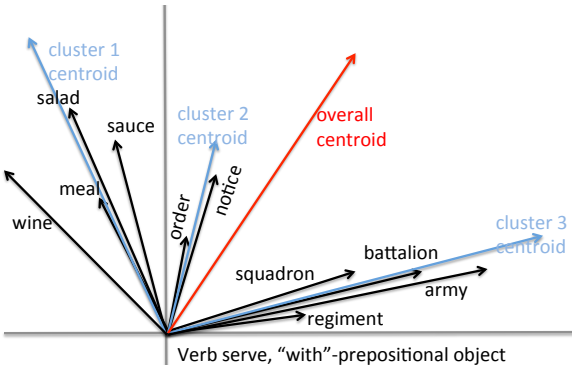

Figure 1: Illustration of *TypeDM* centroid for with-PP arguments of the verb *serve*.

matic fit scores. Also, verbs will be "penalized" for having many senses in that it will seem as though no role filler fits as well as they do with unambiguous verbs. This may produce inconsistent judgements when comparing one verb that is highly polysemous with a second, more restrictive verb whose meaning overlaps with the most dominant meanings of the first verb. For example, *cut* can be used in the sense of "cutting costs," which carries with it restrictions on instruments, locations, and so on that somewhat overlap with *eliminate* as in "eliminating costs." Things that are plausible to be eliminated are also plausible to be cut. But *cut* is also used in the sense of "cutting a cake" or "cutting (editing) a film." Without taking word sense into account, *costs* would be judged by the model as being less appropriate as a patient of *cut* than it should, and also its score for filling the patient role of *eliminate* would be infelicitously higher than its score for filling the patient role of *cut*.

One possible solution to this problem would be to do full word sense disambiguation on the resources from which these vector spaces are constructed. Then, there would be separate entries in the space for each meaning. This would however increase the overall size of the vector space by a significant factor and also cause an additional burden on corpus construction and annotation, even if automatic.

In this paper, we will approach the verb-role sense problem by clustering the most typical role-filler vectors and calculating the maximal cosine similarity for a candidate role filler with respect to each cluster prototype vector. So, to estimate the thematic fit of *salad* as an item with which something is served, in the vector space represented by Figure 1, we would use the cosine similarity with the nearest cluster centroid, the cluster 1 centroid. For a thematic fit task, the correlation between calculated estimates and human judgements can be expected to improve. In particular, good role fillers that are very different from one another and belong to different senses of a verb can all be assigned thematic fit scores as high as those of good role fillers of monosemous verbs.

We will evaluate our system using three distributional spaces: *TypeDM* (Baroni and Lenci, 2010), which is based on a syntactic dependency parser, *SDDM* (Sayeed and Demberg, 2014), which uses features obtained from the semantic role labeller SENNA (Collobert et al., 2011), and *SDDMX*, a novel extension of *SDDM*. This way, we can draw conclusions about feature space-specific and feature space-general trends.

The effects of clustering and choice of distributional space will be evaluated against the Padó (2007) and McRae et al. (1998) datasets of human judgements on thematic fit of agent and patient roles, and the Ferretti et al. (2001) datasets of human judgements on thematic fit of instrument and location roles. These different roles are conceptually interesting to compare, as instruments tend to be more strongly constrained by verbs than locations.

2 Background and related work

2.1 Thematic fit

The fit of a filler of a thematic role can be characterized as a semantic constraint on what can fill potentially available syntactic slots for a given predicate. For example, not every noun can satisfy the agent or patient roles of the typically transitive verb *eat*. There must be a valid "eater" for the agent and a valid "eatee" for the patient. Some nouns are simply more plausible than others in these positions: *lunch* is eaten, but rarely ever eats. But there can also be optional role assignments: there are certain utensils with which one is more or less likely to eat (i.e., appropriate instrument role-fillers) and even places where one is more or less likely to eat (i.e., location roles).

Verb	Noun	Semantic role	Score
advise	doctor	agent	6.8
advise	doctor	patient	4.0
confuse	baby	agent	3.7
confuse	baby	patient	6.0
eat	lunch	agent	1.1
eat	lunch	patient	6.9
kill	lion	agent	2.7
kill	lion	patient	4.9
kill	man	agent	3.4
kill	man	patient	5.4

Table 1: Sample of judgements from Padó (2007).

In order to model thematic roles, we use the insight that thematic fit correlates with human plausibility judgements (Padó et al., 2009; Vandekerckhove et al., 2009). Therefore, we can use datasets of human plausibility judgements to evaluate computational thematic fit estimates. One such dataset by Padó (2007) includes 18 verbs with up to 12 candidate nominal arguments and totals 414 verb-noun-role triples. The words were chosen based on their frequencies in the Penn Treebank and FrameNet. Human participants were asked to rate the appropriateness of given nouns as agents and as patients for given verbs on a scale from 1 to 7. The judgements were then averaged. We provide a small sample of these judgements in Table 1.

We use three other datasets as well. Ferretti et al. (2001) provide two datasets, one with 248 verb-instrument pairs and one with 274 verb-location pairs. Additionally, McRae et al. (1998) give a dataset of 1444 more agent/patient judgements. We write agent/patient as such because like Padó (2007), the agent plausibility and patient plausibility are given in the same dataset, albeit separately. Once again, human participants were asked to rate the appropriateness of given nouns as locations, instruments, and agents/patients, respectively, of the verbs in each dataset on a scale from 1 to 7. We will make use of these in our evaluation in order to see how well the models and algorithms we propose apply to various thematic roles, not just the most commonly tested and to-date most accurately estimated roles of agent and patient.

2.2 Distributional Semantics

2.2.1 Distributional Memory

Our semantic modeling technique comes from Baroni and Lenci (2010), who developed an explicitly multifunctional, i.e. not tightly bound to a particular task, framework for recording distributional information about linguistic co-occurrence. Distributional Memory (DM) records frequency information about links between words in a sentence as a third order tensor, in which words or lemmata are represented as two of the tensor axes and the syntactic or semantic link between them is the third axis.

The following corpora were used to construct the Baroni and Lenci (2010) version of DM:

- ukWaC, a corpus of about two billion words collected by crawling the `.uk` web domain (Ferraresi et al., 2008).
- WackyPedia, a snapshot selection of Wikipedia articles.
- The British National Corpus (BNC), a 100-million word corpus including documents such as books and periodicals.

The sentences from these sources were first run through MaltParser (Nivre et al., 2007). The dependency links (e.g. `SBJ`, `NMOD`) were run through a set of hand-crafted patterns to identify higher-level lexicalized links (e.g. `as-long-as`, `in-a-kind-of`). They then counted link type frequencies, so that links that involve the same lexical item (e.g. `long`, `kind`, as in the lexicalized links just mentioned) were collapsed into a single link, and the number of surface form realizations was used as the frequency count. All words were lemmatized and stored with basic part of speech information.

All these counts were then adjusted by Local Mutual Information (Baroni and Lenci, 2010), which is given by

$$LMI(i,j,k) = O_{ijk} \log \frac{O_{ijk}}{E_{ijk}} \qquad (1)$$

where i, j are words, k is the link between them, O is the observed frequency, and E is the expected frequency under independence. Tuples with nonpositive LMI values were removed. They called this tensor $TypeDM$.

2.2.2 DM Based on Semantic Role Labels

In order to create a competitor to the much less manually pruned cousin of $TypeDM$ named DepDM, Sayeed and Demberg (2014) based $SDDM$ (short for SENNA-DepDM) on similar corpora but used alternative features. Namely, this tensor was built from ukWaC and BNC, but the features came from a semantic role labelling (SRL) system called SENNA (Collobert and Weston, 2007; Collobert et al., 2011). SENNA uses a multi-layer neural network architecture that learns in a sliding window over token sequences working on raw text instead of syntactic parses, as other semantic role labellers do (Bohnet, 2010). SENNA extracts word features related to identity, capitalization, and suffix/tense (approximated by the last two characters of the word). From these features, in a process similar to decoding a conditional random field, the network derives features related to verb position, part of speech, and chunk membership.

SENNA was trained on PropBank and large amounts of unlabelled data. It achieves a role labelling F-score of 75.49% (in this case, tested on CoNNL 2005 data), which is slightly lower than state of the art SRL systems which use parse trees as input.

$SDDM$ was built by running the sentences from the input corpora through SENNA and using the role labels as links between predicates and role-fillers. Unlike $TypeDM$, $SDDM$ required almost no further processing; the raw frequency counts of triples were used in the LMI calculation.

In this paper, we present $SDDMX$, an extended version of the $SDDM$ model[1]. $SDDMX$ contains the same links as $SDDM$ and also contains links between nouns that belong to the same predicate instance, using the predicate as a link label. For example, supposing that during training the system encountered *the man eats a donut* with a role link between *man* and *eat* and another role link between *donut* and *eat*, then in $SDDMX$, a link was created between *man* and *donut*. This link was labelled with the verb lemma for the 400 most frequent verbs (`eat` in our example), and `vb` otherwise.

Sayeed and Demberg (2014) found that although

[1]We provide $SDDM$ and $SDDMX$ at `http://rollen.mmci.uni-saarland.de/`.

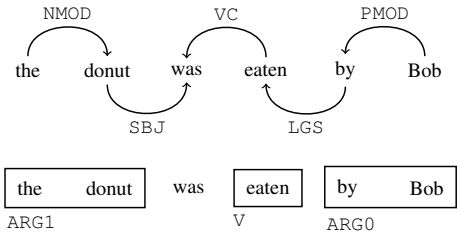

Figure 2: The same sentence with MaltParser (above) and SENNA (below) labels. Sayeed and Demberg (2014) used a simplified approach similar to the head percolation table of Magerman (1994) to find head nouns from SENNA annotation.

$SDDM$ is an arguably simpler DM model than $TypeDM$, it performs nearly as well as $TypeDM$ on a thematic fit estimation task using the Padó (2007) and McRae et al. (1998) agent/patient datasets. They also found that averaging the thematic fit scores of $SDDM$ with those of $TypeDM$ outperforms $TypeDM$ alone and nearly reaches the performance of a supervised model (Herdağdelen and Baroni, 2009). This suggests that $TypeDM$ and $SDDM$ cover different aspects of the corpora on which they were trained. Links generated by SENNA may directly access semantic role features that the MaltParser-based $TypeDM$ must infer through hand-crafted rules, such as tagging the subject as a patient instead of an agent in passive-voice contexts. Figure 2 illustrates the differences between the labelling approaches.

We make use of the $SDDM$, $SDDMX$, and $TypeDM$ tensors in our experiments to demonstrate how our techniques improve performance in thematic fit modelling across different feature spaces.

2.2.3 Centroid-based thematic fit calculation in DM

Investigating alternative ways to calculate thematic fit over the DM framework is a major goal of this work, so we now describe the baseline process.

Baroni and Lenci (2010) used the following approach to estimate thematic fit on the Padó (2007) agent/patient dataset: To assess the fit of a noun w_1 in a role r for a verb w_2, they construct a centroid from the 20 highest-ranked fillers for r with w_2 selected by LMI, using the relevant syntactic dependency links, such as subject and object, instead of

thematic roles. To illustrate, in order to determine how well *workshop* fits as a location for *eat*, they would construct a centroid of other locations for *eat* that appear in the DM, e.g. *kitchen, restaurant, cafeteria* up to 20.

Each of these top 20 represent a "slice" of the tensor along one of the word axes. One such slice, corresponding to w_1, is a matrix of links and words to which w_1 is connected. This tensor slice is collapsed into a vector whose components are word-link pairs. This is the vector of w_1.

All 20 such vectors are added up and the sum is the centroid that represents, e.g., the typical locations of *eat*. Then a vector is constructed from the slice of the tensor corresponding to *workshop*. The thematic fit score is the cosine of the location centroid of *eat* and the vector of *workshop*.

Accessing thematic roles in *SDDM* and *SDDMX* is straightforward, as the links in these models are PropBank roles. Agent is `ARG0`, patient is `ARG1`, location is `ARGM-LOC`, and we use a combination of `ARGM-MNR`, `ARG2`, and `ARG3` to represent instruments, based on a translation of the roles used by Ferretti et al. (2001). The role mapping for *TypeDM* involves a combination of `sbj_tr` and `subj_intr` (transitive and intransitive subjects) for agents, `obj` for patients, the prepositional links `in`, `at`, and `on` for locations, and `with` for instruments.

2.3 Word Sense Disambiguation in Distributional Models

While distributional models carry important information about the relative frequencies of word usages, and perhaps even phrase usages, they often must collapse such usages into one representation. For example, suppose within the domain of cooking recipes, *serve* occurs in its food sense (see cluster 1 in Figure 1) 97% of the time. The other senses will have negligible effect on the representation of *serve* because their frequencies are so much lower. But in a web crawl, the distribution is quite likely to be more uniform, which means the senses will "split the difference" in the representation and end up not being that similar to any instance of *serve*.

Many systems work to alleviate this problem by performing manipulations on words as they occur in training corpora (e.g., Thater et al., 2011). Namely, the base vector for the potentially ambiguous word is contextualized, as in scaled element-wise, by the vectors of the neighboring words for that instance. This is quite intuitive because if *serve* and *cake* occur next to each other, the chance that a non-food sense of the word *serve* was intended would be extremely small, in fact much smaller than a corpus-wide distribution would predict. These systems have been effective at improving correlation with human judgements for a verb-object composition model, i.e. approximating a vector for *serve cake* given a vector for *serve* and a vector for *cake* (Kartsaklis et al., 2014), and also reducing noise in similarity scores for a nearest neighbor-based prepositional phrase attachment disambiguator (Greenberg, 2014).

It remains a choice of the system whether to store explicit senses separately, and relatedly, whether to consult a knowledge base for the number of senses for each word, or even for meaning representations of those senses. Using a task-general knowledge base, in addition to the inherent cost of building one, is not particularly suited for our task because the items to be disambiguated are verb-role pairs, as opposed to just verbs, and usually such knowledge bases do not handle individual thematic roles separately. For instance, it may be optimal to analyze *serve* as having three senses with respect to instruments, two senses with respect to patients, and one sense with respect to agents.

Assigning semantic categories to the slots of a verb subcategorization frame harks back to work by Resnik (1996) and Rooth et al. (1999). Resnik's work presupposes predefined noun classes obtained from WordNet. Rooth et al. induced latent role-filler classes via expectation maximization. Erk et al. (2010) found that neither are good models of thematic fit. Padó et al. (2009) provided thematic fit scores that take into account verb class using a supervised model. In the vector space context, inducing different vectors for multiple verb senses has been investigated recently by Reisinger and Mooney (2010), Huang et al. (2012), and Neelakantan et al. (2014), although these were not focused on role-fillers for verbs. Our contribution is to make use of a large-scale, unsupervised vector space model to provide thematic fit scores after inducing implicit verb sense classes relative to thematic role.

3 Methods

We begin our discussion of sense disambiguation for thematic fit with the following insight: the baseline ($Centroid$) method takes as input a set of typical role-fillers, the highest-ranked ones according to the DM, and returns a single prototype vector. However, if we allow the system to return a *set* of prototype vectors, then the framework gains the capacity to handle multiple senses of the verb-role pair.

The first choice is how to handle the output. Now instead of one cosine similarity, we would have a set of cosines corresponding to the similarities between the test role-filler and each prototype vector in the set. But if we make the theoretical assumption that each prototype corresponds to a sense, then roughly only one should apply at a time. So, we choose to use the one that is most relevant, i.e. similar, to the test role-filler. Therefore, we use the maximum of the cosine similarities as the thematic fit score.

3.1 One best or nearest

In the extreme case, we can just use the unaltered set of highly-ranked role-fillers as our set of prototypes. For example, if we query $TypeDM$ for the top four instrument-fillers of *eat*, we would retrieve *spoon, hand, bread,* and *sauce*. Then, to assign a thematic fit score for *fork* as an instrument-filler, we compute the cosine similarities of (*fork*, *spoon*), (*fork*, *hand*), (*fork*, *bread*), and (*fork*, *sauce*). The cosine similarity of (*fork*, *spoon*) is the highest, so this cosine determines the score. We refer to this method as $OneBest$. Note that $OneBest$ requires the calculation of a large number of cosines, which is a relatively expensive operation given the sparse representations of words in DM spaces.

The number of retrieved top role-fillers (n) appears to be the only parameter for $OneBest$. Yet, this method poses a few theoretical questions. First, there most likely should be an upper bound on the number of role-fillers that the system can retrieve at once. Mathematically, allowing the system to retrieve the entire relevant cross-section of the tensor would be equivalent to reducing the thematic fit evaluation task to a binary decision, i.e. whether the verb-role has occurred with the test role-filler in the training data. So, we would not be able to model any graded effect on the fit of two seen role-fillers, even if one of them fits with the verb-role better than the other. Also, psycholinguistically, it seems implausible that one must remember all of the times that one has encountered a word in order to use it. Therefore, we impose 50 as an arbitrary upper bound on n. We also set a lower bound of 10 on n because values smaller than this generated quite erratic sets of top role-fillers.

Second, $OneBest$ might return a cosine of 1.0 if the DM retrieves the test role-filler itself as one of the top role-fillers. This could unfairly help the correlation between the cosines returned by the system and human judgements because the good role-fillers would all have the same cosine value, thus reducing the effect of the cosine ratings produced for the more distant (interesting) role-fillers. Therefore, we prohibit our system from returning any cosines of 1.0. The test role-filler thus achieves a high score by having a closely related role-filler in the prototype set, not by being present itself.

3.2 Clustering

In order to reduce noise from $OneBest$, we cluster similar top role-fillers together, calculate centroids for each cluster, and use these cluster centroids as the prototype set. This way, the presence of an anomalous vector in the centroid set has less effect. We use the group average agglomerative clustering package within NLTK (Bird et al., 2009). This algorithm works by initializing each top role-filler in its own cluster and iteratively combining the two most similar clusters.

For the stopping criterion, which determines the final number of clusters for the verb-role, we use the Variance Ratio Criterion (VRC) method (Caliński and Harabasz, 1974). Let c be the baseline centroid of all top role-fillers retrieved, f be a top role-filler, and c_f be the cluster centroid of the cluster to which f is assigned. Then, this method works by (a) calculating the VRC metric for each number of clusters (k), given by

$$VRC(k) = \frac{SS_B}{k-1} / \frac{SS_W}{n-k} \tag{2}$$

where we define

$$SS_B = \sum\nolimits_f (1 - \cos^2(c_f, c)) \tag{3}$$

and

$$SS_W = \sum\nolimits_f (1 - \cos^2(f, c_f)) \quad (4)$$

and then (2) choosing the final number of clusters such that

$$\omega_k = (VRC_{k+1} - VRC_k) - (VRC_k - VRC_{k-1}) \quad (5)$$

is minimized. Intuitively, this procedure is meant to find the number of clusters for which adding another cluster does not explain significantly more variance in the data. Also, note that the VRC metric is equivalent to the F-score in a one way ANOVA.

The main drawback of the VRC method is that it cannot evaluate fewer than three clusters, due to having both a VRC_{k+1} and a VRC_{k-1} term in Equation (5). However, as long as enough top role-fillers are retrieved, it should not hurt the system. Equivalently, we set VRC_0 and VRC_1 equal to VRC_2. To examine the effect of this choice, we evaluate two clustering methods: $2Clusters$, which chooses two clusters for every verb-role, and $kClusters$, which dynamically chooses a number of clusters between 3 and 10 based on the above criterion.

Once again, the system is prohibited from returning a cosine of 1.0. This means that if the DM retrieves the test role-filler itself as one of the top role-fillers, the system would skip comparing the test role-filler against itself if it were in a singleton cluster, but would not skip it if it were a member of a cluster of size two or greater. The alternative to this would have been removing the test role-filler before clustering, but we saw these role-filler-specific partitions as a form of supervision.

3.3 Evaluation procedure

The $Centroid$, $OneBest$, $2Clusters$, and $kClusters$ methods each determine their own prototype vector set for a verb-role, and then return the maximum cosine similarity value for each test role-filler. Prototype sets are stored in a dictionary so they can be reused. It is necessary to expand the sparse data structure of each vector in order to efficiently compute all of the necessary cosine similarities. Finally, we calculate Spearman's ρ values to measure the correlations between these sets of thematic fit scores and the four datasets of human judgements.

Dataset	$SDDM(X)$	$TypeDM$
Padó (2007)	98.6	100.0
McRae et al. (1998)	96.0	95.2
Ferretti et al. (2001) inst.	94.0	93.1
Ferretti et al. (2001) loc.	99.6	98.9

Table 2: Coverage (%) by dataset for each DM model.

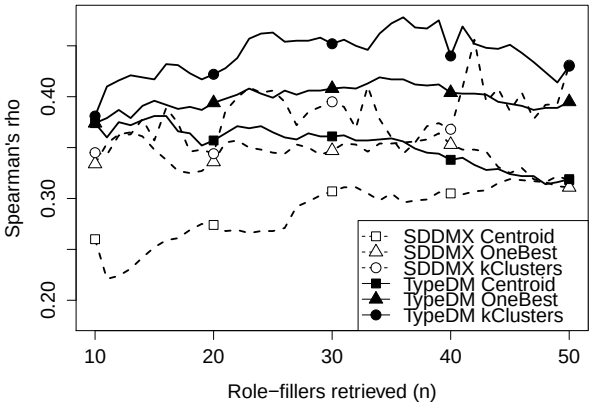

Figure 3: Spearman's ρ values for Ferretti et al. (2001) instruments vs. the number of vectors retrieved.

For our main experiment, we always retrieve the top 20 highest-ranked role-fillers for the verb-role pair to compute the prototype set. This allows our work to be more directly comparable with other implementations. Also, choosing a value of n that maximizes ρ would make this unsupervised system more supervised. However, it is useful to know how the number of top role-fillers retrieved affects the correlation with human judgements, so as a follow-up experiment, we evaluate versions of the $Centroid$, $OneBest$, and $kClusters$ methods, with the $SDDMX$ and $TypeDM$ models, retrieving from 10 to 50 top role-fillers, against the Ferretti et al. (2001) instruments dataset.

4 Results

In Table 2, we report the coverage percentages for the DM models on each of the thematic fit datasets. Note that since $SDDM$ and $SDDMX$ differ only in the additional links added between existing pairs of words, their coverages are the same.

Figure 3 shows the relationship between the number of vectors retrieved from the DM model and the correlation of the system with human judgements.

Table 3: Spearman's ρ for each method on each dataset and on all datasets together, using the 20 highest ranked words per verb-role.

The first six sections of Table 3 give the Spearman's ρ values for our four centroid set construction methods evaluated against the four datasets of human judgements, organized by thematic role, all using the 20 highest-ranked words per verb-role. We note that the ρ value for the Padó (2007) dataset using $TypeDM$ and the $Centroid$ method is slightly higher than the value reported in Baroni and Lenci (2010) due to correcting some transpositions in the original file. Finally, the last three sections of Table 3 give the performance of each method on the two whole agent/patient datasets (for comparison with previous work), as well as on all datasets merged together.

5 Discussion

While $SDDM$ and $SDDMX$ have marginally better coverage than $TypeDM$, we do not expect that this had an effect on our results. Figure 3 shows that for the various numbers of vectors retrieved from the DM models, $kClusters$ consistently outperforms $OneBest$, which consistently outperforms $Centroid$ on the Ferretti et al. (2001) instruments dataset. So, using just a single centroid that is a mixture of all possible good role-fillers for a verb leads to problems due to conflating different word meanings. But at the other extreme, we see how the ρ values for the $OneBest$ method peak (at $n = 13$ for $SDDMX$ and $n = 34$ for $TypeDM$) and then decrease instead of increasing monotonically. This is because we disallowed cosines of 1.0 and because as we increase the number of vectors retrieved, the easier it becomes to be close to one of the prototype vectors, regardless of thematic fit distinctions within the prototype set.

For the model comparison, we see that while $TypeDM$ generally performs better than $SDDMX$ on instruments, clustering reduces the gap considerably. Also $SDDMX$ outperforms $TypeDM$ for all methods on locations as shown in Table 3. This difference suggests that locations appear in sufficiently diverse syntactic configurations such that the handcrafted rules from $TypeDM$ do not work well.

From the All datasets section of Table 3, we see that both $OneBest$ and $kClusters$ improve the ρ values over the $Centroid$ baseline for all three DM models. This holds, too, for the individual instruments and locations datasets. Also, the two clustering methods perform better than $Centroid$ on Padó (2007) patients with all DM models and on McRae et al. (1998) patients with $TypeDM$. The fact that $Centroid$ performs best on Padó (2007) agents con-

firms previous analyses that have shown that the distribution of objects is more sensitive to verb sense than subjects. $kClusters$ outperforming $OneBest$ in a majority of cases suggests that clustering has successfully smoothed the top role-fillers, thus capturing sense-like patterns in the verb-roles.

As an example of the effect of the $kClusters$ method, we obtained the following top 20 instrument-fillers for the verb "eat" in 4 clusters using $TypeDM$:

- *gusto, relish*
- *family, friend*
- *chopstick, finger, fork, hand, knife, spoon*
- *appetite, bread, butter, cheese, food, meal, meat, mouth, rice, sauce*

The VRC method selected 7 to 9 clusters a little more often than 3 to 6, which is perhaps more clusters than the number of senses we could expect from a task general knowledge base. We can see from this example that the four clusters do not all correspond to separate senses, but instead, they rather nicely separate out noise from true instruments. Note that since these role-fillers came from $TypeDM$, they appeared as the object of "with," as a proxy for finding instruments. The true instruments ended up all in the third cluster, which created a cluster centroid that is less affected by noise and errors from the syntactic or semantic parse. So, the higher number of senses seems appropriate for this task and data.

We attribute the differences in results between the Padó (2007) and McRae et al. (1998) datasets to the differences in how these datasets were constructed. First, the Padó (2007) dataset contains only frequent verbs and most, but not all, of the verb-role pairs contain well-fitting and poorly-fitting role-fillers. The latter point is especially important because if the range of human judgements is small for a certain verb, then it is much more difficult to achieve a large ρ value regardless of the general performance level of the system. McRae et al. (1998), however, selected role-fillers much more automatically for their psycholinguistic study, so the data points do not necessarily reflect a typical sample of thematic role fitness decisions that occur in naturalistic language samples. So, it makes sense that the McRae et al. (1998) ρ values are systematically lower than those of Padó (2007). In fact, the Padó (2007) ρ values approach the ceiling of 0.6 as approximated by the supervised system.

Lastly, the effect of clustering was larger on instruments and locations than on agents and patients. A possible explanation is that instruments and locations are less-precisely defined thematic roles and better explained by several subclasses, i.e. clusters. In addition it could be that clustering helps to combat SRL inconsistencies.

6 Conclusions and future work

We show that clustering verb-roles into "senses" within a vector space framework achieves a higher correlation with human judgements on thematic fit over pure $Centroid$ and $OneBest$ methods. While we demonstrated this using the Distributional Memory technique by Baroni and Lenci (2010), the method will also be applicable to other vector space models.

This task has also been useful for comparing among DM models and the different thematic fit datasets. In particular, we can qualitatively evaluate how reliable syntax can be for determining the semantic notion of thematic fit, and the relative strength of human intuitions on verb-imposed restrictions on the various roles (agent, patient, instrument, and location).

In future work, we can investigate more sophisticated methods of vector clustering (such as expectation maximization and non-negative matrix factorization), interactions with verb and noun frequency, and interactions with number of word senses from a task-general knowledge-base such as WordNet. It would be especially useful to evaluate this system of a dataset of human judgements with verbs that systematically vary in polysemy, as this would more clearly expose the general trends we wish to model computationally.

Abstract

Vector Space Models (VSMs) of Semantics are useful tools for exploring the semantics of single words, and the composition of words to make phrasal meaning. While many methods can estimate the meaning (i.e. vector) of a phrase, few do so in an interpretable way. We introduce a new method (CNNSE) that allows word and phrase vectors to adapt to the notion of composition. Our method learns a VSM that is both tailored to support a chosen semantic composition operation, and whose resulting features have an intuitive interpretation. Interpretability allows for the exploration of phrasal semantics, which we leverage to analyze performance on a behavioral task.

1 Introduction

Vector Space Models (VSMs) are models of word semantics typically built with word usage statistics derived from corpora. VSMs have been shown to closely match human judgements of semantics (for an overview see Sahlgren (2006), Chapter 5), and can be used to study semantic composition (Mitchell and Lapata, 2010; Baroni and Zamparelli, 2010; Socher et al., 2012; Turney, 2012).

Composition has been explored with different types of composition functions (Mitchell and Lapata, 2010; Mikolov et al., 2013; Dinu et al., 2013) including higher order functions (such as matrices) (Baroni and Zamparelli, 2010), and some have considered which corpus-derived information is most useful for semantic composition (Turney, 2012; Fyshe et al., 2013). Still, many VSMs act like a black box - it is unclear what VSM dimensions represent (save for broad classes of corpus statistic types) and what the application of a composition function to those dimensions entails. Neural network (NN) models are becoming increasingly popular (Socher et al., 2012; Hashimoto et al., 2014; Mikolov et al., 2013; Pennington et al., 2014), and some model introspection has been attempted: Levy and Goldberg (2014) examined connections between layers, Mikolov et al. (2013) and Pennington et al. (2014) explored how shifts in VSM space encodes semantic relationships. Still, interpreting NN VSM dimensions, or factors, remains elusive.

This paper introduces a new method, Compositional Non-negative Sparse Embedding (CNNSE). In contrast to many other VSMs, our method learns an *interpretable* VSM that is tailored to suit the semantic composition function. Such interpretability allows for deeper exploration of semantic composition than previously possible. We will begin with an overview of the CNNSE algorithm, and follow with empirical results which show that CNNSE produces:

1. more interpretable dimensions than the typical VSM,
2. composed representations that outperform previous methods on a phrase similarity task.

Compared to methods that do not consider composition when learning embeddings, CNNSE produces:

1. better approximations of phrasal semantics,
2. phrasal representations with dimensions that more closely match phrase meaning.

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 32–41,
Denver, Colorado, May 31 – June 5, 2015.

2 Method

Typically, word usage statistics used to create a VSM form a sparse matrix with many columns, too unwieldy to be practical. Thus, most models use some form of dimensionality reduction to compress the full matrix. For example, Latent Semantic Analysis (LSA) (Deerwester et al., 1990) uses Singular Value Decomposition (SVD) to create a compact VSM. SVD often produces matrices where, for the vast majority of the dimensions, it is difficult to interpret what a high or low score entails for the semantics of a given word. In addition, the SVD factorization does not take into account the phrasal relationships between the input words.

2.1 Non-negative Sparse Embeddings

Our method is inspired by Non-negative Sparse Embeddings (NNSEs) (Murphy et al., 2012). NNSE promotes interpretability by including sparsity and non-negativity constraints into a matrix factorization algorithm. The result is a VSM with extremely coherent dimensions, as quantified by a behavioral task (Murphy et al., 2012). The output of NNSE is a matrix with rows corresponding to words and columns corresponding to latent dimensions.

To interpret a particular latent dimension, we can examine the words with the highest numerical values in that dimension (i.e. identify rows with the highest values for a particular column). Though the representations in Table 1 were created with our new method, CNNSE, we will use them to illustrate the interpretability of both NNSE and CNNSE, as the form of the learned representations is similar. One of the dimensions in Table 1 has top scoring words *guidance, advice* and *assistance* - words related to help and support. We will refer to these word list summaries as the dimension's **interpretable summarization**. To interpret the meaning of a particular word, we can select its highest scoring dimensions (i.e. choose columns with maximum values for a particular row). For example, the interpretable summarizations for the top scoring dimensions of the word *military* include both positions in the military (e.g. commandos), and military groups (e.g. paramilitary). More examples in Supplementary Material (`http://www.cs.cmu.edu/~fmri/papers/naacl2015/`).

NNSE is an algorithm which seeks a lower dimensional representation for w words using the c-dimensional corpus statistics in a matrix $X \in \mathbb{R}^{w \times c}$. The solution is two matrices: $A \in \mathbb{R}^{w \times \ell}$ that is sparse, non-negative, and represents word semantics in an ℓ-dimensional latent space, and $D \in \mathbb{R}^{\ell \times c}$: the encoding of corpus statistics in the latent space. NNSE minimizes the following objective:

$$\underset{A,D}{\operatorname{argmin}} \frac{1}{2} \sum_{i=1}^{w} \left\| X_{i,:} - A_{i,:} \times D \right\|^2 + \lambda_1 \left\| A_{i,:} \right\|_1 \tag{1}$$

$$\text{st: } D_{i,:} D_{i,:}^T \leq 1, \forall\, 1 \leq i \leq \ell \tag{2}$$

$$A_{i,j} \geq 0,\ 1 \leq i \leq w,\ 1 \leq j \leq \ell \tag{3}$$

where $A_{i,j}$ indicates the entry at the ith row and jth column of matrix A, and $A_{i,:}$ indicates the ith row of the matrix. The L_1 constraint encourages sparsity in A; λ_1 is a hyperparameter. Equation 2 constrains D to eliminate solutions where the elements of A are made arbitrarily small by making the norm of D arbitrarily large. Equation 3 ensures that A is non-negative. Together, A and D factor the original corpus statistics matrix X to minimize reconstruction error. One may tune ℓ and λ_1 to vary the sparsity of the final solution.

Murphy et al. (2012) solved this system of constraints using the Online Dictionary Learning algorithm described in Mairal et al. (2010). Though Equations 1-3 represent a non-convex system, when solving for A with D fixed (and vice versa) the loss function is convex. Mairal et al. break the problem into two alternating optimization steps (solving for A and D) and find the system converges to a stationary solution. The solution for A is found with a LARS implementation for lasso regression (Efron et al., 2004); D is found via gradient descent. Though the final solution may not be globally optimal, this method is capable of handling large amounts of data and has been shown to produce useful solutions in practice (Mairal et al., 2010; Murphy et al., 2012).

2.2 Compositional NNSE

We add an additional constraint to the NNSE loss function that allows us to learn a latent representation that respects the notion of semantic composition. As we will see, this change to the loss function has a huge effect on the learned latent space. Just as

Table 1: CNNSE interpretable summarizations for the top 3 dimensions of an adjective, noun and adjective-noun phrase.

military	aid	military aid (observed)
servicemen, commandos, military intelligence	guidance, advice, assistance	servicemen, commandos, military intelligence
guerrilla, paramilitary, anti-terrorist	mentoring, tutoring, internships	guidance, advice, assistance
conglomerate, giants, conglomerates	award, awards, honors	compliments, congratulations, replies

the L_1 regularizer can have a large impact on sparsity, our composition constraint represents a considerable change in composition compatibility.

Consider a phrase p made up of words i and j. In the most general setting, the following composition constraint could be applied to the rows of matrix A corresponding to p, i and j:

$$A_{(p,:)} = f(A_{(i,:)}, A_{(j,:)}) \tag{4}$$

where f is some composition function. The composition function constrains the space of learned latent representations $A \in \mathbb{R}^{w \times \ell}$ to be those solutions that are compatible with the composition function defined by f. Incorporating f into Equation 1 we have:

$$\underset{A,D,\Omega}{\operatorname{argmin}} \sum_{i=1}^{w} \frac{1}{2}\left\|X_{i,:} - A_{i,:} \times D\right\|^2 + \lambda_1 \left\|A_{i,:}\right\|_1 + \frac{\lambda_c}{2} \sum_{\substack{\text{phrase } p, \\ p=(i,j)}} \left(A_{(p,:)} - f(A_{(i,:)}, A_{(j,:)})\right)^2 \tag{5}$$

Where each phrase p is comprised of words (i, j) and Ω represents all parameters of f to be optimized. We have added a squared loss term for composition, and a new regularization parameter λ_c to weight the importance of respecting composition. We call this new formulation Compositional Non-Negative Sparse Embeddings (CNNSE). Some examples of the interpretable representations learned by CNNSE for adjectives, nouns and phrases appear in Table 1.

There are many choices for f: addition, multiplication, dilation, etc. (Mitchell and Lapata, 2010). Here we choose f to be weighted addition because it has has been shown to work well for adjective noun composition (Mitchell and Lapata, 2010; Dinu et al., 2013; Hashimoto et al., 2014), and because it lends itself well to optimization. Weighted addition is:

$$f(A_{(i,:)}, A_{(j,:)}) = \alpha A_{(i,:)} + \beta A_{(j,:)} \tag{6}$$

This choice of f requires that we simultaneously optimize for A, D, α and β. However, α and β are simply constant scaling factors for the vectors in A corresponding to adjectives and nouns. For adjective-noun composition, the optimization of α and β can be absorbed by the optimization of A. For models that include noun-noun composition, if α and β are assumed to be absorbed by the optimization of A, this is equivalent to setting $\alpha = \beta$.

We can further simplify the loss function by constructing a matrix B that imposes the composition by addition constraint. B is constructed so that for each phrase $p = (i, j)$: $B_{(p,p)} = 1$, $B_{(p,i)} = -\alpha$, and $B_{(p,j)} = -\beta$. For our models, we use $\alpha = \beta = 0.5$, which serves to average the single word representations. The matrix B allows us to reformulate the loss function from Eq 5:

$$\underset{A,D}{\operatorname{argmin}} \frac{1}{2}\left\|X - AD\right\|_F^2 + \lambda_1 \left\|A\right\|_1 + \frac{\lambda_c}{2}\left\|BA\right\|_F^2 \tag{7}$$

where F indicates the Frobenius norm. B acts as a selector matrix, subtracting from the latent representation of the phrase the average latent representation of the phrase's constituent words.

We now have a loss function that is the sum of several convex functions of A: squared reconstruction loss for A, L_1 regularization and the composition constraint. This sum of sub-functions is the format required for the alternating direction method of multipliers (ADMM) (Boyd, 2010). ADMM substitutes a dummy variable z for A in the sub-functions:

$$\underset{A,D}{\operatorname{argmin}} \frac{1}{2}\left\|X - AD\right\|_F^2 + \lambda_1 \left\|z_1\right\|_1 + \frac{\lambda_c}{2}\left\|Bz_c\right\|_F^2 \tag{8}$$

and, in addition to constraints in Eq 2 and 3, incorporates constraints $A = z_1$ and $A = z_c$ to ensure dummy variables match A. ADMM uses an aug-

mented Lagrangian to incorporate and relax these new constraints. We optimize for A, z_1 and z_c separately, update the dual variables and repeat until convergence (see Supplementary material for Lagrangian form, solutions and updates). We modified code for ADMM, which is available online[1]. ADMM is used when solving for A in the Online Dictionary Learning algorithm, solving for D remains unchanged from the NNSE implementation (see Algorithms 1 and 2 in Supplementary Material).

We use the weighted addition composition function because it performed well for adjective-noun composition in previous work (Mitchell and Lapata, 2010; Dinu et al., 2013; Hashimoto et al., 2014), maintains the convexity of the loss function, and is easy to optimize. In contrast, an element-wise multiplication, dilation or higher-order matrix composition function will lead to a non-convex optimization problem which cannot be solved using ADMM. Though not explored here, we hypothesize that A could be molded to respect many different composition functions. However, if the chosen composition function does not maintain convexity, finding a suitable solution for A may prove challenging. We also hypothesize that even if the chosen composition function is not the "true" composition function (whatever that may be), the fact that A can change to suit the composition function may compensate for this mismatch. This has the flavor of variational inference for Bayesian methods: an approximation in place of an intractable problem often yields better results with limited data, in less time.

3 Data and Experiments

We use the semantic vectors made available by Fyshe et al. (2013), which were compiled from a 16 billion word subset of ClueWeb09 (Callan and Hoy, 2009). We used the 1000 dependency SVD dimensions, which were shown to perform well for composition tasks. Dependency features are tuples consisting of two POS tagged words and their dependency relationship in a sentence; the feature value is the pointwise positive mutual information (PPMI) for the tuple. The dataset is comprised of 54,454 words and phrases. We randomly split the approximately 14,000 adjective noun phrases into a train (2/3) and test (1/3) set. From the test set we removed 200 randomly selected phrases as a development set for parameter tuning. We did not lexically split the train and test sets, so many words appearing in training phrases also appear in test phrases. For this reason we cannot make specific claims about the generalizability of our methods to unseen words.

[1] http://www.stanford.edu/~boyd/papers/admm/

Table 2: Median rank, mean reciprocal rank (MRR) and percentage of test phrases ranked perfectly (i.e. first in a sorted list of approx. 4,600 test phrases) for four methods of estimating the test phrase vectors. w.add$_{\text{SVD}}$ is weighted addition of SVD vectors, w.add$_{\text{NNSE}}$ is weighted addition of NNSE vectors.

Model	Med. Rank	MRR	Perfect
w.add$_{\text{SVD}}$	99.89	35.26	20%
w.add$_{\text{NNSE}}$	99.80	28.17	16%
Lexfunc	99.65	28.96	20%
CNNSE	**99.91**	**40.65**	**26%**

NNSE has one parameter to tune (λ_1); CNNSE has two: λ_1 and λ_c. In general, these methods are not overly sensitive to parameter tuning, and searching over orders of magnitude will suffice. We found the optimal settings for NNSE were $\lambda_1 = 0.05$, and for CNNSE $\lambda_1 = 0.05, \lambda_c = 0.5$. Too large λ_1 leads to overly sparse solutions, too small reduces interpretability. We set $\ell = 1000$ for both NNSE and CNNSE and altered sparsity by tuning only λ_1.

3.1 Phrase Vector Estimation

To test the ability of each model to estimate phrase semantics we trained models on the training set, and used the learned model and the composition function to estimate vectors of held out phrases. We sort the vectors for the test phrases, X_{test}, by their cosine distance to the predicted phrase vector $\hat{X}_{(p,:)}$.

We report two measures of accuracy. The first is median rank accuracy. Rank accuracy is: $100 \times (1 - \frac{r}{P})$, where r is the position of the correct phrase in the sorted list of test phrases, and $P = |X_{test}|$ (the number of test phrases). The second measure is mean reciprocal rank (MRR), which is often used to evaluate information retrieval tasks (Kantor and Voorhees, 2000). MRR is

$$100 \times (\frac{1}{P} \sum_{i=1}^{P} (\frac{1}{r})). \quad (9)$$

For both rank accuracy and MRR, a perfect score is 100. However, MRR places more emphasis on ranking items close to the top of the list, and less on differences in ranking lower in the list. For example, if the correct phrase is always ranked 2, 50 or 100 out of list of 4600, median rank accuracy would be 99.95, 98.91 or 97.83. In contrast, MRR would be 50, 2 or 1. Note that rank accuracy and reciprocal rank produce identical orderings of methods. That is, whatever method performs best in terms of rank accuracy will also perform best in terms of reciprocal rank. MRR simply allows us to discriminate between very accurate models. As we will see, the rank accuracy of all models is very high ($> 99\%$), approaching the rank accuracy ceiling.

3.1.1 Estimation Methods

We will compare to two other previously studied composition methods: weighted addition (**w.add$_{\text{SVD}}$**), and **lexfunc** (Baroni and Zamparelli, 2010). Weighted addition finds α, β to optimize

$$(X_{(p,:)} - (\alpha X_{(i,:)} + \beta X_{(j,:)}))^2$$

Note that this optimization is performed over the SVD matrix X, rather than on A. To estimate X for a new phrase $p = (i, j)$ we compute

$$\hat{X}_{(p,:)} = \alpha X_{(i,:)} + \beta X_{(j,:)}$$

Lexfunc finds an adjective-specific matrix M_i that solves

$$X_{(p,:)} = M_i X_{(j,:)}$$

for all phrases $p = (i, j)$ for adjective i. We solved each adjective-specific problem with Matlab's partial least squares implementation, which uses the SIMPLS algorithm (Dejong, 1993). To estimate X for a new phrase $p = (i, j)$ we compute

$$\hat{X}_{(p,:)} = M_i X_{(j,:)}$$

We also optimized the weighted addition composition function over NNSE vectors, which we call **w.add$_{\text{NNSE}}$**. After optimizing α and β using the training set, we compose the latent word vectors to estimate the held out phrase:

$$\hat{A}_{(p,:)} = \alpha A_{(i,:)} + \beta A_{(j,:)}$$

For CNNSE, as in the loss function, $\alpha = \beta = 0.5$ so that the average of the word vectors approximates the phrase.

$$\hat{A}_{(p,:)} = 0.5 \times (A_{(i,:)} + A_{(j,:)})$$

Crucially, w.add$_{\text{NNSE}}$ estimates α, β *after* learning the latent space A, whereas CNNSE *simultaneously* learns the latent space A, while taking the composition function into account. Once we have an estimate $\hat{A}_{(p,:)}$ we can use the NNSE and CNNSE solutions for D to estimate the corpus statistics X.

$$\hat{X}_{(p,:)} = \hat{A}_{(p,:)} D$$

Results for the four methods appear in Table 2. Median rank accuracies were all within half a percentage point of each other. However, MRR shows a striking difference in performance. CNNSE has MRR of 40.64, more than 5 points higher than the second highest MRR score belonging to w.add$_{\text{SVD}}$ (35.26). CNNSE ranks the correct phrase in the first position for 26% of phrases, compared to 20% for w.add$_{\text{SVD}}$. Lexfunc ranks the correct phrase first for 20% of the test phrases, w.add$_{\text{NNSE}}$ 16%. So, while all models perform quite well in terms of rank accuracy, when we use the more discriminative MRR, CNNSE is the clear winner. Note that the performance of w.add$_{\text{NNSE}}$ is much lower than CNNSE. Incorporating a composition constraint into the learning algorithm has produced a latent space that surpasses all methods tested for this task.

We were surprised to find that lexfunc performed relatively poorly in our experiments. Dinu et al. (2013) used simple unregularized regression to estimate M. We also replicated that formulation, and found phrase ranking to be worse when compared to the Partial Least Squares method described in Baroni and Zamparelli (2010). In addition, Baroni and Zamparelli use 300 SVD dimensions to estimate M. We found that, for our dataset, using all 1000 dimensions performed slightly better.

We hypothesize that our difference in performance could be due to the difference in input corpus statistics (in particular the thresholding of infrequent words and phrases), or due to the fact that we did not specifically create the training and tests sets to evenly distribute the phrases for each adjective. If an adjective i appears only in phrases in the test set, lexfunc cannot estimate M_i using training data (a hindrance not present for other methods, which

require only that the adjective appear in the training data). To compensate for this possibly unfair train/test split, the results in Table 2 are calculated over only those adjectives which could be estimated using the training set.

Though the results reported here are not as high as previously reported, lexfunc was found to be only slightly better than w.add$_{SVD}$ for adjective noun composition (Dinu et al., 2013). CNNSE outperforms w.add$_{SVD}$ by a large margin, so even if Lexfunc could be tuned to perform at previous levels on this dataset, CNNSE would likely still dominate.

3.1.2 Phrase Estimation Errors

None of the models explored here are perfect. Even the top scoring model, CNNSE, only identifies the correct phrase for 26% of the test phrases. When a model makes a "mistake", it is possible that the top-ranked phrase is a synonym of, or closely related to, the actual phrase. To evaluate mistakes, we chose test phrases for which all 4 models are incorrect and produce a different top ranked phrase (likely these are the most difficult phrases to estimate). We then asked Mechanical Turk (Mturk `http://mturk.com`) users to evaluate the mistakes. We presented the 4 mistakenly top-ranked phrases to Mturk users, who were asked to choose the one phrase most related to the actual test phrase.

We randomly selected 200 such phrases and asked 5 Mturk users to evaluate each, paying $0.01 per answer. We report here the results for questions where a majority (3) of users chose the same answer (82% of questions). For all Mturk experiments described in this paper, a screen shot of the question appears in the Supplementary Material.

Table 3 shows the Mturk evaluation of model mistakes. CNNSE and lexfunc make the most reasonable mistakes, having their top-ranked phrase chosen as the most related phrase 35.4% and 31.7% of the time, respectively. This makes us slightly more comfortable with our phrase estimation results (Table 2); though lexfunc does not reliably predict the correct phrase, it often chooses a close approximation. The mistakes from CNNSE are chosen slightly more often than lexfunc, indicating that CNNSE also has the ability to reliably predict the correct phrase, or a phrase deemed more related than those chosen by other methods.

Table 3: A comparison of mistakes in phrase ranking across 4 composition methods. To evaluate mistakes, we chose phrases for which all 4 models rank a different (incorrect) phrase first. Mturk users were asked to identify the phrase that was semantically closest to the target phrase.

Model	Predicted phrase deemed closest match to actual phrase
w.add$_{SVD}$	21.3%
w.add$_{NNSE}$	11.6%
Lexfunc	31.7%
CNNSE	**35.4%**

3.2 Interpretability

Though our improvement in MRR for phrase vector estimation is compelling, we seek to explore the meaning encoded in the word space features. We turn now to the *interpretation* of phrasal semantics and semantic composition.

3.2.1 Interpretability of Latent Dimensions

Due to the sparsity and non-negativity constraints, NNSE produces dimensions with very coherent semantic groupings (Murphy et al., 2012). Murphy et al. used an intruder task to quantify the interpretability of semantic dimensions. The intruder task presents a human user with a list of words, and they are to choose the one word that does not belong in the list (Chang et al., 2009). For example, from the list (red, green, desk, pink, purple, blue), it is clear to see that the word "desk" does not belong in the list of colors.

To create questions for the intruder task, we selected the top 5 scoring words in a particular dimension, as well as a low scoring word from that same dimension such that the low scoring word is also in the top 10th percentile of another dimension. Like the word "desk" in the example above, this low scoring word is called the *intruder*, and the human subject's task is to select the intruder from a shuffled list of 6 words. Five Mturk users answered each question, each paid $0.01 per answer. If Mturk users identify a high percentage of intruders, this indicates that the latent representation groups words in a human-interpretable way. We chose 100 questions for each of the NNSE, CNNSE and SVD representations. Because the output of lexfunc is the SVD

Table 4: Quantifying the interpretability of learned semantic representations via the intruder task. Intruders detected: % of questions for which the majority response was the intruder. Mturk agreement: the % of questions for which a majority of users chose the same response.

Method	Intruders Detected	Mturk Agreement
SVD	17.6%	74%
NNSE	86.2%	94%
CNNSE	88.9%	90%

representation X, SVD interpretability is a proxy for lexfunc interpretability.

Results for the intruder task appear in Table 4. Consistent with previous studies, NNSE provides a much more interpretable latent representation than SVD. We find that the additional composition constraint used in CNNSE has maintained the interpretability of the learned latent space. Because intruders detected is higher for CNNSE, but agreement amongst Mturk users is higher for NNSE, we consider the interpretability results for the two methods to be equivalent. Note that SVD interpretability is close to chance ($1/6 = 16.7\%$).

3.2.2 Coherence of Phrase Representations

The dimensions of NNSE and CNNSE are comparably interpretable. But, has the composition constraint in CNNSE resulted in better phrasal representations? To test this, we randomly selected 200 phrases, and then identified the top scoring dimension for each phrase in both the NNSE and CNNSE models. We presented Mturk users with the interpretable summarizations for these top scoring dimensions. Users were asked to select the list of words (interpretable summarization) most closely related to the target phrase. Mturk users could also select that neither list was related, or that the lists were equally related to the target phrase. We paid \$0.01 per answer and had 5 users answer each question. In Table 5 we report results for phrases where the majority of users selected the same answer (78% questions). CNNSE phrasal representations are found to be much more consistent, receiving a positive evaluation almost twice as often as NNSE.

Together, these results show that CNNSE representations maintain the interpretability of NNSE dimensions, while improving the coherence of phrase representations.

Table 5: Comparing the coherence of phrase representations from CNNSE and NNSE. Mturk users were shown the interpretable summarization for the top scoring dimension of target phrases. Representations from CNNSE and NNSE were shown side by side and users were asked to choose the list (summarization) most related to the phrase, or that the lists were equally good or bad.

Model	Model representation deemed most consistent with phrase
CNNSE	**54.5%**
NNSE	29.5%
Both	4.5%
Neither	11.5%

3.3 Evaluation on Behavioral Data

We now compare the performance of various composition methods on an adjective-noun phrase similarity dataset (Mitchell and Lapata, 2010). This dataset is comprised of 108 adjective-noun phrase pairs split into high, medium and low similarity groups. Similarity scores from 18 human subjects are averaged to create one similarity score per phrase pair. We then compute the cosine similarity between the composed phrasal representations of each phrase pair under each compositional model. As in Mitchell and Lapata (2010), we report the correlation of the cosine similarity measures to the behavioral scores. We withheld 12 of the 108 questions for parameter tuning, four randomly selected from each of the high, medium and low similarity groups.

Table 6 shows the correlation of each model's similarity scores to behavioral similarity scores. Again, Lexfunc performs poorly. This is probably attributable to the fact that there are, on average, only 39 phrases available for training each adjective in the dataset, whereas the original Lexfunc study had at least 50 per adjective (Baroni and Zamparelli, 2010). CNNSE is the top performer, followed closely by weighted addition. Interestingly, weighted NNSE correlation is lower than CNNSE by nearly 0.15, which shows the value of allowing the learned latent space to conform to the desired composition function.

3.3.1 Interpretability and Phrase Similarity

CNNSE has the additional advantage of interpretability. To illustrate, we created a web page to explore the dataset under the CNNSE model. The page `http://www.cs.cmu.edu/~fmri/papers/naacl2015/cnnse_mitchell_lapata_all.html` displays phrase pairs sorted by average similarity score. For each phrase in the pair we show a summary of the CNNSE composed phrase meaning. The scores of the 10 top dimensions are displayed in descending order. Each dimension is described by its interpretable summarization. As one scrolls down the page, the similarity scores increase, and the number of dimensions shared between the phrase pairs (highlighted in red) increases. Some phrase pairs with high similarity scores share no top scoring dimensions. Because we can interpret the dimensions, we can begin to understand how the CNNSE model is failing, and how it might be improved.

For example, the phrase pair judged most similar by the human subjects, but that shares none of the top 10 dimensions in common, is "large number" and "great majority" (behavioral similarity score 5.61/7). Upon exploration of CNNSE phrasal representations, we see that the representation for "great majority" suffers from the multiple word senses of majority. Majority is often used in political settings to describe the party or group with larger membership. We see that the top scoring dimension for "great majority" has top scoring words "candidacy, candidate, caucus", a politically-themed dimension. Though the CNNSE representation is not incorrect for the word, the common theme between the two test phrases is not political.

The second highest scoring dimension for "large number" is "First name, address, complete address". Here we see another case of the collision of multiple word senses, as this dimension is related to identifying numbers, rather than the quantity-related sense of number. While it is satisfying that the word senses for majority and number have been separated out into different dimensions for each word, it is clear that both the composition and similarity functions used for this task are not gracefully handling multiple word senses. To address this issue, we could partition the dimensions of A into sense-related groups and use the maximally correlated groups to score phrase pairs. CNNSE interpretability allows us to perform these analyses, and will also allow us to iterate and improve future compositional models.

Table 6: Correlation of phrase similarity judgements (Mitchell and Lapata, 2010) to pairwise distances in several adjective-noun composition models.

Model	Correlation to behavioral data
w.add$_{\text{SVD}}$	0.5377
w.add$_{\text{NNSE}}$	0.4469
Lexfunc	0.1347
CNNSE	**0.5923**

4 Conclusion

We explored a new method to create an interpretable VSMs that respects the notion of semantic composition. We found that our technique for incorporating phrasal relationship constraints produced a VSM that is more consistent with observed phrasal representations and with behavioral data.

We found that, compared to NNSE, human evaluators judged CNNSE phrasal representations to be a better match to phrase meaning. We leveraged this improved interpretability to explore composition in the context of a previously published compositional task. We note that the collision of word senses often hinders performance on the behavioral data from Mitchell and Lapata (2010).

More generally, we have shown that incorporating constraints to represent the task of interest can improve a model's performance on that task. Additionally, incorporating such constraints into an *interpretable* model allows for a deeper exploration of performance in the context of evaluation tasks.

Abstract

In this paper, we introduce a new approach for joint segmentation, POS tagging and dependency parsing. While joint modeling of these tasks addresses the issue of error propagation inherent in traditional pipeline architectures, it also complicates the inference task. Past research has addressed this challenge by placing constraints on the scoring function. In contrast, we propose an approach that can handle arbitrarily complex scoring functions. Specifically, we employ a randomized greedy algorithm that jointly predicts segmentations, POS tags and dependency trees. Moreover, this architecture readily handles different segmentation tasks, such as morphological segmentation for Arabic and word segmentation for Chinese. The joint model outperforms the state-of-the-art systems on three datasets, obtaining 2.1% TedEval absolute gain against the best published results in the 2013 SPMRL shared task.[1]

1 Introduction

Parsing accuracy is greatly impacted by the quality of preprocessing steps such as tagging and word segmentation. Li et al. (2011) report that the difference between using the gold POS tags and using the automatic counterparts reaches about 6% in dependency accuracy. Prior research has demonstrated that joint prediction alleviates error propagation inherent in pipeline architectures, where mistakes cascade from one task to the next (Bohnet et al., 2013; Tratz, 2013; Hatori et al., 2012; Zhang et al., 2014a). However, jointly modeling all the processing tasks inevitably increases inference complexity. Prior work addressed this challenge by introducing constraints on scoring functions to keep inference tractable (Qian and Liu, 2012).

In this paper, we propose a method for joint prediction that imposes no constraints on the scoring function. The method is able to handle high-order and global features for each individual task (e.g., parsing), as well as features that capture interactions between tasks. The algorithm achieves this flexibility by operating over full assignments that specify segmentation, POS tags and dependency tree, moving from one complete configuration to another.

Our approach is based on the randomized greedy algorithm from our earlier dependency parsing system (Zhang et al., 2014b). We extend this algorithm to jointly predict the segmentation and the POS tags in addition to the dependency parse. The search space for the algorithm is a combination of parse trees and lattices that encode alternative morphological and POS analyses. The inference algorithm greedily searches over this space, iteratively making local modifications to POS tags and dependency trees. To overcome local optima, we employ multiple restarts.

This simple, yet powerful approach can be easily applied to a range of joint prediction tasks. In prior work, joint models have been designed for a specific language. For instance, joint models for Chinese are designed with word segmentation in mind (Hatori et al., 2012), while algorithms for processing Semitic languages are tailored for morpho-

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 42–52,
Denver, Colorado, May 31 – June 5, 2015.

logical analysis (Tratz, 2013; Goldberg and Elhadad, 2011). In contrast, we show that our algorithm can be effortlessly applied to all these distinct languages. Language-specific characteristics drive the lattice construction and the feature selection, while the learning and inference methods are language-agnostic.

We evaluate our model on three datasets: SPMRL (Modern Standard Arabic), classical Arabic and CTB5 (Chinese). Our model consistently outperforms state-of-the-art systems designed for these languages. We obtain a 2.1% TedEval gain against the best published results in the 2013 SPMRL shared task (Seddah et al., 2013). The joint model results in significant gains against its pipeline counterpart, yielding 2.4% absolute F-score increase in dependency parsing on the same dataset. Our analysis reveals that most of this gain comes from the improved prediction on OOV words.

2 Related Work

Joint Segmentation, POS tagging and Syntactic Parsing It has been widely recognized that joint prediction is an appealing alternative for pipeline architectures (Goldberg and Tsarfaty, 2008; Hatori et al., 2012; Habash and Rambow, 2005; Gahbiche-Braham et al., 2012; Zhang and Clark, 2008; Bohnet and Nivre, 2012). These approaches have been particularly prominent for languages with difficult preprocessing, such as morphologically rich languages (e.g., Arabic and Hebrew) and languages that require word segmentation (e.g., Chinese). For the former, joint prediction models typically rely on a lattice structure to represent alternative morphological analyses (Goldberg and Tsarfaty, 2008; Tratz, 2013; Cohen and Smith, 2007). For instance, transition-based models intertwine operations on the lattice with operations on a dependency tree. Other joint architectures are more decoupled: in Goldberg and Tsarfaty (2008), a lattice is used to derive the best morphological analysis for each part-of-speech alternative, which is in turn provided to the parsing algorithm. In both cases, tractable inference is achieved by limiting the representation power of the scoring function. Our model also uses a lattice to encode alternative analyses. However, we employ this structure in a different way. The model samples the full path from the lattice, which corresponds to a valid segmentation and POS tagging assignment. Then the model improves the path and the corresponding tree via a hill-climbing strategy. This architecture allows us to incorporate arbitrary features for segmentation, POS tagging and parsing.

In joint prediction models for Chinese, lattice structures are not typically used. Commonly these models are formulated in a transition-based framework at the character level (Zhang and Clark, 2008; Zhang et al., 2014a; Wang and Xue, 2014). While this formulation can handle a large space of possible word segmentations, it can only capture features that are instantiated based on the stack and queue status. Our approach offers two advantages over prior work: (1) we can incorporate arbitrary features for word segmentation and parsing; (2) we demonstrate that a lattice-based approach commonly used for other languages can be effectively utilized for Chinese.

Randomized Greedy Inference Our prior work has demonstrated that a simple randomized greedy approach delivers near optimal dependency parsing (Zhang et al., 2014b). Our analysis explains this performance with the particular properties of the search space in dependency parsing. We show how to apply this strategy to a more challenging inference task and demonstrate that a randomized greedy algorithm achieves excellent performance in a significantly larger search space.

3 Randomized Greedy System for Joint Prediction

In this section, we introduce our model for joint morphological segmentation, tagging and parsing. Our description will first assume that word boundaries are provided (e.g., the case of Arabic). Later, we will describe how this model can be applied to a joint prediction task that involves word segmentation (e.g., Chinese).

3.1 Notation

Let $x = \{x_i\}_{i=1}^{|x|}$ be a sentence of length $|x|$ that consists of tokens x_i. We use $s = \{s_i\}_{i=1}^{|x|}$ to denote a segmentation of all the tokens in sentence x, and $s_i = \{s_{i,j}\}_{j=1}^{|s_i|}$ to denote a segmentation of the token x_i, where $s_{i,j}$ is the jth morpheme of the token x_i. Similarly, we use t, t_i and $t_{i,j}$ for the POS

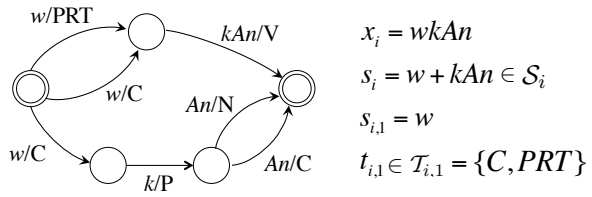

Figure 1: Example lattice structures for the Arabic token "*wkAn*". It has two candidate segmentations: *w+kAn* or *w+k+An*. The first segmentation consists of two morphemes. The first morpheme *w* has two candidate POS.

tags for each sentence, token and morpheme. We use y to denote a dependency tree over morphemes, and $y_{i,j}$ to denote the head of morpheme $s_{i,j}$. During training, the algorithm is provided with tuples that specify ground truth values for all the variables $\mathcal{D} = \{(x, \hat{s}, \hat{t}, \hat{y})\}$.

We also assume access to a morphological analyzer and a POS tagger that provide candidate analyses. Specifically, for each token x_i, the algorithm is provided with candidate segmentations $\mathcal{S}_i$, and candidate POS tags $\mathcal{T}_i$ and $\mathcal{T}_{i,j}$. These alternative analyses are captured in the **lattice structure** (see Figure 1 for an example). Finally, we use $\mathcal{Y}$ to denote the set of all valid dependency trees defined over morphemes.

3.2 Decoding

We parameterize the scoring function as

$$score(x, s, t, y) = \theta \cdot f(x, s, t, y) \qquad (1)$$

where θ is the parameter vector and $f(x, s, t, y)$ is the feature vector associated with the sentence and all variables.

The goal of decoding is to find a set of valid values for $(s, t, y) \in \mathcal{S} \times \mathcal{T} \times \mathcal{Y}$ that maximizes the score defined in Eq. 1. Our randomized greedy algorithm finds a high scoring assignment for (s, t, y) via a hill-climbing process with multiple random restarts. (Section 3.3 describes how the parameters θ are learned.)

Figure 2 shows the framework of our randomized greedy algorithm. First, we draw a full path from the lattice structure in two steps: (1) sampling a morphological segmentation s from $\mathcal{S}$; (2) sampling POS tags t for each morpheme. Next, we sample a dependency tree y from the parse space. Based on this random starting point, we iteratively hill-climb t and y in a bottom-up order.[2] In our earlier work (Zhang et al., 2014b), we showed this strategy guarantees that we can climb to any target tree in a finite number of steps. We repeat the sampling and the hill-climbing processes above until we do not find a better solution for K iterations. We introduce the details of this process below.

SampleSeg and SamplePOS: Given a sentence x, we first draw segmentations s and POS tags $t^{(0)}$ from the first-order distribution using the current learned parameter values. For segmentation, first-order features only depend on each token x_i and its morphemes $s_{i,j}$. Similarly, for POS, first-order features are defined based on $s_{i,j}$ and $t_{i,j}$. The sampling process is straightforward due to the fact that the candidate sets $|\mathcal{S}_i|$ and $|\mathcal{T}_{i,j}|$ are both small. We can enumerate and compute the probabilities proportional to the exponential of the first-order scores as follows.[3]

$$\begin{aligned} p(s_i) &\propto \exp\{\theta \cdot f(x, s_i)\} \\ p(t_{i,j}) &\propto \exp\{\theta \cdot f(x, s_i, t_{i,j})\} \end{aligned} \qquad (2)$$

SampleTree: Given a random sample of the segmentations s and the POS tags $t^{(0)}$, we draw a random tree $y^{(0)}$ from the first-order distribution using Wilson's algorithm (Wilson, 1996).[4]

HillClimbPOS: After sampling the initial values s, $t^{(0)}$ and $y^{(0)}$, the hill-climbing algorithm improves the solution via locally greedy changes. The hill-climbing algorithm iterates between improving the POS tags and the dependency tree. For POS tagging, it updates each $t_{i,j}$ in a bottom-up order as follows

$$t_{i,j} \leftarrow \underset{t_{i,j} \in \mathcal{T}_{i,j}}{\arg\max}\, score(x, s, t_{i,j}, t_{-(i,j)}, y) \qquad (3)$$

where $t_{-(i,j)}$ are the rest of the POS tags when we update $t_{i,j}$.

[2] We do not hill-climb segmentation, or else we have to jointly find the optimal t and y, and the resulting computational cost is too high.

[3] We notice that the distribution becomes significantly sharper after training for several epochs. Therefore, we also smooth the distribution by multiplying the score with a scaling factor.

[4] We also smooth the distribution in the same way as in segmentation and POS tagging.

Input: parameter θ, sentence x
Output: segmentations s, POS tags t and dependency tree y

1: $s \leftarrow SampleSeg(x)$
2: $t^{(0)} \leftarrow SamplePos(x, s)$
3: $y^{(0)} \leftarrow SampleTree(x, s, t^{(0)})$
4: $k = 0$
5: **repeat**
6: $\quad t^{(k+1)} \leftarrow HillClimbPOS(x, s, t^{(k)}, y^{(k)})$
7: $\quad y^{(k+1)} \leftarrow HillClimbTree(x, s, t^{(k+1)}, y^{(k)})$
8: $\quad k \leftarrow k + 1$
9: **until** no change in this iteration
10: **return** $(s, t^{(k)}, y^{(k)})$

Figure 2: The hill-climbing algorithm with random initializations. Details of the sampling and hill-climbing functions in Line 1-3 and 6-7 are provided in Section 3.2.

HillClimbTree: We improve the dependency tree y via a similar hill-climbing process. Specifically, we greedily update the head $y_{i,j}$ of each morpheme in a bottom-up order as follows

$$y_{i,j} \leftarrow \underset{y_{i,j} \in \mathcal{Y}_{i,j}}{\arg\max}\, score(x, s, t, y_{i,j}, y_{-(i,j)}) \quad (4)$$

where $\mathcal{Y}_{i,j}$ is the set of candidate heads such that changing $y_{i,j}$ to any candidate does not violate the tree constraint.

3.3 Training

We learn the parameters θ in a max-margin framework, using on-line updates. For each update, we need to compute the segmentations, POS tags and the tree that maximize the cost-augmented score:

$$(\tilde{s}, \tilde{t}, \tilde{y}) = \underset{s \in \mathcal{S}, t \in \mathcal{T}, y \in \mathcal{Y}}{\arg\max} \{\theta \cdot f(x, s, t, y) + Err(s, t, y)\} \quad (5)$$

where $Err(s, t, y)$ is the number of errors of (s, t, y) against the ground truth $(\hat{s}, \hat{t}, \hat{y})$. The parameters are then updated to guide the selection against the violation. This is done via standard passive-aggressive updates (Crammer et al., 2006).

3.4 Adapting to Chinese Joint Prediction

In this section we describe how the proposed model can be adapted to languages that do not delineate words with spaces, and thus require word segmentation. The main difference lies in the construction of the lattice structure. We employ a state-of-the-art word segmenter to produce candidate word boundaries. We consider boundaries common across all the top-k candidates as true word boundaries. The remaining tokens (i.e., strings between these boundaries) are treated as words to be further segmented and labeled with POS tags. Figure 3 shows an example of the Chinese word lattice structure we construct. Once the lattice is constructed, the joint prediction model is applied as described above.

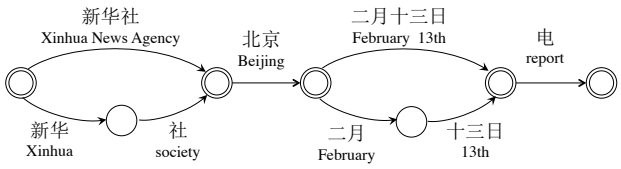

Figure 3: Example lattice structures for the Chinese sentence "新华社北京二月十三日电" (Xinhua Press at Beijing reports on February 13th). The token 新华社 has two candidate segmentations: 新华社 or 新华 + 社.

4 Features

Segmentation Features For both Arabic and Chinese, each segmentation is represented by its score from the preprocessing system, and by the corresponding morphemes (or words in Chinese). Following previous work (Zhang and Clark, 2010), we also add character-based features for Chinese word segmentation, including the first and the last characters in the word, and the length of the word.

POS Tag Features Table 1 summarizes the POS tag features employed by the model. First, we use the feature templates proposed in our previous work on Arabic joint parsing and POS correction (Zhang et al., 2014c). In addition, we incorporate character-based features specifically designed for Chinese. These features are mainly inspired by previous transition-based models on Chinese joint POS tagging and word segmentation (Zhang and Clark, 2010).

Dependency Parsing Features The feature templates for dependency parsing are mainly drawn from our previous work (Zhang et al., 2014b). Fig-

1-gram	$\langle t_0, w_{-2}\rangle, \langle t_0, w_{-1}\rangle, \langle t_0, w_0\rangle, \langle t_0, w_1\rangle, \langle t_0, w_2\rangle,$ $\langle t_0, w_{-1}, w_0\rangle, \langle t_0, w_0, w_1\rangle, \langle s(t_0)\rangle, \langle t_0, s(t_0)\rangle$
2-gram	$\langle t_{-1}, t_0\rangle, \langle t_{-2}, t_0\rangle, \langle t_{-1}, t_0, w_{-1}\rangle, \langle t_{-1}, t_0, w_0\rangle$
3-gram	$\langle t_{-1}, t_0, t_1\rangle, \langle t_{-2}, t_0, t_1, \rangle, \langle t_{-1}, t_0, t_2\rangle,$ $\langle t_{-2}, t_0, t_2\rangle$
4-gram	$\langle t_{-2}, t_{-1}, t_0, t_{+1}\rangle, \langle t_{-2}, t_{-1}, t_0, t_2\rangle,$ $\langle t_{-2}, t_0, t_1, t_2\rangle$
5-gram	$\langle t_{-2}, t_{-1}, t_0, t_1, t_2\rangle$
Character	$\langle t_0, pre_1(w_0)\rangle, \langle t_0, pre_2(w_0)\rangle, \langle t_0, suf_1(w_0)\rangle,$ $\langle t_0, suf_2(w_0)\rangle, \langle t_0, c_n(w_0)\rangle, \langle t_0, len(w_0)\rangle$

Table 1: POS tag feature templates. t_0 and w_0 denotes the POS tag and the word at the current position. t_{-x} and t_x denote left and right context tags, and similarly for words. $s(\cdot)$ denotes the score of the POS tag produced by the preprocessing tagger. The last row shows the "Character"-based features for Chinese. $pre_1(\cdot)$ and $pre_2(\cdot)$ denote the word prefixes with one and two characters respectively. $suf_1(\cdot)$ and $suf_2(\cdot)$ denote the word suffixes similarly. $c_n(\cdot)$ denotes the n-th character in the word. $len(\cdot)$ denotes the length of the word, capped at 5 if longer.

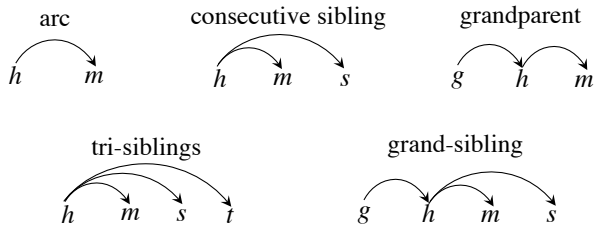

Figure 4: First- to third-order dependency parsing features.

ure 4 shows the first- to third-order feature templates that we use in our model. We also use global features to capture the adjacent conjuncts agreement in a coordination structure, and the valency patterns for each POS category. Note that most dependency features are implicitly cross-task in that they include POS tag and segmentation information. For example, the standard feature involves the POS tags of the words on both ends of the arc.

5 Experimental Setup

5.1 Datasets

We evaluate our model on two Arabic datasets and one Chinese dataset. For the first Arabic dataset, we use the dataset used in the Statistical Parsing of Morphologically Rich Languages (SPMRL) Shared Task 2013 (Seddah et al., 2013).[5] We follow the official split for training, development and testing set. We use the core set of 12 POS categories provided by Marton et al. (2013). In the second Arabic dataset, the training set is a dependency conversion of the Arabic Treebank, which primarily includes Modern Standard Arabic (MSA) text. However, we test on a new corpus, which consists of classical Arabic text obtained from the Comprehensive Islamic Library (CIS).[6] A native Arabic speaker with background in computational linguistics annotated the morphological segmentation and POS tags. This corpus is an excellent testbed for a joint model because classical Arabic may use rather different vocabulary from MSA, while their syntactic grammars are very similar to each other. Therefore incorporating syntactic information should be particularly beneficial to morphological segmentation and POS tagging. For Chinese, we use the Chinese Penn Treebank 5.0 (CTB5) and follow the split in previous work (Zhang and Clark, 2010).

Dataset		SPMRL	Classical	CTB5
Language		Arabic	Arabic	Chinese
Train	#sent	14.4k	15.4k	17.5k
	#token	451k	573k	442k
Dev.	#sent	1.8k	–	348
	#token	56.9k	–	6.6k
Test.	#sent	1.8k	163	348
	#token	55.6k	7.9k	8.0k

Table 2: Statistics of datasets.

Table 2 summarizes the statistics of the datasets. For the SPMRL test set, we follow the common practice which limits the sentence lengths up to 70 (Seddah et al., 2013). For classical Arabic and Chinese, we evaluate on all the test sentences.

5.2 Generating Lattice Structures

In this section we introduce the methodology for constructing candidate sets for segmentation and

[5]This dataset is originally provided by the LDC (Maamouri et al., 2004), specifically its SPMRL 2013 dependency instance, derived from the Columbia Catib Treebank (Habash and Roth, 2009; Habash et al., 2009) and extended according to the SPMRL 2013 extension scheme (Seddah et al., 2013).

[6]This classical Arabic dataset is publicly available at `http://farasa.qcri.org/`

MADA analysis

Lattice structure

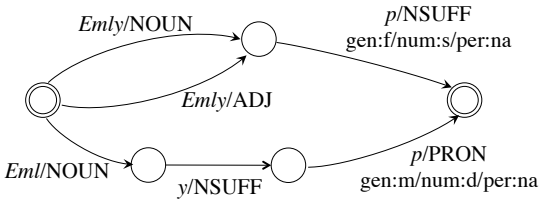

Figure 5: Example MADA analysis for the word *Emlyp* and the corresponding lattice structure.

POS tagging. Table 3 provides statistics on the generated candidate sets.

SPMRL 2013 Following Marton et al. (2013), we use the MADA system to generate candidate morphological analyses and POS tags. For each token in the sentence, MADA provides a list of possible morphological analyses and POS tags, each associated with a score. The score of each segmentation or POS tag equals the highest score of the MADA analysis in which it appears. In addition, we associate each segmentation with MADA analyses on gender, number and person. Figure 5 shows an example of MADA output for the token *Emlyp* and the corresponding lattice structure.

Classical Arabic We construct the lattice for this corpus in a similar fashion to the SPMRL dataset with two main departures. First, we use the Arabic morphological analyzer developed by Darwish et al. (2014) because MADA is primarily trained for MSA and performs poorly on classical Arabic. Second, we implement a CRF-based morpheme-level POS tagger and generate the POS tag candidates for each morpheme based on their marginal probabilities, truncated by a probability threshold.

CTB5 We first re-train the Stanford Chinese word segmenter on CTB5 and generate a top-10 list for each sentence.[7] We treat the word boundaries shared across all the 10 candidates as the confident ones, and construct the lattice as described in Section 3.4. Our model then focuses on disambiguating the rest of the word boundaries in the candidates. To generate POS candidates, we apply a CRF-based tagger with Chinese-specific features used in previous work (Hatori et al., 2011).

[7] We use 10-fold cross validation to avoid overfitting on the training set.

Dataset	Seg			POS	
	F1	Oracle	Avg. $\lvert\mathcal{S}_i\rvert$	F1	Avg. $\lvert\mathcal{T}_{i,j}\rvert$
SPMRL	99.4	99.8	1.23	96.9	1.71
Classical	92.4	97.0	1.16	82.4	3.01
CTB5	95.3	99.0	1.22	91.4	2.02

Table 3: Quality of the lattice structures on each dataset. For SPMRL and CTB5, we show the statistics on the development sets. For classical Arabic, we directly show the statistics on the testing set because the development set is not available.

5.3 Evaluation Measures

Following standard practice in previous work (Hatori et al., 2012; Zhang et al., 2014a), we use F-score as the evaluation metric for segmentation, POS tagging and dependency parsing. We report the morpheme-level F-score for Arabic and the word-level F-score for Chinese. In addition, we use TedEval (Tsarfaty et al., 2012) to evaluate the joint prediction on the SPMRL dataset, because TedEval score is the only evaluation metric used in the official report. We directly use the evaluation tools provided on the SPMRL official website.[8]

5.4 Baselines

State-of-the-Art Systems For the SPMRL dataset, we directly compare with Björkelund et al. (2013). This system achieves the best TedEval score in the track of dependency parsing with predicted information and we directly republish the official result. We also compute the F-score of this system on each task using our own evaluation script.[9] For the CTB5 dataset, we directly compare to the arc-eager system by Zhang et al. (2014a), which slightly outperforms the arc-standard system by Hatori et al. (2012).

[8] http://www.spmrl.org/spmrl2013-sharedtask.html

[9] F-score evaluation for Arabic is not straightforward due to the stem changes in the morphological analysis. Therefore, the comparison of F-scores is only approximate.

Model	SPMRL				Classical Arabic		CTB5

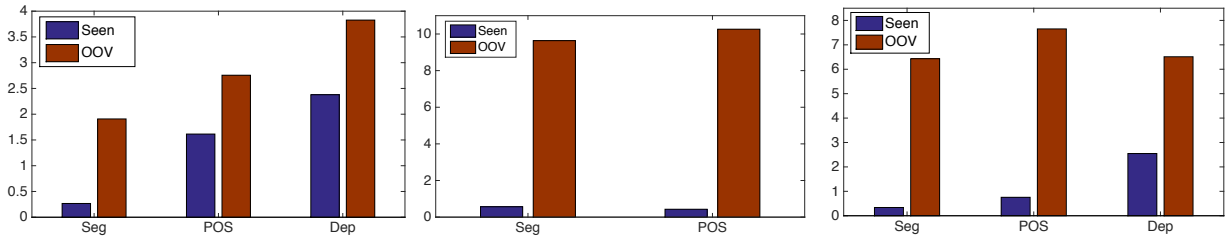
Joint	**99.52**	**97.43**	**87.23**	**93.87**	**94.35**	**84.44**	**98.04**	**94.47**	**82.01**
Best Published	96.42	91.66	82.41	91.74	–	–	97.76	94.36	81.70

Table 4: Segmentation, POS tagging and unlabeled attachment dependency F-scores (%) and TedEval score (%) on different datasets. The first line denotes the performance by the pipeline variation of our model. The second row shows the results by our joint model. "Best Published" includes the best reported results: Björkelund et al. (2013) for the SPMRL 2013 shared task and Zhang et al. (2014a) for the CTB5 dataset. Note that the POS F-scores are not directly comparable because Björkelund et al. (2013) use a different POS tagset from us.



(a) SPMRL (b) Classical Arabic (c) CTB5

Figure 6: Absolute F-score (%) improvement of the joint model over the pipeline counterpart on seen and out-of-vocabulary (OOV) words.

System Variants We also compare against a pipeline variation of our model. In our pipeline model, we predict segmentations and POS tags by the same system that we use to generate candidates. The subsequent standard parsing model then operates on the predicted segmentations and POS tags.

5.5 Experimental Details

Following our earlier work (Zhang et al., 2014b), we train a first-order classifier to prune the dependency tree space.[10] Following common practice, we average parameters over all iterations after training with passive-aggressive online learning algorithm (Crammer et al., 2006; Collins, 2002). We use the same adaptive random restart strategy as in our earlier work (Zhang et al., 2014b) and set $K = 300$. In addition, we also apply an aggressive early-stop strategy during training for efficiency. If we have found a violation against the ground truth during the first 50 iterations, we immediately stop and update the parameters based on the current violation. The reasoning behind this early-stop strategy is that weaker violations for some training sentences are already sufficient for separable training sets (Huang et al., 2012).

6 Results

Comparison to State-of-the-art Systems Table 4 summarizes the performance of our model and the best published results for the SPMRL and the CTB5 datasets.[11] On both datasets, our system outperforms the baselines. On the SPMRL 2013 shared task, our approach yields a 2.1% TedEval score gain over the top performing system (Björkelund et al., 2013). We also improve the segmentation and dependency F-scores by 3.1% and 4.8% respectively. Note that the POS F-scores are not directly comparable because Björkelund et al. (2013) use a different POS tagset from us. On the CTB5 dataset, we outperform the state-of-the-art with respect to all

[10] We set the probability threshold to 0.05 and limit the number of candidate heads up to 20, which gives a 99.5% pruning recall on both the SPMRL and the CTB5 development sets.

[11] We are not aware of any published results on the Classical Arabic Dataset.

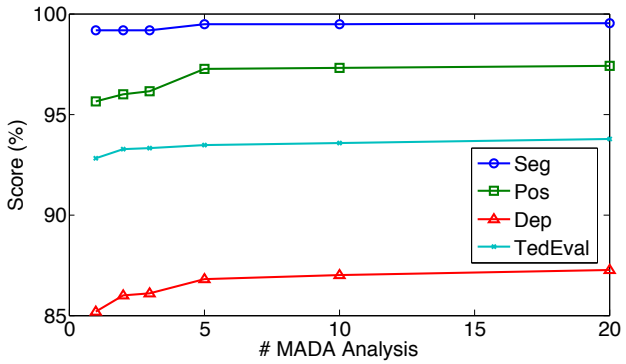


Figure 7: Performance with different sizes of the candidate sets on the SPMRL dataset. The graph shows the TedEval and F-scores when considering the best k analyses by MADA, and the variation is achieved by changing k.

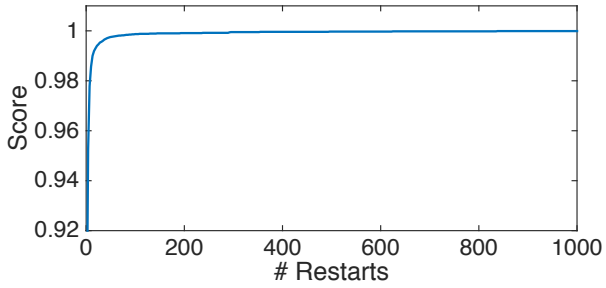

Figure 8: The normalized score of the output tree as the function of the number of restarts. We normalize scores of each sentence by the highest score among 3,000 restarts for this sentence. We show the curve up to 1,000 restarts because it reaches convergence after 500 restarts.

tasks: segmentation (0.3%), tagging (0.1%), and dependency parsing (0.3%).[12]

Impact of the Joint Prediction As Table 4 shows, our joint prediction model consistently outperforms the corresponding pipeline model in all three tasks. This observation is consistent with findings in previous work (Hatori et al., 2012; Tratz, 2013). We also observe that gains are higher (2%) on the classical Arabic dataset, which demonstrates that joint prediction is particularly helpful in bridging the gap between MSA and classical Arabic.

[12]Zhang et al. (2014a) improve the dependency F-score to 82.14% by adding manually annotated intra-word dependency information. Even without such gold word structure annotations, our model still achieves a comparable result.

Dataset	Seg		POS		Dep	
	Seen	OOV	Seen	OOV	Seen	OOV
SPMRL	48.4	27.8	44.7	15.0	15.9	17.5
Classical	13.8	34.8	4.2	17.2	–	–
CTB5	20.3	25.7	14.2	19.9	13.0	15.6

Table 5: F-score error reductions (%) of the joint model over the pipeline counterpart on seen and OOV words.

Figure 6 shows the break of the improvement based on seen and out-of-vocabulary (OOV) words. As expected, across all languages OOV words benefit more from the joint prediction, as they constitute a common source of error propagation in a pipeline model. The extent of improvement depends on the underlying accuracy of the preprocessing for segmentation and POS tagging on OOV words. For instance, we observe a higher gain (7%) on Chinese OOV words which have a 61.5% accuracy when processed by the original stand-along POS tagger. On the SPMRL dataset, the gain on OOV words is lower (3%), while preprocessing accuracy is higher (82%). Their error reductions on OOV words are nevertheless close to each other. Table 5 summarizes the results on F-score error reduction.

We also observe that the error reductions of OOV words/morphemes on the Chinese and the Classical Arabic dataset are larger than that of the in-vocabulary counterparts (e.g. 26% vs. 20% on Chinese word segmentation). However, we have the opposite observation on the segmentation and POS tagging on the SPMRL dataset (28% vs. 48%). This can be explained by analyzing the oracle performance in which we select the best solution from possible candidates. The oracle error reduction of OOV morphemes in the SPMRL dataset is relatively low (44%), compared to the 61% oracle error reduction of OOV morphemes in the Classical Arabic dataset.

Impact of the Number of Alternative Analyses In Figure 7, we plot the performance on the SPMRL dataset as a function of the number k of MADA analyses that we use to construct the candidate sets. For low k, increasing the number of analyses improves performance across all evaluation metrics. However, the performance converges at around $k = 15$.

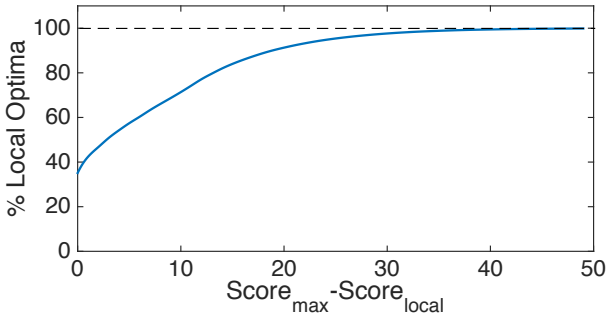

Figure 9: Cumulative distribution function (CDF) for the number of local optima versus the score of these local optima obtained from each restart, on the SPMRL dataset. The score captures the difference between a local optimum and the best one among 3,000 restarts.

Convergence Properties To assess the quality of the approximation obtained by the randomized greedy inference, we would like to compare it against the optimal solution. Following our earlier work (Zhang et al., 2014b), we use the highest score among 3,000 restarts for each sentence as a proxy for the optimal solution. Figure 8 shows the normalized score of the retrieved solution as a function of the number of restarts. We observe that most sentences converge quickly.[13] Specifically, more than 97% of the sentences converge within first 300 restarts. Since for the vast majority of cases our system converges fast, we achieve a comparable speed to that of other state-of-the-art joint systems. For example, our model achieves high performance on Chinese at about 0.5 sentences per second. The speed is about the same as that of the transition-based system (Hatori et al., 2012) with beam size 64, the setting that achieved best accuracy in their work.

Quality of Local Optima Figure 9 shows the cumulative distribution function (CDF) for the number of local optima versus the score of these local optima obtained from each restart. More specifically, the score captures the difference between a local optimum and the maximal score among 3,000 restarts. We can see that most of the local optima reached by hill-climbing have scores close to the maximum. For instance, about 30% of the local optima are identical to the best solution, namely $score_{max} - score_{local} = 0$.

[13] As expected, we also observe that convergence is slower when comparing to standard dependency parsing with a similar randomized greedy algorithm (Zhang et al., 2014b), because joint prediction results in a harder inference problem.

7 Conclusions

In this paper, we propose a general randomized greedy algorithm for joint segmentation, POS tagging and dependency parsing. On both Arabic and Chinese, our model achieves improvement on the three tasks over state-of-the-art systems and pipeline variants of our system. In particular, we demonstrate that OOV words benefits more from the power of joint prediction. Finally, our experimental results show that increasing candidate sizes improves performance across all evaluation metrics.

Acknowledgments

Abstract

Incremental parsers have potential advantages for applications like language modeling for machine translation and speech recognition. We describe a new algorithm for incremental transition-based Combinatory Categorial Grammar parsing. As English CCGbank derivations are mostly right branching and non-incremental, we design our algorithm based on the dependencies resolved rather than the derivation. We introduce two new actions in the shift-reduce paradigm based on the idea of 'revealing' (Pareschi and Steedman, 1987) the required information during parsing. On the standard CCGbank test data, our algorithm achieved improvements of 0.88% in labeled and 2.0% in unlabeled F-score over a greedy non-incremental shift-reduce parser.

1 Introduction

Combinatory Categorial Grammar (CCG) (Steedman, 2000) is an efficiently parseable, yet linguistically expressive grammar formalism. In addition to predicate-argument structure, CCG elegantly captures the unbounded dependencies found in grammatical constructions like relativization, coordination etc. Availability of the English CCGbank (Hockenmaier and Steedman, 2007) has enabled the creation of several robust and accurate wide-coverage CCG parsers (Hockenmaier and Steedman, 2002; Clark and Curran, 2007; Zhang and Clark, 2011). While the majority of CCG parsers use chart-based approaches (Hockenmaier and Steedman, 2002; Clark and Curran, 2007), there has been some work on developing shift-reduce parsers for CCG (Zhang and Clark, 2011; Xu et al., 2014). Most of these parsers model normal-form CCG derivations (Eisner, 1996), which are mostly right-branching trees : hence are not incremental in nature. The dependency models of Clark and Curran (2007) and Xu et al. (2014) model dependencies rather than derivations, but do not guarantee incremental analyses.

Besides being cognitively plausible (Marslen-Wilson, 1973), incremental parsing is more useful than non-incremental parsing for some applications. For example, an incremental analysis is required for integrating syntactic and semantic information into language modeling for statistical machine translation (SMT) and automatic speech recognition (ASR) (Roark, 2001; Wang and Harper, 2003).

This paper develops a new incremental shift-reduce algorithm for parsing CCG by building a dependency graph in addition to the CCG derivation as a representation. The dependencies in the graph are extracted from the CCG derivation. A node can have multiple parents, and hence we construct a dependency graph rather than a tree. Two new actions are introduced in the shift-reduce paradigm for "revealing" (Pareschi and Steedman, 1987) unbuilt structure during parsing. We build the dependency graph in parallel to the incremental CCG derivation and use this graph for revealing, via these two new actions. On the standard CCGbank test data, our algorithm achieves improvements of 0.88% in labeled F-score and 2.0% in unlabeled F-score over a greedy non-incremental shift-reduce algorithm. As our algorithm does not model derivations, but rather models transitions, we do not need a treebank

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 53–63,
Denver, Colorado, May 31 – June 5, 2015.

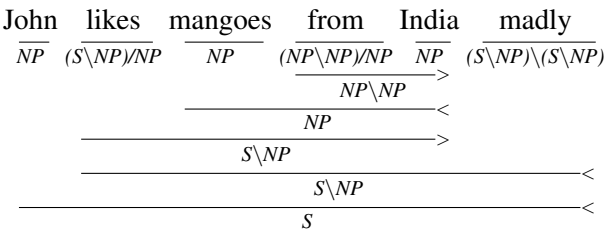

Figure 1: Normal form CCG derivation.

of incremental CCG derivations and can train on the dependencies in the existing treebank. Our approach can therefore be adapted to other languages with dependency treebanks, since CCG lexical categories can be easily extracted from dependency treebanks (Cakici, 2005; Ambati et al., 2013).

The rest of the paper is arranged as follows. Section 2 gives a brief introduction to related work in the areas of CCG parsing and incremental parsing. In section 3, we describe our incremental shift-reduce parsing algorithm. Details about the experiments, evaluation metrices and analysis of the results are in section 4. We conclude with possible future directions in section 5.

2 Related Work

In this section, we first give a brief introduction to various available CCG parsers. Then we describe approaches towards incremental and greedy parsing.

2.1 CCG Parsers

There has been a significant amount of work on developing chart-based parsers for CCG. Both generative (Hockenmaier and Steedman, 2002) and discriminative (Clark et al., 2002; Clark and Curran, 2007; Auli and Lopez, 2011; Lewis and Steedman, 2014) models have been developed. As these parsers employ a bottom-up chart-parsing strategy and use normal-form CCGbank derivations which are right-branching, they are not incremental in nature. In an SVO (Subject-Verb-Object) language, these parsers first attach the object to the verb and then the subject.

Two major works in shift-reduce CCG parsing with accuracies competitive with the widely used Clark and Curran (2007) parser (C&C) are Zhang and Clark (2011) and Xu et al. (2014). Zhang and Clark (2011) used a global linear model trained discriminatively with the averaged perceptron (Collins, 2002) and beam search for their shift-reduce CCG parser. Xu et al. (2014) developed a dependency model for shift-reduce CCG parsing using a dynamic oracle technique. Unlike the chart parsers, both these parsers can produce fragmentary analyses when a complete spanning analysis is not found. Both these shift-reduce parsers are more incremental than standard chart based parsers. But, as they employ an arc-standard (Yamada and Matsumoto, 2003) shift-reduce strategy on CCG-bank, given an SVO language, these parsers are not guaranteed to attach the subject before the object.

2.2 Incremental Parsers

A strictly incremental parser is one which computes the relationship between words as soon as they are encountered in the input. Shift-reduce CCG parsers rely either on CCGbank derivations (Zhang and Clark, 2011) which are non-incremental, or on dependencies (Xu et al., 2014) which could be incremental in simple cases, but do not guarantee incrementality. Hassan et al. (2009) developed a semi-incremental CCG parser by transforming the English CCGbank into left branching derivation trees. The strictly incremental version performed with very low accuracy but a semi-incremental version gave a balance between incrementality and accuracy. There is also some work on incremental parsing using grammar formalisms other than CCG like phrase structure grammar (Collins and Roark, 2004) and tree substitution grammar (Sangati and Keller, 2013).

2.3 Greedy Parsers

There has been a significant amount of work on greedy shift-reduce dependency parsing. The Malt parser (Nivre et al., 2007) is one of the earliest parsers based on this paradigm. Goldberg and Nivre (2012) improved learning for greedy parsers by using dynamic oracles rather than a single static transition sequence as the oracle. In all the standard shift-reduce parsers, when two trees combine, only the top node (root) of each tree participates in the action. Sartorio et al. (2013) introduced a technique where in addition to the root node, nodes on the right and left periphery respectively are also available for attachment in the parsing process. A non-monotonic parsing strategy was introduced by Honnibal et al. (2013), where an action taken during the parsing process is revised based on future context.

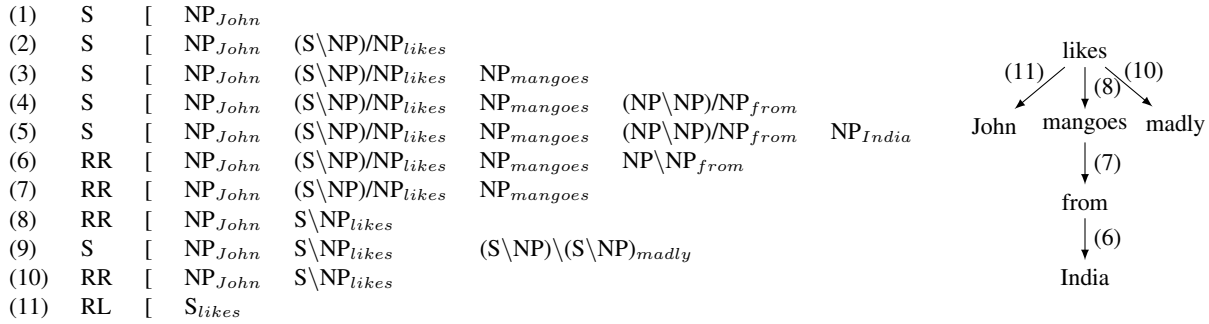

Figure 2: NonInc - Sequence of actions with parser configuration and the corresponding dependency graph.

Though the performance of these greedy parsers is less accurate than related parsers using a beam (Zhang and Nivre, 2011), greedy parsers are interesting as they are very fast and are practically useful in large-scale applications such as parsing the web and online machine translation or speech recognition. In this work, we develop a new greedy transition-based algorithm for incremental CCG parsing, which is more incremental than Zhang and Clark (2011) and Xu et al. (2014) and more accurate than Hassan et al. (2009). Our algorithm is not strictly incremental as we only produce derivations which are compatible with the Strict Competence Hypothesis (Steedman, 2000) (details in §3.2.3).

3 Algorithms

We first describe the Zhang and Clark (2011) style shift-reduce algorithm for CCG parsing. Then we explain our incremental algorithm based on the "revealing" technique for shift-reduce CCG parsing.

3.1 Non Incremental Algorithm (NonInc)

This is our baseline algorithm and is similar to Zhang and Clark (2011)'s algorithm (henceforth NonInc). It consists of an input buffer and a stack and has four major parsing actions.

- Shift - X `(S)` : Pushes a word from the input buffer to the stack and assigns a CCG category X. This action performs category disambiguation as well, as X can be any of the categories assigned by a supertagger.
- Reduce Left - X `(RL)` : Pops the top two nodes from the stack, combines them into a new node and pushes it back onto the stack with a category X. This corresponds to binary rules in the CCGbank (e.g. CCG combinators like function application, composition etc., and punctuation rules). In this action the right node is the head and hence the left node is reduced.
- Reduce Right - X `(RR)` : This action is similar to the RL (Reduce Left -X) action, except that in this action the right node is reduced since the left node is the head.
- Unary - X `(U)` : Pops the top node from the stack, converts it into a new node with category X and pushes it back on the stack. The head remains the same in this action. This action corresponds to unary rules in the CCGbank (unary type-changing and type-raising rules).

Figure 1 shows a normal-form CCG derivation for an example sentence 'John likes mangoes from India madly'. Figure 2 shows the sequence of steps using the NonInc algorithm for parsing the sentence. For simplicity and space reasons, unary productions leading to `NP` are not described. From step 1 through step 5, the first five words in the sentence (John, likes, mangoes, from, India) are shifted with corresponding categories using shift actions (S). In step 6, `(NP\NP)/NP:from` and `NP:India` are combined using the Reduce-Right (RR) action to form `NP\NP:from` which is combined with `NP:mangoes` in step 7 to form `NP:mangoes`. Step 8 combines `(S\NP)/NP:likes` with `NP:mangoes` to form `S\NP:likes` using RR action. Then the next word 'madly' is shifted in step 9, which is then combined with `S\NP:likes` in step 10. In step 11, `NP:John` and `S\NP:likes` are combined using Reduce-Left (RL) action leading to `S:likes`. The parsing process terminates at this step as there are no more tokens in the input buffer and as there is only a single node left in the stack.

(1)	S	[	NP_{John}		
(2)	S	[	NP_{John}	$(\text{S}\backslash\text{NP})/\text{NP}_{likes}$	
(3)	RL	[	S/NP_{likes}		
(4)	S	[	S/NP_{likes}	$\text{NP}_{mangoes}$	
(5)	RR	[	S_{likes}		
(6)	S	[	S_{likes}	$(\text{NP}\backslash\text{NP})/\text{NP}_{from}$	
(7)	S	[	S_{likes}	$(\text{NP}\backslash\text{NP})/\text{NP}_{from}$	NP_{India}
(8)	RR	[	S_{likes}	$\text{NP}\backslash\text{NP}_{from}$	
(9)	RRev	[	S_{likes}		
(10)	S	[	S_{likes}	$(\text{S}\backslash\text{NP})\backslash(\text{S}\backslash\text{NP})_{madly}$	
(11)	LRev	[	S_{likes}		

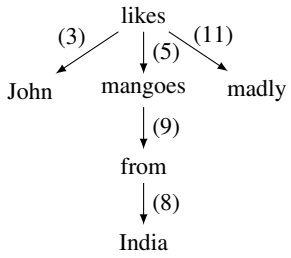

Figure 3: RevInc - Sequence of actions with parser configuration and the corresponding dependency graph.

We use indexed CCG categories (Clark et al., 2002) and obtain the CCG dependencies after every action to build the dependency graph in parallel to the CCG derivation. This is similar to Xu et al. (2014) but differs from Zhang and Clark (2011), who extract the dependencies at the end after obtaining a derivation for the entire sentence. Figure 2 also shows the dependency graph generated and the arc labels give the step ID after which the dependency is generated.

3.2 Revealing based Incremental Algorithm (RevInc)

The NonInc algorithm described above is not incremental because it relies purely on the mostly right-branching CCG derivation. In our example sentence, the verb (likes) combines with the subject (John) only at the end (step ID = 11) after all the remaining words in the sentence are processed, making the parse non-incremental. In this section we describe a new incremental algorithm based on a 'revealing' technique (Pareschi and Steedman, 1987) which tries to build the most incremental derivation.

3.2.1 Revealing

Pareschi and Steedman (1987)'s original version of revealing was defined in terms of (implicitly higher-order) unification. It was based on the following observation. If we think of categories as terms in a logic programming language, then while we usually think of CCG combinatory rules like the following as applying with the two categories on the left X/Y and Y as inputs, say instantiated as S/NP and NP, to define the category X on the right as S, in fact instantiating *any* two of those categories defines the third.

$$X/Y \;\; Y \implies X$$

For example, if we define X and X/Y as S and S/NP, we clearly define Y as NP. They proposed to use unification-based revealing to recover unbuilt constituents in from the result of overly-greedy incremental parsing. A related second-order matching-based mechanism was used by (Kwiatkowski et al., 2010) to decompose logical forms for semantic parser induction.

The present incremental parser uses a related revealing technique confined to the right periphery. Using CCG combinators and rules like type-raising followed by forward composition, we combine nodes in the stack if there is a dependency between them. However, this can create problems for the newly shifted node as its dependent might already have been reduced. For instance, if the object 'mangoes' is reduced after it is shifted to the stack, then it won't be available for the preposition phrase (PP) 'from India' (of course, this goes for more complex NPs as well). We have to extract 'mangoes', which is hidden in the derivation, so as to make the correct attachment to the PP. This is where revealing comes into play. Mangoes is 'revealed' so that it is available to attach to the PP following it, although it has already been reduced. To handle this, in addition to the four actions of the NonInc algorithm, we introduce two new actions: Left Reveal (`LRev`) and Right Reveal (`RRev`). For this, after every action, in addition to updating the stack we also keep track of the dependencies resolved and update the dependency graph accordingly[1]. In other words, we build the dependency graph for the

[1]Xu et al. (2014) also obtain CCG dependencies after every action. But they don't have a dependency graph which is updated based on the CCG derivation and used in the CCG parsing (in our case for LRev and RRev actions).

(a) RRev (b) LRev

Figure 4: RRev and LRev actions.

sentence in parallel to the CCG derivation. As these dependencies are extracted from the CCG derivation, a node can have multiple parents and hence we construct a dependency graph rather than a tree.

- Left Reveal (`LRev`) : Pop the top two nodes in the stack (left, right). Identify the left node's child with a subject dependency. Abstract over this child node and split the category of left node into two categories. Combine the nodes using CCG combinators accordingly. VP modifiers like VP coordination require this action.
- Right Reveal (`RRev`) : Pop the top two nodes in the stack (left, right). Check the right periphery of the left node in the dependency graph, extract all the nodes with compatible CCG categories and identify all the possible nodes that the right node can combine with. Abstract over this node (e.g. object), split the category into two categories accordingly and combine the nodes using CCG combinators. Constructions like NP coordination, and PP attachment require this action.

3.2.2 Worked Example

Figure 3 shows the sequence of steps for the example sentence described above. In steps 1 and 2, the first two words in the sentence: 'John' and 'likes', are shifted from the input buffer to the stack. In addition to standard CCG combinators of application and composition, we also use type-raising followed by forward composition[2]. In step 3, the category of the left node 'John', `NP`, is type-raised to `S/(S\NP)` which is then combined with the category of right node 'likes', `(S\NP)/NP`, using forward composition operator to yield the category `S/NP`. This step also updates the dependency graph with an edge between 'John' and 'likes', where 'likes' is the parent and 'John' is the child. The next word 'mangoes' is shifted in step 4 and combined with `S/NP:likes` in step 5 using RR action yielding `S:likes`. After this step, the dependency graph will have 'likes' as the root, with 'John' and 'mangoes' as its children. In this way, as our algorithm tries to be more incremental, both subject and object arguments are resolved as soon as the corresponding tokens are shifted to the stack.

In steps 6 and 7, the next two words 'from' and 'India' are shifted to the stack. Step 8 combines `(NP\NP)/NP:from` and `NP:India` using RR action to form `NP\NP:from`. Now, we apply the `RRev` action in step 9 to correctly attach 'from' to 'mangoes'. In `RRev` we first check the right periphery and identify a possible node to be attached, 'mangoes', which is the object argument of the verb 'likes'. We abstract over this object and split the category in the following manner: If `X` is the category of the left node and `Y\Y` is the category of the right node, then `X` is split into `X/Y` and `Y` with corresponding heads. The head of the left node will be the head of `X/Y`, and the dependency graph helps in identifying the correct head for `Y`. Now, `Y` and `Y\Y` can be combined using the backward application rule to form `Y`, which can be combined with `X/Y` to form `X` back. In our example sentence, `S:likes` is split into `S/NP:likes` and `NP:mangoes`. `NP:mangoes` is combined with `NP\NP:from` to form `NP:mangoes`, which in return combines with `S/NP:likes` and forms back `S:likes`. Figure 4(a) sketches this process. This action also updates the dependency graph with a dependency between 'mangoes' and 'from'.

The next word 'madly' is shifted in step 10, after which the stack has two nodes `S:likes` and `(S\NP)\(S\NP):madly`. We apply the `LRev` action to combine these two nodes. We abstract over the subject of the left node, 'likes', and split the category. Here, `S:likes` is split into `NP:John` and `S\NP:likes`. `S\NP:likes` is combined with `(S\NP)\(S\NP):madly` to form `S\NP:likes`,

[2]Type-raising followed by forward composition is treated as a single step. Without this, after type-raising, the parser has to check all possible actions before applying forward composition, making it slower.

which in return combines with NP:John and forms back S:likes. The dependency graph is updated with a dependency between 'likes' and 'madly'. Note that the final output is a standard CCG tree. Figure 4(b) shows this LRev action.

3.2.3 Analysis

Our incremental algorithm uses a combination of the CCG derivation and a dependency graph that helps to 'reveal' unbuilt structure in the CCG derivation by identifying heads of the revealed categories. For example in Figure-4a, in RRev action, S:likes is split into S/NP:likes and NP:mangoes. The splitting of categories is deterministic but the right periphery of the dependency graph helps in identifying the head, which is 'mangoes'. The theoretical idea of 'revealing' is from Pareschi and Steedman (1987), but they used only a toy grammar without a model or empirical results. Checking the right periphery is similar to Sartorio et al. (2013) and abstracting over the left or right argument is similar to Dalrymple et al. (1991). Currently, we abstract only over arguments. Adding a new action to abstract over the verb as well will make our algorithm handle ellipses in the sentences like 'John likes mangoes and Mary too' similar to Dalrymple et al. (1991) but we leave that for future work.

Our system is monotonic in the sense that the set of dependency relationships grows monotonically during the parsing process. Our algorithm gives derivations almost as incremental as Hassan et al. (2009) but without changing the lexical categories and without backtracking. The only change we made to the CCGbank is making the main verb the head of the auxiliary rather than the reverse as in CCGbank derivations. In the right derivational trees of CCGbank, the main verb is the head for its right side arguments and the auxiliary verb is the head for the left side arguments in the derivation. Not changing the head rule would make our algorithm use the costly reveal actions significantly more, which we avoid by changing the head direction. 3% of the total dependencies are affected by this modification.

Though our algorithm can be completely incremental, we currently compromise incrementality in the following cases:

(a) no dependency between the nodes in the stack
(b) unary type-changing and non-standard binary rules
(c) adjuncts like VP modifiers and coordinate constructions like VP, sentential coordination.

We find empirically that extending incrementality to cover these cases actually reduces parsing performance significantly. It also violates the Strict Competence Hypothesis (SCH) (Steedman, 2000), which argues on evolutionary and developmental grounds that the parser can only build constituents that are typable by the competence grammar. We explored the adjunct case of attaching only the preposition first rather than creating a complete prepositional phrase and then attaching it to correct parent. In our example sentence, this would be the case of attaching the preposition 'from' to its parent using RRev and then combining the NP 'India' accordingly as opposed to creating the preposition phrase 'from India' first and then using RRev action to attach it to the correct parent. Though the former is more incremental, it is inconsistent with the SCH. The latter analysis is consistent with strict competence and also gave better parsing performance while compromising incrementality only slightly. The empirical impact of these differing degrees of incrementality on extrinsic evaluation of our algorithm in terms of language modeling for SMT or ASR is left for future work.

Using our incremental algorithm, we converted the CCGbank derivations into a sequence of shift-reduce actions. We could convert around 98% of the derivations, which is the coverage of our algorithm, recovering around 99% dependencies. Problematic cases are mainly the ones which involve non-standard binary rules, and punctuations with lexical CCG categories other than 'conj', used as a conjunction, or ',' which is treated as a punctuation mark.

4 Experiments and Results

We re-implemented Zhang and Clark (2011)'s model for our experiments. We used their global linear model trained with the averaged perceptron (Collins, 2002). We applied the early-update strategy of Collins and Roark (2004) while training. In this strategy, when we don't use a beam, decoding is stopped when the predicted action is different from the gold action and weights are updated accordingly. We use the feature set of Zhang and Clark (2011) (Z&C) for the NonInc algorithm. This feature set comprises of features over the top four nodes in the

stack and the next four words in the input buffer. Complete details of the feature set can be found in their paper. For our own model, RevInc, in addition to these features used for NonInc, we also provide features based on the right periphery of top node in the stack. For nodes in the right periphery, we provide uni-gram and bi-gram features based on the node's CCG category. For example, if S0 is the node on the top of the stack, B1 is the bottom most node in the right periphery, and c represent the node's CCG category, then B1c, and B1cS0c are the uni-gram and bi-gram features respectively.

Unlike Z&C, we do not use a beam for our experiments, although we use a beam of 16 for comparison of our results with their parser. The latter gives competitive results with the state-of-the-art CCG parsers. Z&C and Xu et al. (2014), use C&C's `generate` script and unification mechanism respectively to extract dependencies for evaluation. C&C's grammar doesn't cover all the lexical categories and binary rules in the CCGbank. To avoid this, we adapted Hockenmaier's scripts used for extracting dependencies from the CCGbank derivations. These are the two major divergences in our re-implementation from Z&C.

4.1 Data and Settings

We use standard CCGbank training (sections 02 − 21), development (section 00) and testing (section 23) splits for our experiments. All sentences in the training set are used to train NonInc. But for RevInc, we used 98% of the training set (the coverage of our algorithm). We use automatic POS-tags and lexical CCG categories assigned using the C&C POS tagger and supertagger respectively for development and test data. For training data, these tags are assigned using ten-way jackknifing. Also, for lexical CCG categories, we use a multitagger which assigns k-best supertags to a word rather than 1-best supertagging (Clark and Curran, 2004). The number of supertags assigned to a word depends on a β parameter. Unlike Z&C, the default value of β gave us better results rather than decreasing the value. Not using a beam could be the reason for this.

Following Z&C and Xu et al. (2014), during training, we also provide the gold CCG lexical category to the list of CCG lexical categories for a word if it is not assigned by the supertagger.

4.2 Connectedness and Waiting Time

Before evaluating the performance of our algorithm, we introduce two measures of incrementality: connectedness and waiting time. In a shift-reduce parser, a derivation is fully connected when all the nodes in the stack are connected leading to only one node in the stack at any point of time. We measure the average number of nodes in the stack before shifting a new token from input buffer to the stack, which we call as connectedness. For a fully connected incremental parser like Hassan et al. (2009), connectedness would be one. As our RevInc algorithm is not fully connected, this number will be greater than one. For example, in a noun phrase 'the big book', when 'the' and 'big' are in the stack, as there is no dependency between these two words, our algorithm doesn't combine these two nodes resulting in having two nodes in the stack[3]. Second column in Table 1 gives this number for both NonInc and RevInc algorithms. Though our algorithm is not fully connected, connectedness of our algorithm is significantly lower than the NonInc algorithm as our algorithm is more incremental.

Algorithm	*Connectedness*	*Waiting Time*
NonInc	4.62	2.98
RevInc	**2.15**	**0.69**

Table 1: Connectedness and waiting time.

We define waiting time as the number of nodes that need to be shifted to the stack before a dependency between any two nodes in the stack is resolved. In our example sentence, there is a dependency between 'John' and 'likes'. For NonInc, this dependency is resolved only after all the four remaining words in the sentence are shifted. In other words, it has to wait for four more words before this dependency is resolved and hence the waiting time is four. Whereas, in our RevInc algorithm, this dependency is resolved immediately, without waiting for more words to be shifted, and hence the waiting time is zero. The third column in Table 1 gives the waiting time for both the algorithms. Since we compromised incrementality in cases like coordination, waiting time for our RevInc algorithm is not zero but it is significantly lower than the

[3]This is a case where the dependencies are not true to the CCG grammar, and make our algorithm less incremental than SCH would allow.

Algorithm	*UP*	*UR*	*UF*	*LP*	*LR*	*LF*	*Cat Acc.*
NonInc (beam=1)	**92.57**	82.60	87.30	**85.12**	75.96	80.28	91.10
RevInc (beam=1)	91.62	**85.94**	**88.69**	83.42	**78.25**	**80.75**	90.87
NonInc (beam=16)	92.71	89.66	91.16	85.78	82.96	84.35	92.51
Z&C (beam=16)*	-	-	-	87.15	82.95	85.00	92.77

Table 2: Performance on the development data. *: These results are from the Z&C paper.

NonInc algorithm and hence more incremental. This property is likely to be crucial for future applications in ASR and SMT language modeling.

4.3 Results and Analysis

We trained the perceptron for both NonInc and RevInc algorithms using the CCGbank training data for 30 iterations, and the models which gave best results on development data are directly used for test data. Table 2 gives the unlabeled precision (UP), recall (UR), F-score (UF) and labeled precision (LP), recall (LR), F-score (LF) results of both NonInc and RevInc approaches on the development data. Last column in the table gives the category accuracy. We used the modified CCGbank for all experiments, including NonInc, for consistent comparisons. For NonInc, the modification decreased unlabeled F-score by 0.45%, without a major difference in labeled F-score.

Our incremental algorithm gives 1.39% and 0.47% improvements over the NonInc algorithm in unlabeled and labeled F-scores respectively. For both unlabeled and labeled scores, precision of RevInc is slightly lower than NonInc but the recall of RevInc is much higher than NonInc resulting in a better F-score for RevInc. As NonInc is not incremental and as it uses more context to the right while making a decision, it makes more precise actions. But, on the other hand, if a node is reduced, it is not available for future actions. This is not a problem for our RevInc algorithm which is the reason for higher recall. For example, in the example sentence, 'John likes mangoes from India madly', if the object 'mangoes' is reduced after it got shifted to the stack, then in case of NonInc, the preposition phrase 'from India' can never be attached to 'mangoes'. But, RevInc makes the correct attachment using `RRev` action. Category accuracy of NonInc is better than RevInc, since NonInc can use more context before taking a complex action and is less prone to error propagation compared to RevInc.

To compare these results in the perspective of Z&C's parser we also trained our NonInc parser with a beam size of 16 similar to Z&C. The second last row in Table 2 (NonInc (beam=16)) shows these results and the last row presents the results from their paper. Results with our implementation of Z&C are 0.65% lower than the published results, possibly due to the modification made in the head rule, and other minor differences like the supertagger beta value. Unlabeled and labeled F-scores of our RevInc parser are lower than these numbers. But, given that our RevInc parser doesn't use any beam, these margins are reasonable.

We also analyzed the label-wise scores of both NonInc and RevInc. In general, NonInc is better in precision and RevInc is better in recall. In the case of verbal arguments (`(S\NP)/NP`) and verbal modifiers (`(S\NP)\(S\NP)`), the F-score of RevInc is better than that of NonInc. But NonInc performed better than RevInc in the case of preposition phrase (PP) attachments (`(NP\NP)/NP`, `((S\NP)\(S\NP))/NP`). More context is required for better PP attachment which is provided by the fact that NonInc has a context of several unreduced types for the model to work with, whereas RevInc has fewer. Whereas actions like `LRev` are required to correctly attach the verbal modifiers ('madly') if the subject argument ('John') of the verb ('likes') is reduced early. Table 3 gives the results of these CCG lexical categories.

Category	*RevInc*	*NonInc*
(NP\NP)/**NP**	81.36	**83.21**
(NP**NP**)/NP	78.66	**82.94**
((S\NP)\(S\NP))/**NP**	65.09	**66.98**
((S\NP)\(**S\NP**))/NP	62.69	**65.89**
((S[dcl]\NP)/**NP**	**78.96**	78.29
((S[dcl]**NP**)/NP	**76.71**	75.22
(S\NP)\(**S\NP**)	**80.49**	76.90

Table 3: Label-wise F-score of RevInc and NonInc parsers (both with beam=1). Argument slots in the relation are in bold.

Algorithm	*UP*	*UR*	*UF*	*LP*	*LR*	*LF*	*Cat Acc.*
NonInc (beam=1)	**92.45**	82.16	87.00	**85.59**	76.06	80.55	91.39
RevInc (beam=1)	91.83	**86.35**	**89.00**	84.02	**79.00**	**81.43**	91.17
NonInc (beam=16)	92.68	89.57	91.10	86.20	83.32	84.74	92.70
Z&C (beam=16)*	-	-	-	87.43	83.61	85.48	93.12
Hassan et al. 09*	-	-	86.31	-	-	-	-

Table 4: Performance on the test data. *: These results are from their paper.

We also analyzed the performance of the greedy (beam=1) NonInc and RevInc parsers in terms of parsing speed (excluding pos tagger and supertagger time). NonInc and RevInc parse 110 and 125 sentences/second respectively. Despite the complexity of the revealing actions, RevInc is faster than the NonInc. Significant amount of parsing time is spent on the feature extraction step. Features from top four nodes in the stack and their children are extracted for both the algorithms. Since the average connectedness of RevInc and NonInc are 4.62 and 2.15 respectively, on average, all four nodes in the stack are processed for NonInc and only two nodes are processed for RevInc. Because of this there is significant reduction in the feature extraction step for RevInc compared to NonInc. Also, the complex LRev and RRev actions only constituted 5% of the total actions in the parsing process.

Table 4 presents the results of our approaches on test data. Our incremental algorithm, RevInc, gives 2.0% and 0.88% improvements over NonInc in unlabeled and labeled F-scores respectively on the test data. Results of RevInc without a beam are reasonably close to the results of Z&C which uses a beam of 16. We compare our results with Incremental+Lookahead model of Hassan et al. (2009). They reported 86.31% unlabeled F-score on test data which is 2.69% lower. Note that these F-scores are not directly comparable since Hassan et al. (2009) use simplified lexicalized CCG categories. Our evaluation is based on CCG dependencies which are different from dependencies in the dependency grammar. Hence, we can't directly compare our results with dependency parsers like Zhang and Nivre (2011) and Honnibal et al. (2013).

5 Conclusion and Future Plan

We have designed and implemented a new incremental shift-reduce algorithm based on a version of revealing for parsing CCG (Pareschi and Steedman, 1987). On the standard CCGbank test data, our algorithm achieved improvements of 0.88% and 2.0% in labeled and unlabeled F-scores respectively over the baseline non-incremental shift-reduce algorithm. We achieved this without changing any CCG lexical categories and only changing a single head rule of making the main verb rather than the auxiliary verb the head. Our algorithm models transitions rather than incremental derivations, and hence we don't need an incremental CCGbank. Our approach can therefore be adapted to languages with dependency treebanks, since CCG lexical categories can be easily extracted from dependency treebanks (Cakici, 2005; Ambati et al., 2013). We also designed new measures of incrementality and showed that our algorithm is more incremental than the standard shift-reduce CCG parsing algorithm.

We expect to improve our current model in a number of ways. Providing information about lexical category probabilities (Auli and Lopez, 2011) assigned by the supertagger can be useful during parsing. We would like to explore the limited use of a beam to handle lexical ambiguity by only keeping analyses derived from distinct lexical categories in the beam. Following Xu et al. (2014), we also plan to explore a dynamic oracle strategy. Ultimately, we intend to evaluate the impact of our incremental parser extrinsically in terms of language modeling for SMT or ASR.

Because Syntax Does Matter: Improving Predicate-Argument Structures Parsing with Syntactic Features

Abstract

Parsing full-fledged predicate-argument structures in a deep syntax framework requires graphs to be predicted. Using the DeepBank (Flickinger et al., 2012) and the Predicate-Argument Structure treebank (Miyao and Tsujii, 2005) as a test field, we show how transition-based parsers, extended to handle connected graphs, benefit from the use of topologically different syntactic features such as dependencies, tree fragments, spines or syntactic paths, bringing a much needed context to the parsing models, improving notably over long distance dependencies and elided coordinate structures. By confirming this positive impact on an accurate 2nd-order graph-based parser (Martins and Almeida, 2014), we establish a new state-of-the-art on these data sets.

1 Introduction

For the majority of the state-of-the-art parsers that routinely reach ninety percent performance plateau in capturing tree structures, the question of *what next* crucially arises. Indeed, it has long been thought that the bottleneck preventing the advent of accurate syntax-to-semantic interfaces lies in the quality of the preceding phase of analysis: the better the parse, the better the output. The truth is that most of the structures used to train current parsing models are degraded versions of a more informative data set: the Wall Street journal section of the Penn treebank (PTB, (Marcus et al., 1993)) which is often stripped of its richer set of annotations (*i.e.* traces and functional labels are removed), while, for reasons of efficiency and availability, projective dependency trees are often given preference over richer graph structures (Nivre and Nilsson, 2005; Sagae and Tsujii, 2008). This led to the emergence of *surface* syntax-based parsers (Charniak, 2000; Nivre, 2003; Petrov et al., 2006) whose output cannot by themselves be used to extract full-fledged predicate-argument structures. For example, control verb constructions, it-cleft structures, argument sharing in ellipsis coordination, etc. are among the phenomena requiring a graph to be properly accounted for. The dichotomy between what can usually be parsed with high accuracy and what lies in the deeper syntactic description has initiated a line of research devoted to closing the gap between surface syntax and richer structures. For most of the previous decade, the term *deep syntax* was used for rich parsing models built upon enriched versions of a constituency treebank, either with added HPSG or LFG annotation or CCG (almost) full rewrites (Miyao and Tsujii, 2005; Cahill et al., 2004; Hockenmaier, 2003). Its use now spreads by misnomer to models that provide more abstract structures, capable of generalizing classical functional labels to more semantic (in a logical view) arguments, potentially capable of neutralizing diathesis distinctions and of providing accurate predicate-argument structures. Although the building of syntax-to-semantic interface seems inextricably linked to an efficient parsing stage, inspirational works on semantic role labelling (Toutanova et al., 2005) and more recently on broad coverage semantic parsing (Du et al., 2014) that provide state-of-the-art results without relying on surface syntax, lead us to question the usefulness of syntactic parses for predicate-argument structure parsing.

In this study, we investigate the impact of syntactic features on a transition-based graph parser by testing on two treebanks. We take advantage of the recent release for the *SemEval 2014 shared task* on semantic dependency parsing, by Oepen et

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 64–74,
Denver, Colorado, May 31 – June 5, 2015.

al. (2014) of two semantic-based treebanks, derived from two HPSG resources, the DeepBank (DM, (Flickinger et al., 2012)) and the Enju's predicate argument structure (PAS, (Miyao and Tsujii, 2005)), to investigate the impact of syntactic features on a transition-based graph parser. Our results show that surface syntactic features significantly improve the parsing of predicate-argument structures. More specifically, we show that adding syntactic context improves the recognition of long distance dependencies and elliptical constructions. We finally discuss the usefulness of our approach, when applied on a second-order model based on dual decomposition (Martins and Almeida, 2014), showing that our use of syntactic features enhances this model accuracy and provides state-of-the-art performance.

2 Deep Syntax and Underspecified Semantic Corpora

DeepBank Corpus Semantic dependency graphs in the DM Corpus are the result of a two-step simplification of the underspecified logical-form meaning representations, based on Minimal Recursion Semantic (MRS, (Copestake et al., 1995; Copestake et al., 2005)), derived from the manually annotated DeepBank treebank (Flickinger et al., 2012). First, Oepen and Lønning (2006) define a conversion from original MRS formulae to variable-free Elementary Dependency Structures (EDS), which (a) maps each predication in the MRS logical-form meaning representation to a node in a dependency graph and (b) transforms argument relations represented by shared logical variables into directed dependency links between graph nodes. Then, in a second conversion step, the EDS graphs are further reduced into strict bi-lexical form, *i.e.* a set of directed, binary dependency relations holding exclusively between lexical units (Ivanova et al., 2012). Even though both conversion steps are, by design, lossy, DM semantic dependency graphs present a true subset of the information encoded in the full, original MRS data set.

Predicate-Argument Structure Corpus Enju Predicate-Argument Structures (PAS Corpus) are derived from the automatic HPSG-style annotation of the Penn Treebank (Miyao and Tsujii, 2004) that was primarily used for the development of the Enju parsing system (Miyao and Tsujii, 2005). The PAS data set is an extraction of predicate-argument structures from the Enju HPSG treebank and contains word-to-word semantic dependencies. Each dependency type is made of two elements: a coarse part-of-speech of the head predicate dependent (e.g. verb and adjective), and the argument (e.g. ARG1 and ARG2).

Although both are derived from HSPG resources (a hand-crafted grammar for DM, a treebank-based one for PAS), they differ in their core linguistic choices (functional heads vs lexical heads, coordination scheme, *etc.*) leading to different views of the predicate argument structure for the same sentence (Ivanova et al., 2012). Thus, even though both corpora may appear to contain a similar number of dependency labels, as shown in Table 1, their annotation schemes depict a deeply divergent linguistic reality exposed by two very different distributions. In DM, 9 labels account for almost 95% of all dependencies whereas a label set twice as large covers the same percentage for PAS, as shown in Table 2. Furthermore, semantically empty elements are widespread in the DeepBank (around 21.5%), compared to a low rate of 4.3% in PAS. In other words, the latter is somewhat more *dense* and consequently more syntactic. This is due to the fact that PAS integrates markers for infinitives, auxiliaries, and most punctuation marks into its graphs, whereas DM considers them as semantically void. DM corpus is clearly heading toward more semantic analysis while the PAS corpus aims at providing a more abstract deep syntax analysis than regular surface syntax trees. Both treebanks are used in their bi-lexical dependency formats.

\end{array}
$$

Figure 1: Set of transitions for dependency graphs.

Shift-reduce transition-based parsers essentially rely on *configurations* formed of a stack and a buffer, with stack transitions used to move from a configuration to the next one, until reaching a final configuration. Following Kübler et al. (2009), we define a configuration by $c = (\sigma, \beta, \mathcal{A})$ where σ denotes a stack of words w_i, β a buffer of words, and $\mathcal{A}$ a set of dependency arcs of the form (w_i, r, w_j), with w_i the head, w_j the dependent, and r a label in some set R. As shown in Figure 1, besides the usual *shift* and *reduce* transitions (lR & rR) of the *arc-standard* strategy, we introduced the new left and right *attach* (lA & rA) transitions for adding new dependencies (while keeping the dependent on the stack) and a *pop0* transition to remove a word from the stack after attachment of its dependents. All the transitions that add an edge must also satisfy the condition that the newly created edge does not introduce a cycle or multiple edges between the same pair of nodes. It is to be noted that the *pop0* action may also be used to remove words with no heads.

$\text{Word}_{\sigma_1,\sigma_2,\sigma_3}$	$\text{Lemma}_{\sigma_1,\sigma_2,\sigma_3}$	$\text{POS}_{\sigma_1,\sigma_2,\sigma_3}$
$\text{Word}_{\beta_1,\beta_2}$	$\text{Lemma}_{\beta_1,\beta_2}$	$\text{POS}_{\beta_1,\beta_2,\beta_3}$
$\text{leftPOS}_{\sigma_1,\sigma_2}$	$\text{rightPOS}_{\sigma_1,\sigma_2}$	$\text{leftLabel}_{\sigma_1,\sigma_2}$
$\text{rightLabel}_{\sigma_1,\sigma_2}$	a	d_{12} d'_{11}

Table 3: Baseline features for the parser.
$\text{X}\sigma_i, \ldots, \sigma_j$ stands for $\text{X}\sigma_i, \ldots, \text{X}\sigma_j$.

We base our work on the the DAG parser of Sagae and Tsujii (2008) (henceforth S&T) which we extended with the set of actions displayed above (Figure 1) to cope with partially connected planar graphs, and we gave it the ability to take advantage of an extended set of features. Finally, for efficiency reasons (memory consumption and speed), we replaced the original Maxent model with an averaged structured perceptron (Freund and Schapire, 1999; Collins, 2002).

4 Feature Design

4.1 Baseline Features

We define Word_{β_i} (resp. Lemma_{β_i} and POS_{β_i}) as the word (resp. lemma and part-of-speech) at position i in the queue. The same goes for σ_i, which is the position i in the stack. Let $d_{i,j}$ be the distance between Word_{σ_i} and Word_{σ_j}. We also define $d'_{i,j}$, the distance between Word_{β_i} and Word_{σ_j}. In addition, we define $\text{leftPOS}_{\sigma_i}$ (resp. $\text{leftLabel}_{\sigma_i}$) the part-of-speech (resp. the label if any) of the word immediately to the left of σ_i, and the same goes for $\text{rightPOS}_{\sigma_i}$ (resp. $\text{rightLabel}_{\sigma_i}$). Finally, a is the previous action predicted by the parser. Table 3 lists our baseline features. $\text{X}\sigma_i, \sigma_j, \sigma_k$ means that we use $\text{X}\sigma_i$, $\text{X}\sigma_j$, $\text{X}\sigma_k$ as unigram features as well as bigram and trigram features.

4.2 Syntactic Features

We combined the previous features with different types of syntactic features (constituents and dependencies), our intuition being that syntax and semantic are interdependent, and that syntactic features should therefore help predicate-argument parsing. In fact, we considered that the low density of syntactic information (compared to regular dependency treebanks) would be counterbalanced by

adding more context. We considered the following pieces of information in particular.

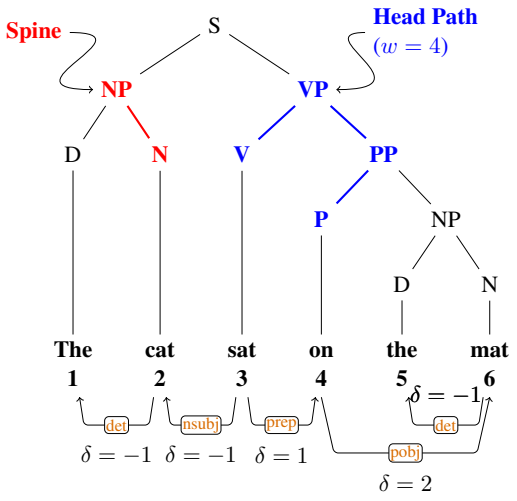

Figure 2: Schema of Syntactic Features

Constituent Tree Fragments These consist of fragments of syntactic trees predicted by the Petrov et al. (2006) parser in a 10-way jackknife setting. They can be used as enhanced POS or as features.

Spinal Elementary Trees A full set of parses was reconstructed from the tree fragments using a slightly tweaked version of the CoNLL 2009 shared task processing tools (Hajič et al., 2009). We then extracted a *spine grammar* (Seddah, 2010) using the head percolation table of the Bikel (2002) parser, slightly modified to avoid certain determiners being marked as heads in certain configurations. The resulting spines were assigned in a deterministic way (red part in Figure 2).

Predicted MATE Dependency Labels These consist of the dependency labels predicted by the MATE parser (Bohnet, 2010), trained on a Stanford surface dependency version of the Penn Treebank. We combined the labels with a distance $\delta = t - h$ where t is the token position and h the head position (brown labels and δ in Figure 2). In addition, we expanded these features with the part-of-speech of the head of a given token (HPOS). The idea is to evaluate the informativeness of more abstract syntactic features since a <LABEL,HPOS> pair can be seen as generalizing many constituent subtrees.

Constituent Head Paths. Inspired by Björkelund et al. (2013), we used MATE dependencies to extract the shortest path between a token and its lexical head and included the path length w (in terms of traversed nodes) as a feature (blue part in Figure 2). The global idea is to use the phrase-based features to provide different kinds of syntactic context and the dependency-based features to provide generalisations over the functional label governing a token. The spines are seen as deterministic supertags, bringing a vertical context.

We report, in Table 4, the counts for each syntactic feature on each set.

	TREE FRAG.	MATE LABELS+δ	SPINES TREES	HEAD PATHS
TRAIN	648	1305	637	27,670
DEV	272	742	265	3,320
TEST	273	731	268	2,389

Table 4: Syntactic features statistics (Counts).

5 Experiments

Experimental Setup Both DM and PAS treebanks consist of texts from the PTB and which were either automatically derived from the original annotations or annotated with a hand-crafted grammar (see above). We use them in their bi-lexical dependency format, aligned at the token level as provided by Oepen et al. (2014)[1]. The following split is used: sections 00-19 for training, 20 for the dev. set and 21 for test[2]. All predicted parses are evaluated against the gold standard with *labeled precision, recall and f-measure* metrics.

Results Our experiments are based on the evaluation of the combinations of the 4 main types of syntactic features described in section 4: tree fragments (BKY), predicted mate dependencies (BN) and their extension with POS heads (BN(HPOS)), spinal elementary trees (SPINES) and head paths (PATHS).

The results are shown in Tables 5 and 6. All improvements from the baseline are significant with a p-value $p < 0.05$. There was no significant difference of the same p value between our two best mod-

[1]This alignment entailed the removal of all unparsed sentences.

[2]We used the same unusual split as in (Oepen et al., 2014) to be able to conduct meaningful comparisons with others.

els for each of the treebanks. [3]

As expected from the rapid overview of our datasets exposed earlier in section 2, the use of each single feature alone increases the performance over the baseline by 0.5 points for the BN feature in DM to 1.44 for PATHS, and by 1.10 for the SPINES to 1.85 for the PATHS features in PAS. Looking at the conjunction of two classes in the DM table, it seems that dependency-based features benefit from the extra context brought by constituents features, reaching an increase of 2.21 points for BKY+BN(HPOS). Interestingly, the maximum gain is brought by the addition of topologically different phrase-based features such as SPINES (+2.80, inherently vertical) or BKY (+2.76, often wider) to the previous best. Regarding PAS, similar trends can be observed, although the gains are more distributed. As opposed to DM where the conjunction of more features led to inferior results, here using a four-features class provides the second best improvement (ALL(HPOS) = BKY+BN(HPOS)+SPINES+PATHS), +2.82) while removing the SPINES slightly increases the score (+2.92). In fact, adding too many features to the model slightly degrades our scores, at least with regard to DM which has a larger label set than PAS.

Results show that syntactic information improves our parser performances. As each feature represents one unique piece of information, they benefit from being combined in order to provide more structural information.

6 Results Analysis

Following Mcdonald and Nivre (2007), we conducted an error analysis based on the two best models and the baseline for each corpus. As shown in section 5, syntactic features greatly improve semantic parsing. However, it is interesting to explore more precisely what kind of syntactic information boosts or penalizes our predictions. We consider, among other factors, the impact in terms of distance between the head and the dependent (edge length) and the labels. We also explore several linguistic phenomena well known to be difficult to recover.

[3]We tested the statistical significance between our best models and the baseline with the paired bootstrap test (Berg-Kirkpatrick et al., 2012).

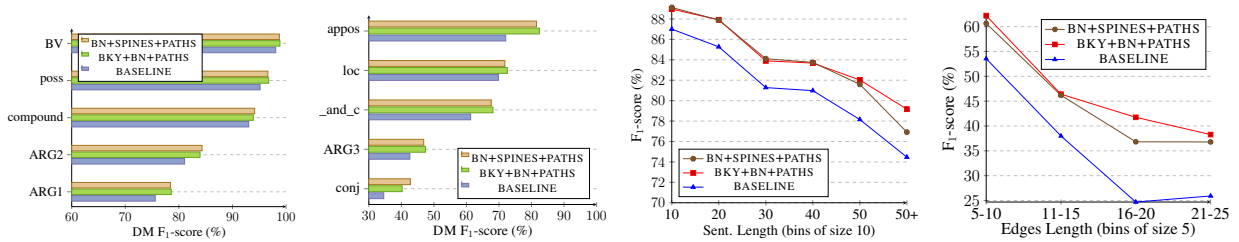
Table 6: Best results and gains on PAS.

6.1 Breakdown by Labels

In Figures 3(a) and 4(a), we detail the scores for the five most frequent labels.



(a) Most frequent labels. (b) Best improved labels. (c) Sentence length. (d) Long-distance dependencies.

Figure 3: Error analysis on DM (dev. set).

As observed in the charts, the scores are higher for the most frequent labels on both corpora, especially when dealing with verbal arguments. There are also two interesting cases for DM: the predictions of *_and_c* and *ARG3* edges show an improvement by at least 5 points (Figures 3(b) & 4(b)), showing that the recovery of coordination structures and the disambiguation of less frequent or more distant arguments is achieved by adding non-local features.

6.2 Length Factor

Longer sentences are notoriously difficult to parse for most parsing models. Figures 3(c) and 4(c) show the F_1-measure of our models with respect to sentence length (in bins of size 10: 1-10, 11-20, etc.) for the DM and PAS corpora.

It is worth noting that we greatly improve the scores for longer sentences. The use of paths and of the output of a graph-based parser (Bohnet, 2010) favors the capture of complex dependencies and enhances the learning of these constructions for our local transition-based parser. However, we also observe that the features are not able to completely stop the loss of F_1-score for longer sentences. The slopes of the curves in the different charts show the same trend: the longer the sentence, the lower the score.

6.3 Linguistic Factors

We now center our analysis on long-distance dependencies (LDDs), by focusing our attention on edges length, *i.e.* the distance between two words linked by an edge. We will then concentrate on subject ellipsis, in a treatment of LDDs more similar to the linguistic definition of Cahill et al. (2004).

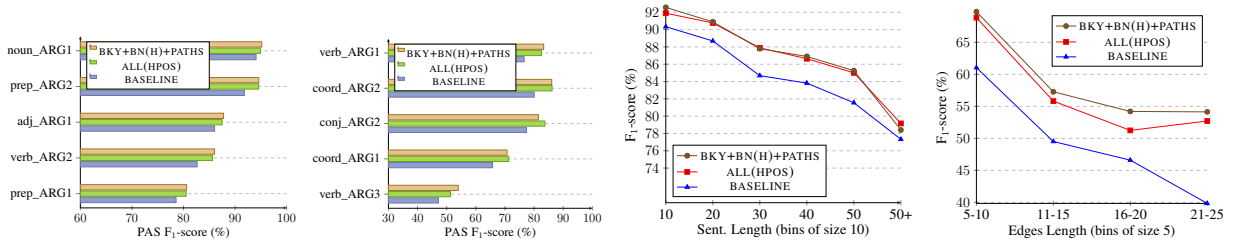
Long-distance Dependencies (LDDs) For many systems, LDDs are difficult to recover because they are generally under-represented in the training corpus and the constructions involved in LDDs often require deep linguistic knowledge to be recovered. In Figure 7, we report the distribution of long-distance dependencies by bins of size 5 up to 40. They only account for 15% of all the dependencies in both corpora. The longest dependencies consist of the first and second arguments of the verb as well as coordination links. In the case of elided coordination structures, we have long-distance dependencies when two coordinated verbs share the same first or second argument, which explains the distribution of lengths.

BINS	5-10	11-15	16-20	21-25	26-40
DM	2907	734	329	141	92
PAS	3705	1007	408	175	127

Table 7: Number of LDDs edges (dev. set).

As outlined in Figures 3(d) and 4(d), we can see that without structural information such as spines, surfacic dependencies or paths, the longest dependencies have low F_1-scores. When using these features, our models tend to perform better, with a gain of up to 25 points for high-dependency lengths (bins between 16-20 and 21-25).

In Table 8, we show the global improvement when considering edge lengths between 5 and 40. For both corpora, the improvement is the same (around 9 points), showing that structural information is the key to better predictions. Looking into this improvement more closely, we found that PATHS combined with BN tend to be crucial, whereas SPINES



(a) Most frequent labels. (b) Best improved labels. (c) Sentence length. (d) Long-distance dependencies.

Figure 4: Error analysis on PAS (dev. set).
BKY+BN(H)+PATHS stands for BKY+BN(HPOS)+PATHS.

may sometimes penalize the models. Even though, BN+SPINES+PATHS is the best model for DM, a spine is only a *partial projection* which lacks attachment information. Spines alone only therefore provide a local context and are unable to cope well with LDDs.

Coordination Structures We now focus on structures with subject ellipsis. We extracted them by using a simple graph pattern, *i.e.* two verbs with a shared *ARG1* and a coordination dependency.

Our best models' scores are displayed in Tables 9. Once again, our models improve the F_1 score, but not in the same proportion. DM considers the conjunction as a semantically empty word and attaches an edge *_and_c* between the two verbs to mark the coordination. Consequently this edge is more difficult to predict, because it is less informative, our baseline model relying on tokens, lemmas and POS.

We note that the difference in the number of evaluated dependencies in both corpora comes from an annotation scheme divergence between PAS and DM regarding subject ellipsis. DM opts for coordinate structures with a chain of dependencies rooted at the first conjunct, the coordinating conjunctions being therefore semantically empty. In PAS, the final coordinating conjunction and each coordinating conjunction is a two-place predicate, taking left and right conjuncts as its arguments.

The gain of 6.30 points for DM (Table 9(a), resp. +3 for PAS) indicates that, when an annotation scheme is designed to have many semantically empty words, using syntactic information tends to enhance the parser accuracy. This gives a clear insight into what type of information is required to parse semantic graphs: the greater the distance between the head and the dependent, the larger the context needed to disambiguate the attachments.

6.4 Ruling out the Structural Factor Bias

It may argued that the improvement we noticed could stem from a potentially strong overlap between surface trees and predicate-argument structures, both in terms of edges and labels. In fact, the conversion from surfacic parses into predicate-argument structures requires a large amount of edges relabeling (for instance, when *nsubj* is relabeled to *ARG1*). We tested this hypothesis by computing the number of common edges between MATE predictions and DM and PAS. The overlap corresponds to about 22% of all edges in PAS and 27% in DM. Although important, it does not represent the majority of dependencies in our corpora, because most of edges are not present in surface predictions. We evaluated the improvement of the overlap as well as for the rest. Results show that our best models perform roughly the same on both sets. Interestingly, as opposed to PAS's model, DM's model performs better on the non-overlap part. This suggests that the use of PTB-based features is somehow not optimal when applied on a none PTB-based treebank, such as DM which comes from a handcrafted grammar.

	PAS	DM
Overlap	+2.87	+2.67
Rest	+2.70	+2.74

7 Discussion

Our point was to prove that providing more syntactic context, in the form of phrased-based tree fragments and surface dependencies, helps transition-

based parsers to predict predicate-argument structures, especially for LDDs. Yet, compared to state-of-the-art systems, our results built on the S&T parser score lower than the top performers (Table 10).

However, we are currently extending a more advanced lattice-aware transition-based parser (DSR) with beams (Villemonte De La Clergerie, 2013) that takes advantage of cutting-edge techniques (dynamic programming, averaged perceptron with early updates, *etc.* following (Goldberg et al., 2013; Huang et al., 2012)) [4], which proves effective by reaching the state-of-the-art on PAS, outperforming Thomson et al. (2014) and second to the model of Martins and Almeida (2014). [5]

The point here is that using the same syntactic features as our base system exhibits the same improvement over a now much stronger baseline. We can conjecture that the ambiguities added by the relative scarcity of the deep annotations is efficiently handled by a more complete exploration of the search space, made possible by beam optimization.

We can also wonder whether the lower improvement brought to DM parsing by the PTB-based syntactic features does not come from the fact that the DM corpus and the PTB have divergent annotation schemes. In that aspect, PTB syntactic features may add some noise to the learning process, because they give more weight to conflicting decisions that led to correct structures in one but not in the other scheme.

By using features which, to a certain extent, (i) extend the domain of locality available at a given node and (ii) generalize some structural and functional contexts otherwise unavailable, we tried to overcome the main issue of transition-based parsers: they remain local in the sense that they lack a global view of the whole sentence.

Impact Beyond Transition-based Parser Of course, it can be argued that improving over a somewhat weak baseline is of limited interest. Our point was to investigate how the direct parsing of relatively sparse graph structures would benefit from the inclusion of more context via the use of topologically different syntactic pieces of information. However in that work, we mostly focused on transition based-parsing, which raises the question of the impact of our feature-set on a much more powerful and state-of-the-art model such as the TURBOSEMANTICPARSER developed by Martins and Almeida (2014).

To this end, we extended the T.PARSER so that it could cope with our syntactic features and studied the interaction of our best feature set with second order features (*i.e.* grand-parents and co-parents). Results in Table 11 show that the gain brought by adding syntactic features (+2.14 on DM over the baseline) is higher than the sole use of second order ones (+1.09). Furthermore, the gain brought by

[4] It uses a different set of transitions, notably *pop* actions instead of *left* and *right reduce*, and a *swap* that allow limited amount of non-planarity. Such a set raises issues with beams (several paths leading to a same item, final items reached with paths of various lengths, ...), overcome by adding a 'noop' action only applied on final items to balance path lengths.

[5] Leaving aside the multiple (19) ensemble models of Du et al. (2014), because of the impracticability of the approach.

the second-order features is reduced by half when used jointly with our feature set (+1.09 vs +0.57 with them). However, although we could assess that the need of second order models is thus alleviated, the conjunction of both types of features still improves the parser performance by an overall gain of 1.62 points on DM (1.18 on PAS), suggesting that both feature sets contribute to different types of "structures". In short, the use of syntactic features is also relevant with a strong baseline, as they provide a global view to graph-based models, establishing a new state-of-the-art on these corpora.

Related Work A growing interest for semantic parsing has emerged over the past few years, with the availability of resources such as PropBank and NomBank (Palmer et al., 2005; Meyers et al., 2004) built on top of the Penn Treebank. The shallow semantic annotations they provide were among the targets of successful shared tasks on semantic role labeling (Surdeanu et al., 2008; Carreras and Màrquez, 2005). Actually, the conjoint use of such annotations with surface syntax dependencies bears some resemblance with predicate-argument structure parsing like we presented here. However, they diverge in that Propbank/Nombank annotations do not form connected graphs by themselves, as they only cover argument identification and nominal predicates. The range of phenomena they describe is also limited, compared to a full predicate-argument analysis as provided by DM and PAS (Oepen et al., 2014). More importantly, as pointed out by Yi et al. (2007), being verb-specific, Propbank's roles do not generalize well beyond the ARG0 argument (i.e. the subject/agent role) leading to inconsistencies.
However, the advent of such semantic-based resources have ignited a fruitful line of research, of which the use of heterogeneous sources of information to boost parsing performance has been investigated over the past decade (Chen and Rambow, 2003; Tsuruoka et al., 2004) with a strong regain of interest raised by the work of Moschitti et al. (2008), Henderson et al. (2008), Sagae (2009).

8 Conclusion

We described the use and combination of several kinds of syntactic features to improve predicate-argument parsing. To do so, we tested our approach of injecting surface-syntax features by thoroughly evaluating their impact on one transition-based graph parser, then validating on two more efficient parsers, over two deep syntax and semantic treebanks. Results of the syntax-enhanced *semantic* parsers exhibit a constant improvement, regardless of the annotation scheme and the parser used.
The question is now to establish whether will this be verified in other semantic data sets? From the parsing of deep syntax treebanks *a la* Meaning Text Theory (Ballesteros et al., 2014), to Framenet semantic parsing (Das et al., 2014) or data-driven approaches closer to ours (Flanigan et al., 2014), it is difficult to know which models will predominate from this bubbling field and what kind of semantic data sets will benefit the most from syntax.

A Hybrid Generative/Discriminative Approach To Citation Prediction

Abstract

Text documents of varying nature (e.g., summary documents written by analysts or published, scientific papers) often cite others as a means of providing evidence to support a claim, attributing credit, or referring the reader to related work. We address the problem of predicting a document's cited sources by introducing a novel, discriminative approach which combines a content-based generative model (LDA) with author-based features. Further, our classifier is able to learn the importance and quality of each topic within our corpus – which can be useful beyond this task – and preliminary results suggest its metric is competitive with other standard metrics (Topic Coherence). Our flagship system, *Logit-Expanded,* provides state-of-the-art performance on the largest corpus ever used for this task.

1 Introduction

The amount of digital documents (both online and offline) continues to grow greatly for several reasons, including the eagerness of users to generate content (e.g., social media, Web 2.0) and the decrease in digital storage costs. Many different types of documents link to or cite other documents (e.g., websites, analyst summary reports, academic research papers), and they do so for various reasons: to provide evidence, attribute credit, refer the reader to related work, etc. Given the plethora of documents, it can be highly useful to have a system which can automatically predict relevant citations, for this could (1) aid authors in citing relevant, useful sources which they may otherwise not know about; and (2) aid readers in finding useful documents which otherwise might not have been discovered, due to the documents' being unpopular or poorly cited by many authors. Specifically, we are interested in *citation prediction* – that is, we aim to predict which *sources* each report document cites. We define a *report* as any document that cites another document in our corpus, and a *source* as a document that is cited by at least one report. Naturally, many documents within a corpus can be both a report and a source. Note, we occasionally refer to *linking* a report and source, which is synonymous with saying the report cites the source.

Citation prediction can be viewed as a special case of the more general, heavily-researched area of *link prediction.* In fact, past research mentioned in Section 2 refers to this exact task as both *citation prediction* and *link prediction*. However, *link prediction* is a commonly used phrase which may be used to describe other problems not concerning documents and citation prediction. In these general cases, a link may be relatively abstract and represent any particular relationship between other objects (such as users' interests or interactions). Traditionally, popular techniques for link prediction and recommendation systems have included feature-based classification, matrix factorization, and other collaborative filtering approaches – all of which typically use meta-data features (e.g., names and interests) as opposed to modelling complete content such as full text documents (Sarwar et al., 2001; Al Hasan and Zaki, 2011). However, starting with Hofmann and Cohn's (2001) seminal work on ci-

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 75–83,
Denver, Colorado, May 31 – June 5, 2015.

tation prediction (PHITS), along with Erosheva et. al.'s (2004) work (LinkLDA), content-based modelling approaches have extensively used generative models – while largely ignoring meta-data features which collaborative filtering approaches often use – thus creating somewhat of a dichotomy between two approaches towards the same problem. We demonstrate that combining (1) a simple, yet effective, generative approach to modelling content with (2) author-based features into a discriminative classifier can improve performance. We show state-of-the-art performance on the largest corpus for this task. Finally, our classifier learns the importance of each topic within our corpus, which can be useful beyond this task.

In the next section, we describe related research. In Section 3 we describe our models and motivations for them. In Section 4 we detail our experiments, including data and results, and compare our work to the current state-of-the-art system. We finally conclude in Section 5.

2 Related Work

Hofmann and Cohn's (2001) *PHITS* seminal work on citation prediction included a system that was based on probabilistic latent semantic analysis (PLSA) (Hofmann, 1999). Specifically, they extended PLSA by representing each distinct link to a document as a separate word token – as shown in Equation 1 and represented by s_l. (Note: Table 1 displays common notation that is used consistently throughout this paper.) PHITS assumes both the links and words are generated from the same global topic distributions, and like PLSA, a topic distribution is inferred for each document in the corpus.

$$P(w_i|d_j) = \sum_{k=1}^{K} P(w_i|z_k)P(z_k|d_j), \qquad P(s_l|d_j) = \sum_{k=1}^{K} P(s_l|z_k)P(z_k|d_j) \tag{1}$$

Later, Erosheva et. al.'s (2004) system replaced PLSA with LDA as the fundamental generative process; thus, the topic distributions were assumed to be sampled from a Dirichlet prior, as depicted in the plate notation of Figure 1. We will refer to this model as it is commonly referred, *LinkLDA*, and it is the closest model to our baseline approach (later introduced as *LDA-Bayes*).

M	total # documents in the corpus (both reports and sources)
N	# of words in the particular document
r	a report document
s	a source document
d	a document (report and/or source)
w	a word in a document
K	total # of topics
z	a particular topic
V	corpus' vocabulary size
α, β	concentration parameters to corpus-wide Dirichlet priors
$\triangle(p)$	a simplex of dimension (p-1)
L	number of citations in a particular document
$\Omega_{kd'}$	probability of a link to document d' w.r.t. topic k
s_l	a token representing a link to source s

Table 1: Notation Guide

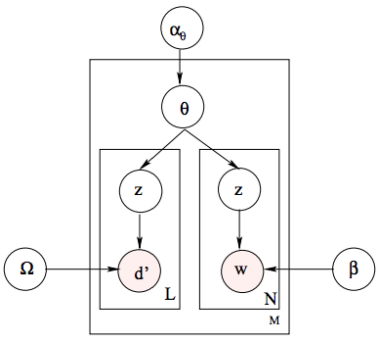

Figure 1: Plate notation of LinkLDA

Others have researched several variants of this LDA-inspired approach, paving the field with promising, generative models. For example, Link-PLSA-LDA is the same as LinkLDA but it treats the generation of the source documents as a separate process inferred by PLSA (Nallapati et al., 2008). Related, Cite-LDA and Cite-PLSA-LDA (Kataria et al., 2010) extend LinkLDA and Link-PLSA-LDA, respectively, by asserting that the existence of a link between a report and source is influenced by the context of where the citation link occurs within the report document. Note, the authors supplemented corpora to include context that surrounds each citation; however, there is currently no freely-available, widely-used corpus which allows one to discern *where* citations appear within each report. Therefore, few systems rely on citation context.

TopicBlock (Ho et al., 2012) models citation prediction with a hierarchical topic model but only uses the first 200 words of each document's abstract. To

our knowledge, *Topic-Link-LDA* (Liu et al., 2009) is the only research which includes both author information and document content into a generative model in order to predict citations. *Topic-Link-LDA* estimates the probability of linking a report-source pair according to the similarity between the documents' (1) author communities and (2) topic distributions – these two latent groups are linearly combined and weighted, and like the aforementioned systems, are inferred by a generative process. PMTLM (Zhu et al., 2013) is reported as the current state-of-the-art system. In short, it is equivalent to PLSA but extended by having a variable associated with each document, which represents that document's propensity to form a link.

As mentioned, although Collaborative Filtering has been used towards citation prediction (McNee et al., 2002), there is little research which includes features based on the entire content (i.e., documents). Very recently, (Wilson et al., 2014) used topic modelling to help predict movie recommendations. Specifically, one feature into their system was the KL-divergence between candidate items' topic distributions, but applying this towards citation prediction has yet to be done. Most similar to our work, (Bethard and Jurafsky, 2010) used a classifier to predict citations, based on meta-data features and compressed topic information (e.g., one feature is the cosine similarity between a report-source pair's topic distribution). As explained in Section 4, we expand the topic information into a vector of length K, which not only improves performance but yields an estimate of the most important, "quality" topics. Further, our system also uses our *LDA-Bayes* baseline as a feature, which by itself yields excellent results compared to other systems on our large corpus. Notably, Bethard and Jurafsky's system (2010) also differs from ours in that (1) their system has an iterative process that alternates between retrieving candidate source documents and learning model weights by training a supervised classifier; and (2) they only assume access to the content of the abstract, not the entire documents. Nonetheless, we use their system's most useful features to construct a comparable system (which we name **WSIC** – "Who Should I Cite"), which we describe in more detail in Section 3.3 and show results for in Section 4.3.

3 New Models

3.1 LDA-Bayes

For a baseline system, we first implemented LDA (Blei et al., 2003) topic modelling and ran it on our entire corpus. However, unlike past systems, after our model was trained, we performed citation prediction (i.e., $P(s|r)$) according to Equation 2. Notice, although LDA does not explicitly estimate $P(s|z)$, we can approximate it via Bayes Rule, and we consequently call our baseline *LDA-Bayes*. Doing so allows us to include the prior probability of the given source being cited (i.e., $P(s)$), according to the maximum-likelihood estimate seen during training.

$$P(s|r) = \sum_{k}^{K} P(s|z_k)P(z_k|r), \quad \text{where } P(s|z_j) = \frac{P(z_j|s)P(s)}{\sum_{s'} P(z_j|s')P(s')} \tag{2}$$

Of the past research which uses generative models for citation prediction, we believe LinkLDA is the only other system in which a source's prior citation probability plays any role in training the model. Specifically, in LinkLDA, the prediction metric is identical to ours in that the topics are marginalized over topics (Equation 3). It differs, however, in that their model directly infers $P(s|z_k)$, for it treats each citation link as a word token. Although this does not explicitly factor in each source's prior probability of being cited, it is implicitly influenced by such, for the sources which are more heavily cited during training will tend to have a higher probability of being generated from topics.

$$P(s|r) = \sum_{k}^{K} P(s|z_k)P(z_k|r), \tag{3}$$

Note: the other generative models mentioned in Section 2, after inference, predict citations by sampling from a random variable (typically a Bernoulli or Poisson distribution) which has been conditioned on the topic distributions.

3.2 Logit-Expanded

In attempt to combine the effectiveness of LDA in generating useful topics with the ability of dis-

Table 2: A randomly chosen report and its predicted sources, per LDA-Bayes, illustrating that a report and predicted source may be contextually similar but that their titles may have few words in common.

criminative classifiers to learn important features for classification, we use logistic regression with a linear kernel. Specifically, we train using L2-regularization, which during test time allows us to get a probability estimate for each queried vector (i.e., a report-source pair).

The details of the training and testing data are provided in Section 4.2. However, it is important to understand that each training and testing instance corresponds to a distinct report-source document pair and is represented as a single fixed-length vector. The vector is comprised of the following features, which our experiments illustrate are useful for determining if there exists a link between the associated report and source:

3.2.1 Topic/Content-Based Features

- **LDA-Bayes:** Our baseline system showed strong results by itself, so we include its predictions as a feature (that is, $P(s|r)$).

- **Topics:** LDA-Bayes ranks report-source pairs by marginalizing over all topics (see Equation 2); however, we assert that not all topics are equally important. Allowing each topic to be represented as its own feature, while keeping the value based on the report-source's relationship for that topic (i.e., the absolute value of the difference), can potentially allow the logistic regression to learn both (1) the importance for report-source pairs to be generally similar across most topics and (2) the relative importance of each topic. For all of our experiments (including LDA-Bayes) we used 125 topics to model the corpus; thus, this feature becomes expanded to 125 individual indices within our vector, which is why we name this system Logit-Expanded. Namely, $\forall i \in K$, let feature $f_i = |\theta_{r_i} - \theta_{s_i}|$.

3.2.2 Meta-data Features

- **Report Author Previously Cited Source?:** We believe authors have a tendency to cite documents they have cited in the past

- **Report Author Previously Cited a Source Author?:** Authors also have a tendency to "subscribe" to certain authors and are more familiar with particular people's works, and thus cite those papers more often.

- **Prior Citation Probability:** A distinguishing feature of our LDA-Bayes model is that it factors in the prior probability of a source being cited, based on the maximum likelihood estimate from the training data. So, we explicitly include this as a feature.

- **Number of Overlapping Authors:** Authors have a tendency to cite their co-authors, in part because their co-authors' past work has an increased chance of being relevant.

- **Number of Years between Report and Source:** Authors tend to cite more recent papers.

- **Title Similarity between Report and Source:** As shown in Table 2, some sources erroneously returned by our baseline system could have been discarded had we judged them by how dissimilar their titles are from the report's title. In Table 2's example, the one correct source to find (within ∼12,000) was returned at position 15 and has many words in common with the report (namely, "Japanese Dependency Structure Analysis Based On" appears in the titles of both the report and correctly predicted source).

3.3 WSIC (Who Should I Cite?)

In attempt to compare our systems against Bethard and Jurafsky's system (2010), we implemented the features they concluded to be most useful for retrieval, and like our Logit-Expanded system, used logistic regression as the mechanism for learning citation prediction. Instead of using only the text from the abstracts, like in their research, to make the comparison more fair we used text from the entire documents – just like we did for the rest of our systems. Specifically, adhering to their naming convention, the features from their system that we used are: *citation-count, venue-citation-count, author-citation-count, author-h-index, age (# years between report and source), terms-citing, topics, authors, authors-cited-article, and authors-cited-author.*

4 Experiments

4.1 Corpora

The past research mentioned in Section 2 primarily makes use of three corpora: Cora, CiteSeer, and WebKB. As shown in Table 3, these corpora are relatively small with ~3,000 documents, an average of less than three links per document, and a modest number of unique word types.

We wanted to use a corpus which was larger, provided the complete text of the original documents, and included meta-data such as author information. Thus, we used the ACL Anthology (Radev et al., 2013) (the December 2013 release), which provides author and year information for each paper, and the corpus details are listed in Table 3. For the task of citation prediction, we are the first to use full content information from a corpus this large.

4.2 Training/Testing Data

The research listed in Section 2 commonly uses 90% of all positive links (i.e., a distinct report-to-source instance) for training purposes and 10% for testing. LDA-based topic modelling approaches, which are standard for this task, require that at testing time each report and candidate source has already been observed during training. This is because at test time the topic distribution for each document must have already been inferred. Additionally, it is common to make the assumption that the corpus is split into a bipartite graph: a priori we know which documents are reports and which are sources, with most being both. At testing time, one then predicts sources from the large set of candidate sources, all of which were seen at some point during training (as either a report or a source document).

We follow suit with the past research and randomly split the ACL Anthology's report-to-source links (citations) into 90% for training and 10% for testing, with the requirement that every candidate source document during testing was seen during training as either a report or a source – ensuring we have a topic distribution for each document. On average, each report has 6.8 sources, meaning typically at test time each report has just a few (e.g., 1-5) sources which we hope to predict from our 12,265 candidate sources. For all of our experiments, the systems (e.g., LDA-Bayes, LinkLDA, Logit-Expanded, etc) were evaluated on the exact same randomly chosen split of training/testing data.

As for training Logit-Expanded, naturally there are vastly more negative examples (i.e., no link between the given report-source pair) than positive examples; most sources are not cited for a given report. This represents a large class-imbalance problem, which could make it difficult for the classifier to learn our task. Consequently, we downsampled the negative examples. Specifically, for each report, we included all positive examples (the cited sources), and for each positive example, we included 5 randomly selected negative examples (sources). Note, for testing our system, we still need to evaluate every possible candidate report-source pair – that is $\sim$12,265 candidate sources per tested report.

Table 3: Report-to-Source Citation Prediction Corpora

	Cora	CiteSeer	WebKB	ACL
# docs	2,708	3,312	3,453	17,298
# links	5,429	4,608	1,733	106,992
vocab size	1,433	3,703	24,182	137,885
# authors	-	-	-	14,407

4.3 Results

4.3.1 Report-To-Source Citation Prediction

First, we tested our LDA-Bayes baseline system and compared it to LinkLDA and PMTLM (Zhu et

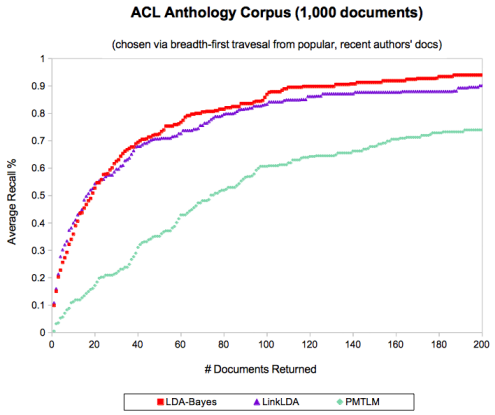

Figure 2: Average Recall Performance across all Reports from a 1,000 document subset of the ACL Anthology

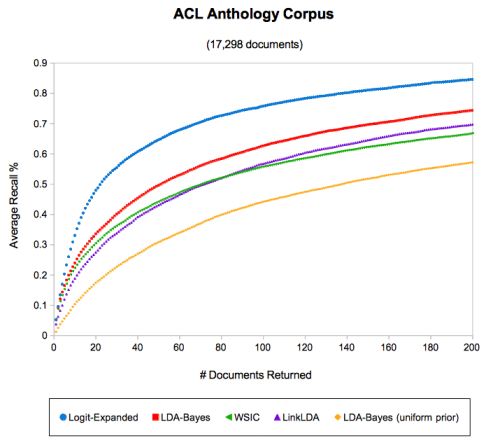

Figure 3: Average Recall Performance across all reports from the full ACL Anthology

al., 2013) – the current state-of-the-art system. Due to the slow running time of PMTLM, we restricted our preliminary experiment to just 1,000 documents of the ACL Anthology, and Figure 2 shows the average recall performance across all reports. Surprisingly, PMTLM performed worst. Note: the authors of PMTLM compared their system to LinkLDA for a different task (predicting research area) but did not compare to LinkLDA during their analysis of citation prediction performance. Thus, it was not previously asserted that PMTLM would outperform LinkLDA.

As we can see, LDA-Bayes, despite being simple, performs well. As mentioned, LDA-Bayes explicitly captures the prior probability of each source being cited (via maximum-likelihood estimate), whereas LinkLDA and PMTLM approximates this during inference. We believe this contributes towards the performance differences.

It was expected that when run on the entire ACL corpus, WSIC and our Logic-Expanded systems would have sufficient data to learn authors' citing preferences and would outperform the other generative models. As shown in Figure 3 and 4, our flagship Logit-Expanded system greatly outperformed all other systems, while our baseline LDA-Bayes continued to offer strong results. Note, the full recall performance results include returning 12,265 sources, but we only show the performance for returning the first 200 returned sources. Further, Table 4 shows the same experimental results but for the performance when returning just the first 50 predicted sources per report.

Table 4: Performance of each system, averaged across all reports while returning the top 50 predicted sources for each. 125 topics were used for every system.

	recall	precision	fscore
Logit-Expanded	.647	.016	.031
LDA-Bayes	.496	.012	.024
WSIC	.442	.011	.021
LinkLDA	.431	.011	.021
LDA-Bayes (uniform prior)	.309	.007	.014

Again, we further see how effective it is to have a model influenced by a source's prior probability, for when we change LDA-Bayes such that $P(SourceCited)$ is uniform for all sources, performance falls greatly – represented as *LDA (uniform prior)*.

We analyzed the benefits of each feature of Logit-Expanded in 2 ways: (1) starting with the full-feature set experiment (whose results we showed), we evaluate each feature by running an experiment whereby the said feature is removed; and (2) starting with our LDA-Bayes baseline as the only feature for our Logit-Expanded system, we evaluate each feature by running an experiment whereby the said feature is paired with LDA-Bayes as the only two features used. For both of these approaches, we measure performance by looking at recall, precision, and f-score when returning the first 50 predicted sources. The results are shown in Table 5; technique (1) is shown in column *removal*, and (2)

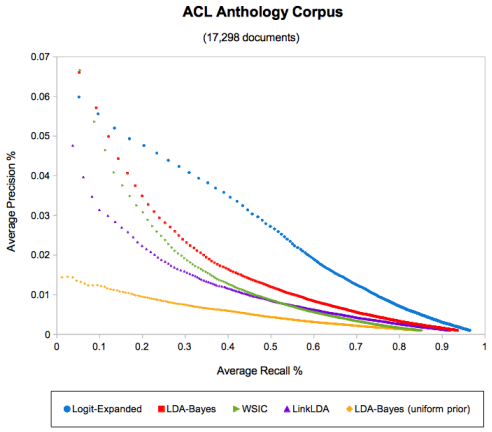

Figure 4: Recall vs Precision Performance across all Reports from the full ACL Anthology. Logit-Expanded's slight blips at recall = 0.25, 0.33, and 0.5 is due to the truth set having many reports with only 4, 3, or 2 golden sources, respectively.

is in column *addage*.

Table 5 reveals insightful results: it is clear that LDA-Bayes is a strong baseline and useful feature to include in our system, for removing it from our feature list causes performance to decrease more than removing any other feature. *PrevCitedSource* and *Topics Expanded* are the second and third strongest features, respectively. We suspect that *PrevCitedSource* was a good feature because our corpus was sufficiently large; had our corpus been much smaller, there might not have been enough data for this feature to provide any benefit. Next, *Title Similarity* and *# Shared Authors* were comparably good features. *PrevCitedAuthor* and *# Years Between* were the worst features, as we see negligible performance difference when we (1) pair either with LDA-Bayes, or (2) remove either from our full feature list. An explanation for the former feature's poor performance could be that authors vary in (1) how often they repeatedly cite authors, and most likely (2) many authors have small publication histories within training, so it might be unwise to base prediction on this limited information. Last, it is worth noting that when we pair Topics Expanded with LDA-Bayes, that alone is not enough to give the best performance from a pair. An explanation is that it dominates the system with too much content-based (i.e., topic) information, overshadowing the prior-citation-probability that plays a role in LDA-Bayes. Supporting this idea, we see the biggest performance increase when we pair LDA-Bayes with the PrevCitedSource feature – a non-topic-based feature, which provides the system with a different *type* of data to leverage.

Table 5: Analysis of each feature used in Logit-Expanded. Results based on the first 50 sources returned, averaged over all reports. Our *Starting Point** system listed within the "Addage" columns used LDA-Bayes as the only feature. Our *Starting Point** system within the "Removal" columns used every feature.

	Addage			Removal		
	recall	precision	fscore	recall	precision	fscore
Starting Point*	.496	.012	.024	.647	.016	.031
LDA-Bayes	-	-	-	**.583**	**.014**	**.028**
Topics Expanded	**.564**	**.014**	**.027**	**.606**	**.015**	**.028**
PrevCitedSource	**.581**	**.014**	**.028**	**.599**	**.014**	**.028**
PrevCitedAuthor	.484	.012	.023	.641	.016	.030
# Shared Authors	.543	.013	.026	.636	.015	.029
Prior Prob. Cited	.501	.012	.023	.639	.015	.030
Title Similarity	.513	.012	.023	.623	.015	.029
# Years Between	.498	.012	.023	.645	.016	.030

Additionally, when using only the metadata features (i.e., not LDA-Bayes or Topics-Expanded), performance for returning 50 sources averaged 0.403, 0.010, and 0.019 for recall, precision, and fscore, respectively – demonstrating that the metadata features alone do not yield strong results but that they complement the LDA-Bayes and Topics-Expanded features.

4.3.2 Topic Importance

Although Report-to-Source citation prediction was our primary objective, our feature representation of topics allows logistic regression to appropriately learn which *topics* are most useful for predicting citations. In turn, these topics are arguably the most cohesive; thus, our system, as a byproduct, provides a metric for measuring the "quality" of each topic. Namely, the weight associated with each topic feature indicates the topic's importance – the lower the weight the better.

Table 6 shows our system's ranking of the most important topics, signified by "Logit-weight." We did not prompt humans to evaluate the quality of the topics, so in attempt to offer a comparison, we also rank each topic according to two popular metrics: Pointwise Mutual Information (PMI) and Topic Coherence (TC) (Mimno et al., 2011). For a topic k,

let $V^{(k)}$ represent the top M words for K; where $V^{(k)} = (v_i^{(k)}, ..., v_M^{(k)})$ and $D(v)$ represents the document frequency of word type v. Then, $PMI(k)$ is defined by Equation 4 and $TC(k)$ is defined by Equation 5.

In Table 6, we see that our most useful topic (Topic 49) concerns vision research, and since our corpus is heavily filled with research concerning (non-vision-related) natural language processing, it makes sense for this topic to be highly important for predicting citations. Similarly, we see the other top-ranking topics all represent a well-defined, subfield of natural language processing research, including parsing, text generation, and Japanese-English machine translation.

$$PMI(k; V^{(k)}) = \sum_{m=2}^{M} \sum_{l=1}^{m-1} \log \frac{p(V_m^{(k)}, V_l^{(k)})}{p(V_m^{(k)}) p(V_l^{(k)})} \quad (4)$$

$$TC(k; V^{(k)}) = \sum_{m=2}^{M} \sum_{l=1}^{m-1} \log \frac{D(V_m^{(k)}, V_l^{(k)})}{D(V_m^{(k)})} \quad (5)$$

Table 7 shows the worst 5 topics according to Logit-Expanded. Topic 96 concerns Wikipedia as a corpus, which naturally encompasses many areas of research, and as we would expect, the mention of such is probably a poor indicator for predicting citations. Topic 77 concerns artifacts from the OCR-rendering of our corpus, which offers no meaningful information. In general, the worst-ranking topics concern words that span many documents and do not represent cohesive, well-defined areas of research. Additionally, in both Table 6 and 7 we see that Pointwise Mutual Information (PMI) disagrees quite a bit with our Logit-Expanded's ranking, and from this initial result, it appears Logit-Expanded's ranking might be a better metric than PMI – at least in terms of quantifying relevance towards documents being related and linked via a citation.

This cursory, qualitative critique of the metrics warrants more research, ideally with human-evaluation. However, one can see how these metrics differ: TC and PMI are both entirely concerned with just the co-occurrence of terms, normalized by the general popularity of the said terms. Therefore, words could highly co-occur together but otherwise represent nothing special about the corpus at large. On the other hand, Logit-Expanded's ranking is mainly concerned with quantifying how well each topic represents discriminatively useful content within a document.

Table 6: The highest quality topics (out of 125), sorted according to Logit-Expanded's estimate. Topics are also ranked according to Pointwise Mutual Information (PMI) and Topic Coherence (TC).

Logit's Rank	PMI Rank	TC Rank	Logit Weight	Topic #	Top Words
1	116	103	-5.50	49	image, visual, multimodal, images, spatial, gesture, objects, object, video, scene, instructions, pointing
2	33	44	-4.76	25	grammar, parsing, grammars, left, derivation, terminal, nonterminal, items, free, string, item, derivations, cfg
3	68	37	-4.71	65	generation, generator, generated, realization, content, planning, choice, nlg, surface, generate
4	49	27	-4.28	32	noun, nouns, phrases, adjectives, adjective, compound, verb, head, compounds, preposition
5	107	61	-4.24	0	japanese, ga, expressions, wo, accuracy, bunsetsu, ni, dictionary, wa, kanji, noun, expression

Table 7: The lowest quality topics (out of 125), sorted by Logit-Expanded's estimate. Topics are also ranked according to Pointwise Mutual Information (PMI) and Topic Coherence (TC).

Logit's Rank	PMI Rank	TC Rank	Logit Weight	Topic #	Top Words
121	13	110	-1.45	96	wikipedia, links, link, articles, article, title, page, anchor, pages, wiki, category, attributes
122	83	122	-1.20	77	x1, x2, c1, c2, p2, a1, p1, a2, r1, l1, xf, fi
123	42	36	-1.09	91	annotation, agreement, annotated, annotators, annotator, scheme, inter, annotate, gold, kappa
124	10	34	-0.75	43	selection, learning, active, selected, random, confidence, sample, sampling, cost, size, select
125	65	115	-0.33	30	region, location, texts, city, regions, weather, locations, map, place, geographic, country

5 Conclusions

We have provided a strong baseline, LDA-Bayes, which when run on the largest corpus for this task, offers compelling performance. We have demonstrated that modelling the prior probability of each candidate source being cited is simple yet important, for it allows all of our systems to outperform the previous state-of-the-art – our large corpus helps towards making this a useful feature, too.

Our biggest contribution is our new system, Logit-Expanded, which combines both the effectiveness of the generative model LDA with the power of logistic regression to discriminately learn important features for classification. By representing each topic as its own feature, while still modelling the re-

lationship between the candidate report-source pair, we allow our system to learn (1) that having similar topic distributions between reports and sources is indicative of a link, and (2) which topics are most important for predicting a link. Because we used a linear kernel, we are able to discern exactly how important it ranks each topic. A cursory, qualitative assessment of its metric shows promising and competitive performance with that of Pointwise Mutual Information and Topic Coherence.

Abstract

In this paper, we apply a weakly-supervised learning approach for slot tagging using conditional random fields by exploiting web search click logs. We extend the constrained lattice training of Täckström et al. (2013) to non-linear conditional random fields in which latent variables mediate between observations and labels. When combined with a novel initialization scheme that leverages unlabeled data, we show that our method gives significant improvement over strong supervised and weakly-supervised baselines.

1 Introduction

A key problem in natural language processing (NLP) is to effectively utilize large amounts of unlabeled and partially labeled data in situations where little or no annotations are available for a task of interest. Many recent work tackled this problem mostly in the context of part-of-speech (POS) tagging by transferring POS tags from a supervised language via automatic alignment and/or constructing tag dictionaries from the web (Das and Petrov, 2011; Li et al., 2012; Täckström et al., 2013).

In this work, we attack this problem in the context of slot tagging, where the goal is to find correct semantic segmentation of a given query, which is an important task for information extraction and natural language understanding. For instance, answering the question "when is the new bill murray movie release date?" requires recognizing and labeling key phrases: e.g., "bill murray" as `actor` and "movie" as `media type`.

The standard approach to slot tagging involves training a sequence model such as a conditional random field (CRF) on manually annotated data. An obvious limitation of this approach is that it relies on fully labeled data, which is both difficult to adapt and changing tasks and schemas. Certain films, songs, and books become more or less popular over time, and the performance of models trained on outdated data will degrade. If not updated, models trained on live data feeds such as movies, songs and books become obsolete over time and their accuracy will degrade. In order to achieve high accuracy continuously data and even model schemas have to be refreshed on a regular basis.

To remedy this limitation, we propose a weakly supervised framework that utilizes the information available in web click logs. A web click log is a mapping from a user query to URL link. For example, users issuing queries about movies tend to click on links from the IMDB.com or rottentomatoes.com, which provide rich structured data for entities such as title of the movie ("The Matrix"), the director ("The Wachowski Brothers"), and the release date ("1999"). Web click logs present an opportunity to learn semantic tagging models from large-scale and naturally occurring user interaction data (Volkova et al., 2013).

While some previous works (Li et al., 2009) have applied a similar strategy to incorporate click logs in slot tagging, they do not employ recent advances in machine learning to effectively leverage the incomplete annotations. In this paper, we pursue and extend learning from partially labeled sequences, in particular the approach of Täckström et al. (2013).

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 84–92,
Denver, Colorado, May 31 – June 5, 2015.

Instead of projecting labels from a high-resource to a low-resource languages via parallel text and word alignment, we project annotations from structured data found in click logs. This can be seen as a benefit since typically a much larger volume of click log data is available than parallel text for low-resource languages.

We also extend the constrained lattice training method of Täckström et al. (2013) from linear CRFs to non-linear CRFs. We propose a perceptron training method for hidden unit CRFs (Maaten et al., 2011) that allows us to train with partially labeled sequences. We show that combined with a novel pretraining methodology that leverages large quantities of unlabeled data, this training method achieves significant improvements over several strong baselines.

2 Model definitions and training methods

In this section, we describe the two sequence models in our experiments: a conditional random field (CRF) of Lafferty et al. (2001) and a hidden unit CRF (HUCRF) of Maaten et al. (2011). Note that since we only have partially labeled sequences, we need a technique to learn from incomplete data. For a CRF, we follow a variant of the training method of Täckström et al. (2013). In addition, we make a novel extension of their method to train a HUCRF from partially labeled sequences. The resulting perceptron-style algorithm (Figure 2) is simple but effective. Furthermore, we propose an initialization scheme that naturally leverages unlabeled data for training a HUCRF.

2.1 Partially Observed CRF

A first-order CRF parametrized by $\theta \in \mathbb{R}^d$ defines a conditional probability of a label sequence $y = y_1 \dots y_n$ given an observation sequence $x = x_1 \dots x_n$ as follows:

$$p_\theta(y|x) = \frac{\exp(\theta^\top \Phi(x, y))}{\sum_{y' \in \mathcal{Y}(x)} \exp(\theta^\top \Phi(x, y'))}$$

where $\mathcal{Y}(x)$ is the set of all possible label sequences for x and $\Phi(x, y) \in \mathbb{R}^d$ is a global feature function that decomposes into local feature functions $\Phi(x, y) = \sum_{j=1}^{n} \phi(x, j, y_{j-1}, y_j)$ by the first-order Markovian assumption. Given fully labeled sequences $\{(x^{(i)}, y^{(i)})\}_{i=1}^{N}$, the standard training method is to find θ that maximizes the log likelihood of the label sequences under the model with l_2-regularization:

$$\theta^* = \arg\max_{\theta \in \mathbb{R}^d} \sum_{i=1}^{N} \log p_\theta(y^{(i)}|x^{(i)}) - \frac{\lambda}{2} ||\theta||^2$$

Unfortunately, in our problem we do not have fully labeled sequences. Instead, for each token x_j in sequence $x_1 \dots x_n$ we have the following two sources of label information:

- A set of allowed label types $\mathcal{Y}(x_j)$. (Label dictionary)
- A label $\tilde{y}_j$ transferred from a source data. (Optional: transferred label)

Täckström et al. (2013) propose a different objective that allows training a CRF in this scenario. To this end, they define a constrained *lattice* $\mathcal{Y}(x, \tilde{y}) = \mathcal{Y}(x_1, \tilde{y}_1) \times \dots \times \mathcal{Y}(x_n, \tilde{y}_n)$ where at each position j a set of allowed label types is given as:

$$\mathcal{Y}(x_j, \tilde{y}_j) = \begin{cases} \{\tilde{y}_j\} & \text{if } \tilde{y}_j \text{ is given} \\ \mathcal{Y}(x_j) & \text{otherwise} \end{cases}$$

In addition to these existing constraints, we introduce constraints on the *label structure*. In our segmentation problem, labels are structured (e.g., some label types cannot follow certain others). We can easily incorporate this restriction by disallowing invalid label types as a post-processing step of the form:

$$\mathcal{Y}(x_j, \tilde{y}_j) \leftarrow \mathcal{Y}(x_j, \tilde{y}_j) \cap \overline{\mathcal{Y}}(x_{j-1}, \tilde{y}_{j-1})$$

where $\overline{\mathcal{Y}}(x_{j-1}, \tilde{y}_{j-1})$ is the set of valid label types that can follow $\mathcal{Y}(x_{j-1}, \tilde{y}_{j-1})$.

Täckström et al. (2013) define a conditional probability over label lattices for a given observation sequence x:

$$p_\theta(\mathcal{Y}(x, \tilde{y})|x) = \sum_{y \in \mathcal{Y}(x, \tilde{y})} p_\theta(y|x)$$

Given a label dictionary $\mathcal{Y}(x_j)$ for every token type x_j and training sequences $\{(x^{(i)}, \tilde{y}^{(i)})\}_{i=1}^{N}$ where $\tilde{y}^{(i)}$ is (possibly non-existent) transferred labels for

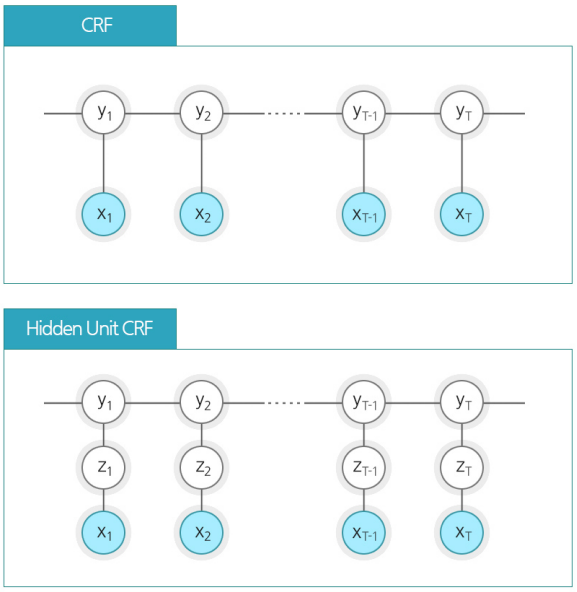

Figure 1: Illustration of CRFs and hidden unit CRFs

$x^{(i)}$ and, the new training method is to find θ that maximizes the log likelihood of the label lattices:

$$\theta^* = \arg\max_{\theta \in \mathbb{R}^d} \sum_{i=1}^{N} \log p_\theta(\mathcal{Y}(x^{(i)}, \tilde{y}^{(i)}) | x^{(i)}) - \frac{\lambda}{2} ||\theta||^2$$

Since this objective is non-convex, we find a local optimum with a gradient-based algorithm. The gradient of this objective at each example $(x^{(i)}, \tilde{y}^{(i)})$ takes an intuitive form:

$$\begin{aligned} &\frac{\partial}{\partial \theta} \log p_\theta(\mathcal{Y}(x^{(i)}, \tilde{y}^{(i)}) | x^{(i)}) - \frac{\lambda}{2} ||\theta||^2 \\ &= \sum_{y \in \mathcal{Y}(x^{(i)}, \tilde{y})} p_\theta(y | x^{(i)}) \Phi(x^{(i)}, y) \\ &\quad - \sum_{y \in \mathcal{Y}(x^{(i)})} p_\theta(y | x^{(i)}) \Phi(x^{(i)}, y) - \lambda \theta \end{aligned}$$

This is the same as the standard CRF training except the first term where the gold features $\Phi(x^{(i)}, y^{(i)})$ are replaced by the expected value of features in the constrained lattice $\mathcal{Y}(x^{(i)}, \tilde{y})$.

2.2 Partially Observed HUCRF

While effective, a CRF is still a linear model. To see if we can benefit from nonlinearity, we use a HUCRF (Maaten et al., 2011): a CRF that introduces a layer of binary-valued hidden units $z = z_1 \dots z_n \in \{0, 1\}$ for each pair of label sequence $y = y_1 \dots y_n$ and observation sequence $x = x_1 \dots x_n$. A HUCRF parametrized by $\theta \in \mathbb{R}^d$ and $\gamma \in \mathbb{R}^{d'}$ defines a joint probability of y and z conditioned on x as follows:

$$p_{\theta,\gamma}(y, z | x) = \frac{\exp(\theta^\top \Phi(x, z) + \gamma^\top \Psi(z, y))}{\sum_{\substack{z' \in \{0,1\}^n \\ y' \in \mathcal{Y}(x, z')}} \exp(\theta^\top \Phi(x, z') + \gamma^\top \Psi(z', y'))}$$

where $\mathcal{Y}(x, z)$ is the set of all possible label sequences for x and z, and $\Phi(x, z) \in \mathbb{R}^d$ and $\Psi(z, y) \in \mathbb{R}^{d'}$ are global feature functions that decompose into local feature functions:

$$\Phi(x, z) = \sum_{j=1}^{n} \phi(x, j, z_j)$$

$$\Psi(z, y) = \sum_{j=1}^{n} \psi(z_j, y_{j-1}, y_j)$$

In other words, it forces the interaction between the observations and the labels at each position j to go through a latent variable z_j: see Figure 1 for illustration. Then the probability of labels y is given by marginalizing over the hidden units,

$$p_{\theta,\gamma}(y | x) = \sum_{z \in \{0,1\}^n} p_{\theta,\gamma}(y, z | x)$$

As in restricted Boltzmann machines (Larochelle and Bengio, 2008), hidden units are conditionally independent given observations and labels. This allows for efficient inference with HUCRFs despite their richness (see Maaten et al. (2011) for details).

2.2.1 Training with partially labeled sequences

We extend the perceptron training method of Maaten et al. (2011) to train a HUCRF from partially labeled sequences. This can be viewed as a modification of the constrained lattice training method of Täckström et al. (2013) for HUCRFs.

A sketch of our training algorithm is shown in Figure 2. At each example, we predict the most likely label sequence with the current parameters. If this sequence does not violate the given constrained lattice, we make no updates. If it does, we predict the most likely label sequence within the con-

Input: constrained lattices $\{(x^{(i)}, \tilde{y}^{(i)})\}_{i=1}^{N}$, step size η
Output: HUCRF parameters $\Theta := \{\theta, \gamma\}$

1. Initialize Θ randomly.
2. Repeatedly select $i \in \{1 \dots N\}$ at random:
   (a) $y^* \leftarrow \arg\max_{y \in \mathcal{Y}(x^{(i)})} p_\Theta(y|x^{(i)})$
   (b) If $y^* \notin \mathcal{Y}(x^{(i)}, \tilde{y}^{(i)})$:
      i. $y^+ \leftarrow \arg\max_{y \in \mathcal{Y}(x^{(i)}, \tilde{y}^{(i)})} p_\Theta(y|x^{(i)})$
      ii. Make parameter updates:

$$\Theta \leftarrow \Theta + \eta \times \frac{\partial}{\partial \Theta}\Big(p_\Theta(y^+, z^+|x^{(i)}) - p_\Theta(y^*, z^*|x^{(i)})\Big)$$

where the following hidden units are computed in closed-form (see Gelfand et al. (2010)):

$$z^+ := \arg\max_z p_\Theta(z|x^{(i)}, y^+)$$
$$z^* := \arg\max_z p_\Theta(z|x^{(i)}, y^*)$$

Figure 2: A sketch of the perceptron training algorithm for a partially observed hidden unit CRF.

strained lattice. We treat this as the gold label sequence, and perform the perceptron updates accordingly (Gelfand et al., 2010). Even though this training algorithm is quite simple, we demonstrate its effectiveness in our experiments.

2.2.2 Initialization from unlabeled data

Rather than initializing the model parameters randomly, we propose an effective initialization scheme (in a similar spirit to the pre-training methods in neural networks) that naturally leverages unlabeled data.

First, we cluster observation types in unlabeled data and treat the clusters as labels. Then we train a fully supervised HUCRF on this clustered data to learn parameters θ for the interaction between observations and hidden units $\Phi(x, z)$ and γ for the interaction between hidden units and labels $\Phi(z, y)$. Finally, for task/domain specific training, we discard γ and use the learned θ to initialize the algorithm in Figure 2. We hypothesize that if the clusters are non-trivially correlated to the actual labels, we can capture the interaction between observations and hidden units in a meaningful way.

3 Mining Click Log Data

We propose using search click logs which consist of queries and their corresponding web documents. Clicks are an implicit signal for related entities and information in the searched document. In this work, we will assume that the web document is *structured* and generated from an underlying database. Due to the structured nature of the web, this is not an unrealistic assumption (see Adamic and Huberman (2002) for discussion). Such structural regularities make obtaining annotated queries for learning a semantic slot tagger almost cost-free.

As an illustration of how to project annotation, consider Figure 3, where we present an example taken from queries about video games. In the figure, the user queries are connected to a structured document via a click log, and then the document is parsed and stored in a structured format. Then annotation types are projected to linked queries through structural alignment. In the following subsections we describe each step in our log mining approach in detail.

3.1 Click Logs

Web search engines keep a record of search queries, clicked document and URLs which reveal the user behavior. Such records are proven to be useful in improving the quality of web search. We focus on utilizing query-to-URL click logs that are essentially a mapping from queries to structured web documents. In this work, we use a year's worth of query logs (from July 2013 to June 2014) at a commercial search engine. We applied a simple URL normalization procedure to our log data including trimming and removal of prefixes, e.g. "www".

3.2 Parsing Structured Web Document

A simple wrapper induction algorithm described in Kushmerick (1997) is applied for parsing web documents. Although it involves manually engineering a rule-based parser and is therefore website-specific, a single wrapper often generates large amounts of data for large structured websites, for example IMDB. Furthermore, it is very scalable to large quantities of data, and the cost of writing such a rule-based sys-

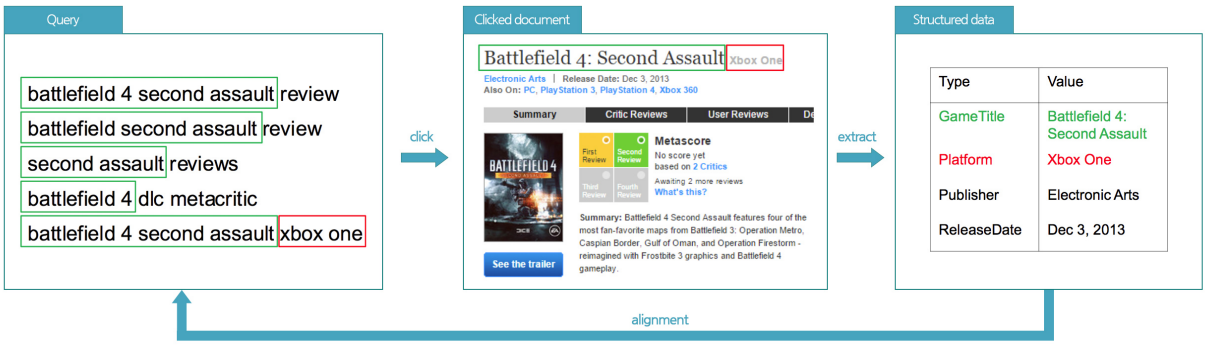

Figure 3: An example illustrating annotation projection via click-log and wrapper induction.

tem is typically much lower than the annotation cost of queries.

Figure 4 shows the statistics of parsed web documents on 24 domains with approximately 500 template rules. One of the chosen domains in our experiment, Music, has over 130 million documents parsed by our approach.

3.3 Annotation Projection via Structural Alignment

We now turn to the annotation projection step where structural alignment is used to transfer type annotation from structured data to queries. Note that this is different from the word-based or phrase-based alignment scenario in machine translation since we need to align a word sequence to a type-value pair.

Let us assume that we are given the user query as a word sequence, $w = w_1, w_2, \ldots, w_n$ and a set of structured data, $s = \{s_1, s_2, \ldots, s_m\}$, where s_i is a pair of slot-type and value. We define a measurement of dissimilarity between word tokens and slots, $dist(w_i, s_j) = 1 - sim(w_i, s_j)$ where $sim(\cdot, \cdot)$ is cosine similarity over character trigrams of w_i and s_j. Next we construct a n-by-n score matrix S of which element is $\max_j dist(w_{t'\ldots t}, s_j)$ meaning that a score of the most similar type-value s_j and a segment $\{t' \ldots t\}$ where $1 \leq t' < t \leq n$. Finally, given this approximate score matrix S, we use a dynamic programming algorithm to find the optimal segments to minimize the objective function:

$$T(t) = \min_{t'<t} T(t')S(t', t).$$

Our approach results in a large amount of high-quality partially-labeled data: 314K, 1.2M, and 1.1M queries for the Game, Movie and Music domain, respectively.

4 Experiments

To test the effectiveness of our approach, we perform experiments on a suite of three entertainment domains for slot tagging: queries about movies, music, and games. For each domain, we have two types of data: engineered data and log data. *Engineered data* is a set of synthetic queries to mimic the behavior of users. This data is created during development at which time no log data is available. *Log data* is a set of queries created by actual users using deployed spoken dialogue systems: thus it is directly transcribed from users' voice commands with automatic speech recognition (ASR). In general we found log data to be fairly noisy, containing many ASR and grammatical errors, whereas engineered data consisted of clean, well-formed text.

Not surprisingly, synthetic queries in engineered data are not necessarily representative of real queries in log data since it is difficult to accurately simulate what users' queries will be before a fully functioning system is available and real user data can be gathered. Hence this setting can greatly benefit from weakly-supervised learning methods such as ours since it is critical to learn from new incoming log data. We use search engine log data to project lattice constraints for weakly supervised learning.

In this setup, a user issues a natural language query to retrieve movies, music titles, games and/or information there of. For instance, a user could say

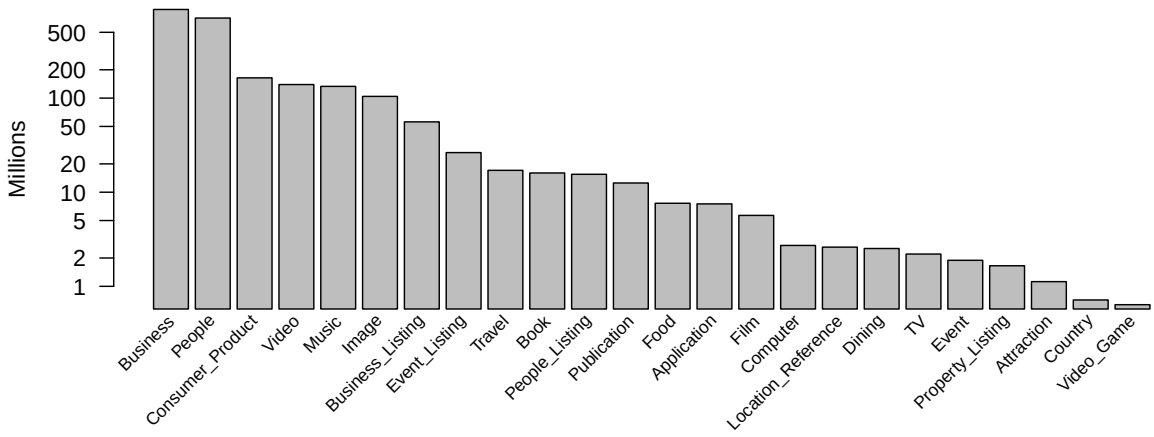

Figure 4: Statistics of structured web documents. The vertical axis shows the number of documents (in millions); the horizontal axis shows the web domain types.

"play the latest batman movie" or "find beyonce's music". Our slot sequence tagger is trained with variants of CRF using lexical features, gazetteers, Brown clusters and context words. The domains consist of 35 slot types for movies, 25 for music and 24 for games. Slot types correspond to both named entities (e.g., game name, music title, movie name) as well as more general categories (genre, media type, description). Table 1 shows the size of the datasets used in our experiments.

Domains	Training	Test
games	32017	5508
movies	48173	7074
music	46377	8890

Table 1: Labeled data set size for games, movies and music domains partitioned into training and test set.

Domains	Engineered	Log	Diff.
games	89.63	68.58	21.05
movies	88.67	74.21	14.45
music	88.77	37.13	51.64
AVG.	89.02	59.97	29.05

Table 2: The difference in F1 performance of CRF models trained only on engineered data but tested on both engineered and log data.

4.1 Discrepancy between Engineered Data and Log Data

To empirically highlight the need for learning from real user queries, we first train a standard CRF on the (fully labeled) engineered data and test it on the log data. We have manually annotated some log data for evaluation purposes. For features in the CRF, we use n-grams, gazetteer, and clusters. The clusters were induced from a large body of unlabeled data which consist of log data and click log data. Table 2 shows the F1 scores in this experiment. They indicate that a model fully supervised with engineered data performs very poorly on log data. The difference between the scores within engineered data and the scores in log data is very large (29.05 absolute F1).

4.2 Experiments with CRF Variants

Our main contribution is to leverage search log data to improve slot tagging in spoken dialogue systems. In this section, we assume that we have no log data in training slot taggers.[1]

For parameter estimation, both CRFs and POCRFs employ L-BFGS, while POHUCRF uses

[1]In practice, this assumption is not necessarily true because a deployed system can benefit from actual user logs. However, this controlled setting allows us to show the benefits of employing web search click log data.

Domains	games	music	movies	AVG.
CRF	74.21	37.13	68.58	59.97
POCRF	77.23	44.55	76.89	66.22
POHCRF	78.93	46.81	76.46	67.40
POHCRF+	**79.28**	**47.35**	**78.33**	**68.32**

Table 3: The F1 performance of variants of CRF across three domains, test on log data

average perceptron. We did not see a significant difference between perceptron and LBFGS in accuracy, but perceptron is faster and thus favorable for training complex HUCRF models. We used 100 as the maximum iteration count and 1.0 for the L2 regularization parameter. The number of hidden variables per token is set to 300. The same features described in the previous section are used here.

We perform experiments with the following CRF variants (see Section 2):

- CRF: A fully supervised linear-chain CRF trained with manually labeled engineered samples.
- POCRF: A partially observed CRF of Täckström et al. (2013) trained with both manually labeled engineered samples and click logs.
- POHUCRF: A partially observed hidden unit CRF (Figure 2) trained with both manually labeled engineered samples and click logs.
- POHUCRF+: POHUCRF with pre-training.

Table 3 summarizes the performance of these CRF variants. All results were tested on log data only. A standard CRF without click log data yields 59.97% of F1 on average. By using click log data, POCRF consistently improves F1 scores across domains, resulting into 66.22% F1 measure. Our model POHUCRF achieves extra gains on games and music, achieving 67.4% F1 measure on average. Finally, the pre-training approach yields significant additional gains across all domains, achieving 68.32% average performance. Overall we achieve a relative error reduction of about 21% over vanilla CRFs.

Domain	CRF	HUCRF	HUCRF+
alarm	91.79	91.79	**91.96**
calendar	87.60	87.65	**88.21**
communication	91.84	92.49	**92.80**
note	87.72	88.48	**88.72**
ondevice	89.37	90.14	**90.64**
places	88.02	88.64	**88.99**
reminder	87.72	89.21	**89.72**
weather	96.93	97.38	**97.63**
AVG.	90.12	90.75	**91.08**

Table 4: Performance comparison between HUCRF and HUCRF with pre-training.

4.3 Weakly-Supervised Learning without Projected Annotations via Pre-Training

We also present experiments within Cortana personal assistant domain where the click log data is not available. The amount of training data we used was from 50K to 100K across different domains and the test data was from 5k to 10k. In addition, the unlabeled log data were used and their amount was from 100k to 200k.

In this scenario, we have access to both engineered and log data to train a model. However, we do not have access to web search click log data. The goal of these experiments is to show the effectiveness of the HUCRF and pre-training method in the absence of weakly supervised labels projected via click logs. Table 4 shows a series of experiments on eight domains.

For all domains other than alarm, using non-linear CRF (HUCRF) improve performance from 90.12% to 90.75% on average. Initializing HUCRF with pre-training (HUCRF+) boosts the performance up to 91.08%, corresponding to a 10% decrease in error relative to a original CRF. Notably in the weather and reminder domains, we have relative error reduction of 23 and 16%, respectively. We speculate that pretraining is helpful because it provides better initialization for training HUCRF: initialization is important since the training objective of HUCRF is non-convex.

In general, we find that HUCRF delivers better performance than standard CRF: when the training procedure is initialized with pretraining (HUCRF+), it improves further.

5 Related Work

Previous works have explored weakly supervised slot tagging using aligned labels from a database as constraints. Wu and Weld (2007) train a CRF on heuristically annotated Wikipedia articles with relations mentioned in their structured infobox data. Li et al. (2009) applied a similar strategy incorporating structured data projected through click-log data as both heuristic labels and additional features. Knowledge graphs and search logs have been also considered as extra resources (Liu et al., 2013; El-Kahky et al., 2014; Anastasakos et al., 2014; Sarikaya et al., 2014; Marin et al., 2014).

Distant supervision methods (Mintz et al., 2009; Riedel et al., 2010; Surdeanu et al., 2012; Agichtein and Gravano, 2000) learn to extract relations from text using weak supervision from related structured data sources such as Freebase or Wikipedia. These approaches rely on named entity recognition as a pre-processing step to identify text spans corresponding to candidate slot values. In contrast, our approach jointly segments and predicts slots.

Works on weakly supervised POS tagging are also closely related to ours (Toutanova and Johnson, 2007; Haghighi and Klein, 2006). Täckström et al. (2013) investigate weakly supervised POS tagging in low-resource languages, combining dictionary constraints and labels projected across languages via parallel corpora and automatic alignment. Our work can be seen as an extension of their approach to the structured-data projection setup presented by Li et al. (2009). A notable component of our extension is that we introduce a training algorithm for learning a hidden unit CRF of Maaten et al. (2011) from partially labeled sequences. This model has a set of binary latent variables that introduce non-linearity by mediating between observations and labels.

6 Conclusions

In this paper, we applied weakly-supervised learning approach for slot tagging, projecting annotations from structured data to user queries by leveraging click log data. We extended the Täckström et al. (2013) model to nonlinear CRFs by introducing latent variables and applying a novel pre-training methodology. The proposed techniques provide an effective way to leverage incomplete and ambiguous annotations from large amounts of naturally occurring click log data. All of our improvements taken together result in a 21% error reduction over vanilla CRFs trained on engineered data used during system development.

Abstract

Character n-grams have been identified as the most successful feature in both single-domain and cross-domain Authorship Attribution (AA), but the reasons for their discriminative value were not fully understood. We identify subgroups of character n-grams that correspond to linguistic aspects commonly claimed to be covered by these features: morpho-syntax, thematic content and style. We evaluate the predictiveness of each of these groups in two AA settings: a single domain setting and a cross-domain setting where multiple topics are present. We demonstrate that character n-grams that capture information about affixes and punctuation account for almost all of the power of character n-grams as features. Our study contributes new insights into the use of n-grams for future AA work and other classification tasks.

1 Introduction

Authorship Attribution (AA) tackles the problem of determining who, among a set of authors, wrote the document at hand. AA has relevant applications ranging from plagiarism detection (Stamatatos, 2011) to Forensic Linguistics, such as identifying authorship of threatening emails or malicious code. Applied areas such as law and journalism can also benefit from authorship attribution, where identifying the true author of a piece of text (such as a ransom note) may help save lives or catch the offenders.

We know from state of the art research in AA that the length of the documents and the number of potential candidate authors have an important effect on the accuracy of AA approaches (Moore, 2001; Luyckx and Daelemans, 2008; Luyckx and Daelemans, 2010). We can also point out the most common features that have been used successfully in AA work, including: bag-of-words (Madigan et al., 2005; Stamatatos, 2006), stylistic features (Zheng et al., 2006; Stamatatos et al., 2000), and word and character level n-grams (Kjell et al., 1994; Keselj et al., 2003; Peng et al., 2003; Juola, 2006).

The utility of bag-of-words features is well understood: they effectively capture correlations between authors and topics (Madigan et al., 2005; Kaster et al., 2005). The discriminative value of these features is thus directly related to the level of content divergence among authors and among train and test sets.

The utility of stylistic features is also well understood: they model author preferences for the use of punctuation marks, emoticons, white spaces, and other traces of writing style. Such preferences are less influenced by topic, and directly reflect some of the unique writing patterns of an author.

Character n-grams are the single most successful feature in authorship attribution (Koppel et al., 2009; Frantzeskou et al., 2007; Koppel et al., 2011), but the reason for their success is not well understood. One hypothesis is that character n-grams carry a little bit of everything: lexical content, syntactic content, and even style by means of punctuation and white spaces (Koppel et al., 2011). While this argument seems plausible, it falls short of a rigorous explanation.

In this paper, we investigate what in the make-up

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 93–102,
Denver, Colorado, May 31 – June 5, 2015.

of these small units of text makes them so powerful. Our goal is two-fold: on the one hand we want to have a principled understanding of character n-grams that will inform their use as features for AA and other tasks; on the other hand we want to make AA approaches more accessible to non-experts so that, for example, they could be acceptable pieces of evidence in criminal cases.

The research questions we aim to answer are:

- *Are all character n-grams equally important?* For example, are the prefix of '**the**re', the suffix of 'brea**the**' and the whole word '**the**' all equivalent? More generally, are character n-grams that capture morpho-syntactic information, thematic information and style information equally important?

- *Are the character n-grams that are most important for single-domain settings also the most important for cross-domain settings?* Which character n-grams are more like bag-of-words features (which tend to track topics), and which are more like stylistic features (which tend to track authors)?

- *Do different classifiers agree on the importance of the different types of character n-grams?* Are some character n-grams consistently the best regardless of the learning algorithm?

- *Are some types of character n-grams irrelevant in AA tasks?* Are there categories of character n-grams that we can exclude and get similar (or better) performance than using all n-grams? If there are, are they the same for both single-domain and cross-domain AA settings?

Our study shows that using the default bag-of-words representation of char n-grams results in collapsing sequences of characters that correspond to different linguistic aspects, and that this yields suboptimal prediction performance. We further show that we can boost accuracy by loosing some categories of n-grams. Char n-grams closely related to thematic content can be completely removed without loss of accuracy, even in cases where the train and test sets have the same topics represented, a counter-intuitive argument. Given the wide spread use of char n-grams in text classification tasks, our findings have significant implications for future work in related areas.

2 Categories of Character N-grams

To answer our research questions and explore the value of character n-grams in authorship attribution, we propose to separate character n-grams into ten distinct categories. Unlike previous AA work where all character n-grams were combined into a single bag-of-n-grams, we evaluate each category separately to understand its behavior and effectiveness in AA tasks. These categories are related to the three linguistic aspects hypothesized to be represented by character n-grams: morpho-syntax (as represented by affix-like n-grams), thematic content (as represented by word-like n-grams) and style (as represented by punctuation-based n-grams). We refer to these three aspects as super categories (SC).

The following sections describe the different types of n-grams. We use the sentence in Table 1 as a running example for the classes and in Table 2 we show the resulting n-grams in that sentence. For ease of understanding, we replace spaces in n-grams with underscores (_).

The actors wanted to see if the pact seemed like an old-fashioned one.

Table 1: Example sentence to demonstrate the selection of different n-gram categories.

2.1 Affix n-grams

Character n-grams are generally too short to represent any deep syntax, but some of them can reflect morphology to some degree. In particular, we consider the following affix-like features by looking at n-grams that begin or end a word:

prefix A character n-gram that covers the first n characters of a word that is at least $n + 1$ characters long.

suffix A character n-gram that covers the last n characters of a word that is at least $n + 1$ characters long.

space-prefix A character n-gram that begins with a space.

SC	Category	Character n-grams
affix	*prefix*	**act** wan pac **see** lik fas
	suffix	ors ted **act** med ike ned
	space-prefix	_ac _wa _to _se _if _th _pa _li _an _ol _on
	space-suffix	he_ rs_ ed_ to_ ee_ if_ ct_ ke_ an_
word	*whole-word*	The **see** the old **one**
	mid-word	cto tor ant nte eem eme ash shi hio ion **one**
	multi-word	e_a s_w d_t o_s e_i f_t e_p t_s d_l n_o d_o
punct	*beg-punct*	-fa
	mid-punct	d-f
	end-punct	ld- ne.

Table 2: Example of the n-gram categories (n = 3) for the sentence in Table 1. The first column represents the super category (SC). The n-grams that appear in more than one category are in bold.

space-suffix A character n-gram that ends with a space.

2.2 Word n-grams

While character n-grams are often too short to capture entire words, some types can capture partial words and other word-relevant tokens. We consider the following such features:

whole-word A character n-gram that covers all characters of a word that is exactly n characters long.

mid-word A character n-gram that covers n characters of a word that is at least $n + 2$ characters long, and that covers neither the first nor the last character of the word.

multi-word N-grams that span multiple words, identified by the presence of a space in the middle of the n-gram.

2.3 Punctuation n-grams

The main stylistic choices that character n-grams can capture are the author's preferences for particular patterns of punctuation. The following features characterize punctuation by its location in the n-gram.

beg-punct A character n-gram whose first character is punctuation, but middle characters are not.

mid-punct A character n-gram with at least one punctuation character that is neither the first nor the last character.

end-punct A character n-gram whose last character is punctuation, but middle characters are not.

The above ten categories are intended to be disjoint, so that a character n-gram belongs to exactly one of the categories. For n-grams that contain both spaces and punctuation, we first categorize by punctuation and then by spaces. For example, 'e,_' is assigned to the *mid-punct* category, not the *space-suffix* category.

We have observed that in our data almost 80% of the n-grams in the *punct-beg* and *punct-mid* categories contain a space. This tight coupling of punctuation and spaces is due to the rules of English orthography: most punctuation marks require a space following them. The 20% of n-grams that have punctuation but no spaces correspond mostly to the exceptions to this rule: quotation marks, mid-word hyphens, etc. An interesting experiment for future work would be to split out these two types of punctuation into separate feature categories.

3 Datasets

We consider two corpora, a single-domain corpus, where there is only one topic that all authors are writing about, and a multi-domain corpus, where there are multiple different topics. The latter allows us to test the generalization of AA models, by testing them on a different topic from that used for training.

The first collection is the CCAT topic class, a subset of the Reuters Corpus Volume 1 (Lewis et al., 2004). Although this collection was not gathered for the goal of doing authorship attribution studies, previous work has reported results for AA with 10 and 50 authors (Stamatatos, 2008; Plakias and Stamatatos, 2008; Escalante et al., 2011). We refer to these as CCAT_10 and CCAT_50, respectively. Both CCAT_10 and CCAT_50 belong to CCAT category (about corporate/industrial news) and are balanced across authors, with 100 documents sampled for each author. Manual inspection of the dataset revealed that some of the authors in this collection consistently used signatures at the end of documents. Also, we noticed some writers use quotations a lot. Con-

Corpus	#authors	#docs /author/topic	#sentences /doc	#words /doc
CCAT_10	10	100	19	425
CCAT_50	50	100	19	415
Guardian1	13	13	53	1034
Guardian2	13	65	10	207

Table 3: Some statistics about the datasets.

sidering these parts of text for measuring the frequencies of character n-grams is not a good idea because signatures provide direct clues about the authorship of document and quotations do not reflect the author's writing style. Therefore, to clean up the CCAT collection, we preprocessed it to remove signatures and quotations from each document. Since the CCAT collection contains documents belonging to only corporate/industrial topic category, this will be our single-domain collection.

The other collection consists of texts published in The Guardian daily newspaper written by 13 authors in four different topics (Stamatatos, 2013). This dataset contains opinion articles on the topics: World, U.K., Society, and Politics. Following prior work, to make the collection balanced across authors, we choose at most ten documents per author for each of the four topics. We refer to this corpus as Guardian1. We also consider a variation of this corpus that makes it more challenging but that more closely matches realistic scenarios of forensic investigation that deal with short texts such as tweets, SMS, and emails. We chunk each of the documents by sentence boundaries into five new short documents. We refer to this corpus as Guardian2.

Table 3 shows some of the statistics of the CCAT and Guardian corpora and Table 4 presents some of the top character n-grams for each category (taken from an author in the Guardian data, but the top n-grams look qualitatively similar for other authors).

4 Experimental Settings

We performed various experiments using different categories of character n-grams. We chose n=3 since our preliminary experiments found character 3-grams to be more effective than other higher level character n-grams. For each category, we considered only those 3-grams that occur at least five times in the training documents.

The performance of different authorship attribution models was measured in terms of accuracy. In the single-domain CCAT experiments, accuracy was measured using the train/test partition of prior work. In the cross-domain Guardian experiments, accuracy was measured by considering all 12 possible pairings of the 4 topics, treating one topic as training data and the other as testing data, and averaging accuracy over these 12 scenarios. This ensured that in the cross-domain experiments, the topics of the training data were always different from that of the test data.

SC	**Category**	**N-grams**				
affix	*prefix*	tha	the	wit	con	hav
	suffix	ing	hat	ion	ent	ers
	space-prefix	_th	_of	_to	_an	_in
	space-suffix	he_	of_	to_	ed_	ng_
word	*whole-word*	the	and	for	was	not
	mid-word	tio	ati	iti	men	ent
	multi-word	e_t	s_a	t_t	s_t	n_t
punct	*beg-punct*	._T	's_	,_t	,_a	._I
	mid-punct	s,_	e,_	s._	e's	y's
	end-punct	es,	on.	on,	es.	er,

Table 4: Top character 3-grams in each category for author 'Catherine Bennet' in the cross-domain training data.

We trained support vector machine (SVM) classifiers using the Weka implementation (Witten and Frank, 2005) with default parameters. We also ran some comparative experiments with the Weka implementation of naive Bayes classifiers and the LibSVM implementation of SVMs. In the results below, when performance of a single classifier is presented, it is the result of Weka's SVM, which generally gave the best performance. When performance of other classifiers are presented, the classifiers are explicitly indicated.

5 Experimental Results and Evaluation

In this section, we present various results on authorship attribution tasks using both single as well as cross-domain datasets. We will explore character n-grams in depth and try to understand why they are so effective in discriminating authors.

5.1 Which n-gram Categories are Most Author-Discriminative?

After breaking character n-grams into ten disjoint categories, we empirically illustrate what categories are

	affix				word			punct		
Dataset	*prefix*	*suffix*	*space-prefix*	*space-suffix*	*multi-word*	*whole-word*	*mid-word*	*beg-punct*	*mid-punct*	*end-punct*
CCAT_10	**74.6**	**71.0**	**71.2**	66.0	65.8	48.0	**70.0**	60.2	35.4	56.2
CCAT_50	**61.9**	**59.6**	**57.0**	51.0	51.2	35.4	**61.0**	39.7	12.4	36.5

(a) Single Domain

	affix				word			punct		
Dataset	*prefix*	*suffix*	*space-prefix*	*space-suffix*	*multi-word*	*whole-word*	*mid-word*	*beg-punct*	*mid-punct*	*end-punct*
Guardian1	**41.6**	36.7	**41.9**	38.1	32.2	38.1	37.8	**43.5**	**46.1**	37.3
Guardian2	**31.0**	26.9	**29.7**	27.0	23.2	26.8	27.2	**33.6**	**33.5**	24.5

(b) Cross-Domain

Table 5: Accuracy of AA classifiers trained on each of the character n-gram categories. The top four accuracies for each dataset are in bold.

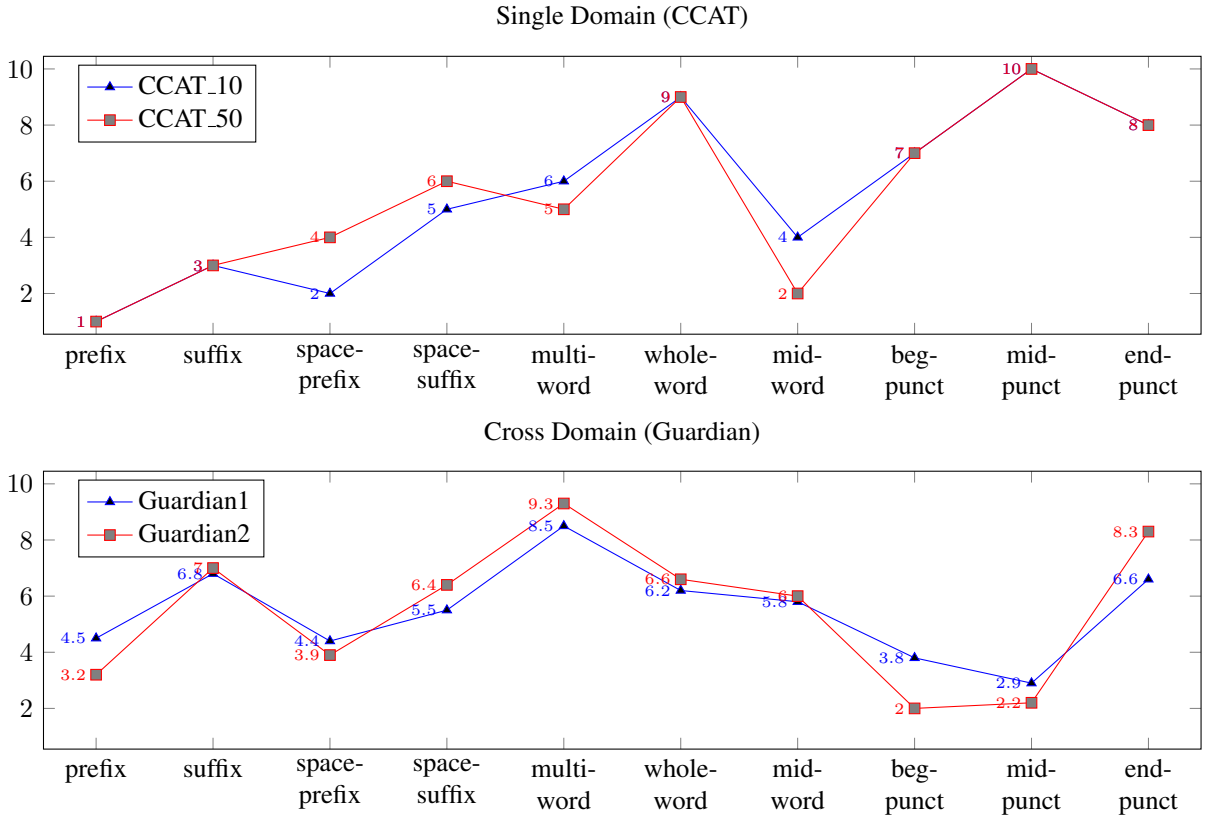

Figure 1: Average rank of the performance of each n-gram category on the single-domain CCAT tasks (top) and the cross-domain Guardian tasks (bottom).

most discriminative. Table 5 shows the accuracy of each type of n-gram for each of the different corpora.

Table 5(a) shows that the top four categories for single-domain AA are: *prefix*, *suffix*, *space-prefix*, and *mid-word*. These four categories have the best performance on both CCAT_10 and CCAT_50. In contrast, Table 5(b) shows that the top four categories for cross-domain AA are: *prefix*, *space-prefix*, *beg-punct*, and *mid-punct*.

For both single-domain and cross-domain AA, *prefix* and *space-prefix* are strong features, and are generally better than the suffix features, perhaps because authors have more control over prefixes in English, while suffixes are often obligatory for grammatical reasons. For cross-domain AA, *beg-punct* and *mid-punct* are the top features, likely because an author's

use of punctuation is consistent even when the topic changes. For single-domain AA, *mid-word* was also a good feature, probably because it captured lexical information that correlates with authors' preferences towards writing about specific topics.

Figure 1 shows an alternate view of these results, graphing the rank of each n-gram type. For computing the rank, the accuracies of the ten different n-gram type classifiers are sorted in decreasing order and ranked from 1 to 10 respectively with ties getting the same rank. For the Guardian corpora, the average rank of each n-gram category was computed by averaging its rank across the 12 possible test/train cross-domain combinations. In both of the single-domain CCAT corpora, the classifier based on *prefix* n-grams had the top accuracy (rank 1), and the classifier based on *mid-punct* had the worst accuracy (rank 10). In both of the cross-domain Guardian corpora, on the other hand, *mid-punct* was among the top-ranked n-gram categories. This suggests that punctuation features generalize the best across topic, but if AA is more of a topic classification task (as in the single-domain CCAT corpora), then punctuation adds little over other features that more directly capture the topic.

Since our cross-domain datasets are small, we performed a small number of planned comparisons using a two-tailed t-test over the accuracies on the Guardian1 and Guardian2 corpora. We found that in both corpora, the best punctuation category (*punct-mid*) is better than the best word category (*whole-word*) with $p < 0.001$. In the Guardian2 corpus, the best affix category (*space-prefix*) is also better than the best word category (*whole-word*) with $p < 0.05$, but this does not hold in the Guardian1 corpus ($p = 0.14$). Also, we observed that in both Guardian1 and Guardian2 datasets, both *punct-mid* and *space-prefix* are better than *multi-word* ($p < 0.01$).

Overall, we see that **affix** n-grams are generally effective in both single-domain and cross-domain settings, **punctuation** n-grams are effective in cross-domain settings, and *mid-word* is the only effective **word** n-gram, and only in the single-domain setting.

5.2 Do Different Classifiers Agree on the Importance of Different n-gram Types?

The previous experiments have shown, for example, that *prefix* n-grams are universally predictive in AA tasks, that *mid-word* n-grams are good predictors in single-domain settings, and that *beg-punct* n-grams are good predictors in cross-domain settings. But are these facts about the n-gram types themselves, or are these results only true for the specific SVM classifiers we trained?

Comparison	CCAT	Guardian
Weka SVM vs LibSVM	0.93	0.81
Weka SVM vs Naive Bayes	0.73	0.57
LibSVM vs Naive Bayes	0.77	0.44

Table 6: Spearman's rank correlation coefficient (ρ) for each pair of classifiers on the single-domain (CCAT) and cross-domain (Guardian) settings.

To see whether certain types of n-grams are fundamentally good or bad, regardless of the classifier, we compare performance of the different n-gram types for three classifiers: Weka SVM classifiers (as used in our other experiments), LibSVM classifiers and Weka's naive Bayes classifiers[1]. Figure 2 shows the n-gram category rankings for all these classifiers[2] for both the single-domain CCAT and the cross-domain Guardian settings.

Across the different classifiers, the pattern of feature rankings are similar. Table 6 shows the Spearman's rank correlation coefficient (ρ) for the per-n-gram-type accuracies of each pair of classifiers. We observe fairly high correlations, with ρ above 0.70 for all single-domain pairings, and between 0.44 and 0.81 for cross-domain pairings.

As in Section 5.1, *prefix* and *space-prefix* are among the most predictive n-gram types. In the single-domain settings, we again see that *suffix* and *mid-word* are also highly predictive, while in the cross-domain settings, we again see that *beg-punct* and *mid-punct* are highly predictive. These results all confirm that some types of n-grams are fundamentally more predictive than others, and our results are not specific to the particular type of classifier used.

[1] Weka SVM and LibSVM are both support vector machine classifiers, but Weka uses Platt's sequential minimal optimization algorithm while LibSVM uses working set selection with second order information. The result is that they achieve different performance on our AA tasks.

[2] We also tried a decision tree classifier, C4.5 (J48) from WEKA, and it produced similar patterns (not shown).

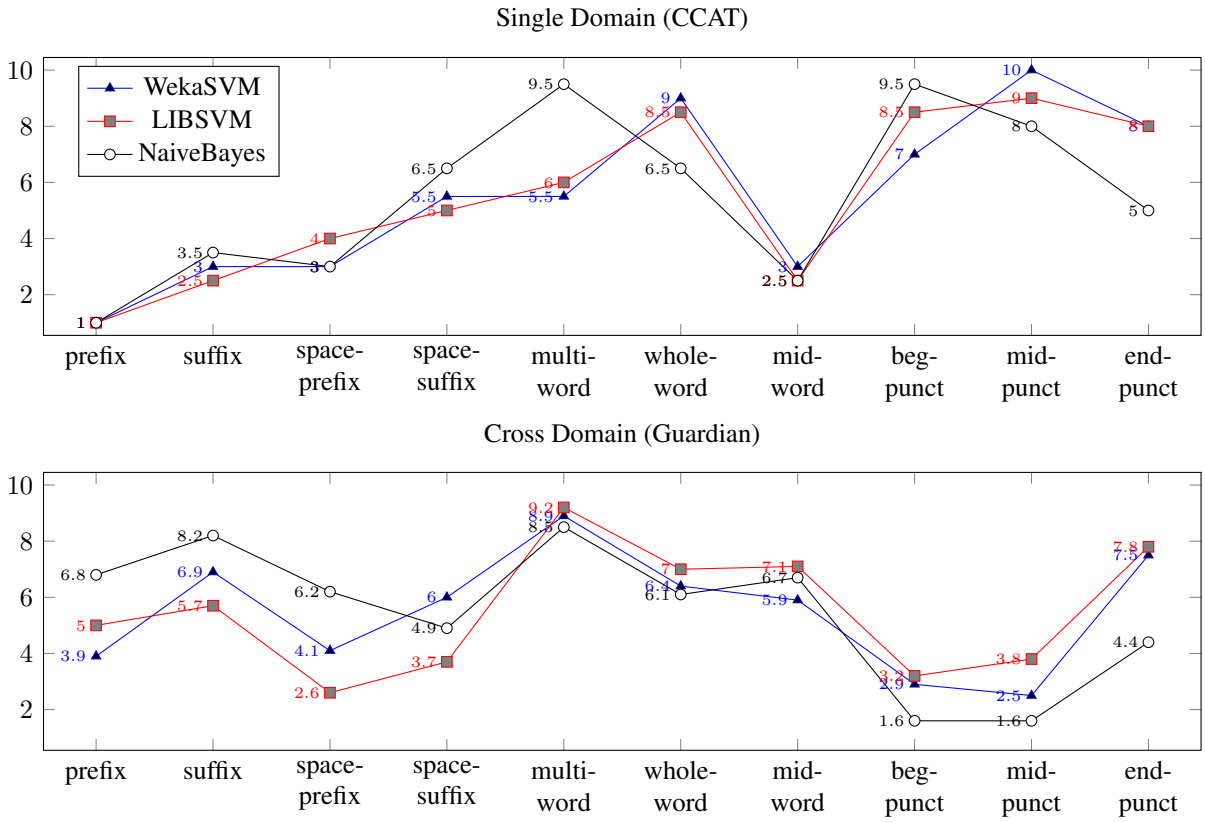

Figure 2: Average rank of the performance of each n-gram category across different types of classifiers on the single-domain CCAT task (top) and the cross-domain Guardian task (bottom).

5.3 Are Some Character N-grams Irrelevant?

In the previous sections, we have seen that some types of character n-grams are more predictive than others - **affix** n-grams performed well in both single domain and cross-domain settings and **punctuation** n-grams performed well in cross-domain settings. In general, **word** n-grams were not as predictive as other types of n-grams (with the one exception being *mid-word* n-grams in the single domain setting). Given this poor performance of **word** n-grams, a natural question is: could we exclude these features entirely and achieve similar performance?

Our goal then is to compare a model trained on **affix** n-grams and **punct** n-grams against a model trained on "all" n-grams. We consider two definitions of "all":

all-untyped The traditional approach to extracting n-grams where n-gram types are ignored (e.g., 'the' as a whole word is no different from 'the' in the middle of a word)

all-typed The approach discussed in this paper, where n-grams of different types are distinguished (equivalent to the set of all **affix+punct+word** n-grams).

We compare these models trained on all the n-grams to our **affix+punct** model.

Table 7 shows this analysis. For either definition of "all", the model that discards all **word** features achieves performance as high or higher than the model with all of the features, and does so with only about two thirds of the features. This is not too surprising in the cross-domain Guardian tasks, where the **word** n-grams were among the worst features. On the single-domain CCAT tasks this result is more surprising, since we have discarded the *mid-word* n-grams, which was one of the best single-domain n-gram types. This indicates that whatever information *mid-word* is capturing it is also being captured in other ways via **affix** and **punct** n-grams. Of all 1024 possible combinations of features, we tried a

Dataset	all-untyped		all-typed		affix+punct	
	Acc	*N*	**Acc**	*N*	**Acc**	*N*
CCAT_10	77.8	*8245*	77.2	*9715*	**78.8**	*5474*
CCAT_50	69.2	*14461*	69.1	*17062*	**69.3**	*9966*
Guardian1	55.6	*5689*	53.6	*6966*	**57.0**	*3822*
Guardian2	45.9	*5687*	45.6	*6965*	**48.0**	*3820*

Table 7: Results of excluding **word** n-grams, compared to using all n-grams, either in the traditional approach (untyped n-grams) or in the approach of this paper (typed n-grams). Accuracy (Acc) and the number of features (*N* in italics) are reported for each classifier. The best accuracy for each dataset is in bold.

number of different combinations and were unable to identify one that outperformed **affix+punct**. Overall, this experiment gives compelling evidence that **affix** and **punct** n-grams are more important than **word** n-grams.

6 Analysis

We did a manual exploration of our datasets. In our cross-domain dataset, the character 3-gram 'sti' shows up as both *prefix* and *mid-word*. All 13 authors use 'sti' frequently as a *mid-word* n-gram in words such as in**sti**tution, exi**sti**ng, ju**sti**ce, and di**sti**nction. For example:

- The government's story is that the exi**sti**ng warheads might be deteriorating.
- For all the ju**sti**ce of many of his accusations, the result is occasionally as dreadful as his title suggests.

But only six authors use 'sti' as a *prefix*, in examples like:

- Their mission was to convince tourists that Britain was **sti**ll open for business.
- There aren't even any dead people on it, since by the very act of being dead and **sti**ll famous, they assert their long-term impact.

Thus 'sti' as a *prefix* is predictive of authorship even though 'sti' as a *mid-word* n-gram is not. Notably, under the traditional untyped bag-of-n-grams approach, both versions of 'sti' would have been treated the same, and this discriminative power would have been lost.

To use old-fashioned language, she is motherly - a plump, rosy-cheeked woman of Kent, whom nature seemed to have created to raise children.
To use old-fas ned lan age, she is mot rly - a plump, rosy-che ked woman of Kent, whom nature seemed to have cre ted to raise chi ren.

Table 8: Example sentence showing the opacity of each character. Darkness of character is determined by the number of categories it belongs to (lowest=lighter, highest=darkest color). Categories in **word** are discarded.

As already demonstrated in Section 5 that **affix+punct** features perform better than using all the features, we would like to use an example from our dataset to visualize the text when features in SC **word** are discarded. Out of seven categories in **affix** and **punct**, we computed in how many of them each character belongs to, three being the maximum possible value. Therefore, we show each character with different opacity level depending on number of categories it belongs to: zero will get white color (word related n-grams), one will get 33% black, two will get 67% black, and three will get 100% black. In Table 8, we show an example sentence before (first row of Table 8) and after (second row of Table 8) showing the opacity level of each character. It is clear that the darkest characters are those around the punctuation characters and those around spaces are second darkest, while the lightest (with 0% darkness) are the ones in the middle of long words. This gives us an idea about the characters in a text that are important for AA tasks.

7 Discussion

Various hypotheses have been put forth to explain the "black magic" (Kestemont, 2014) behind the success of character n-gram features in authorship attribution. Kestemont (2014) conjectured that their utility was in capturing function words and morphology. Koppel et al. (2009) suggested that they were capturing topic information in single domain settings, and style and syntactic information in cross-domain settings. Our study provides empirical evidence for testing these claims. We did indeed find that the ability of character n-grams to capture morphology is useful, as reflected in the high prediction performance of **af-**

fix n-grams in both single-domain and cross-domain settings. And we found that **word** n-grams (capturing topic information) were useful in single domain settings, while **punct** n-grams (capturing style information) were useful in cross-domain settings. We further found that **word** n-grams are unnecessary, even in single-domain settings. Models based only on **affix** and **punct** n-grams performed as well as models with all n-grams regardless of whether it was a single-domain or cross-domain authorship attribution task.

Our findings on the value of selecting n-grams according to the linguistic aspect they represent may also be beneficial in other classification tasks where character n-grams are commonly used. Promising tasks are those related to the stylistic analysis of texts, such as native language identification, document similarity and plagiarism detection.

Morphologically speaking, English is a poor language. The fact that we identified significant differences in performance by selecting n-gram categories that are related to affixation in this poorly inflected language suggests that we may find even larger differences in performance in morphologically richer languages. We leave this research question for future work.

Effective Use of Word Order for Text Categorization with Convolutional Neural Networks

Abstract

Convolutional neural network (CNN) is a neural network that can make use of the internal structure of data such as the 2D structure of image data. This paper studies CNN on text categorization to exploit the 1D structure (namely, word order) of text data for accurate prediction. Instead of using low-dimensional word vectors as input as is often done, we directly apply CNN to high-dimensional text data, which leads to directly learning embedding of small text regions for use in classification. In addition to a straightforward adaptation of CNN from image to text, a simple but new variation which employs bag-of-word conversion in the convolution layer is proposed. An extension to combine multiple convolution layers is also explored for higher accuracy. The experiments demonstrate the effectiveness of our approach in comparison with state-of-the-art methods.

1 Introduction

Text categorization is the task of automatically assigning pre-defined categories to documents written in natural languages. Several types of text categorization have been studied, each of which deals with different types of documents and categories, such as topic categorization to detect discussed topics (e.g., sports, politics), spam detection (Sahami et al., 1998), and sentiment classification (Pang et al., 2002; Pang and Lee, 2008; Maas et al., 2011) to determine the sentiment typically in product or movie reviews. A standard approach to text categorization is to represent documents by *bag-of-word vectors*, namely, vectors that indicate which words appear in the documents but do not preserve word order, and use classification models such as SVM.

It has been noted that loss of word order caused by bag-of-word vectors (*bow vectors*) is particularly problematic on sentiment classification. A simple remedy is to use word bi-grams in addition to unigrams (Blitzer et al., 2007; Glorot et al., 2011; Wang and Manning, 2012). However, use of word n-grams with $n > 1$ on text categorization in general is not always effective; e.g., on topic categorization, simply adding phrases or n-grams is not effective (see, e.g., references in (Tan et al., 2002)).

To benefit from word order on text categorization, we take a different approach, which employs *convolutional neural networks (CNN)* (LeCun et al., 1986). CNN is a neural network that can make use of the internal structure of data such as the *2D structure* of image data through convolution layers, where each computation unit responds to a small region of input data (e.g., a small square of a large image). We apply CNN to text categorization to make use of the *1D structure* (word order) of document data so that each unit in the convolution layer responds to a small region of a document (a sequence of words).

CNN has been very successful on image classification; see e.g., the winning solutions of ImageNet Large Scale Visual Recognition Challenge (Krizhevsky et al., 2012; Szegedy et al., 2014; Russakovsky et al., 2014).

On text, since the work on token-level applications (e.g., POS tagging) by Collobert et al. (2011), CNN has been used in systems for entity search, sentence modeling, word embedding learning, product feature mining, and so on (Xu and Sarikaya, 2013; Gao et al., 2014; Shen et al., 2014; Kalchbrenner et al., 2014; Xu et al., 2014; Tang et al., 2014; Weston

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 103–112,
Denver, Colorado, May 31 – June 5, 2015.

et al., 2014; Kim, 2014). Notably, in many of these CNN studies on text, the first layer of the network converts words in sentences to *word vectors* by table lookup. The word vectors are either trained as part of CNN training, or fixed to those learned by some other method (e.g., word2vec (Mikolov et al., 2013)) from an additional large corpus. The latter is a form of semi-supervised learning, which we study elsewhere. We are interested in the effectiveness of CNN itself *without aid of additional resources*; therefore, word vectors should be trained as part of network training if word vector lookup is to be done.

A question arises, however, whether word vector lookup in a purely supervised setting is really useful for text categorization. The essence of convolution layers is to *convert text regions of a fixed size (e.g., "am so happy" with size 3) to feature vectors*, as described later. In that sense, a word vector learning layer is a special (and unusual) case of convolution layer with region size one. Why is size one appropriate if bi-grams are more discriminating than unigrams? Hence, we take a different approach. We *directly apply CNN to high-dimensional one-hot vectors*; i.e., we *directly* learn *embedding*[1] of text regions without going through word embedding learning. This approach is made possible by solving the computational issue[2] through efficient handling of high-dimensional sparse data on GPU, and it turned out to have the merits of improving accuracy with fast training/prediction and simplifying the system (fewer hyper-parameters to tune). Our CNN code for text is publicly available on the internet[3].

We study the effectiveness of CNN on text categorization and explain why CNN is suitable for the task. Two types of CNN are tested: *seq-CNN* is a straightforward adaptation of CNN from image to text, and *bow-CNN* is a simple but new variation of CNN that employs bag-of-word conversion in the convolution layer. The experiments show that seq-CNN outperforms bow-CNN on sentiment classification, vice versa on topic classification, and the winner generally outperforms the conventional bag-of-n-gram vector-based methods, as well as previous CNN models for text which are more complex. In particular, to our knowledge, this is the first work that has successfully used word order to improve topic classification performance. A simple extension that combines multiple convolution layers (thus combining multiple types of text region embedding) leads to further improvement. Through empirical analysis, we will show that CNN can make effective use of high-order n-grams when conventional methods fail.

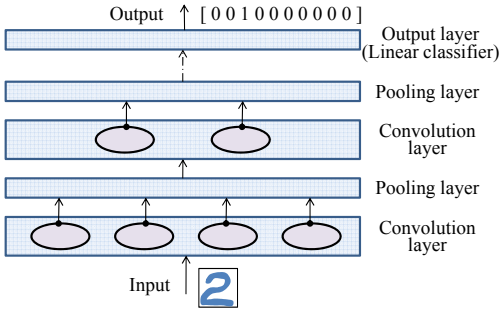

Figure 1: Convolutional neural network.

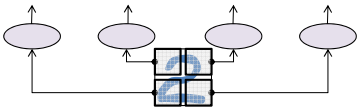

Figure 2: Convolution layer for image. Each computation unit (oval) computes a non-linear function $\boldsymbol{\sigma}(\mathbf{W} \cdot \mathbf{r}_\ell(\mathbf{x}) + \mathbf{b})$ of a small region $\mathbf{r}_\ell(\mathbf{x})$ of input image $\mathbf{x}$, where weight matrix $\mathbf{W}$ and bias vector $\mathbf{b}$ are shared by all the units in the same layer.

2 CNN for document classification

We first review CNN applied to image data and then discuss the application of CNN to document classification tasks to introduce seq-CNN and bow-CNN.

2.1 Preliminary: CNN for image

CNN is a feed-forward neural network with convolution layers interleaved with pooling layers, as illustrated in Figure 1, where the top layer performs classification using the features generated by the layers below. A convolution layer consists of several computation units, each of which takes as input a *region vector* that represents a small region of the input image and applies a non-linear function to it. Typically, the region vector is a concatenation of pixels in the region, which would be, for example,

[1] We use the term 'embedding' loosely to mean a structure-preserving function, in particular, a function that generates low-dimensional features that preserve the predictive structure.

[2] CNN implemented for image would not handle sparse data efficiently, and without efficient handling of sparse data, convolution over high-dimensional one-hot vectors would be computationally infeasible.

[3] `riejohnson.com/cnn_download.html`

75-dimensional if the region is 5×5 and the number of *channels* is three (red, green, and blue). Conceptually, computation units are placed over the input image so that the entire image is collectively covered, as illustrated in Figure 2. The region stride (distance between the region centers) is often set to a small value such as 1 so that regions overlap with each other, though the stride in Figure 2 is set larger than the region size for illustration.

A distinguishing feature of convolution layers is *weight sharing*. Given input $\mathbf{x}$, a unit associated with the ℓ-th region computes $\boldsymbol{\sigma}(\mathbf{W} \cdot \mathbf{r}_\ell(\mathbf{x}) + \mathbf{b})$, where $\mathbf{r}_\ell(\mathbf{x})$ is a region vector representing the region of $\mathbf{x}$ at location ℓ, and $\boldsymbol{\sigma}$ is a predefined component-wise non-linear activation function, (e.g., applying $\sigma(x) = \max(x, 0)$ to each vector component). The matrix of *weights* $\mathbf{W}$ and the vector of *biases* $\mathbf{b}$ are learned through training, and they are *shared* by the computation units in the same layer. This weight sharing enables learning useful features irrespective of their location, while preserving the location where the useful features appeared.

We regard the output of a convolution layer as an 'image' so that the output of each computation unit is considered to be a 'pixel' of m channels where m is the number of weight vectors (i.e., the number of rows of $\mathbf{W}$) or the number of *neurons*. In other words, *a convolution layer converts image regions to m-dim vectors*, and the locations of the regions are inherited through this conversion.

The output image of the convolution layer is passed to a pooling layer, which essentially shrinks the image by merging neighboring pixels, so that higher layers can deal with more abstract/global information. A pooling layer consists of pooling units, each of which is associated with a small region of the image. Commonly-used merging methods are average-pooling and max-pooling, which respectively compute the channel-wise average/maximum of each region.

2.2 CNN for text

Now we consider application of CNN to text data. Suppose that we are given a document $D = (w_1, w_2, \ldots)$ with vocabulary V. CNN requires vector representation of data that preserves internal locations (word order in this case) as input. A straightforward representation would be to treat each word as a pixel, treat D as if it were an image of $|D| \times 1$ pixels with $|V|$ channels, and to represent each pixel (i.e., each word) as a $|V|$-dimensional one-hot vector[4]. As a running toy example, suppose that vocabulary $V = \{$ "don't", "hate", "I", "it", "love" $\}$ and we associate the words with dimensions of vector in alphabetical order (as shown), and that document D="I love it". Then, we have a document vector:

$$\mathbf{x} = [\, 0\,0\,1\,0\,0 \,|\, 0\,0\,0\,0\,1 \,|\, 0\,0\,0\,1\,0 \,]^\top \ .$$

2.2.1 seq-CNN for text

As in the convolution layer for image, we represent each region (which each computation unit responds to) by a concatenation of the pixels, which makes $p|V|$-dimensional region vectors where p is the region size fixed in advance. For example, on the example document vector $\mathbf{x}$ above, with $p = 2$ and stride 1, we would have two regions "I love" and "love it" represented by the following vectors:

$$\mathbf{r}_0(\mathbf{x}) = \begin{bmatrix} 0 \\ 0 \\ \mathbf{1} \\ 0 \\ 0 \\ \hline — \\ 0 \\ 0 \\ 0 \\ 0 \\ \mathbf{1} \end{bmatrix} \begin{matrix} \text{don't} \\ \text{hate} \\ \mathbf{I} \\ \text{it} \\ \text{love} \\ \\ \text{don't} \\ \text{hate} \\ \text{I} \\ \text{it} \\ \mathbf{love} \end{matrix} \qquad \mathbf{r}_1(\mathbf{x}) = \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \\ \mathbf{1} \\ \hline — \\ 0 \\ 0 \\ 0 \\ \mathbf{1} \\ 0 \end{bmatrix} \begin{matrix} \text{don't} \\ \text{hate} \\ \text{I} \\ \text{it} \\ \mathbf{love} \\ \\ \text{don't} \\ \text{hate} \\ \text{I} \\ \mathbf{it} \\ \text{love} \end{matrix}$$

The rest is the same as image; *the text region vectors are converted to feature vectors*, i.e., the convolution layer learns to *embed text regions* into low-dimensional vector space. We call a neural net with a convolution layer with this region representation *seq-CNN* ('seq' for keeping sequences of words) to distinguish it from *bow-CNN*, described next.

2.2.2 bow-CNN for text

A potential problem of seq-CNN however, is that unlike image data with 3 RGB channels, the number of 'channels' $|V|$ (size of vocabulary) may be very large (e.g., 100K), which could make each region vector $\mathbf{r}_\ell(\mathbf{x})$ very high-dimensional if the region size

[4] Alternatively, one could use *bag-of-letter-n-gram vectors* as in (Shen et al., 2014; Gao et al., 2014) to cope with out-of-vocabulary words and typos.

p is large. Since the dimensionality of region vectors determines the dimensionality of weight vectors, having high-dimensional region vectors means more parameters to learn. If $p|V|$ is too large, the model becomes too complex (w.r.t. the amount of training data available) and/or training becomes unaffordably expensive even with efficient handling of sparse data; therefore, one has to lower the dimensionality by lowering the vocabulary size $|V|$ and/or the region size p, which may or may not be desirable, depending on the nature of the task.

An alternative we provide is to perform bag-of-word conversion to make region vectors $|V|$-dimensional instead of $p|V|$-dimensional; e.g., the example region vectors above would be converted to:

$$\mathbf{r}_0(\mathbf{x}) = \begin{bmatrix} 0 \\ 0 \\ \mathbf{1} \\ 0 \\ \mathbf{1} \end{bmatrix} \begin{matrix} \text{don't} \\ \text{hate} \\ \mathbf{I} \\ \text{it} \\ \mathbf{love} \end{matrix} \qquad \mathbf{r}_1(\mathbf{x}) = \begin{bmatrix} 0 \\ 0 \\ 0 \\ \mathbf{1} \\ \mathbf{1} \end{bmatrix} \begin{matrix} \text{don't} \\ \text{hate} \\ \text{I} \\ \mathbf{it} \\ \mathbf{love} \end{matrix}$$

With this representation, we have fewer parameters to learn. Essentially, the expressiveness of bow-convolution (which loses word order only within small regions) is somewhere between seq-convolution and bow vectors.

2.2.3 Pooling for text

Whereas the size of images is fixed in image applications, documents are naturally variable-sized, and therefore, with a fixed stride, the output of a convolution layer is also variable-sized as shown in Figure 3. Given the variable-sized output of the convolution layer, standard pooling for image (which uses a fixed pooling region size and a fixed stride) would produce variable-sized output, which can be passed to another convolution layer. To produce fixed-sized output, which is required by the fully-connected top layer[5], we fix the number of pooling units and dynamically determine the pooling region size on each data point so that the entire data is covered without overlapping.

In the previous CNN work on text, pooling is typically max-pooling over the entire data (i.e., one pooling unit associated with the whole text). The *dynamic k-max pooling* of (Kalchbrenner et al., 2014) for sentence modeling extends it to take the k largest values where k is a function of the sentence length, but it is again over the entire data, and the operation is limited to max-pooling. Our pooling differs in that it is a natural extension of standard pooling for image, in which not only max-pooling but other types can be applied. With multiple pooling units associated with different regions, the top layer can receive locational information (e.g., if there are two pooling units, the features from the first half and last half of a document are distinguished). This turned out to be useful (along with average-pooling) on topic classification, as shown later.

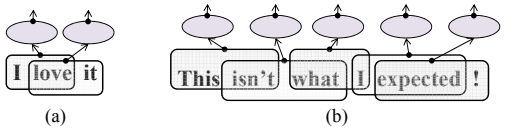

Figure 3: Convolution layer for variable-sized text.

2.3 CNN vs. bag-of-n-grams

Traditional methods represent each document *entirely* with one bag-of-n-gram vector and then apply a classifier model such as SVM. However, since high-order n-grams are susceptible to data sparsity, use of a large n such as 20 is not only infeasible but also ineffective. Also note that a bag-of-n-gram represents each n-gram by a one-hot vector and ignores the fact that some n-grams share constituent words. By contrast, CNN internally learns *embedding of text regions* (given the consituent words as input) *useful for the intended task*. Consequently, a large n such as 20 can be used especially with the bow-convolution layer, which turned out to be useful on topic classification. A neuron trained to assign a large value to, e.g., "I love" (and a small value to "I hate") is likely to assign a large value to "we love" (and a small value to "we hate") as well, *even though "we love" was never seen during training*. We will confirm these points empirically later.

2.4 Extension: parallel CNN

We have described CNN with the simplest network architecture that has one pair of convolution and pooling layers. While this can be extended in several ways (e.g., with deeper layers), in our experiments, we explored *parallel CNN*, which has two or

[5] In this work, the top layer is fully-connected (i.e., each neuron responds to the entire data) as in CNN for image. Alternatively, the top layer could be convolutional so that it can receive variable-sized input, but such CNN would be more complex.

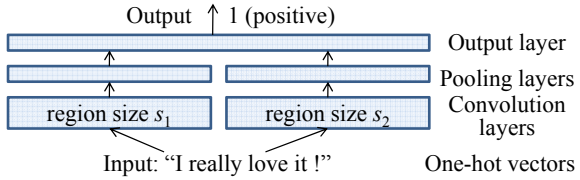

Figure 4: CNN with two convolution layers in parallel.

more convolution layers in parallel[6], as illustrated in Figure 4. The idea is to learn multiple types of embedding of small text regions so that they can complement each other to improve model accuracy. In this architecture, multiple convolution-pooling pairs with different region sizes (and possibly different region vector representations) are given one-hot vectors as input and produce feature vectors for each region; the top layer takes the concatenation of the produced feature vectors as input.

3 Experiments

We experimented with CNN on two tasks, topic classification and sentiment classification. Detailed information for reproducing the results is available on the internet along with our code.

3.1 CNN

We fixed the activation function to rectifier $\sigma(x) = \max(x, 0)$ and minimized square loss with L_2 regularization by *stochastic gradient descent* (SGD). We only used the 30K words that appeared most frequently in the training set; thus, for example, in seq-CNN with region size 3, a region vector is 90K dimensional. Out-of-vocabulary words were represented by a zero vector. On bow-CNN, to speed up computation, we used *variable region stride* so that a larger stride was taken where repetition[7] of the same region vectors can be avoided by doing so. Padding[8] size was fixed to $p - 1$ where p is the region size.

[6]Similar architectures have been used for image. Kim (2014) used it for text, but it was on top of a word vector conversion layer.

[7]For example, if we slide a window of size 3 over "* * foo * *" where "*" is out of vocabulary, a bag of "foo" will be repeated three times with stride fixed to 1.

[8]As is commonly done, to the beginning and the end of each document, special words that are treated as unknown words (and converted to zero vectors instead of one-hot vectors) were added as 'padding'. The purpose is to equally treat the words at the edge and words in the middle.

We used two techniques commonly used with CNN on image, which typically led to small performance improvements. One is *dropout* (Hinton et al., 2012) optionally applied to the input to the top layer. The other is *response normalization* as in (Krizhevsky et al., 2012), which in our case scales the output of the pooling layer $\mathbf{z}$ at each location by multiplying $(1 + |\mathbf{z}|^2)^{-1/2}$.

3.2 Baseline methods

For comparison, we tested SVM with the linear kernel and fully-connected neural networks (see e.g., Bishop (1995)) with bag-of-n-gram vectors as input. To experiment with fully-connected neural nets, as in CNN, we minimized square loss with L_2 regularization and optional dropout by SGD, and activation was fixed to rectifier. To generate bag-of-n-gram vectors, on topic classification, we first set each component to $\log(x + 1)$ where x is the word frequency in the document and then scaled them to unit vectors, which we found always improved performance over raw frequency. On sentiment classification, as is often done, we generated binary vectors and scaled them to unit vectors. We tested three types of bag-of-n-gram: bow1 with $n \in \{1\}$, bow2 with $n \in \{1, 2\}$, and bow3 with $n \in \{1, 2, 3\}$; that is, bow1 is the traditional bow vectors, and with bow3, each component of the vectors corresponds to either uni-gram, bi-gram, or tri-gram of words.

We used SVMlight[9] for the SVM experiments.

NB-LM We also tested NB-LM, which first appeared (but without performance report[10]) as NB-SVM in WM12 (Wang and Manning, 2012) and later with a small modification produced performance that exceeds state-of-the-art supervised methods on IMDB (which we experimented with) in MMRB14 (Mesnil et al., 2014). We experimented with the MMRB14 version, which generates binary bag-of-n-gram vectors, multiplies the component for each n-gram f_i with $\log(P(f_i|Y = 1)/P(f_i|Y = -1))$ (*NB-weight*) where the probabilities are estimated using the training data, and does logistic regression training. We used MMRB14's software[11] with a modification so that

[9]http://svmlight.joachims.org/

[10]WM12 instead reported the performance of an ensemble of NB and SVM as it performed better.

[11]https://github.com/mesnilgr/nbsvm

the regularization parameter can be tuned on development data.

3.3 Model selection

For all the methods, the hyper-parameters such as net configurations and regularization parameters were chosen based on the performance on the development data (held-out portion of the training data), and using the chosen hyper-parameters, the models were re-trained using all the training data.

3.4 Data, tasks, and data preprocessing

IMDB: movie reviews The IMDB dataset (Maas et al., 2011) is a benchmark dataset for sentiment classification. The task is to determine if the movie reviews are positive or negative. Both the training and test sets consist of 25K reviews. For preprocessing, we tokenized the text so that emoticons such as ":-)" are treated as tokens and converted all the characters to lower case.

Elec: electronics product reviews Elec consists of electronic product reviews. It is part of a large Amazon review dataset (McAuley and Leskovec, 2013). We chose electronics as it seemed to be very different from movies. Following the generation of IMDB (Maas et al., 2011), we chose the training set and the test set so that one half of each set consists of positive reviews and the other half is negative, regarding rating 1 and 2 as negative and 4 and 5 as positive, and that the reviewed products are disjoint between the training set and test set. Note that to extract text from the original data, we *only* used the *text section*, and we did *not* use the *summary section*. This way, we obtained a test set of 25K reviews (same as IMDB) and training sets of various sizes. The training and test sets are available on the internet[12]. Data preprocessing was the same as IMDB.

RCV1: topic categorization RCV1 is a corpus of Reuters news articles as described in LYRL04 (Lewis et al., 2004). RCV1 has 103 topic categories in a hierarchy, and one document may be associated with more than one topic. Performance on this task (multi-label categorization) is known to be sensitive to thresholding strategies, which are algorithms additional to the models we would like to test. Therefore, we also experimented with single-label categorization to assign one of 55 second-level topics to each document to directly evaluate models. For this task, we used the documents from a one-month period as the test set and generated various sizes of training sets from the documents with *earlier* dates. Data sizes are shown in Table 1. As in LYRL04, we used the concatenation of the headline and text elements. Data preprocessing was the same as IMDB except that we used the stopword list provided by LYRL04 and regarded numbers as stopwords.

3.5 Performance results

Table 2 shows the error rates of CNN in comparison with the baseline methods. The first thing to note is that on all the datasets, the best-performing CNN outperforms the baseline methods, which demonstrates the effectiveness of our approach.

To look into the details, let us first focus on CNN with one convolution layer (seq- and bow-CNN in the table). On sentiment classification (IMDB and Elec), the configuration chosen by model selection was: region size 3, stride 1, 1000 weight vectors, and max-pooling with one pooling unit, for both types of CNN; seq-CNN outperforms bow-CNN, as well as all the baseline methods except for one. Note that with a small region size and max-pooling, if a review contains a short phrase that conveys strong sentiment (e.g., "A great movie!"), the review could receive a high score irrespective of the rest of the review. It is sensible that this type of configuration is effective on sentiment classification.

By contrast, on topic categorization (RCV1), the configuration chosen for bow-CNN by model selection was: region size 20, variable-stride$\geq$2, average-pooling with 10 pooling units, and 1000 weight vectors, which is very different from sentiment classification. This is presumably because on topic classification, a larger context would be more predictive than short fragments ($\rightarrow$ larger region size), the entire document matters ($\rightarrow$ the effectiveness of average-pooling), and the location of predictive text also matters ($\rightarrow$ multiple pooling units). The last

point may be because news documents tend to have crucial sentences (as well as the headline) at the beginning. On this task, while both seq and bow-CNN outperform the baseline methods, bow-CNN outperforms seq-CNN, which indicates that in this setting the merit of having fewer parameters is larger than the benefit of keeping word order in each region.

Now we turn to parallel CNN. On IMDB, seq2-CNN, which has two seq-convolution layers (region size 2 and 3; 1000 neurons each; followed by one unit of max-pooling each), outperforms seq-CNN. With more neurons (3000 neurons each; Table 3) it further exceeds the best-performing baseline, which is also the best previous supervised result. We presume the effectiveness of seq2-CNN indicates that the length of predictive text regions is variable.

The best performance 7.67 on IMDB was obtained by 'seq2-bow$n$-CNN', equipped with three layers in parallel: two seq-convolution layers (1000 neurons each) as in seq2-CNN above and one layer (20 neurons) that *regards the entire document as one region* and represents the region (document) by a bag-of-n-gram vector (bow3) as input to the computation unit; in particular, we generated bow3 vectors by multiplying the NB-weights with binary vectors, motivated by the good performance of NB-LM. This third layer is a bow-convolution layer[13] with one region of variable size that takes one-hot vectors with n-gram vocabulary as input to learn document embedding. The seq2-bow$n$-CNN for Elec in the table is the same except that the regions sizes of seq-convolution layers are 3 and 4. On both datasets, performance is improved over seq2-CNN. The results suggest that what can be learned through these three layers are distinct enough to complement each other. The effectiveness of the third layer indicates that not only short word sequences but also global context in a large window may be useful on this task; thus, inclusion of a bow-convolution layer with n-gram vocabulary with a large fixed region size might be even more effective, providing more focused context, but we did not pursue it in this work.

Baseline methods Comparing the baseline methods with each other, on sentiment classification, reducing the vocabulary to the most frequent n-grams notably hurt performance (also observed on NB-LM and NN) even though some reduction is a common practice. Error rates were clearly improved by addition of bi- and tri-grams. By contrast, on topic categorization, bi-grams only slightly improved accuracy, and reduction of vocabulary did not hurt performance. NB-LM is very strong on IMDB and poor on RCV1; its effectiveness appears to be data-dependent, as also observed by WM12.

[13]It can also be regarded as a fully-connected layer that takes bow3 vectors as input.

methods	IMDB	Elec	RCV1
SVM bow3 (30K)	10.14	9.16	10.68
SVM bow1 (all)	11.36	11.71	10.76
SVM bow2 (all)	9.74	9.05	10.59
SVM bow3 (all)	9.42	8.71	10.69
NN bow3 (all)	9.17	8.48	10.67
NB-LM bow3 (all)	8.13	8.11	13.97
bow-CNN	8.66	8.39	**9.33**
seq-CNN	8.39	7.64	9.96

seq2-CNN (3K×2) [Ours]	7.94	–
seq2-bow$n$-CNN [Ours]	**7.67**	–

Table 3: Error rate (%) comparison with previous best methods on IMDB.

Comparison with state-of-the-art results As shown in Table 3, the previous best supervised result on IMDB is 8.13 by NB-LM with bow3 (MMRB14), and our best error rate 7.67 is better by nearly 0.5%. (Le and Mikolov, 2014) reports 7.46 with the semi-supervised method that learns low-dimensional vector representations of documents from unlabeled data. Their result is not directly comparable with our supervised results due to use of additional resource. Nevertheless, our best result rivals their result.

We tested bow-CNN on the multi-label topic categorization task on RCV1 to compare with

models	micro-F	macro-F
LYRL04's best SVM	81.6	60.7
bow-CNN	**84.0**	**64.8**

Table 4: RCV1 micro-averaged and macro-averaged F-measure results on multi-label task with LYRL04 split.

LYRL04. We used the same thresholding strategy as LYRL04. As shown in Table 4, bow-CNN outperforms LYRL04's best results even though our data preprocessing is much simpler (no stemming and no tf-idf weighting).

Previous CNN We focus on the sentence classification studies due to its relation to text categorization. Kim (2014) studied fine-tuning of pre-trained word vectors to produce input to parallel CNN. He reported that performance was poor when word vectors were trained as part of CNN training (i.e., no additional method/corpus). On our tasks, we were also unable to outperform the baselines with this type of model. Also, with our approach, a system is simpler with one fewer layer – no need to tune the dimensionality of word vectors or meta-parameters for word vector learning.

Kalchbrenner et al. (2014) proposed complex modifications of CNN for sentence modeling. Notably, given word vectors $\in \mathbb{R}^d$, their convolution with m feature maps produces for each region a matrix $\in \mathbb{R}^{d \times m}$ (instead of a vector $\in \mathbb{R}^m$ as in standard CNN). Using the provided code, we found that their model is too resource-demanding for our tasks. On IMDB and Elec[14] the best error rates we obtained by training with various configurations that fit in memory for 24 hours each on GPU (cf. Fig 5) were 10.13 and 9.37, respectively, which is no better than SVM bow2. Since excellent performances were reported on short sentence classification, we presume that their model is optimized for short sentences, but not for text categorization in general.

Performance dependency CNN training is known to be expensive, compared with, e.g., linear models – linear SVM with bow3 on IMDB only takes 9 minutes using SVMlight (single-core) on a high-end Intel CPU. Nevertheless, with our code on GPU, CNN training only takes minutes (to a few hours) on these datasets shown in Figure 5.

[14]We could not train adequate models on RCV1 on either Tesla K20 or M2070 due to memory shortage.

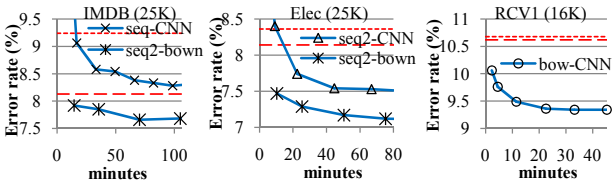

Figure 5: Training time (minutes) on Tesla K20. The horizontal lines are the best-performing baselines.

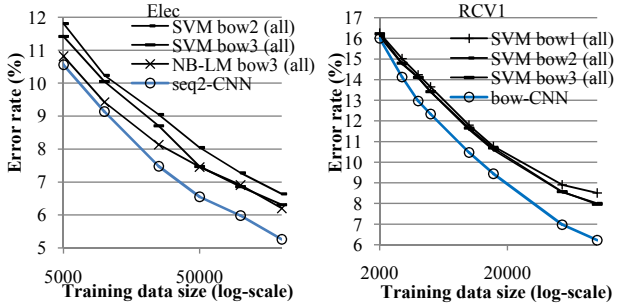

Figure 6: Error rate in relation to training data size. For readability, only representative methods are shown.

Finally, the results with training sets of various sizes on Elec and RCV1 are shown in Figure 6.

3.6 Why is CNN effective?

In this section we explain the effectiveness of CNN through looking into what it learns from training.

First, for comparison, we show the n-grams that SVM with bow3 found to be the most predictive; i.e., the following n-grams were assigned the 10 largest weights by SVM with binary features on Elec for the negative and positive class, respectively:

- poor, useless, returned, not worth, return, worse, disappointed, terrible, worst, horrible
- great, excellent, perfect, love, easy, amazing, awesome, no problems, perfectly, beat

Note that, even though SVM was also given bi- and tri-grams, the top 10 features chosen by SVM with binary features are mostly uni-grams; furthermore, the top 100 features (50 for each class) include 28 bi-grams but only four tri-grams. This means that, with the given size of training data, SVM still heavily counts on uni-grams, which could be ambiguous, and cannot fully take advantage of higher-order n-grams. By contrast, NB-weights tend to promote n-grams with a larger n; the 100 features that were assigned the largest NB-weights are 7 uni-, 33 bi-, and 60 tri-grams. However, as seen above, NB-weights do not always lead to the best performance.

best concept ever, best ideas ever, best hub ever, am wholly satisfied, am entirely satisfied, am incredicbly satisfied, 'm overall impressed, am awfully pleased, am exceptionally pleased, 'm entirely happy, are acoustically good, is blindingly fast,

Table 6: Examples of text regions that contribute to prediction. They are from the *test set*, and they did *not* appear in the training set, either entirely or partially as bi-grams.

In Table 5, we show some of text regions learned by seq-CNN to be predictive on Elec. This net has one convolution layer with region size 3 and 1000 neurons; thus, embedding by the convolution layer produces a 1000-dim vector for each region, which (after pooling) serves as features in the top layer where weights are assigned to the 1000 vector components. In the table, Ni/Pi indicates the component that received the i-th highest weight in the top layer for the negative/positive class, respectively. The table shows the text regions (in the training set) whose embedded vectors have a large value in the corresponding component, i.e., predictive text regions.

Note that the embedded vectors for the text regions listed in the same row are close to each other as they have a large value in the same component. That is, Table 5 also shows that the *proximity of the embedded vectors* tends to reflect the *proximity in terms of the relations to the target classes* (positive/negative sentiment). This is the effect of embedding, which helps classification by the top layer.

With the bag-of-n-gram representation, only the n-grams that appear in the training data can participate in prediction. By contrast, one strength of CNN is that n-grams (or text regions of size n) *can contribute to accurate prediction even if they did not appear in the training data*, as long as (some of) their constituent words did, because input of embedding is the constituent words of the region. To see this point, in Table 6 we show the text regions from the *test set*, which *did not appear in the training data*, either entirely or partially as bi-grams, and yet whose embedded features have large values in the heavily-weighted (predictive) component thus contributing to the prediction. There are many more of these, and we only show a small part of them that fit certain patterns. One noticeable pattern is (beverb, adverb, sentiment adjective) such as "am entirely satisfied" and "'m overall impressed". These adjectives alone could be ambiguous as they may be negated. To know that the writer is indeed "satisfied", we need to see the sequence "am satisfied", but the insertion of adverb such as "entirely" is very common. "best X ever' is another pattern that a discriminating pair of words are not adjacent to each other. These patterns require tri-grams for disambiguation, and seq-CNN successfully makes use of them even though the exact tri-grams were not seen during training, as a result of learning, e.g., "am X satisfied" with non-negative X (e.g., "am very satisfied", "am so satisfied") to be predictive of the positive class through training. That is, CNN can effectively use word order when bag-of-n-gram-based approaches fail.

4 Conclusion

This paper showed that CNN provides an alternative mechanism for effective use of word order for text categorization through direct embedding of small text regions, different from the traditional bag-of-n-gram approach or word-vector CNN. With the parallel CNN framework, several types of embedding can be learned and combined so that they can complement each other for higher accuracy. State-of-the-art performances on sentiment classification and topic classification were achieved using this approach.

Abstract

Syntactic linearization algorithms take a bag of input words and a set of optional constraints, and construct an output sentence and its syntactic derivation simultaneously. The search problem is NP-hard, and the current best results are achieved by bottom-up best-first search. One drawback of the method is low efficiency; and there is no theoretical guarantee that a full sentence can be found within bounded time. We propose an alternative algorithm that constructs output structures from left to right using beam-search. The algorithm is based on incremental parsing algorithms. We extend the transition system so that word ordering is performed in addition to syntactic parsing, resulting in a linearization system that runs in guaranteed quadratic time. In standard evaluations, our system runs an order of magnitude faster than a state-of-the-art baseline using best-first search, with improved accuracies.

1 Introduction

Linearization is the task of ordering a bag of words into a grammatical and fluent sentence. Syntax-based linearization algorithms generate a sentence along with its syntactic structure. Depending on how much syntactic information is available as inputs, recent work on syntactic linearization can be classified into *free word ordering* (Wan et al., 2009; Zhang et al., 2012; de Gispert et al., 2014), which orders a bag of words without syntactic constraints, *full tree linearization* (He et al., 2009; Bohnet et al., 2010; Song et al., 2014), which orders a bag of words given a full-spanning syntactic tree, and *partial tree linearization* (Zhang, 2013), which orders a bag of words given some syntactic relations between them as partial constraints.

Initial State	$([\,], [1...n], \emptyset)$
Final State	$([\,], [\,], A)$
Induction Rules:	
SHIFT	$\frac{(\sigma, [i\|\beta], A)}{([\sigma\| \ i], \beta, A)}$
LEFTARC	$\frac{([\sigma\|j \ i], \beta, A)}{([\sigma\|i], \beta, A \cup \{j \leftarrow i\})}$
RIGHTARC	$\frac{([\sigma\|j \ i], \beta, A)}{([\sigma\|j], \beta, A \cup \{j \rightarrow i\})}$

Figure 1: The *arc-standard* parsing algorithm.

The search space for syntactic linearization is huge. Even with a full syntax tree being available as constraints, permutation of nodes on each level is an NP-hard problem. As a result, heuristic search has been adopted by most previous work, and the best results have been achieved by a time-constrained best-first search framework (White, 2004a; White and Rajkumar, 2009; Zhang and Clark, 2011b; Song et al., 2014). Though empirically highly accurate, one drawback of this approach is that there is no asymptotic upper bound on the time complexity of finding the first full sentence. As a result, it can take 5–10 seconds to process a sentence, and sometimes fail to yield a full sentence at timeout. This issue is more severe for larger bags of words, and makes the algorithms practically less useful.

We study the effect of an alternative learning and search framework for the linearization prob-

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 113–122,
Denver, Colorado, May 31 – June 5, 2015.

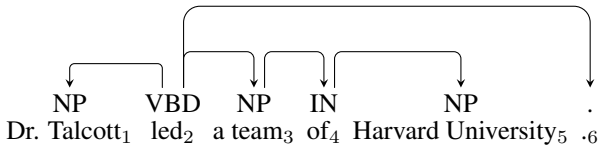

Figure 2: Example dependency tree.

lem, which has a theoretical upper bound on the time complexity, and always yields a full sentence in quadratic time. Our method is inspired by the connection between syntactic linearization and syntactic parsing: both build a syntactic tree over a sentence, with the former performing word ordering in addition to derivation construction. As a result, syntactic linearization can be treated as a generalized form of parsing, for which there is no input word order, and therefore extensions to parsing algorithms can be used to perform linearization.

For syntactic parsing, the algorithm of Zhang and Nivre (2011) gives competitive accuracies under linear complexity. Compared with parsers that use dynamic programming (McDonald and Pereira, 2006; Koo and Collins, 2010), the efficient beam-search system is more suitable for the NP-hard linearization task. We extend the parser of Zhang and Nivre (2011), so that word ordering is performed in addition to syntactic tree construction. Experimental results show that the transition-based linearization system runs an order of magnitude faster than a state-of-the-art best-first baseline, with improved accuracies in standard evaluation. Our linearizer is publicly available under GPL at `http://sourceforge.net/projects/zgen/`.

2 Transition-Based Parsing

The task of *dependency parsing* is to find a *dependency tree* given an input sentence. Figure 2 shows an example dependency tree, which consists of *dependency arcs* that represent syntactic relations between pairs of words. A transition-based dependency parsing algorithm (Nivre, 2008) can be formalized as a *transition system*, $S = (C, T, c_s, C_t)$, where C is the set of states, T is a set of transition actions, c_s is the initial state and C_t is a set of terminal states. The parsing process is modeled as an application of a sequence of actions, transducing the initial state into a final state, while constructing dependency arcs. Each state in the transition system can be formalized as a tuple (σ, β, A), where σ is a stack that maintains a partial derivation, β is a buffer of incoming input words and A is the set of dependency relations that have been built.

	Transition	σ	β	A
0		[]	[1...6]	$\emptyset$
1	SHIFT	[1]	[2...6]	
2	SHIFT	[1 2]	[3...6]	
3	SHIFT	[1 2 3]	[4...6]	
4	SHIFT	[1 2 3 4]	[5,6]	
5	SHIFT	[1 2 3 4 5]	[6]	
6	RIGHTARC	[1 2 3 4]	[6]	$A \cup \{4 \rightarrow 5\}$
7	RIGHTARC	[1 2 3]	[6]	$A \cup \{3 \rightarrow 4\}$
8	RIGHTARC	[1 2]	[6]	$A \cup \{2 \rightarrow 3\}$
9	SHIFT	[1 2 6]	[]	
10	RIGHTARC	[1 2]	[]	$A \cup \{2 \rightarrow 6\}$
11	LEFTARC	[2]	[]	$A \cup \{1 \leftarrow 2\}$

Table 1: *arc-standard* transition action sequence for parsing the sentence in Figure 2.

Our work is based on the *arc-standard* algorithm (Nivre, 2008). The deduction system of the *arc-standard* algorithm is shown in Figure 1. In this system, three transition actions are used: LEFTARC, RIGHTARC and SHIFT. Given a state $s = ([\sigma|\ j\ i], [k|\beta], A)$,

- LEFTARC builds an arc $\{j \leftarrow i\}$ and pops j off the stack.
- RIGHTARC builds an arc $\{j \rightarrow i\}$ and pops i off the stack.
- SHIFT removes the front word k from the buffer β, and shifts it onto the stack.

In the notations above, i, j and k are word indices of an input sentence. The *arc-standard* system assumes that each input word has been assigned a part-of-speech (POS) tag.

The sentence in Figure 2 can be parsed by the transition sequence shown in Table 1. Given an input sentence of n words, the algorithm takes $2n$ transitions to construct an output, because each word needs to be shifted onto the stack once and popped off once before parsing finishes, and all the transition actions are either shifting or popping actions.

Initial State	$([\,], set(1..n), \emptyset)$
Final State	$([\,], \emptyset, A)$

Induction Rules:

$$\textsc{Shift}\text{-}i\text{-}\textsc{pos}\quad \frac{(\sigma, \rho, A)}{([\sigma|i], \rho - \{i\}, A)}$$

$$\textsc{LeftArc}\quad \frac{([\sigma|j\ i], \rho, A)}{([\sigma|i], \rho, A \cup \{j \leftarrow i\})}$$

$$\textsc{RightArc}\quad \frac{([\sigma|j\ i], \rho, A)}{([\sigma|j], \rho, A \cup \{j \rightarrow i\})}$$

Figure 3: Deduction system for transition-based linearization. Indices i, j do not reflect word order.

Algorithm 1: transition-based linearization

Input: C, a set of input syntactic constraints
Output: The highest-scored final state

```
candidates ← ([ ], set(1..n), ∅)
agenda ← ∅
for i ← 1..2n do
    for s in candidates do
        for action in GETPOSSIBLEACTIONS(s, C) do
            agenda ← APPLY(s, action)
    candidates ← TOP-K(agenda)
    agenda ← ∅
best ← BEST(candidates)
return best
```

3 Transition-Based Linearization

The main difference between linearization and dependency parsing is that the input words are unordered for linearization, which results in an unordered buffer ρ. At a certain state $s = (\sigma, \rho, A)$, any word in the buffer ρ can be shifted onto the stack. In addition, unlike a parser, the vanilla linearization task does not assume that input words are assigned POS. To extend the *arc-standard* algorithm for linearization, we incorporate word and POS into the SHIFT operation, transforming the *arc-standard* SHIFT operation to SHIFT-*Word-POS*, which selects the word *Word* from the buffer ρ, tags it with *POS* and shifts it onto the stack. Since the order of words in an output sentence equals to the order in which they are shifted onto the stack, word ordering is performed along with the parsing process.

Under such extension, the sentence in Figure 2 can be generated by the transition sequence (SHIFT-*Dr. Talcott*-NP, SHIFT-*led*-VBD, SHIFT-*of*-NP, SHIFT-*a team*-NP, SHIFT-*of*-IN, SHIFT-*Harvard University*-NP, RIGHTARC, RIGHTARC, RIGHTARC, SHIFT-.-., RIGHTARC, LEFTARC), given the unordered bag of words (*Dr. Talcott*, *led*, *a team*, *of*, *Harvard University*, .).

The deduction system for the linearization algorithm is shown in Figure 3. Given an input bag of n words, this algorithm also takes $2n$ transition actions to construct an output, by the same reason as the *arc-standard* parser.

3.1 Search and Learning

We apply the learning and search framework of Zhang and Clark (2011a), which gives state-of-the-art transition-based parsing accuracies and runs in linear time (Zhang and Nivre, 2011). Pseudocode of the search algorithm is shown in Algorithm 1. It performs beam-search by using an agenda to keep the *k*-best states at each incremental step. When decoding starts, the agenda contains only the initial state. At each step, each state in the agenda is advanced by applying all possible transition actions (GETPOSSIBLEACTIONS), leading to a set of new states. The k best are selected for the new states, and used to replace the current states in the agenda, before the next decoding step starts. Given an input bag of n words, the process repeats for $2n$ steps, after which all the states in the agenda are terminal states, and the highest-scored state in the agenda is taken for the final output. The complexity of this algorithm is n^2, because it takes a fixed $2n$ steps to construct an output, and in each step the number of possible SHIFT action is proportional to the size of ρ.

The search algorithm ranks search hypotheses, which are sequences of state transitions, by their scores. A global linear model is used to score search hypotheses. Given a hypothesis h, its score is calculated by:

$$Score(h) = \Phi(h) \cdot \vec{\theta},$$

where $\vec{\theta}$ is the parameter vector of the model and $\Phi(h)$ is the global feature vector of h, extracted by instantiating the feature templates in Table 2 according to each state in the transition sequence.

In the table, S_0 represents the first word on the top of the stack, S_1 represents the second word on the top of the stack, w represents a word and p rep-

Table 2: Feature templates.

resent a POS-tag. The feature templates can be classified into four types: *unigram*, *bigram*, *trigram* and *linearization*. The first three types are taken from the dependency parser of Zhang and Nivre (2011), which capture context information for S_0, S_1 and their modifiers. The original feature templates of Zhang and Nivre (2011) also contain information of the front words on the buffer. However, since the buffer is unordered for linearization, we do not include these features.

The *linearization* feature templates are specific for linearization, and captures surface ngram information. Each search state represents a partially linearized sentence. We represents the last word in the partially linearized sentence as w_0 and the second last as w_{-1}.

Given a set of labeled training examples, the averaged perceptron (Collins, 2002) with early update (Collins and Roark, 2004; Zhang and Nivre, 2011) is used to train the parameters $\vec{\theta}$ of the model.

3.2 Input Syntactic Constraints

The use of syntactic constraints to achieve better linearization performance has been studied in previous work. Wan et al. (2009) employ POS constraints in learning a dependency language model. Zhang and Clark (2011b) take supertags as constraints to a CCG linearizer. Zhang (2013) demonstrates the possibility of *partial-tree linearization*, which allows a whole spectrum of input syntactic constraints. In practice, input syntactic constraints, including POS and dependency relations, can be obtained from earlier stage of a generation pipeline, such as lexical transfer results in machine translation.

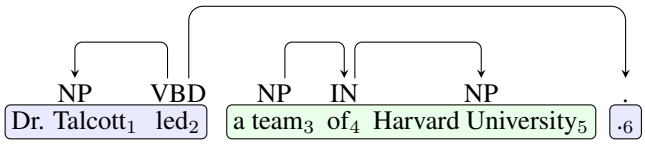

Figure 4: Example partial tree. Words in the same sub dependency trees are grouped by rounded boxes. Word indices do not specify their orders. Base phrases (e.g. *Dr. Talcott*) are treated as single words.

It is relatively straightforward to apply input constraints to a best-first system (Zhang, 2013), but less so for beam-search. In this section, we utilize the input syntactic constraints by letting the information decide the possible actions for each state, namely the return value of GETPOSSIBLEACTIONS in Algorithm 1, thus, when input POS-tags and dependencies are given, the generation system can achieve more specified outputs.

3.2.1 POS Constraints

POS is the simplest form of constraints to the transition-based linearization system. When the POS of an input word is given, the POS-tag component in SHIFT-*Word-POS* operation is fixed, and the number of SHIFT actions for the word is reduced from the number of all POS to 1.

3.2.2 Partial Tree Constraints

In partial tree linearization, a set of dependency arcs that form a partial dependency tree is given to the linearization system as input constraints. Figure 4 illustrate an example. The search space can be reduced by ignoring the transition sequences that do not result in a dependency tree that is consistent with the input constraints. Take the partial tree in Figure 4 for example. At the state s = ([*Harvard University*$_5$], set(1..n)-{5}, $\emptyset$), it is illegal to shift the base phrase *a team*$_3$ onto the stack, be-

Algorithm 2: GETPOSSIBLEACTIONS for partial tree linearization, where C is a partial tree

6          T ← T ∪ (LEFTARC)
7      if REDUCABLE(s, j, i, C) then
8          T ← T ∪ (RIGHTARC)
9      for k ∈ s.β do
10         if SHIFTLEGAL(s, k, C) then
11             T ← T ∪ (SHIFT, POS, k)
12 return T
```

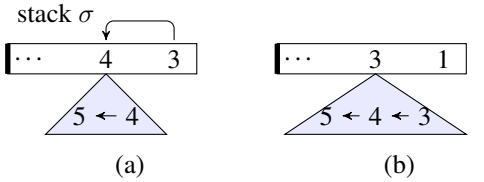

Figure 5: Two conditions for a valid LEFTARC action in partial-tree linearization. The indices correspond to those in Figure 4. A shaded triangle represents the readily built arcs under a root word.

cause this action will result in a sub-sequence (*Harvard University*$_5$, *a team*$_3$, *of*$_4$), which cannot have the dependency arcs $\{3 \rightarrow 4\}, \{4 \rightarrow 5\}$ by using *arc-standard* actions.

Algorithm 3 shows pseudocode of GETPOSSIBLEACTIONS when C is a partial tree. Given a state $s = ([\sigma|j\ i], \rho, A)$ the LEFTARC action builds an arc $\{j \leftarrow i\}$ and pops the word j off the stack. Since the popped word j cannot be linked to any words in future transitions, all the descendants of j should have been processed and removed from the stack. In addition, constrained by the given partial tree, the arc $\{j \leftarrow i\}$ should be an arc in C (Figure 5a), or j should be the root of a sub dependency tree in C (Figure 5b). We denote the conditions as REDUCABLE(s, i, j, C) (lines 5-6). The case for RIGHTARC is similar to LEFTARC (lines 7-8).

For the SHIFT action, the conditions are more complex. Due to space limitation, we briefly sketch

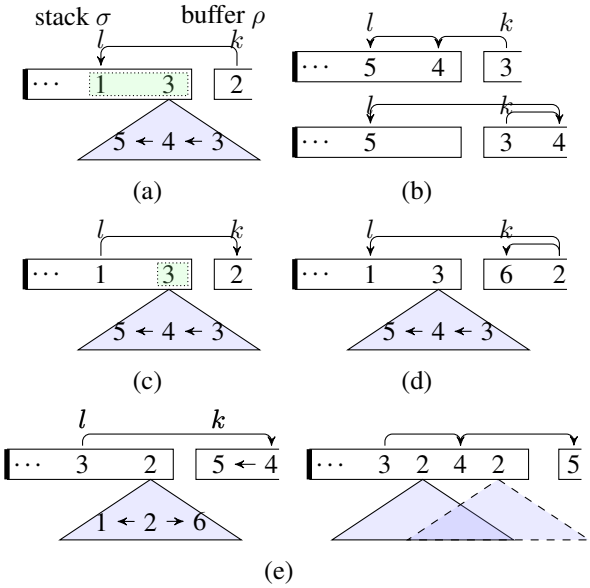

Figure 6: 5 relations between k and l. The indices correspond to those in Figure 4. The words in green boxes must have arcs with k in future transitions.

the SHIFTLEGAL function below. Detailed algorithm pseudocode for SHIFTLEGAL is given in the supplementing material. For a word k in ρ to be shifted onto the stack, all the words on the stack must satisfy certain constraints. There are 5 possible relations between k and a word l on the stack. (1) If l is a child of k in C (Figure 6a), all the words on the stack from l to the top of the stack should be *reducable to* k, because only LEFTARC can be applied between k and these words in future actions. (2) If l is a grand child of k (Figure 6b), no legal sentence can be constructed if k is shifted onto the stack. (3) If l is the parent of k (Figure 6c), legal SHIFTs require all the words on the stack from l to the top to be *reducable* to k. (4) If l is a grand parent of k, all the words on the stack from l to the top will become descendants of l in the output (Figure 6e). Thus these words must be descendants of l in C, or the root of different subdependency trees. (5) If l is a siblings of k, we denote a as the least common ancestor of k and l. a will become in the buffer and l should be a direct child of a. All the words from l to the top of the stack should be the descendants of a in the output (Figure 6d), and thus a should have the same conditions as in (4). Finally, if no word on the stack is in the same subdependency tree as k in C, then k can be safely shifted.

Algorithm 3: GETPOSSIBLEACTIONS for full tree linearization, where C is a full tree

Input: A state $s = ([\sigma|j\ i], \rho, A)$ and gold tree C
Output: A set of possible transition actions T

```
1  T ← ∅
2  if s.σ is empty then
3      for k ∈ s.ρ do
4          T ← T ∪ (SHIFT, POS, k)
5  else
6      if ∃j, j ∈ (DESCENDANTS(i) ∩ s.ρ) then
7          for j ∈ (DESCENDANTS(i) ∩ s.ρ) do
8              T ← T ∪ (SHIFT, POS, j)
9      else
10         if {j → i} ∈ C then
11             T ← T ∪ (RIGHTARC)
12         else if {j ← i} ∈ C then
13             T ← T ∪ (LEFTARC)
14         else
15             for
               k ∈ (SIBLINGS(i) ∪ HEAD(i)) ∩ s.ρ do
16             T ← T ∪ (SHIFT, POS, k)
17 return T
```

3.2.3 Full Tree Constraints

Algorithm 2 can also be used with full-tree constraints, which are a special case of partial-tree constraints. However, there is a conceptually simpler algorithm that leverages full-tree constraints. Because tree linearization is frequently studied in the literature, we describe this algorithm in Algorithm 3. When the stack is empty, we can freely move any word in the buffer ρ onto the stack (line 2-4). If not all the descendants of the stack top i have been processed, the next transition actions should move them onto the stack, so that arcs can be constructed between i and these words (line 6-8). If all the descendants of i have been processed, the next action should eagerly build arcs between top two words i and j on the stack (line 10-13). If no arc exists between i and j, the next action should shift the parent word of i or a word in i's sibling tree (line 14-16).

4 Experiments

We follow previous work and conduct experiments on the Penn Treebank (PTB), using Wall Street Journal sections 2–21 for training, 22 for development testing and 23 for final testing. Gold-standard dependency trees are derived from bracketed sentences in the treebank using Penn2Malt[1], and base noun phrases are treated as a single word (Wan et al., 2009; Zhang, 2013). The BLEU score (Papineni et al., 2002) is used to evaluate the performance of linearization, which has been adopted in former literals (Wan et al., 2009; White and Rajkumar, 2009; Zhang and Clark, 2011b) and recent shared-tasks (Belz et al., 2011). We use our implementation of the best-first system of Zhang (2013), which gives the state-of-the-art results, as the baseline.

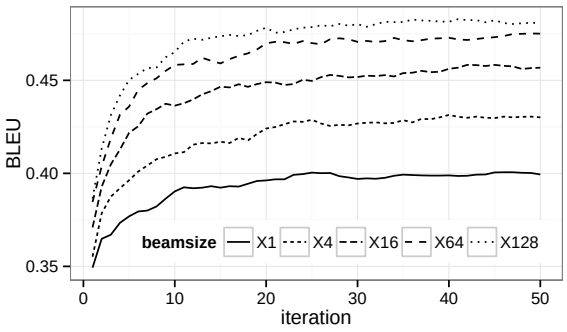

Figure 7: Dev. results with different beam sizes.

4.1 Influence of Beam size

We first study the influence of beam size by performing free word ordering on the development test data. BLEU score curves with different beam sizes are shown in Figure 7. From this figure, we can see that the systems with beam 64 and 128 achieve the best results. However, the 128-beam system does not improve the performance significantly (48.2 vs 47.5), but runs twice slower. As a result, we set the beam size to 64 in the remaining experiments.

4.2 Input Syntactic Constraints

To test the effectiveness of GETPOSSIBLEACTIONS under different input constraints, we follow Zhang (2013) and feed different amounts of POS-tags and dependencies to our transition-based linearization system. Input syntactic constraints are obtained by randomly sampling POS and dependencies from the gold dependency tree. Nine development experiments under different inputs are performed, and the

Table 4: Precision, recall and F-score comparison on different spans lengths.

BLEU scores along with the average time to order one sentence are shown in Table 3.

With more syntactic information in the input, our linearization system achieves better performance, showing that GETPOSSIBLEACTIONS can take advantage of the input constraints and yield more specified output. In addition, because input constraints reduce the search space, the systems with more syntactic information achieve faster decoding speeds. In comparison with Zhang (2013), the transition-based system achieves improved accuracies under the settings, and the decoding speed can be over two orders of magnitude faster (22ms vs. 4218ms). We give more detailed analysis next.

4.3 Comparison with Best-First

The beam-search linearizer takes a very different search strategy compared with best-first search, which affects the error distribution. As mentioned earlier, one problem of best-first is the lack of theoretical guarantee on time complexity. As a result, a time constraint is used and default output can be constructed when no full output is found (White, 2004b; Zhang and Clark, 2011b). This may result in incomplete output sentences and intuitively, this problem is more severe for larger bag of words. In contrast, the transition-based linearization algorithm takes $|2n|$ steps to generate a sentence and thus guarantees to order all the input words. Figure 8 shows the results by comparing the brevity scores (i.e. the number of words in the output divided by the number of words in reference sentence) on different sizes of inputs. Best-search can fail to order all the input words even on bags of 9 – 11 words, and the case is more severe for larger bag of words. On the other hand, the transition-based method uses all the input words to generate output and the brevity score is constant 1. Since the BLEU score consists two parts: the n-gram precision and brevity, this comparison partly explains why the transition-based linearization algorithm achieves higher BLEU scores.

To further compare the difference between the two systems, we evaluate the qualities of projective spans, which are dependency treelets. Both systems build outputs bottom-up by constructing projective spans, and a break-down of span accuracies against span sizes shows the effects of the different search algorithms. The results are shown in Table 4. According to this table, the best-first system tends to construct smaller spans more precisely, but the recall is relatively lower. Overall, higher F-scores are achieved by the transition-based system.

During the decoding process, the best-first system compares spans of different sizes and expands

Table 5: Final results.

those that have higher scores. As a result, the number of expanded spans do not have a fixed correlation with the size, and there can be fewer but better small spans expanded. In contrast, the transition-based system models transition sequences rather than individual spans, and therefore the distribution of spans of different sizes in each hypothesis resembles that of the training data. Figure 9 verifies the analysis by counting the distributions of spans with respect to the length, in the search algorithms of the two systems and the gold dependency trees. The distribution of the transition-based system is closer to that of gold dependency trees, while the best-first system outputs less smaller spans and more longer ones. This explains the higher precision for the best-first system on smaller spans.

4.4 Final Results

The final results on the test set of Penn Treebank are shown in Table 5. Compared with previous studies, our transition-based linearization system achieves the best results on all the tests. Table 6 shows some example output sentences, when there are no input constraints. For longer sentences, the transition-based method gives noticeably better results.

5 Related Work

The input to practical natural language generation (NLG) system (Reiter and Dale, 1997) can range from a bag of words and phrases to a bag of lemmas without punctuation (Belz et al., 2011). The linearization module of this paper can serve as the final stage in a pipeline when the bag of words and their optional syntactic information are given. There has also been work to jointly perform linearization and morphological generation (Song et al., 2014).

There has been work on linearization with unlabeled and labeled dependency trees (He et al., 2009; Zhang, 2013). These methods mostly use greedy or best-first algorithms to order each tree node. Our work is different by performing word ordering using a transition process.

Besides dependency grammar, linearization with other syntactic grammars, such as CFG and CCG (White and Rajkumar, 2009; Zhang and Clark, 2011b), has also been studied. In this paper, we adopt the dependency grammar for transition-based linearization. However, since transition-based parsing algorithms has been successfully applied to different grammars, including CFG (Sagae et al., 2005) and CCG (Xu et al., 2014), our linearization method can be applied to these grammars.

6 Conclusion

We studied transition-based syntactic linearization as an extension to transition-based parsing. Compared with best-first systems, the advantage of our transition-based algorithm includes bounded time complexity, and the guarantee to yield full sentences when given a bag of words. Experimental results show that our algorithm achieves improved accuracies, with significantly faster decoding speed compared with a state-of-the-art best-first baseline. We publicly release our code at `http://sourceforge.net/projects/zgen/`.

For future work, we will study the incorporation of large-scale language models, and the integration of morphology generation and linearization.

Extractive Summarisation Based on Keyword Profile and Language Model

hanx,emartin,ashesh@cse.unsw.edu.au

Abstract

We present a statistical framework to extract information-rich citation sentences that summarise the main contributions of a scientific paper. In a first stage, we automatically discover salient keywords from a paper's citation summary, keywords that characterise its main contributions. In a second stage, exploiting the results of the first stage, we identify citation sentences that best capture the paper's main contributions. Experimental results show that our approach using methods rooted in quantitative statistics and information theory outperforms the current state-of-the-art systems in scientific paper summarisation.

1 Introduction and Motivation

Science is not an isolated endeavour, but benefits from and expands on the work of others, with more or less cross fertilisation between disciplines. The interdependent nature of research has naturally resulted in a network of scientific areas with dense interconnections between related fields. Though research is a highly specialised activity, researchers find themselves constantly in need to explore the network further from the core of their research. Tools that can facilitate understanding the key contributions of papers in those parts of the network being explored can only prove highly valuable.

As an example of such tools, we focus on an application that automatically extracts information-rich sentences describing the main contributions of a given paper. From which corpus the extraction could take place? A natural answer is the abstract of the paper. However, the contributions as perceived by the authors can significantly deviate from those judged extrospectively by the community over time (Mei and Zhai, 2008). Instead, we take as corpus the set of citing sentences to the paper (from other papers). Indeed, those sentences can arguably be deemed as a form of crowd-sourced review of the paper's main contributions. The set of citing sentences is referred to as the *citation summary* of the target paper. Elkiss et al. (2008) carried out a large-scale study and confirmed that citation summaries contain extra information that does not appear in paper abstracts. In addition, they found that the "self-cohesion", measured as the average cosine similarity between sentences, is consistently higher in a paper's citation summary than in its abstract: the former is more focused than the latter in describing papers' main contributions. This work presents our efforts in advancing research along this direction.

Section 2 formally defines the problem we aim to solve: summarise scientific papers using the most informative and diversified part of their citation summaries. It surveys several prominent related studies, and introduces the data used in our experiments and evaluations. In Section 3, we present our statistical framework built upon quantitative statistics and information theory. In Section 4, we evaluate and compare the performance of our method with state-of-the-art systems. We conclude and point to future directions in Section 5.

2 Problem Statement

The problem we tackle in this paper is to generate an *extractive summary* (usually, we will simply say *summary*) from its citation summary. More specifically, we opt for a two stage approach. In the first stage, we automatically discover salient keywords from a paper's citation summary, keywords that are essential in characterising the paper's main contributions. The second stage, exploiting the results of the first stage, identifies citation sentences (to the paper) that best capture the paper's main contributions.

A word of caution: by utilising only citation summaries, one should not expect to obtain well formulated, readily consumable summaries of papers. Indeed, a citation sentence may be not all about the cited paper, but also talk about the citing paper and other co-cited papers, which disqualify citation sum-

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 123–132,
Denver, Colorado, May 31 – June 5, 2015.

maries as a premium source of sentences for building highly readable summaries (Siddharthan and Teufel, 2007). Moreover, a summary built from citing sentences that come for a pool of multiple citing papers is bound to lack coherence. Therefore, it is more appropriate to consider that the output of such a system is to extrinsically gauge a system's effectiveness in indexing information-rich citing sentences containing keywords that facilitate rapidly grasping a paper's important contributions, rather than be treated as a polished, readable summary for human consumption (Qazvinian et al., 2013).

2.1 Related Work

Qazvinian and Radev (2008) first experimented with citation summary based paper summarisations. They proposed a graph-based method, C-LexRank, that first generates a citation summary network for a paper by mapping citing sentences to vertices and creating edges from their lexical similarities. Clusters of sentences capturing the same contribution of the paper are then identified through link-based community detection. Finally, the most central sentence of each cluster is found using a weighted random walk and selected to form a paper summary meant to comprehensively cover the paper's main contributions. Mohammad et al. (2009) further adapted the C-LexRank to multi-document summarisation in an attempt to generate surveys for scientific paradigms.

In a later paper, Qazvinian et al. (2010) proposed a more computationally efficient summariser that does not require clustering citing sentences. As a first step, key phrases are automatically identified as significant n-grams with positive point-wise divergence (Tomokiyo, 2003) from a foreground language model estimated using the citation summary of a paper w.r.t. a background language model built from a large set of paper abstracts. A greedy algorithm is subsequently applied to select citing sentences and form a summary that maximises key phrase coverage.

Mei and Zhai (2008) presented a sophisticated generative approach that frames summarisation under an Information Retrieval (IR) context. Specifically, an impact language model for a paper is first built as a mixture of a language model estimated from the paper's own text, and a weighted citation language model based on its collective citation contexts, using a compound coefficient reflecting both a sentence's proximity to the citation label (anchor) in the citing paper and the citing paper's authority calculated from the citation network using PageRank (Brin and Page, 1998). Finally, documents (sentences in the target paper) that are closest to the query (the impact language model of the target paper) are extracted to form a summary using ad-hoc document retrieval. Note that Mei and Zhai (2008) utilised extra information (i.e., paper full texts and citation networks) to produce summaries that consist of sentences from papers' own texts rather than their citation summaries, making their task related to but different to ours.

2.2 Data

The experiments and evaluations presented here have been based on Qazvinian's single paper summarisation corpus[1]. The dataset consists of 25 highly cited papers in the ACL Anthology Network (AAN) (Radev et al., 2009) from 5 different domains: Dependency Parsing (DP), Phrase Based Machine Translation (PBMT), Text Summarisation (SUM), Question Answering (QA) and Textual Entailment (TE). There are two files provided for each paper: a citation summary file containing all citing sentences to it, and a manually constructed key fact file containing its main contributions hand picked by human annotators after reading the citation summary. The manual annotation has been performed independently by annotators, and a phrase needed to be marked by at least 2 annotators to be qualified as capturing a paper's key fact (Qazvinian and Radev, 2008). This corpus represents a gold standard in research paper summarisation and it has been widely used in system evaluations (Qazvinian and Radev, 2008; Qazvinian et al., 2010).

3 Our Approach

In this section, we first introduce our quantitative statistical method to automatically construct a *keyword profile* of a paper and statistically capture a paper's main contributions in terms of words from its citation summary. We then discuss how we construct a *keyword profile language model*. Finally, we elaborate on how we cast the task of sentence selection from the citation summary as language model divergence based IR in a probabilistic framework.

3.1 Paper Keyword Profile

As indicated in Section 1, the citation summary of a paper can be deemed a collective review of its contributions. Therefore, the main contributions of a

[1] http://www-personal.umich.edu/~vahed/data.html

paper are salient keywords, those keywords which are commonly used by its citers to refer to it and are statistically over-represented in the paper's citation summary w.r.t. the overall distribution of such words across other papers' citation summaries. Put another way, the salience of a word in characterising a paper's main contributions is qualified along *over-representedness* and *exclusiveness* dimensions. Clearly, a proper statistical model of words distribution is required in order to measure words' salience in a paper's citation summary. Consider five papers, $D_1, \ldots, D_5$ with citation summaries $CS_1, \ldots, CS_5$. We aim at identifying salient keywords from D_1's citation summary CS_1, that map to D_1's main contributions. To decide whether a word W is a characterising keyword of D_1, we first collect all n citing sentences containing W from $CS_1, \ldots, CS_5$; suppose there are $n = 20$ of them. Then for each citing sentence S amongst those 20, we perform the binary test: success iff S belongs to CS_1. Suppose that there are $k = 18$ successes and 2 failures. This represents a surprising observation: one would expect a word of no characterising power to appear in roughly the same number of sentences in $CS_1, \ldots, CS_5$, assuming all citation summaries have the same number of sentences[2]. So one would heuristically conclude that W is a good candidate keyword for D_1, a keyword that is likely to represent a main contribution.

The previous process can be abstracted as sampling without replacement from a finite set whose elements can be classified into mutually exclusive binary categories, which itself follows a Hypergeometric distribution. Let N be the total number of citing sentences in citation summaries for papers belonging to collection C, K be the number of sentences in paper D's citation summary, n be the total number of citing sentences containing a certain word W, and X be the number of citing sentences containing W in D's citation summary. The probability of observing exactly k citing sentences in D's citation summary containing W is:

$$H(X{=}k|N,K,n){=}\frac{\binom{K}{k}\binom{N-K}{n-k}}{\binom{N}{n}} \quad (1)$$

We can then calculate a p-value to the observed number of x citing sentences in D's citation summary that contain word W using the Hypergeometric test, which in turn is used to measure word W's salience in characterising D's main contributions:

$$S(W) \stackrel{def}{=} P(X{\geq}x){=}1{-}\textstyle\sum_{i=0}^{x-1} H(X{=}i|N,K,n)) \quad (2)$$

[2]This assumption is only made to simplify the discussion.

The smaller the value of $S(W)$, the more salient W is. Also, words not appearing in D's citation summary have a maximum p-value of 1.0, and common words appearing in many papers' citation summaries are expected to have larger p-values than words that are more exclusively used when citing paper D.

It is worth pointing out that the above formulation can be equivalently expressed as applying the one-tailed Fisher's exact test to measure strengths of statistical associations between words and paper's citation summaries at the sentence level. Our choice of this statistical procedure has been informed by (Moore, 2004). Prior to this work, Dunning (1993) was pointing out that some commonly used methods such as the Pearson's χ^2 test are inappropriate for measuring textual associations due to the fact that the underlying normality assumption is usually violated in textual data. He was subsequently introducing the log-likelihood ratio test (LLR) and showing that it can yield more reliable results. The LLR was then and has since been widely adopted in statistical NLP as a measure of strength of association (Moore, 2004). For instance, Lin and Hovy (2000) successfully applied LLR in mining "topic signatures" of pre-classified document collections. But to further verify LLR's validity applied to rare events, Moore (2004) performed an empirical study comparing results obtained using LLR and Fisher's exact test on bilingual word association and found that albeit being a good approximation to Fisher's exact test, LLR can still introduce a substantial amount of error and the author went on to advocate the use of Fisher's exact test where computationally feasible. Recall that we measured associational strengths at the sentence level. This resulted in marginal frequencies in the order of only hundreds for Qazvinian's small corpus. We therefore followed this empirical advice and used the one-tailed Fisher's exact test (i.e., Hypergeometric test) as our measure of textual association to perform keyword profiling of a scientific paper.

To obtain a set of keywords likely to map to a paper's main contributions, one can simply sort all words according to their statistical significance and pick the top few (e.g., 10 words with the smallest p-values). A more statistically tenable scheme would be to identify the keywords of a paper as all words appearing in its citation summary with p-values below some significance level. A technicality here is that in the identification of keywords, multiple Hypergeometric tests have been performed. For example, all unique words that appeared in the collection

of citation summaries have been individually tested for their salience in a target paper's citation summary in succession. The significance level used to qualify a word as a keyword thus requires correction for multiple tests to reduce type I errors. However, we shall show that the rigid statistical significance is not crucial in our subsequent building of a keyword language model for a paper, and so we did not perform multiple tests corrections, but simply used the raw p-values in subsequent analysis.

Another technicality is special handling of citation anchors. Cited authors' names, almost systematically appearing in citing sentences, are bound to be identified as salient keywords. We thus substituted all citation anchors appearing in a paper's citation summary with the pseudo token "targetanchor" if they refer to the target paper, and "otheranchor" if they refer to other co-cited papers.

Furthermore, our keyword profiling approach allows for a flexible control of the level of selectiveness in its statistical procedure through the choice of the benchmarking collection C. For example, we can choose to use a heterogeneous collection of papers covering multiple domains. Words that are salient in characterising a domain may then evaluate to a high salience for a paper in C on that domain (e.g., word "parsing" for domain Dependency Parsing (DP)). We can also choose C to be a homogeneous collection of papers from the same domain. Only words that are salient in characterising a single paper will then be evaluated to a high salience for that paper (e.g., if C is on DP, "parsing" will not show up as a salient word for any paper in C). Recall from Section 2.2 that we use as data papers from five domains. We exploited the homogeneity of this data and performed keyword profiling intra-domain. This effectively made the keyword profiling all the more selective that the keywords identified for a paper only characterise its *unique* contributions w.r.t. its domain, using five highly cited papers. We shall show in the next section that it is this high selectiveness in keyword profiling that bestows our approach its high discriminative power.

For paper P05-1013, Table 2 lists the top 10 keywords identified from its citation summary using our method, while Table 1 lists the humanly selected gold standard key facts (Qazvinian and Radev, 2008). It can be seen that our method is highly effective in identifying the paper's main contributions which closely mirror those picked by human experts. We term our word list ranked by p-values the *keyword profile* of the paper; it statistically and objectively captures words' salience (measured along the dimensions of over-representedness and exclusiveness) in characterising the paper's main contributions using the statistical surprise given by Hypergeometric tests. While only unigram keywords were considered here, our method can be easily extended to cope with higher order n-gram "key phrases". This is left for future work.

Fact id	Fact	Occurence	Pyramid tier
1	non-projective pseudo-projective projectivizing projective graphs projectivization transformation	15 6 1 1 1	19

3.2 Keyword Profile Language Model

Each sentence in a paper's citation summary covers keywords (possibly none) that map to the paper's main contributions. Intuitively, a good summarisation should be short, and consist of citing sentences that maximise keywords coverage w.r.t. an arbitrarily imposed summary length limit (Qazvinian and Radev, 2008). A good summariser should thus pick citing sentences that contain as many non-redundant keywords as possible. We have shown in the last sec-

tion that not all keywords are of equal importance, so a good summariser should favour sentences covering the most important ones. Intuitively, the keyword profile of a paper containing valuable information on words' salience in characterising the paper's main contributions should be utilised to drive such a discriminative sentence selection process.

Based on the previous considerations, we use a paper's keyword profile to build a discriminative unigram language model that directly encodes words' salience as pseudo generative probabilities to facilitate the seamless incorporation of such information into a generic probabilistic framework. More specifically, we directly translate words' salience (in the form of p-values) into a discriminative unigram language model of a paper that assigns high probabilities to its characterising keywords. The pseudo generative probability of word W according to a paper D's keyword profile language model M_{kp} is:

$$P(W|M_{kp}) = -\frac{1}{Z}\log(S(W)) \quad (3)$$

where $S(W)$ denotes the salience of word W in characterising paper D calculated using (2), and Z is a normalisation factor. An intuitive interpretation of (3) is to deem $-\log(S(W))$ a pseudo word count of W, where more salient words have higher pseudo counts; this makes Z the total length of the pseudo document generated from the paper's keyword profile. We disregard actual word counts to make the keyword profile language model directly encode words' salience. Also, in the previous step, keyword profiling had already implicitly taken such information into account, providing another justification for this design decision. Table 3 shows a miniature example to illustrate how a keyword profile language model is built. In this example, W_5 is automatically eliminated from the resulting language model because it has lowest salience in characterising the imaginary document. Any word S with salience value $S(W)$ close to but strictly less than 1.0 would still have a tiny pseudo probability in the resulting keyword profile language model (e.g., W_4). Words with low salience are not necessarily stop words (*e.g.*, W_4 and W_5), and neither is the reverse true: a content word can possibly be used across the document collection and thus evaluate to a very low salience (and so have a nul or low pseudo generative probability in the resulting keyword profile language model) for the document under consideration. For example, "parsing" would have a low salience for any paper in a collection on Dependency Parsing. It can be seen that our method amounts to a highly adaptive data driven term weighting framework. For brevity, from now on, we use KPLM to refer to keyword profile language model.

Word	**Salience** $S(W)$	**Pseudo count** $-\log(S(W))$	$P(W\|M_{kp})$
W_1	0.01	4.61	0.605
W_2	0.10	2.30	0.303
W_3	0.50	0.69	0.091
W_4	0.99	0.01	0.001
W_5	1.00	0.00	0.000

Table 3: Keyword profile language model built for an imaginary document consists of only 5 distinct words.

Although implicitly conveyed in the formulation of KPLM above, it should be made clear that the KPLM is a pseudo language model that encodes words' salience in the form of pseudo generative probabilities, which functions as a language model, yet should not be interpreted as a true language model under the traditional definition. A traditional unigram language model is constructed using the actual term frequencies in the document, the resulting model capturing generative probabilities. In contrast, the KPLM of a document is built using pseudo term frequencies that directly encode words' salience in characterising a document's contents, measured using a sophisticated quantitative statistical procedure. It can thus be interpreted as a probabilistic description of the document's keywords with significantly boosted discriminative power. Having clarified the nature of KPLM, we treat it as a language model in the rest of the paper.

3.3 KPLM Based Summarisation

3.3.1 Sentence Selection

The KPLM of a paper is a discriminative generative model that incorporates words' salience in characterising a paper's main contributions. It thus represents an effective language model from which a model citing sentence covering the paper's main contributions could be sampled from[3]. So by measuring the statistical surprise between the realistic language model estimated from each citing sentence with the KPLM of a paper, we can select the set of citing sentences that conform best to the optimal model given by the the KPLM and build a summary that well captures keywords. More specifically, we adopt the negative cross entropy retrieval model (Zhai, 2008), use the KPLM of a paper as the

[3] A pseudo citing sentence sampled from KPLM in this manner would simply be a bag of words, not a grammatical sentence. So here "model" has the favour of keywords coverage.

sole document model, and measure the cross entropy of multiple query models from it (one for each citing sentence in that paper's citation summary). Citing sentences whose Maximum Likelihood Estimation (MLE) language models are closest to the paper's KPLM are taken as building blocks of the summary.

Formally, let S be a citing sentence and let $c(W, S)$ denote the number of occurrences of word W in S. The MLE language model M_{mle} of S is the relative frequency of word W in S:

$$P(W|M_{mle}) = \frac{c(W,S)}{|S|} \quad (4)$$

Subsequently, the score for a citing sentence S is given by its negative cross entropy with the M_{kp}:

$$\begin{aligned} Score(S) &= -H(M_{mle}||M_{kp}) \\ &= \sum_{W \in V} P(W|M_{mle}) \log(P(W|M_{kp})) \end{aligned} \quad (5)$$

The larger a citing sentence's score, the closer it is to the cited paper's KPLM, thus the higher the citing sentence would be ranked. To summarise a paper, one can just pick the top k ranked citing sentences where k is the imposed summary length limit.

We are not the first to cast the task of summarisation as document retrieval. Mei and Zhai (2008) pioneered in utilising language models and divergence based IR to select sentences to build summaries. While similar in the fundamental methodology, our approach should be distinguished from this work. First, Mei and Zhai cast the task as ad-hoc retrieval, using the "impact language model" of a paper as sole query, while the paper's sentences are treated as documents whose Kullback-Leibler divergence (Kullback and Leibler, 1951) with the query model is measured in turn. Estimating reliable language models for short documents is challenging due to data sparseness and thus requires prudent smoothing. We purposefully reversed the roles of sentence model and document model, using the shorter sentences as queries and measuring their cross entropy with a sole document model (the KPLM)[4]. This represents a more natural formulation resulting in simpler language models that require fewer parameter estimations. Second, while the impact language model in (Mei and Zhai, 2008) is partially weighted using citing paper authority and sentence proximity to the citation anchor in the citing paper, it is still largely based on actual word occurrences. In contrast, KPLM directly models words' salience in characterising a paper's main contributions using its keyword profile, with expectedly more discriminative power. Last, Mei and Zhai's estimation of an impact language model for a paper assumes the reliable estimation of its citing papers' authority, which cannot always be guaranteed, for example when a paper receives citations from new papers that themselves have not been cited enough. Furthermore, while a citation network can be unavailable, the estimation of KPLM requires only the citation summaries of papers, which is arguably more robust.

[4]Kullback-Leibler divergence, used in (Mei and Zhai, 2008), is unsuitable to our task, as it is not formalised as ad-hoc retrieval (i.e., single query, multiple documents). Instead we compare multiple query models (MLE's of citing sentences) to a single document model (KPLM of the cited paper), making KL-divergence scores not comparable due to query specific entropy terms. See (Zhai, 2008) for a detailed analysis.

3.3.2 Top Sentence Re-ranking

As discussed in Section 3.2, a good summary should capture the most salient keywords of a paper, but also cover as many non-redundant keywords as possible. A summary built using our method is likely to contain citing sentences that concentrate on and repetitively cover salient keywords of the target paper, which may fall short in keywords diversity. Indeed, we can see in the top part of Table 4 that the summary of paper P05-1012 repetitively covers a single keyword, "Minimum Spanning Tree", while it fails to capture other key concepts.

To leverage the diversity in keywords captured in a summary, a simple heuristic is to select the next sentence from a pool of top ranked sentences least similar to the existing summary. From an information theoretic point of view, this amounts to choosing the next sentence that carries the most *extra* information (i.e., statistical surprise), w.r.t. the current contents of the summary. This formulation intuitively suggests that cross entropy, as a natural measure of statistical surprise, could again be employed.

We first need to abstract a citing sentence and the citation summary into probabilistic distributions before their cross entropy can be measured. Again we use unigram language modelling. Since both texts are small in size, data sparseness becomes a major issue, as nul dimensions in the MLE language models would make cross entropy not measurable. Smoothing as a way to alleviate data sparseness is thus required. Another issue that also arises from the texts' small size is the non-negligible amount of cross entropy contributed from non-content words in both texts (English stop words plus the two pseudo tokens: "targetanchor" and "otheranchor"). We therefore remove those non-content words prior to

language model construction to eliminate their noise in the cross entropy calculation. Experiments did support this design decision, and better results have been achieved with non-content words removed.

We perform Dirichlet Prior Smoothing (Zhai and Lafferty, 2001) to both the citing sentence MLE and the summary MLE using the KPLM of the paper as a background model using a Dirichlet Prior (DP) of 20. The choice of 20 has been based on the observation that citing sentences are short (32 words on average) and a large DP is prone to generate overly smoothed language models that are dominated by the KPLM, thus lack discriminative power. Here we choose to use this empirically selected DP parameter without attempting to fine-tune it for best results.

In summary, we implement a top sentence re-ranking heuristic that iteratively selects the next sentence to be appended to the existing summary whose smoothed language model is with the largest cross entropy (so it contains most extra information) with a smoothed language mode built for the summary at its current stage. We shall demonstrate how our top sentence re-ranking method introduces a major performance boost in the next section. For a quick inspection of the effectiveness of this method, compare the summaries constructed for paper P05-1012 with and without sentence re-reranking in Table 4. It shows that the summary constructed with sentence re-ranking covers key facts more comprehensively. The pseudo code for our re-ranking strategy is shown in Algorithm 1. It adopts a straightforward re-ranking approach that simply uses the top k+5 retrieved citing sentences in the previous step as the candidate pool; at each iteration, it selects the best sentence based on its cross entropy with the summary at the current stage. A more sophisticated re-ranking method is to combine the two cross entropy scores in some way (e.g., Maximal Marginal Relevance (Carbonell and Goldstein, 1998)) so that the final score for a citing sentence reflects its value in capturing salient keywords that have not yet been included in the summary. We leave the study of a more sophisticated re-ranking scheme for future work.

Algorithm 1 Top Sentence Re-ranking

```
1: function TopSentenceReranker
2:     k ← summary length limit
3:     top_sent ← top_k_plus_5_sents[0]
4:     es ← top_sent
5:     cp ← top_k_plus_5_sents - top_sent
6:     for s in cp do
7:         cp_lms[s] ← DPSmoothed(s)
8:     for i = 2 to k do
9:         es_lm ← DPSmoothed(es)
10:        s ← argmax_{s∈cp}(CE(cp_lms||es_lm))
11:        es ← es + s
12:        cp ← cp − s
13:        cp_lms ← cp_lms − cp_lms[s]
       return es
```

4 Experimental Setup

4.1 Evaluation Method

Following Qazvinian et al. (2008; 2010), we use the pyramid method (Nenkova and Passonneau, 2004) at sentence level to evaluate our system's performance. The pyramid score is a fact-based evaluation method that has been especially popular in evaluating extractive summarisation systems. It has been widely adopted because it incorporates both fact coverage and fact importance into the scoring process, which resonates well with the goals of summarisation (Qazvinian et al., 2010). More specifically, the pyramid method scores a summary using the ratio between the total facts weights of the facts it covers and that of an optimal summary. First a fact weights pyramid is built using some facts weighting method and each fact is subsequently put into its perspective pyramid tier. Qazvinian et al. (2008; 2010) built a weights pyramid for each paper and assigned each humanly discovered fact into a tier according to the number of citing sentences the fact occurs in that paper's citation summary. For example, fact f_i appearing in $|f_i|$ citing sentences in the citation summary of paper D is assigned to the tier $T_{|f_i|}$ in D's fact weights pyramid P_D. Let F_i denotes the number of facts in the summary ES in tier T_i of P_D. The total facts weights ES covers is calculated as:

$$W(ES)=\sum_{i=1}^{n} i \cdot F_i \quad (6)$$

where n is the highest tier of P_D. Let $ES_{optimal}$ be the optimal summary for D w.r.t. the summary length limit ($ES_{optimal}$ can be found using heuristic-driven exhaustive search). The pyramid score for ES is finally calculated as:

$$Score(ES)=W(ES)/W(ES_{optimal}) \quad (7)$$

Note again that we used exactly the same corpus and evaluation method as in (Qazvinian and Radev, 2008; Qazvinian et al., 2010), which makes our results directly comparable to those described in those papers. Furthermore, both papers report on performance of various baseline methods which are also directly comparable to ours (see next section). We compare our results with the current state-of-the-art; readers are encouraged to refer to (Qazvinian

Rank	Summary
KPLM without sentence re-ranking (Pyramid score: 0.23)	
1	3.1 decoding mcdonald et al (2005b) use the chu-liuedmonds (cle) algorithm to solve the maximum **spanning tree** problem.
2	thus far, the formulation follows mcdonald et al (2005b) and corresponds to the maximum **spanning tree** (mst) problem.
3	while we have presented signi cant improvements using additional constraints, one may won5even when caching feature extraction during training mcdonald et al (2005a) still takes approximately 10 minutes to train.
4	we have successfully replicated the state-of-the-art results for dependency parsing (mcdonald et al, 2005a) for both czech and english, using bayes point machines.
5	the search for the best parse can then be formalized as the search for the maximum **spanning tree** (mst) (mcdonald et al, 2005b).
KPLM with sentence re-ranking (Pyramid score: 0.73)	
1	3.1 decoding mcdonald et al (2005b) use the chu-liuedmonds (cle) algorithm to solve the maximum **spanning tree** problem.
2	to learn these structures we used online **large-margin** learning (mcdonald et al, 2005) that empirically provides state-of-the-art performance for czech.
3	while we have presented signi cant improvements using additional constraints, one may won5even when caching feature extraction during training mcdonald et al (2005a) still takes approximately 10 minutes to train.
4	mcdonald et al (2005a) introduce a dependency parsing framework which treats the task as searching for the **projective tree** that **maximises the sum of local dependency scores**.
5	we take as our starting point a re-implementation of mcdonald's state-of-the-art dependency parser (mcdonald et al, 2005a).

Table 4: Summaries of paper P05-1012 produced using KPLM. Key facts in citing sentences are highlighted and OCR and sentence segmentation errors have been retained as they originally appeared in the corpus.

and Radev, 2008; Qazvinian et al., 2010) for cross-referencing results from a broader set of systems.

4.2 Results and Discussion

Table 5 shows the pyramid score evaluation results for the 25 papers. To facilitate comparison and cross-referencing, the table has been formatted as close as possible to Table 7 in (Qazvinian and Radev, 2008) with figures in the Gold and C-LexRank columns directly copied over. Note that a Gold pyramid score less than 1 suggests that there are more facts than can be covered using k sentences for that paper's citation summary. It can be seen that KPLM based summarisation achieves quite comparable results (especially in terms of the median score) with C-LexRank, even without top sentence re-ranking. When the re-ranking is introduced, our system outperforms the current state-of-the-art C-LexRank by a measurable margin. Albeit the perceived differences in the results, a one-tailed Wilcoxon signed-rank test indicated that our results are not statistically superior at significance level 0.05 (Z=-1.22, P=0.11). A power analysis reveals that in order to achieve a statistically significant result on this small sample of 25 papers, a system would need to score a medium to large effect size (Cohen's d > 0.53), which is a challenging task considering C-LexRank's strong baseline performance. We hope this analysis can inform future studies using Qazvinian's 25 papers corpus. Nevertheless, it should be pointed out that our approach is not only substantially simpler than C-LexRank, it also yields more interpretable results.

We know of a more recent set of results reported in (Qazvinian et al., 2013), which again confirmed C-LexRank's state-of-the-art status with a mean pyramid score of 0.799 (cf. Table 6 in (Qazvinian et al., 2013)). However those results are not comparable with ours for the following reasons. First, Qazvinian et al. (2013) used a slightly different corpus with 30 papers (5 extra papers from the Conditional Random Field domain). Second, results were based on a summary length limit of 200 words, so roughly equivalent to 6.3 sentences per paper, giving evaluations an extra edge. Both changes boosted system performance in those evaluations, as evidenced by comparing Table 7 in (Qazvinian and Radev, 2008) and Table 6 in (Qazvinian et al., 2013).

Qazvinian et al. (2010) used the same corpus and evaluation method as our work; however the results have been presented as box plots (cf. Figure 1 in (Qazvinian et al., 2010)) from which only the five-number summary (i.e., minimum, lower quartile, median, upper quartile and maximum) of the pyramid scores can be reconstructed and consequently no significance test can be performed. Compared with the best performing variants of the system devised in (Qazvinian et al., 2010) based on unigrams, bigrams and trigrams, our system (KPLM+TSR) achieves a higher median score (0.86 vs. 0.80), as well as a lower score variation across the 25 papers.

An arbitrarily imposed constraint in the evaluations is the summary length limit, which may be changed to suit a specific application context. The summarisation task becomes increasingly more challenging when summary length limit is further tightened as this would require a summariser to pinpoint the best sentences from a potentially large cita-

Table 5: Summary pyramid score evaluation results with summary length limit $k = 5$.

tion summary. A desirable property of a good summariser is thus the ability in maintaining its performance while the task becomes increasingly demanding. To further evaluate KPLM's performance under increasingly more stringent summary length limits, we gathered the pyramid scores with summary length limit k decreasing from 5 to 1 and visualised the results in Figure 1. We can see that KPLM's performance decays quite gracefully as more stringent limits are imposed. Even under the harshest constraint with the summary length limit sets to 1, our system still managed a mean pyramid score of close to 0.6 across the 25 papers. Indeed, it can be seen that the variance in pyramid scores gradually spreads wider (the dark band in the figure marks out 95% confidence interval of the mean scores), but this phenomenon is expected as the error margin also shrinks along with the summary length limit.

5 Conclusion and Future Work

We designed a statistical framework to summarise scientific papers, using methods rooted in quantitative statistics and information theory. We first built a keyword profile for a paper using a quantitative statistical method that captures its characterising keywords that are both overly represented and relatively exclusively used in the paper's citation summary. We then used the keyword profile of a paper to build a discriminative pseudo unigram language model that directly incorporates words' salience in characterising a paper's main contributions into pseudo generative probabilities. Based on the fact that a paper's KPLM represents an effective language model from which pseudo citing sentences with good coverage of important keywords could be sampled, we cast the task of summarisation as language model divergence based IR. Finally, we implemented an information-driven sentence reranking algorithm that can effectively leverage diversity in keyword coverage in summaries produced. Experimental results show that our approach outperforms the current state-of-the-art systems in scientific paper summarisation, which is also with good resilience to more stringent summary length limits.

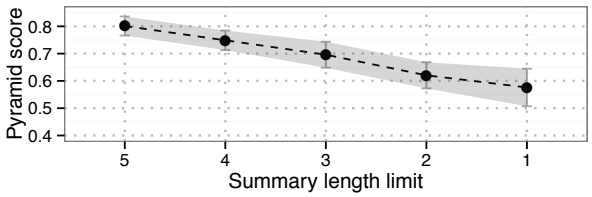

Figure 1: Pyramid scores of KPLM+TSR under different summary length limits.

In the future, we plan to extend our approach to higher order n-grams and see whether larger information units (phrases) would help boost summarisation performance. We also plan to apply our method to the problem of multi-document summarisation. In particular, we are very interested to test our system's performance on automatically generating a technical survey of a scientific paradigm, which thanks to the authors of (Mohammad et al., 2009; Qazvinian et al., 2013), has been established as a well-defined task with high-quality open data. Finally, while we have shown that our approach is effective in summarising a scientific paper's major contributions using its citation summary text, further experiments are required to test our method's effectiveness on more generic summarisation tasks and texts genres.

Acknowledgement

We thank Vahed Qazvinian for making the 25 paper summarisation corpus publicly available; without it, our formal evaluations would have been impossible. We also thank the anonymous reviewers for their highly constructive comments.

Abstract

Automatic headline generation is a sub-task of document summarization with many reported applications. In this study we present a sequence-prediction technique for learning how editors title their news stories. The introduced technique models the problem as a discrete optimization task in a feature-rich space. In this space the global optimum can be found in polynomial time by means of dynamic programming. We train and test our model on an extensive corpus of financial news, and compare it against a number of baselines by using standard metrics from the document summarization domain, as well as some new ones proposed in this work. We also assess the readability and informativeness of the generated titles through human evaluation. The obtained results are very appealing and substantiate the soundness of the approach.

1 Introduction

Document summarization, also known as text summarization, is the process of automatically abridging text documents. Although traditionally the final objective of text summarization is to produce a paragraph or abstract that summarizes a rather large collection of texts (Mani and Maybury, 1999; Das and Martins, 2007; Nenkova and McKeown, 2012), the task of producing a very short summary comprised of 10–15 words has also been broadly studied. There have been many reported practical applications for this endeavor, most notably, efficient web browsing on hand-held devices (Buyukkokten et al., 2001), generation of TV captions (Linke-Ellis, 1999), digitization of newspaper articles that have uninformative headlines (De Kok, 2008), and headline generation in one language based on news stories written in another (Banko et al., 2000; Zajic et al., 2002).

In general terms, a headline of a news article can be defined as a short statement that gives a reader a general idea about the main contents of the story it entitles (Borko and Bernier, 1987; Gattani, 2007). The objective of our study is to develop a novel technique for generating informative headlines for news articles, albeit to conduct experiments we focused on finance articles written in English. In this work we make a number of contributions concerning statistical models for headline generation, training of the models, and their evaluation, specifically:

- We propose a model that learns how an editor generates headlines for news articles, where a headline is regarded as a compression of its article's text. Our model significantly differs from others in the way it represents possible headlines in a feature-rich space. The model tries to learn how humans discern between good and bad compressions. Furthermore, our model can be trained with any monolingual corpus consisting of titled articles, because it does not request special conditions on the headlines' structure or provenance.
- We suggest a slight change of the Margin Infused Relaxed Algorithm (Crammer and Singer, 2003) to fit our model, which yields better empirical results.

* Work done during an internship at Yahoo Labs.

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 133–142,
Denver, Colorado, May 31 – June 5, 2015.

- We present a simple and elegant algorithm that runs in polynomial time and finds the global optimum of our objective function. This represents an important advantage of our proposal because many former techniques resort to heuristic-driven search algorithms that are not guaranteed to find the global optimum.

- With the intention of overcoming several problems suffered by traditional metrics for automatically evaluating the quality of proposed headlines, we propose two new evaluation metrics that correlate with ratings given by human annotators.

2 Related work

There has been a significant amount of research about headline generation. As noted by Gattani (2007), it is possible to identify three main trends of techniques broadly employed through different studies:

Rule-based approaches. These methods make use of handcrafted linguistically-based rules for detecting or compressing important parts in a document. They are simple and lightweight, but fail at exploring complex relationships in the text. The most representative model for this group is the Hedge Trimmer (Dorr et al., 2003).

Statistics-based approaches. These methods make use of statistical models for learning correlations between words in headlines and in the articles. The models are fit under supervised learning environments and therefore need large amounts of labelled data. One of the most influential works in this category is the Naïve Bayes approach presented by Banko et al. (2000), and augmented in works such as Jin and Hauptmann (2001; Zajic et al. (2002). The use of statistical models for learning pruning-rules for parse trees has also been studied, the most notable work on this area is presented in Knight and Marcu (2001) and extended by Unno et al. (2006).

Summarization-based approaches. Headlines can be regarded as very short summaries, therefore traditional summarization methods could be adapted for generating one-line compressions; the common trend consists in performing multiple or combined steps of sentence selection and compression (Hajime et al., 2013; Martins and Smith, 2009). The main problem with these approaches is that they make use of techniques that were not initially devised for generating compressions of less than 10% of the original content, which directly affects the quality of the resulting summary (Banko et al., 2000). It is noteworthy to highlight that most of the modern summarization-based techniques opt for generating headlines just by recycling and reordering words present in the article, which also raises the risk of losing or changing the contextual meaning of the reused words (Berger and Mittal, 2000).

An area that deals with a target similar to headline generation is multi-sentence compression, where its objective is to produce a single short phrase that abridges a set of sentences that conform a document. The main difference between both practices is that headline generation is more strict about the length of the generated output, which should consist of about eight tokens (Banko et al., 2000), whereas the latter accepts longer results. One of the most recent and competitive approaches for multi-sentence compression is described by Filippova (2010).

3 Background on sequence prediction

Sequence models have been broadly used for many Natural Language Processing tasks, such as identification of sentence boundaries (Reynar and Ratnaparkhi, 1997), named entity recognition (McCallum and Li, 2003), part of speech tagging (Kupiec, 1992), dependency tree parsing (McDonald et al., 2005), document summarization (Shen et al., 2007), and single-sentence compression (McDonald, 2006; Nomoto, 2007). These models are formalizations of relationships between observed sequences of variables and predicted categories for each one. Mathematically, let $\mathcal{X} = \{x_1, x_2, ..., x_N\}$ be a finite set of possible atomic observations, and let $\mathcal{Y} = \{y_1, y_2, ..., y_M\}$ be a finite set of possible categories that each atomic observation could belong to.

Statistical sequence models try to approximate a probability distribution P with parameters ϕ capable of predicting for any sequence of n observations $\boldsymbol{x} \in \mathcal{X}^n$, and any sequence of assigned categories per observation $\boldsymbol{y} \in \mathcal{Y}^n$, the probability $P(\boldsymbol{y}|\boldsymbol{x}; \phi)$. The final objective of these models is to predict the

most likely sequence of categories $\hat{\boldsymbol{y}} \in \mathcal{Y}^n$ for any arbitrary observation sequence, which can be expressed as:

$$\hat{\boldsymbol{y}} = \underset{\boldsymbol{y} \in \mathcal{Y}^n}{\arg\max}\ P(\boldsymbol{y}|\boldsymbol{x}; \phi)$$

There have been many proposals for modelling the probability distribution P. Some of the most popular proposals are Hidden Markov Models (Rabiner and Juang, 1986), local log-linear classifiers, Maximum Entropy Markov Models (McCallum et al., 2000), and Conditional Random Fields (Lafferty et al., 2001). The following two sections will briefly introduce the latter, together with a widely used improvement of the model.

3.1 Conditional Random Fields (CRF)

As presented by Lafferty et al. (2001), CRF are sequence prediction models where no Markov assumption is made on the sequence of assigned categories $\boldsymbol{y}$, but a factorizable global feature function is used so as to transform the problem into a log-linear model in feature space. Formally, CRF model the probability of a sequence in the following way:

$$P(\boldsymbol{y}|\boldsymbol{x}; \phi) = \frac{exp\{\boldsymbol{w} \cdot \boldsymbol{F}(\boldsymbol{x}, \boldsymbol{y})\}}{Z(\boldsymbol{x})}$$

Where $\phi = \{\boldsymbol{w}\}$ and $\boldsymbol{w} \in \mathbb{R}^m$ is a weight vector, $\boldsymbol{F} : \mathcal{X}^n \times \mathcal{Y}^n \rightarrow \mathbb{R}^m$ is a global feature function of m dimensions, and $Z(\boldsymbol{x})$ is a normalization function. Moreover, the global feature function is defined in the following factored way:

$$\boldsymbol{F}(\boldsymbol{x}, \boldsymbol{y}) = \sum_{i=1}^{n} \boldsymbol{f}(\boldsymbol{x}, i, y_{i\text{-}1}, y_i)$$

where $\boldsymbol{f} : \mathcal{X}^* \times \mathbb{N}^+ \times \mathcal{Y} \times \mathcal{Y} \rightarrow \mathbb{R}^m$ is a local feature function. Due to this definition, it can be shown that the decoding of CRF is equivalent to:

$$\hat{\boldsymbol{y}} = \underset{\boldsymbol{y} \in \mathcal{Y}^n}{\arg\max}\ \boldsymbol{w} \cdot \boldsymbol{F}(\boldsymbol{x}, \boldsymbol{y})$$

Which is a linear classification in a feature space. The fact that the local feature function $\boldsymbol{f}$ only depends on the last two assigned categories allows the global optimum of the model to be found by means of a tractable algorithm, whereas otherwise it would be necessary to explore all the $|\mathcal{Y}|^n$ possible solutions.

3.2 CRF with state sequences

Since CRF do not assume independence between assigned categories, it is possible to extend the local feature function for enabling it to keep more information about previous assigned categories and not just the last category. These models are derived from the work on weighted automata and transducers presented in studies such as Mohri et al. (2002). Let $\mathcal{S}$ be a state space, s_0 be a fixed initial empty state, and let function $g : \mathcal{S} \times \mathcal{X}^* \times \mathbb{N}^+ \times \mathcal{Y} \rightarrow \mathcal{S}$ model state transitions. Then the global feature function can be redefined as:

$$\boldsymbol{F}(\boldsymbol{x}, \boldsymbol{y}) = \sum_{i=1}^{n} \boldsymbol{f}(\boldsymbol{x}, i, s_{i\text{-}1}, y_i), \quad s_i = g(s_{i\text{-}1}, \boldsymbol{x}, i, y_i)$$

This slight change adds a lot of power to CRF because it provides the model with much more information that it can use for learning complex relations. Finally, the best candidate can be found by solving:

$$\hat{\boldsymbol{y}} = \underset{\boldsymbol{y} \in \mathcal{Y}^n}{\arg\max}\ \boldsymbol{w} \cdot \left[\sum_{i=1}^{n} \boldsymbol{f}(\boldsymbol{x}, i, s_{i\text{-}1}, y_i) \right] \qquad (1)$$

4 Model description: headlines as bitmaps

We model headline generation as a sequence prediction task. In this manner a news article is seen as a series of observations, where each is a possible token in the document. Furthermore, each observation can be assigned to one of two categories: in-headline, or not in-headline. Note that this approach allows a generated headline to be interpreted as a bitmap over the article's tokens.

If this set-up was used for a CRF model, the standard local feature function $\boldsymbol{f}(\boldsymbol{x}, i, y_{i\text{-}1}, y_i)$ would only be able to know whether the previous token was taken or not, which would not be very informative. For solving the problem we integrate a state sequence into the model, where a state $s \in \mathcal{S}$ holds the following information:

- The last token that was chosen as part of the headline.
- The part-of-speech tag[1] of the second-to-last word that was selected as part of the headline.

[1] We used the set of 45 tags from the Penn Treebank Tag-Set.

- The number of words already chosen to be part of the headline, which could be zero.

Therefore, the local feature function $\boldsymbol{f}(\boldsymbol{x}, i, s_{i\text{-}1}, y_i)$ will not only know about the whole text and the current token x_i, whose category y_i is to be assigned, but it will also hold information about the headline constructed so far. In our model, the objective of the local feature function is to return a vector that describes in an abstract euclidean space the outcome of placing, or not placing, token x_i in the headline, provided that the words previously chosen form the state $s_{i\text{-}1}$. We decide to make this feature vector consist of 23 signals, which only fire if the token x_i is placed in the headline (i.e., $y_i = 1$). The signals can be grouped into the following five sets:

Language-model features: they assess the grammaticality of the headline being built. The first feature is the bigram probability of the current token, given the last one placed on the headline. The second feature is the trigram probability of the PoS tag of the current token, given the tags of the two last tokens on the headline.

Keyword features: binary features that help the model detect whether the token under analysis is a salient word. The document's keywords are calculated as a preprocessing step via TF-IDF weighting, and the features fire depending on how good or bad the current token x_i is ranked with respect to the others on the text.

Dependency features: in charge of informing the model about syntactical dependencies among the tokens placed on the headline. For this end the dependency tree of all the sentences in the news article are computed as a pre-processing step[2].

Named-entity features: help the system identify named entities[3] in the text, including those that are composed of contiguous tokens.

Headline-length features: responsible for enabling the model to decide whether a headline is too short or too long. As many previous studies report, an ideal headline must have from 8 to 10 tokens (Banko et al., 2000). Thus, we include three binary features that correspond to the following conditions: (1) if the headline length so far is less than or equal to seven; (2) if the headline length so far is greater than or equal to 11; (3) if the token under analysis is assigned to the headline, which is a bias feature.

[2]We use the Stanford toolkit for computing parse trees.

[3]We only use PER, LOC, and ORG as entity annotations.

5 Decoding the model

Decoding the model involves solving equation (1) being given a weight vector $\boldsymbol{w}$, whose value stays unchanged during the process. A naive way of solving the optimization problem would be to try all possible $|\mathcal{Y}|^n$ sequence combinations, which would lead to an intractable procedure. In order to design a polynomial algorithm that finds the global optimum of the aforementioned formula, the following four observations must be made:

(1) Our model is designed so that the local feature function only fires when a token is selected for being part of a headline. Then, when evaluating an arbitrary solution $\boldsymbol{y}$, only the tokens placed on the headline must be taken into account.

(2) When applying the local feature function to a particular token x_i (assuming $y_i = 1$), the result of the function will vary only depending on the provided previous state $s_{i\text{-}1}$; all the other parameters are fixed. Moreover, a new state s_i will be generated, which in turn will include token x_i. This implies that the entire evaluation of a solution can be completely modeled as a sequence of state transitions; i.e., it becomes possible to recover a solution's bitmap from a sequence of state transitions and vice-versa.

(3) When analyzing the local feature function at any token x_i, the amount of different states $s_{i\text{-}1}$ that can be fed to the function depend solely on the tokens taken before, for which there are $2^{i\text{-}1}$ different combinations. Nevertheless, because a state only holds three pieces of information, a better upper-bound to the number of possible reachable states is equal to $i^2 \times |PoS|$, which accounts to: all possible candidates for the last token chosen before x_i, times all possible combinations of total number of tokens taken before x_i, times all possible PoS tags of the one-before-last token taken before x_i.

(4) The total amount of producible states in the whole text is equal to $\sum_{i=1}^{n} i^2 \times |PoS| = O(n^3 \times |PoS|)$. If the model is also constrained to produce headlines containing no more than H tokens, the asymptotic bound drops to $O(H \times n^2 \times |PoS|)$.

The final conclusion of these observations is as follows: since any solution can be modelled as a chain of state sequences, the global optimum can be found by generating all possible states and fetching the one that, when reached from the initial state, yields the maximum score. This task is achievable with a number of operations linearly proportional to the number of possible states, which at the same time is polynomial with respect to the number of tokens in the document. In conclusion, the model can be decoded in quadratic time. The pseudo-code in algorithm 1 gives a sketch of a $O(H \times n^2 \times |PoS|)$ bottom-up implementation.

Algorithm 1 Sketch of a bottom-up algorithm for finding the top-scoring state s^* that leads to the global optimum of our model's objective function. It iteratively computes two functions: $\pi(i, l)$, which returns the set of all reachable states that correspond to headlines having token-length l and finishing with token x_i, and $\alpha(s)$, which returns the maximum score that can be obtained by following a chain of state sequences that ends in the provided state, and starts on s_0.

//Constants.
$H \leftarrow$ Max. number of allowed tokens in headlines.
$n \leftarrow$ Number of tokens in the document.

    for i in $\{l, ..., n\}$ **do**
        for j in $\{l-1, ..., i-1\}$ **do**
            for z in $\pi(j, l-1)$ **do**
                $s \leftarrow g(z, x, i, 1)$
                $s_{\text{score}} \leftarrow \alpha(z) + \boldsymbol{w} \cdot \boldsymbol{f}(\boldsymbol{x}, i, z, 1)$
                $\pi(i, l) \leftarrow \pi(i, l) \cup \{s\}$
                $\alpha(s) \leftarrow max(\alpha(s), s_{\text{score}})$
                if $\alpha(s) > \alpha(s^*)$ **then**
                    $s^* \leftarrow s$

6 Training the model: learning what human-generated headlines look like

The global feature function $\boldsymbol{F}$ is responsible for taking a document and a bitmap, and producing a vector that describes the candidate headline in an abstract feature space. We defined the feature function so it only focuses on evaluating how a series of tokens that comprise a headline relate to each other and to the document as a whole. This implies that if $\boldsymbol{h} = \{h_1, h_2, ..., h_k\}$ is the tokenized form of any arbitrary headline consisting of k tokens, and we define vectors $\boldsymbol{a} \in \mathcal{X}^{k+n}$ and $\boldsymbol{b} \in \mathcal{Y}^{k+n}$ as:

$$\boldsymbol{a} = \{h_1, h_2, ..., h_k, x_1, x_2, ..., x_n\}$$

$$\boldsymbol{b} = \{1_1, 1_2, ..., 1_k, 0_1, 0_2, ..., 0_n\}$$

where $\boldsymbol{a}$ is the concatenation of $\boldsymbol{h}$ and $\boldsymbol{x}$, and $\boldsymbol{b}$ is a bitmap for only selecting the actual headline tokens, it follows that the feature vector that results from calling the global feature function, which we define as

$$\boldsymbol{u} = \boldsymbol{F}(\boldsymbol{a}, \boldsymbol{b}) \tag{2}$$

is equivalent to a description of how headline $\boldsymbol{h}$ relates to document $\boldsymbol{x}$. This observation is the core of our learning algorithm, because it implies that it is possible to "insert" a human-generated headline in the text and get its description in the abstract feature space induced by $\boldsymbol{F}$. The objective of the learning process will consist in molding a weight vector $\boldsymbol{w}$, such that it makes the decoding algorithm favor headlines whose descriptions in feature space resemble the characteristics of human-generated titles.

For training the model we follow the on-line learning schemes presented by Collins (2002) and applied in studies that deal with CRF models with state sequences, such as the dependency parsing model of McDonald et al. (2005). The learning framework consists of an averaged perceptron that iteratively sifts through the training data and performs the following error-correction update at each step:

$$\boldsymbol{w}^* \leftarrow \boldsymbol{w} + \tau \times (\boldsymbol{u} - \hat{\boldsymbol{v}}), \quad \hat{\boldsymbol{v}} = \boldsymbol{F}(\boldsymbol{x}, \hat{\boldsymbol{y}})$$

where $\boldsymbol{u}$ is the vector defined in equation (2), $\hat{\boldsymbol{y}}$ is the result of solving equation (1) with the current weight

vector, and $\tau \in \mathbb{R}$ is a learning factor. We try three different values for τ, which lead to the following learning algorithms:

- **Perceptron:** $\tau = 1$
- **MIRA:** $\tau = max\left(0, \frac{1-\boldsymbol{w}\cdot(\boldsymbol{u}-\hat{\boldsymbol{v}})}{||\boldsymbol{u}-\hat{\boldsymbol{v}}||^2}\right)$
- **Forced-MIRA:** $\tau = \frac{1-\boldsymbol{w}\cdot(\boldsymbol{u}-\hat{\boldsymbol{v}})}{||\boldsymbol{u}-\hat{\boldsymbol{v}}||^2}$

The first value is a simple averaged perceptron as presented by Collins (2002), the second value is a Margin Infused Relaxed Algorithm (MIRA) as presented by Crammer and Singer (2003), and the third value is a slight variation to the MIRA update. We propose it for making the algorithm acknowledge that the objective feature vector $\boldsymbol{u}$ cannot be produced from document $\boldsymbol{x}$, and thus force an update at every step. The reason for this is that if $\boldsymbol{w} \cdot \boldsymbol{u} > \boldsymbol{w} \cdot \hat{\boldsymbol{v}}$, then MIRA sets $\tau = 0$, because an error was not made (i.e. the human-generated headline got a higher score than all of the others). Nevertheless, we observed in our experiments that this behaviour biases the process towards learning weights that exploit patterns that can occur in human-generated titles, but are almost never observed in the titles that can be generated by our model, which hinders the quality of the final headlines.

7 Automatic evaluation set-up

7.1 Evaluation metrics

For performing an automatic evaluation of the headlines generated by our system we follow the path taken by related work such as Zajic et al. (2004) and use a subset of the ROUGE metrics for comparing candidate headlines with reference ones, which have been proven to strongly correlate with human evaluations (Lin, 2003; Lin, 2004).

We decide to use as metrics ROUGE-1, ROUGE-2, and ROUGE-SU. We also propose as an experimental new metric a weighted version of ROUGE-SU, which we name ROUGE-WSU. The rationale of our proposal is that ROUGE-SU gives the same importance to all skip-bigrams extracted from a phrase no matter how far apart they are. We address the problem by weighting each shared skip-gram between phrases by the inverse of the token's average gap distance. Formally:

$$Sim(R,C) = \frac{\sum_{(a,b)\in su(R)\cap su(C)} \frac{2}{dist_R(a,b)+dist_C(a,b)}}{\sum_{(a,b)\in su(R)} \frac{1}{dist_R(a,b)}}$$

Where function $dist_H(a,b)$ returns the skip distance between tokens "a" and "b" in headline H, and $su(H)$ returns all skip-bigrams in headline H.

With the objective of having a metric capable of detecting abstract concepts in phrases and comparing headlines at a semantic level, we resort to Latent Semantic Indexing (LSI) (Deerwester et al., 1990). We use the method for extracting latent concepts from our training corpus so as to be able to represent text in an abstract latent space. We then compute the similarity of a headline with respect to a news article by calculating the cosine similarity of their vector representations in latent space.

7.2 Baselines

In order to have a point of reference for interpreting the performance of our model, we implement four baseline models. We arbitrarily decide to make all the baselines generate, if possible, nine-token-long headlines, where the last token must always be a period. This follows from the observation that good headlines must contain about eight tokens (Banko et al., 2000). The implemented baselines are the following:

Chunked first sentence: the first eight tokens from the article, plus a period at the end.

Hidden Markov Model: as proposed by Zajic et al. (2002), but adapted for producing eight-token sentences, plus an ending period.

Word Graphs: as proposed by Filippova (2010). This is a state-of-the-art multi-sentence compression algorithm. To ensure it produces headlines as output, we keep the shortest path in the graph with length equal to or greater than eight tokens. An ending period is appended if not already present. Note that the original algorithm would produce the top-k shortest paths and keep the one with best average edge weight, not caring about its length.

Keywords: the top eight keywords in the article, as ranked by TF-IDF weighting, sorted in descending order of relevance. This is not a real baseline

because it does not produce proper headlines, but it is used for naively trying to maximize the achievable value of the evaluation metrics. This is based on the assumption that keywords are the most likely tokens to occur in human-generated headlines.

7.3 Experiments and Results

We trained our model with a corpus consisting of roughly 1.3 million financial news articles fetched from the web, written in English, and published on the second half of 2012. We decided to add three important constraints to the learning algorithm which proved to yield positive empirical results:

(1) Large news articles are simplified by eliminating their most redundant or least informative sentences. For this end, the text ranking algorithm proposed by Mihalcea and Tarau (2004) is used for discriminating salient sentences in the article. Furthermore, a news article is considered large if it has more than 300 tokens, which corresponds to the average number of words per article in our training set.

(2) Because we observed that less than 2% of the headlines in the training set contained more than 15 tokens, we constraint the decoding algorithm to only generate headlines consisting of 15 or fewer tokens.

(3) We restrain the decoding algorithm from placing symbols such as commas, quotation marks, and question marks on headlines. Nonetheless, only headlines that end with a period are considered as solutions; otherwise the model tends to generate non-conclusive phrases as titles.

For automated testing purposes we use a training set consisting of roughly 12,000 previously unseen articles, which were randomly extracted from the initial dataset before training. The evaluation consisted in producing seven candidate headlines per article: one for each of the four baselines, plus one for each of the three variations of our model (each differing solely on the scheme used to learn the weight vector). Then each candidate is compared against the article's reference headline by means of the five proposed metrics.

Table 1 summarizes the obtained results of the models with respect to the ROUGE metrics. The results show that our model, when trained with our proposed forced-MIRA update, outperforms all the other baselines on all metrics, except for ROUGE-2, where all differences are statistically significant when assessed via a paired t-test ($p < 0.001$). Also, as initially intended, the keywords baseline does produce better scores than all the other methods, therefore it is considered as a naive upper-bound. It must be highlighted that all the numbers on the table are rather low, this occurs because, as noted by Zajic et al. (2002), humans tend to use a very different vocabulary and writing-style on headlines than on articles. The effect of this is that our methods and baselines are not capable of producing headlines with wordings strongly similar to human-written ones, which as a consequence makes it almost impossible to obtain high ROUGE scores.

	R-1	R-2	R-SU	R-WSU

Keywords	**0.313**	0.021	**0.112**	**0.148**

Table 1: Result of the evaluation of our models and baselines with respect to ROUGE metrics.

For having a more objective assessment of our proposal, we carried out a human evaluation of the headlines generated by our model when trained with the f-MIRA scheme and the word graphs approach by Filippova (2010). For this purpose, 100 articles were randomly extracted from the test set and their respective candidate headlines were generated. Then different human raters were asked to evaluate on a Likert scale, from 1 to 5, both the grammaticality and informativeness of the titles. Each article-headline pair was annotated by three different raters. The median of their ratings was chosen as a final mark. As a reference, the raters were also asked to annotate the actual human-generated headlines from the articles, although they were not informed about the provenance of the titles. We measured inter-judge agreement by means of their Intra-Class Correlation (ICC) (Cicchetti, 1994). The ICC for grammaticality was 0.51 ± 0.07, which represents fair agreement, and the ICC for informativeness was 0.63 ± 0.05, which represents substantial agreement.

Table 2 contains the results of the models with

	H. Len.	LSI	Gram.	Inf.
Perceptron	10.096	0.446	–	–

Table 2: Result of the evaluation of our models and baselines with LSI document similarity, grammaticality and informativeness as assessed by human raters, and average headline length.

respect to the LSI document similarity metric, and the human evaluations for grammaticality and informativeness. For exploratory purposes the table also contains the average length for the generated headlines of each of the models (which also counts the imposed final period). The results in this table are satisfying: with respect to LSI document similarity, our model outperforms all of the baselines and its value is close to the one achieved by human-generated headlines. On the other hand, the human evaluations are middling: the word-graphs method produces more readable headlines, but our model proves to be more informative because it does better work at detecting abstract word relationships in the text. All differences in this table are statistically significant when computed as paired t-tests ($p < 0.001$).

It is worth noting that the informativeness of human-generated headlines did not get a high score. The reason for this is the fact that editors tend to produce rather sensationalist or partially informative titles so as to attract the attention of readers and engage them to read the whole article; human raters penalized the relevance of such headlines, which was reflected on this final score.

Finally, table 3 contains the mutual correlation between automated and manual metrics. The first thing to note is that none of the used metrics proved to be good for assessing grammaticality of headlines. It is also worth noting that our proposed metric ROUGE-WSU performs as well as the other ROUGE metrics, and that the proposed LSI document similarity does not prove to be as strong a metric as the others.

	R-1	R-2	R-SU	R-WSU	LSI-DS

8 Conclusions and Discussion

In this study we proposed a CRF model with state transitions. The model tries to learn how humans title their articles. The learning is performed by means of a mapping function that, given a document, translates headlines to an abstract feature-rich space, where the characteristics that distinguish human-generated titles can be discriminated. This abstraction allows our model to be trained with any monolingual corpus of news articles because it does not impose conditions on the provenance of stories' headlines –i.e, our model maps reference headlines to a feature space and only learns what abstract properties characterize them. Furthermore, our model allows defining the task of finding the best possible producible headline as a discrete optimization problem. By doing this each candidate headline is modelled as a path in a graph of state sequences, thus allowing the best-scoring path to be found in polynomial time by means of dynamic programming. Our results, obtained through reliable automatic and human-assessed evaluations, provide a proof of concept for the soundness of our model and its capabilities. Additionally, we propose a new evaluation metric, ROUGE-WSU, which, as shown in table 3, correlates as good as traditional ROUGE metrics with human evaluations for informativeness of headlines.

The further work we envisage for augmenting our research can be grouped in the following areas:

- Exploring more advanced features that manage to detect abstract semantic relationships or discourse flows in the compressed article.
- Complementing our system with a separate translation model capable of transforming to "Headlinese" the titles generated with the language used in the bodies of articles.
- Attempting to achieve a more objective evaluation of our generated headlines, through the use of semantic-level measures.

Abstract

We present a novel method for aligning a sequence of instructions to a video of someone carrying out a task. In particular, we focus on the cooking domain, where the instructions correspond to the recipe. Our technique relies on an HMM to align the recipe steps to the (automatically generated) speech transcript. We then refine this alignment using a state-of-the-art visual food detector, based on a deep convolutional neural network. We show that our technique outperforms simpler techniques based on keyword spotting. It also enables interesting applications, such as automatically illustrating recipes with keyframes, and searching within a video for events of interest.

1 Introduction

In recent years, there have been many successful attempts to build large "knowledge bases" (KBs), such as NELL (Carlson et al., 2010), KnowItAll (Etzioni et al., 2011), YAGO (Suchanek et al., 2007), and Google's Knowledge Graph/ Vault (Dong et al., 2014). These KBs mostly focus on declarative facts, such as "Barack Obama was born in Hawaii". But human knowledge also encompasses procedural information not yet within the scope of such declarative KBs – instructions and demonstrations of how to dance the tango, for example, or how to change a tire on your car. A KB for organizing and retrieving such procedural knowledge could be a valuable resource for helping people (and potentially even robots – e.g., (Saxena et al., 2014; Yang et al., 2015)) learn to perform various tasks.

In contrast to declarative information, procedural knowledge tends to be inherently multimodal. In particular, both language and perceptual information are typically used to parsimoniously describe procedures, as evidenced by the large number of "how-to" videos and illustrated guides on the open web. To automatically construct a multimodal database of procedural knowledge, we thus need tools for extracting information from both textual and visual sources. Crucially, we also need to figure out how these various kinds of information, which often complement and overlap each other, fit together to a form a structured knowledge base of procedures.

As a small step toward the broader goal of aligning language and perception, we focus in this paper on the problem of aligning video depictions of procedures to steps in an accompanying text that corresponds to the procedure. We focus on the cooking domain due to the prevalence of cooking videos on the web and the relative ease of interpreting their recipes as linear sequences of canonical actions. In this domain, the textual source is a user-uploaded recipe attached to the video showing the recipe's execution. The individual steps of procedures are cooking actions like "peel an onion", "slice an onion", etc. However, our techniques can be applied to any domain that has textual instructions and corresponding videos, including videos at sites such as youtube.com, howcast.com, howdini.com or videojug.com.

The approach we take in this paper leverages the fact that the speech signal in instructional videos is often closely related to the actions that the person is performing (which is not true in more general

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 143–152,
Denver, Colorado, May 31 – June 5, 2015.

videos). Thus we first align the instructional steps to the speech signal using an HMM, and then refine this alignment by using a state of the art computer vision system.

In summary, our contributions are as follows. First, we propose a novel system that combines text, speech and vision to perform an alignment between textual instructions and instructional videos. Second, we use our system to create a large corpus of 180k aligned recipe-video pairs, and an even larger corpus of 1.4M short video clips, each labeled with a cooking action and a noun phrase. We evaluate the quality of our corpus using human raters. Third, we show how we can use our methods to support applications such as within-video search and recipe auto-illustration.

2 Data and pre-processing

We first describe how we collected our corpus of recipes and videos, and the pre-processing steps that we run before applying our alignment model. The corpus of recipes, as well as the results of the alignment model, will be made available for download at `github.com/malmaud/whats_cookin`.

2.1 Collecting a large corpus of cooking videos with recipes

We first searched Youtube for videos which have been automatically tagged with the Freebase mids /m/01mtb (Cooking) and /m/0p57p (recipe), and which have (automatically produced) English-language speech transcripts, which yielded a collection of 7.4M videos. Of these videos, we kept the videos that also had accompanying descriptive text, leaving 6.2M videos.

Sometimes the recipe for a video is included in this text description, but sometimes it is stored on an external site. For example, a video's text description might say "Click here for the recipe". To find the recipe in such cases, we look for sentences in the video description with any of the following keywords: "recipe", "steps", "cook", "procedure", "preparation", "method". If we find any such tokens, we find any URLs that are mentioned in the same sentence, and extract the corresponding document, giving us an additional 206k documents. We then combine the original descriptive text with any additional text that we retrieve in this way.

Class	Precision	Recall	F1
Background	0.97	0.95	0.96
Ingredient	0.93	0.95	0.94
Recipe step	0.94	0.95	0.94

Table 1: Test set performance of text-based recipe classifier.

Finally, in order to extract the recipe from the text description of a video, we trained a classifier that classifies each sentence into 1 of 3 classes: *recipe step*, *recipe ingredient*, or *background*. We keep only the videos which have at least one ingredient sentence and at least one recipe sentence. This last step leaves us with 180,000 videos.

To train the recipe classifier, we need labeled examples, which we obtain by exploiting the fact that many text webpages containing recipes use the machine-readable markup defined at `http://schema.org/Recipe`. From this we extract 500k examples of recipe sentences, and 500k examples of ingredient sentences. We also sample 500k sentences at random from webpages to represent the non-recipe class. Finally, we train a 3-class naïve Bayes model on this data using simple bag-of-words feature vectors. The performance of this model on a separate test set is shown in Table 1.

2.2 Parsing the recipe text

For each recipe, we apply a suite of in-house NLP tools, similar to the Stanford Core NLP pipeline. In particular, we perform POS tagging, entity chunking, and constituency parsing (based on a re-implementation of (Petrov et al., 2006)).[1] Following (Druck and Pang, 2012), we use the parse tree structure to partition each sentence into "micro steps". In particular, we split at any token categorized by the parser as a conjunction only if that token's parent in the sentence's constituency parse is a verb phrase. Any recipe step that is missing a verb is considered noise and discarded.

We then label each recipe step with an optional action and a list of 0 or more noun chunks. The ac-

[1] Sometimes the parser performs poorly, because the language used in recipes is often full of imperative sentences, such as "Mix the flour", whereas the parser is trained on newswire text. As a simple heuristic for overcoming this, we classify any token at the beginning of a sentence as a verb if it lexically matches a manually-defined list of cooking-related verbs.

tion label is the lemmatized version of the head verb of the recipe step. We look at all chunked noun entities in the step which are the direct object of the action (either directly or via the preposition "of", as in "Add a cup of flour").

We canonicalize these entities by computing their similarity to the list of ingredients associated with this recipe. If an ingredient is sufficiently similar, that ingredient is added to this step's entity list. Otherwise, the stemmed entity is used. For example, consider the step "Mix tomato sauce and pasta"; if the recipe has a known ingredient called "spaghetti", we would label the action as "mix" and the entities as "tomato sauce" and "spaghetti", because of its high semantic similarity to "pasta". (Semantic similarity is estimated based on Euclidean distance between word embedding vectors computed using the method of (Mikolov et al., 2013) trained on general web text.)

In many cases, the direct object of a transitive verb is elided (not explicitly stated); this is known as the "zero anaphora" problem. For example, the text may say "Add eggs and flour to the bowl. Mix well.". The object of the verb "mix" is clearly the stuff that was just added to the bowl (namely the eggs and flour), although this is not explicitly stated. To handle this, we use a simple recency heuristic, and insert the entities from the previous step to the current step.

2.3 Processing the speech transcript

The output of Youtube's ASR system is a sequence of time-stamped tokens, produced by a standard Viterbi decoding system. We concatenate these tokens into a single long document, and then apply our NLP pipeline to it. Note that, in addition to errors introduced by the ASR system[2], the NLP system can introduce additional errors, because it does not work well on text that may be ungrammatical and which is entirely devoid of punctuation and sentence boundary markers.

To assess the impact of these combined sources of error, we also collected a much smaller set of 480 cooking videos (with corresponding recipe text) for which the video creator had uploaded a manually curated speech transcript; this has no transcription errors, it contains sentence boundary markers, and it also aligns whole phrases with the video (instead of just single tokens). We applied the same NLP pipeline to these manual transcripts. In the results section, we will see that the accuracy of our end-to-end system is indeed higher when the speech transcript is error-free and well-formed. However, we can still get good results using noisier, automatically produced transcripts.

[2]According to (Liao et al., 2013), the Youtube ASR system we used, based on using Gaussian mixture models for the acoustic model, has a word error rate of about 52% (averaged over all English-language videos; some genres, such as news, had lower error rates). The newer system, which uses deep neural nets for the acoustic model, has an average WER of 44%; however, this was not available to us at the time we did our experiments.

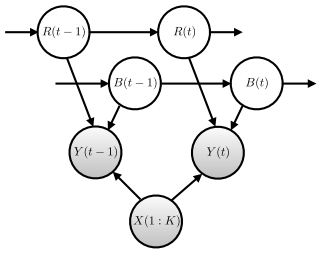

Figure 1: Graphical model representation of the factored HMM. See text for details.

3 Methods

In this section, we describe our system for aligning instructional text and video.

3.1 HMM to align recipe with ASR transcript

We align each step of the recipe to a corresponding sequence of words in the ASR transcript by using the input-output HMM shown in Figure 1. Here $X(1:K)$ represents the textual recipe steps (obtained using the process described in Section 2.2); $Y(1:T)$ represent the ASR tokens (spoken words); $R(t) \in \{1,\ldots,K\}$ is the recipe step number for frame t; and $B(t) \in \{0,1\}$ represents whether timestep t is generated by the background ($B=1$) or foreground model ($B=0$). This background variable is needed since sometimes sequences of spoken words are unrelated to the content of the recipe, especially at the beginning and end of a video.

The conditional probability distributions (CPDs) for the Markov chain is as follows:

$$p(R(t)=r|R(t-1)=r') = \begin{cases} \alpha & \text{if } r=r'+1 \\ 1-\alpha & \text{if } r=r' \\ 0.0 & \text{otherwise} \end{cases}$$

$$p(B(t)=b|B(t-1)=b) = \gamma.$$

This encodes our assumption that the video follows the same ordering as the recipe and that background/foreground tokens tend to cluster together. Obviously these assumptions do not always hold, but they are a reasonable approximation.

For each recipe, we set $\alpha = K/T$, the ratio of recipe steps to transcript tokens. This setting corresponds to an *a priori* belief that each recipe step is aligned with the same number of transcript tokens. The parameter γ in our experiments is set by cross-validation to 0.7 based on a small set of manually-labeled recipes.

For the foreground observation model, we generate the observed word from the corresponding recipe step via:

$$\log p(Y(t) = y | R(t) = k, X(1:K), B(t) = 0) \propto \max(\{\text{WordSimilarity}(y, x) : x \in X(k)\}),$$

where $X(k)$ is the set of words in the k'th recipe step, and WordSimilarity(s, t) is a measure of similarity between words s and t, based on word vector distance.

If this frame is aligned to the background, we generate it from the empirical distribution of words, which is estimated based on pooling all the data:

$$p(Y(t) = y | R(t) = k, B(t) = 1) = \hat{p}(y).$$

Finally, the prior for $p(B(t))$ is uniform, and $p(R(1))$ is set to a delta function on $R(1) = 1$ (i.e., we assume videos start at step 1 of the recipe).

Having defined the model, we "flatten" it to a standard HMM (by taking the cross product of R_t and B_t), then estimate the MAP sequence using the Viterbi algorithm. See Figure 2 for an example.

Finally, we label each segment of the video as follows: use the segmentation induced by the alignment, and extract the action and object from the corresponding recipe step as described in Section 2.2. If the segment was labeled as background by the HMM, we do not apply any label to it.

3.2 Keyword spotting

A simpler approach to labeling video segments is to just search for verbs in the ASR transcript, and then to extract a fixed-sized window around the timestamp where the keyword occurred. We call this approach "keyword spotting". A similar method from (Yu et al., 2014) filters ASR transcripts by part-of-speech tag and finds tokens that match a small vocabulary to create a corpus of video clips (extracted from instructional videos), each labeled with an action/object pair.

In more detail, we manually define a whitelist of $\sim$200 actions (all transitive verbs) of interest, such as "add", "chop", "fry", etc. We then identify when these words are spoken (relying on the POS tags to filter out non-verbs), and extract an 8 second video clip around this timestamp. (Using 2 seconds prior to the action being mentioned, and 6 seconds following.) To extract the object, we take all tokens tagged as "noun" within 5 tokens after the action.

3.3 Hybrid HMM + keyword spotting

We cannot use keyword spotting if the goal is to align instructional text to videos. However, if our goal is just to create a labeled corpus of video clips, keyword spotting is a reasonable approach. Unfortunately, we noticed that the quality of the labels (especially the object labels) generated by keyword spotting was not very high, due to errors in the ASR. On the other hand, we also noticed that the recall of the HMM approach was about 5 times lower than using keyword spotting, and furthermore, that the temporal localization accuracy was sometimes worse.

To get the best of both worlds, we employ the following hybrid technique. We perform keyword spotting for the action in the ASR transcript as before, but use the HMM alignment to infer the corresponding object. To avoid false positives, we only use the output of the HMM for this video if at least half of the recipe steps are aligned by it to the speech transcript; otherwise we back off to the baseline approach of extracting the noun phrase from the ASR transcript in the window after the verb.

3.4 Temporal refinement using vision

In our experiments, we noticed that sometimes the narrator describes an action before actually performing it (this was also noted in (Yu et al., 2014)). To partially combat this problem, we used computer vision to refine candidate video segments as follows. We first trained visual detectors for a large collection of food items (described below). Then, given a candidate video segment annotated with an action/object pair (coming from any of the previous

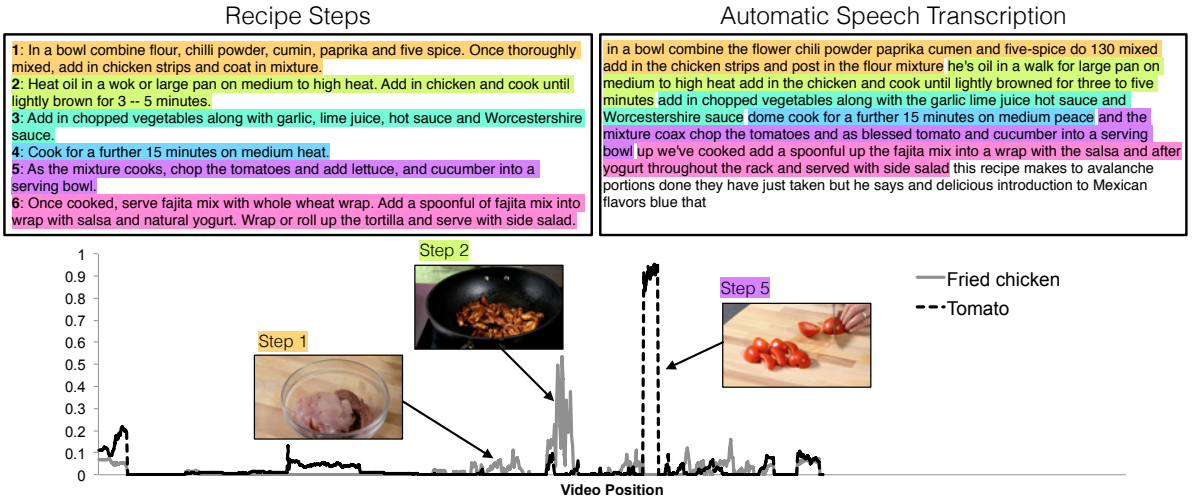

Figure 2: Examples from a Chicken Fajitas recipe at `https://www.youtube.com/watch?v=mGpvZE3udQ4` (figure best viewed in color). Top: Alignment between (left) recipe steps to (right) automatic speech transcript. Tokens from the ASR are allowed to be classified as background steps (see e.g., the uncolored text at the end). Bottom: Detector scores for two ingredients as a function of position in the video.

three methods), we find a translation of the window (of up to 3 seconds in either direction) for which the average detector score corresponding to the object is maximized. The intuition is that by detecting when the object in question is visually present in the scene, it is more likely that the corresponding action is actually being performed.

Training visual food detectors. We trained a deep convolutional neural network (CNN) classifier (specifically, the 16 layer VGG model from (Simonyan and Zisserman, 2014)) on the FoodFood-101 dataset of (Bossard et al., 2014), using the Caffe open source software (Jia et al., 2014). The Food-101 dataset contains 1000 images for 101 different kinds of food. To compensate for the small training set, we pretrained the CNN on the ImageNet dataset (Russakovsky et al., 2014), which has 1.2M images, and then fine-tuned on Food-101. After a few hours of fine tuning (using a single GPU), we obtained 79% classification accuracy (assuming all 101 labels are mutually exclusive) on the test set, which is consistent with the state of the art results.[3]

[3]In particular, the website `https://www.metamind.io/vision/food` (accessed on 2/25/15) claims they also got 79% on this dataset. This is much better than the 56.4% for a CNN reported in (Bossard et al., 2014). We believe the main reason for the improved performance is the use of pre-training on ImageNet.

We then trained our model on an internal, proprietary dataset of 220 million images harvested from Google Images and Flickr. About 20% of these images contain food, the rest are used to train the background class. In this set, there are 2809 classes of food, including 1005 raw ingredients, such as avocado or beef, and 1804 dishes, such as ratatouille or cheeseburger with bacon. We use the model trained on this much larger dataset in the current paper, due to its increased coverage. (Unfortunately, we cannot report quantitative results, since the dataset is very noisy (sometimes half of the labels are wrong), so we have no ground truth. Nevertheless, qualitative behavior is reasonable, and the model does well on Food-101, as we discussed above.)

Visual refinement pipeline. For storage and time efficiency, we downsample each video temporally to 5 frames per second and each frame to 224×224 before applying the CNN. Running the food detector on each video then produces a vector of scores (one entry for each of 2809 classes) per timeframe.

There is not a perfect map from the names of ingredients to the names of the detector outputs. For example, an omelette recipe may say "egg", but there are two kinds of visual detectors, one for "scrambled egg" and one for "raw egg". We therefore decided to define the match score between an ingredient and a frame by taking the maximum

score for that frame over all detectors whose names matched any of the ingredient tokens (after lemmatization and stopword filtering).

Finally, the match score of a video segment to an object is computed by taking the average score of all frames within that segment. By then scoring and maximizing over all translations of the candidate segment (of up to three seconds away), we produce a final "refined" segment.

3.5 Quantifying confidence via vision and affordances

The output of the keyword spotting and/or HMM systems is an (action, object) label assigned to certain video clips. In order to estimate how much confidence we have in that label (so that we can trade off precision and recall), we use a linear combination of two quantities: (1) the final match score produced by the visual refinement pipeline, which measures the visibility of the object in the given video segment, and (2) an *affordance probability*, measuring the probability that o appears as a direct object of a.

The affordance model allows us to, for example, prioritize a segment labeled as (peel, garlic) over a segment labeled as (peel, sugar). The probabilities $P(\text{object} = o | \text{action} = a)$ are estimated by first forming an inverse document frequency matrix capturing action/object co-occurrences (treating actions as documents). To generalize across actions and objects we form a low-rank approximation to this IDF matrix using a singular value decomposition and set affordance probabilities to be proportional to exponentiated entries of the resulting matrix. Figure 3 visualizes these affordance probabilities for a selected subset of frequently used action/object pairs.

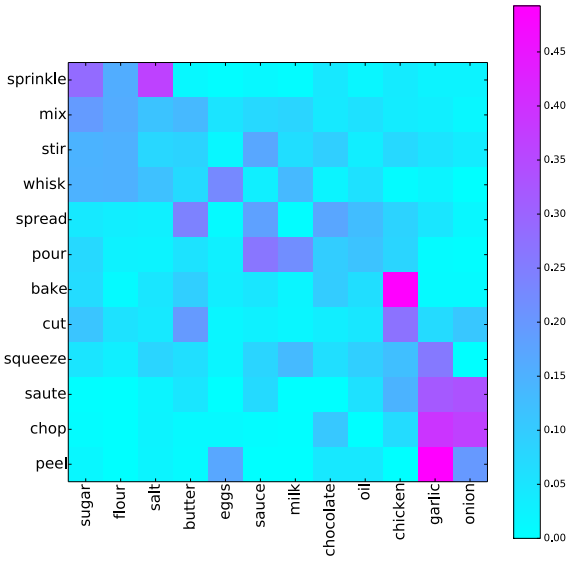

Figure 3: Visualization of affordance model. Entries (a, o) are colored according to $P(\text{object} = o \,|\, \text{action} = a)$.

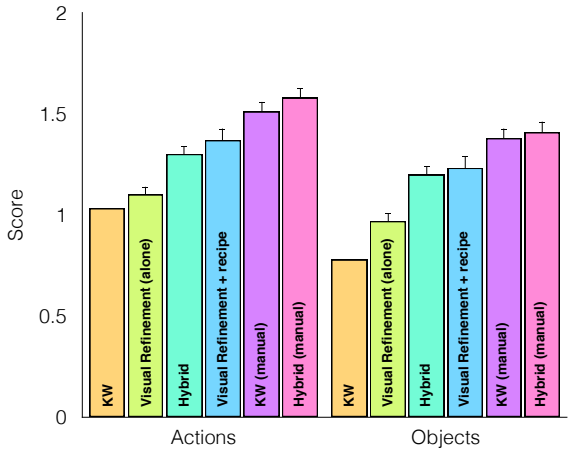

Figure 4: Clip quality, as assessed by Mechanical Turk experiments on 900 trials. Figure best viewed in color; see text for details.

4 Evaluation and applications

In this section, we experimentally evaluate how well our methods work. We then briefly demonstrate some prototype applications.

4.1 Evaluating the clip database

One of the main outcomes of our process is a set of video clips, each of which is labeled with a verb (action) and a noun (object). We generated 3 such labeled corpora, using 3 different methods: keyword spotting ("KW"), the hybrid HMM + keyword spotting ("Hybrid"), and the hybrid system with visual food detector ("visual refinement"). The total number of clips produced by each method is very similar, approximately 1.4 million. The coverage of the clips is approximately 260k unique (action, noun phrase) pairs.

To evaluate the quality of these methods, we created a random subset of 900 clips from each corpus using stratified sampling. That is, we picked an action uniformly at random, and then picked a corresponding object for that action from its support set uniformly at random, and finally picked a clip with that (action, object) label uniformly at random from the clip corpuses produced in Section 3; this ensures

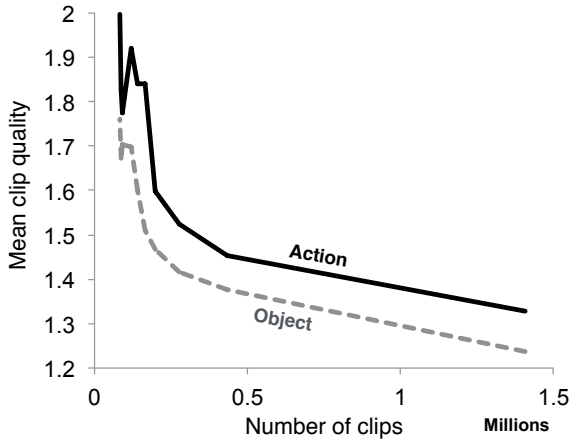

Figure 5: Average clip quality (precision) after filtering out low confidence clips versus # clips retained (recall).

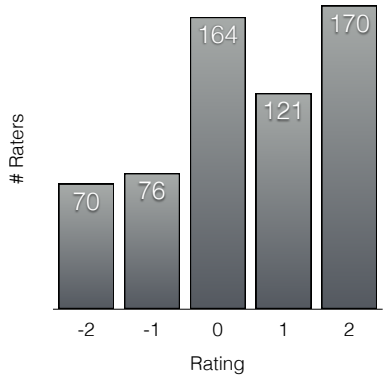

Figure 6: Histogram of human ratings comparing recipe steps against ASR descriptions of a video clip. "2" indicate a strong preference for the recipe step; "-2" a strong preference for the transcript. See text for details.

the test set is not dominated by frequent actions or objects.

We then performed a Mechanical Turk experiment on each test set. Each clip was shown to 3 raters, and each rater was asked the question "How well does this clip show the given action/object?". Raters then had to answer on a 3-point scale: 0 means "not at all", 1 means "somewhat", and 2 means "very well".

The results are shown in Figure 4. We see that the quality of the hybrid method is significantly better than the baseline keyword spotting method, for both actions and objects.[4] While a manually curated speech transcript indeed yields better results (see the bars labeled 'manual'), we observe that automatically generated transcripts allow us to perform almost as well, especially using our alignment model with visual refinement.

Comparing accuracy on actions against that on objects in the same figure, we see that keyword spotting is far more accurate for actions than it is for objects (by over 30%). This disparity is not surprising since keyword spotting searches only for action keywords and relies on a rough heuristic to recover objects. We also see that using alignment (which extracts the object from the "clean" recipe text) and visual refinement (which is trained explicitly to detect ingredients) both help to increase the relative accuracy of objects — under the hybrid method, for example, the accuracy for actions is only 8% better than that of objects.

Note that clips from the HMM and hybrid methods varied in length between 2 and 10 seconds (mean 4.2 seconds), while clips from the keyword spotting method were always exactly 8 seconds. Thus clip length is potentially a confounding factor in the evaluation when comparing the hybrid method to the keyword-spotting method; however, if there is a bias to assign higher ratings to longer clips (which are *a priori* more likely to contain a depiction of a given action than shorter clips), it would benefit the keyword spoting method.

Segment confidence scores (from Section 3.5) can be used to filter out low confidence segments, thus improving the precision of clip retrieval at the cost of recall. Figure 5 visualizes this trade-off as we vary our confidence threshold, showing that indeed, segments with higher confidences tend to have the highest quality as judged by our human raters. Moreover, the top 167,000 segments as ranked by our confidence measure have an average rating exceeding 1.75.

We additionally sought to evaluate how well recipe steps from the recipe body could serve as captions for video clips in comparison to the often noisy ASR transript, which serves as a rough proxy for evaluating the quality of the alignment model as well as demonstration a potential application of our method for "cleaning up" noisy ASR captions into complete grammatical sentences. To that end, we randomly selected 200 clips from our corpus that

[4]Inter-rater agreement, measured via Fleiss's kappa by aggregating across all judgment tasks, is .41, which is statistically significant at a $p < .05$ level.

both have an associated action keyword from the transcript as well as an aligned recipe step selected by the HMM alignment model. For each clip, three raters on Mechanical Turk were shown the clip, the text from the recipe step, and a fragment of the ASR transcript (the keyword, plus 5 tokens to the left and right of the keyword). Raters then indicated which description they preferred: 2 indicates a strong preference for the recipe step, 1 a weak preference, 0 indifference, -1 a weak preference for the transcript fragment, and -2 a strong preference. Results are shown in Figure 6. Excluding raters who indicated indiffierence, 67% of raters preferred the recipe step as the clip's description.

A potential confound for using this analysis as a proxy for the quality of the alignment model is that the ASR transcript is generally an ungrammatical sentence fragment as opposed to the grammatical recipe steps, which is likely to reduce the raters' approval of ASR captions in the case when both accurately describe the scene. However, if users still on average prefer an ASR sentence fragment which describes the clip correctly versus a full recipe step which is unrelated to the scene, then this experiment still provides evidence of the quality of the alignment model.

4.2 Automatically illustrating a recipe

One useful byproduct of our alignment method is that each recipe step is associated with a segment of the corresponding video.[5] We use a standard keyframe selection algorithm to pick the best frame from each segment. We can then associate this frame with the corresponding recipe step, thus automatically illustrating the recipe steps. An illustration of this process is shown in Figure 7.

4.3 Search within a video

Another application which our methods enable is search within a video. For example, if a user would like to find a clip illustrating how to knead dough, we can simply search our corpus of labeled clips,

[5]The HMM may assign multiple non-consecutive regions of the video to the same recipe step (since the background state can turn on and off). In such cases, we just take the "convex hull" of the regions as the interval which corresponds to that step. It is also possible for the HMM not to assign a given step to any interval of the video.

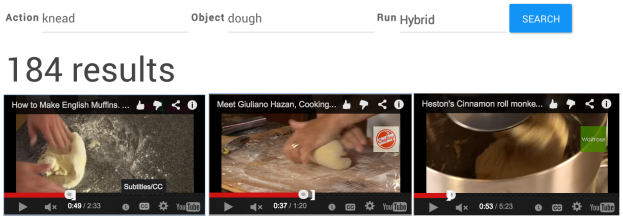

Figure 8: Searching for "knead dough". Note that the videos have automatically been advanced to the relevant frame.

and return a list of matches (ranked by confidence). Since each clip has a corresponding "provenance", we can return the results to the user as a set of videos in which we have automatically "fast forwarded" to the relevant section of the video (see Figure 8 for an example). This stands in contrast to standard video search on Youtube, which returns the whole video, but does not (in general) indicate where within the video the user's search query occurs.

5 Related work

There are several pieces of related work. (Yu et al., 2014) performs keyword spotting in the speech transcript in order to label clips extracted from instructional videos. However, our hybrid approach performs better; the gain is especially significant on automatically generated speech transcripts, as shown in Figure 4.

The idea of using an HMM to align instructional steps to a video was also explored in (Naim et al., 2014). However, their conditional model has to generate images, whereas ours just has to generate ASR words, which is an easier task. Furthermore, they only consider 6 videos collected in a controlled lab setting, whereas we consider over 180k videos collected "in the wild".

Another paper that uses HMMs to process recipe text is (Druck and Pang, 2012). They use the HMM to align the steps of a recipe to the comments made by users in an online forum, whereas we align the steps of a recipe to the speech transcript. Also, we use video information, which was not considered in this earlier work.

(Joshi et al., 2006) describes a system to automatically illustrate a text document, however they only generate one image, not a sequence, and their techniques are very different.

There is also a large body of other work on connecting language and vision; we only have space

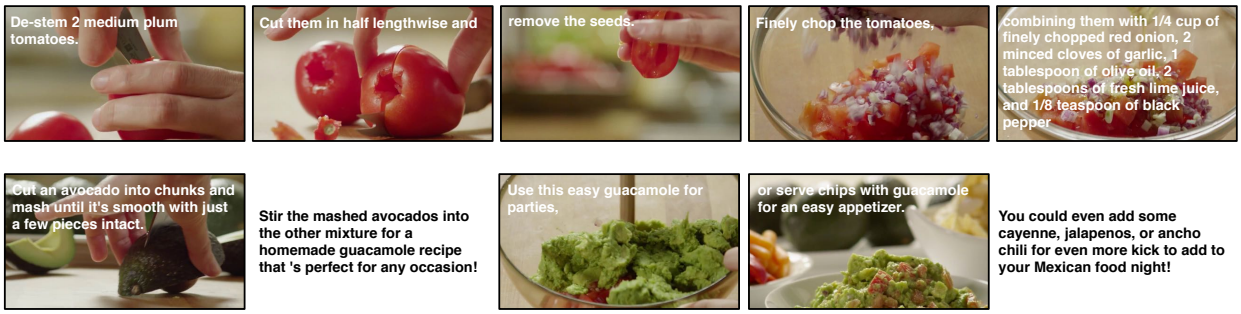

Figure 7: Automatically illustrating a Guacamole recipe from `https://www.youtube.com/watch?v=H7Ne3s202lU`.

to briefly mention a few key papers. (Rohrbach et al., 2012b) describes the MPII Cooking Composite Activities dataset, which consists of 212 videos collected in the lab of people performing various cooking activities. (This extends the dataset described in their earlier work, (Rohrbach et al., 2012a).) They also describe a method to recognize objects and actions using standard vision features. However, they do not leverage the speech signal, and their dataset is significantly smaller than ours.

(Guadarrama et al., 2013) describes a method for generating subject-verb-object triples given a short video clip, using standard object and action detectors. The technique was extended in (Thomason et al., 2014) to also predict the location/ place. Furthermore, they use a linear-chain CRF to combine the visual scores with a simple (s,v,o,p) language model (similar to our affordance model). They applied their technique to the dataset in (Chen and Dolan, 2011), which consists of 2000 short video clips, each described with 1-3 sentences. By contrast, we focus on aligning instructional text to the video, and our corpus is significantly larger.

(Yu and Siskind, 2013) describes a technique for estimating the compatibility between a video clip and a sentence, based on relative motion of the objects (which are tracked using HMMs). Their method is tested on 159 video clips, created under carefully controlled conditions. By contrast, we focus on aligning instructional text to the video, and our corpus is significantly larger.

6 Discussion and future work

In this paper, we have presented a novel method for aligning instructional text to videos, leveraging both speech recognition and visual object detection. We have used this to align 180k recipe-video pairs, from which we have extracted a corpus of 1.4M labeled video clips – a small but crucial step toward building a multimodal procedural knowlege base. In the future, we hope to use this labeled corpus to train visual action detectors, which can then be combined with the existing visual object detectors to interpret novel videos. Additionally, we believe that combining visual and linguistic cues may help overcome longstanding challenges to language understanding, such as anaphora resolution and word sense disambiguation.

Acknowledgments. We would like to thank Alex Gorban and Anoop Korattikara for helping with some of the experiments, and Nancy Chang for feedback on the paper.

Combining Language and Vision with a Multimodal Skip-gram Model

Angeliki Lazaridou Nghia The Pham Marco Baroni

Abstract

We extend the SKIP-GRAM model of Mikolov et al. (2013a) by taking visual information into account. Like SKIP-GRAM, our *multimodal* models (MMSKIP-GRAM) build vector-based word representations by learning to predict linguistic contexts in text corpora. However, for a restricted set of words, the models are also exposed to visual representations of the objects they denote (extracted from natural images), and must predict linguistic and visual features jointly. The MMSKIP-GRAM models achieve good performance on a variety of semantic benchmarks. Moreover, since they propagate visual information to all words, we use them to improve image labeling and retrieval in the zero-shot setup, where the test concepts are never seen during model training. Finally, the MMSKIP-GRAM models discover intriguing visual properties of abstract words, paving the way to realistic implementations of embodied theories of meaning.

1 Introduction

Distributional semantic models (DSMs) derive vector-based representations of meaning from patterns of word co-occurrence in corpora. DSMs have been very effectively applied to a variety of semantic tasks (Clark, 2015; Mikolov et al., 2013b; Turney and Pantel, 2010). However, compared to human semantic knowledge, these purely textual models, just like traditional symbolic AI systems (Harnad, 1990; Searle, 1984), are severely impoverished, suffering of *lack of grounding* in extra-linguistic modalities (Glenberg and Robertson, 2000). This observation has led to the development of *multimodal distributional semantic models* (MDSMs) (Bruni et al., 2014; Feng and Lapata, 2010; Silberer and Lapata, 2014), that enrich linguistic vectors with perceptual information, most often in the form of visual features automatically induced from image collections.

MDSMs outperform state-of-the-art text-based approaches, not only in tasks that directly require access to visual knowledge (Bruni et al., 2012), but also on general semantic benchmarks (Bruni et al., 2014; Silberer and Lapata, 2014). However, current MDSMs still have a number of drawbacks. First, they are generally constructed by first separately building linguistic and visual representations of the same concepts, and then merging them. This is obviously very different from how humans learn about concepts, by hearing words in a situated perceptual context. Second, MDSMs assume that both linguistic and visual information is available for all words, with no generalization of knowledge across modalities. Third, because of this latter assumption of full linguistic and visual coverage, current MDSMs, paradoxically, cannot be applied to computer vision tasks such as image labeling or retrieval, since they do not generalize to images or words beyond their training set.

We introduce the *multimodal skip-gram* models, two new MDSMs that address all the issues above. The models build upon the very effective skip-gram approach of Mikolov et al. (2013a), that constructs vector representations by learning, incrementally, to predict the linguistic contexts in which target words occur in a corpus. In our extension, for a subset of the target words, relevant visual evidence from

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 153–163,
Denver, Colorado, May 31 – June 5, 2015.

natural images is presented together with the corpus contexts (just like humans hear words accompanied by concurrent perceptual stimuli). The model must learn to predict these visual representations jointly with the linguistic features. The joint objective encourages the propagation of visual information to representations of words for which no direct visual evidence was available in training. The resulting multimodally-enhanced vectors achieve remarkably good performance both on traditional semantic benchmarks, and in their new application to the "zero-shot" image labeling and retrieval scenario. Very interestingly, indirect visual evidence also affects the representation of abstract words, paving the way to ground-breaking cognitive studies and novel applications in computer vision.

2 Related Work

There is by now a large literature on multimodal distributional semantic models. We focus here on a few representative systems. Bruni et al. (2014) propose a straightforward approach to MDSM induction, where text- and image-based vectors for the same words are constructed independently, and then "mixed" by applying the Singular Value Decomposition to their concatenation. An empirically superior model has been proposed by Silberer and Lapata (2014), who use more advanced visual representations relying on images annotated with high-level "visual attributes", and a multimodal fusion strategy based on stacked autoencoders. Kiela and Bottou (2014) adopt instead a simple concatenation strategy, but obtain empirical improvements by using state-of-the-art convolutional neural networks to extract visual features, and the skip-gram model for text. These and related systems take a two-stage approach to derive multimodal spaces (unimodal induction followed by fusion), and they are only tested on concepts for which both textual and visual labeled training data are available (the pioneering model of Feng and Lapata (2010) did learn from text and images jointly using Topic Models, but was shown to be empirically weak by Bruni et al. (2014)).

Howell et al. (2005) propose an incremental multimodal model based on simple recurrent networks (Elman, 1990), focusing on *grounding propagation* from early-acquired concrete words to a larger vocabulary. However, they use subject-generated features as surrogate for realistic perceptual information, and only test the model in small-scale simulations of word learning. Hill and Korhonen (2014), whose evaluation focuses on how perceptual information affects different word classes more or less effectively, similarly to Howell et al., integrate perceptual information in the form of subject-generated features and text from image annotations into a skip-gram model. They inject perceptual information by merging words expressing perceptual features with corpus contexts, which amounts to linguistic-context re-weighting, thus making it impossible to separate linguistic and perceptual aspects of the induced representation, and to extend the model with non-linguistic features. We use instead authentic image analysis as proxy to perceptual information, and we design a robust way to incorporate it, easily extendible to other signals, such as feature norm or brain signal vectors (Fyshe et al., 2014).

The recent work on so-called *zero-shot learning* to address the annotation bottleneck in image labeling (Frome et al., 2013; Lazaridou et al., 2014; Socher et al., 2013) looks at image- and text-based vectors from a different perspective. Instead of combining visual and linguistic information in a common space, it aims at learning a mapping from image- to text-based vectors. The mapping, induced from annotated data, is then used to project images of objects that were not seen during training onto linguistic space, in order to retrieve the nearest word vectors as labels. Multimodal word vectors should be better-suited than purely text-based vectors for the task, as their similarity structure should be closer to that of images. However, traditional MDSMs cannot be used in this setting, because they do not cover words for which no manually annotated training images are available, thus defeating the generalizing purpose of zero-shot learning. We will show below that our multimodal vectors, that are not hampered by this restriction, do indeed bring a significant improvement over purely text-based linguistic representations in the zero-shot setup.

Multimodal language-vision spaces have also been developed with the goal of improving caption generation/retrieval and caption-based image retrieval (Karpathy et al., 2014; Kiros et al., 2014;

Mao et al., 2014; Socher et al., 2014). These methods rely on necessarily limited collections of captioned images as sources of multimodal evidence, whereas we automatically enrich a very large corpus with images to induce general-purpose multimodal word representations, that could be used as input embeddings in systems specifically tuned to caption processing. Thus, our work is complementary to this line of research.

3 Multimodal Skip-gram Architecture

3.1 Skip-gram Model

We start by reviewing the standard SKIP-GRAM model of Mikolov et al. (2013a), in the version we use. Given a text corpus, SKIP-GRAM aims at inducing word representations that are good at predicting the *context* words surrounding a *target* word. Mathematically, it maximizes the objective function:

$$\frac{1}{T}\sum_{t=1}^{T}\left(\sum_{-c\leq j\leq c, j\neq 0}\log p(w_{t+j}|w_t)\right) \quad (1)$$

where $w_1, w_2, ..., w_T$ are words in the training corpus and c is the size of the window around target w_t, determining the set of context words to be predicted by the induced representation of w_t. Following Mikolov et al., we implement a subsampling option randomly discarding context words as an inverse function of their frequency, controlled by hyperparameter t. The probability $p(w_{t+j}|w_t)$, the core part of the objective in Equation 1, is given by softmax:

$$p(w_{t+j}|w_t) = \frac{e^{{u'_{w_{t+j}}}^{T} u_{w_t}}}{\sum_{w'=1}^{W} e^{{u'_{w'}}^{T} u_{w_t}}} \quad (2)$$

where u_w and u'_w are the context and target vector representations of word w respectively, and W is the size of the vocabulary. Due to the normalization term, Equation 2 requires $O(|W|)$ time complexity. A considerable speedup to $O(\log|W|)$, is achieved by using the hierarchical version of Equation 2 (Morin and Bengio, 2005), adopted here.

3.2 Injecting visual knowledge

We now assume that word learning takes place in a *situated* context, in which, for a subset of the target words, the corpus contexts are accompanied by a visual representation of the concepts they denote (just like in a conversation, where a linguistic utterance will often be produced in a visual scene including some of the word referents). The visual representation is also encoded in a vector (we describe in Section 4 below how we construct it). We thus make the skip-gram "multimodal" by adding a second, *visual* term to the original *linguistic* objective, that is, we extend Equation 1 as follow:

$$\frac{1}{T}\sum_{t=1}^{T}\left(\mathcal{L}_{ling}(w_t) + \mathcal{L}_{vision}(w_t)\right) \quad (3)$$

where $\mathcal{L}_{ling}(w_t)$ is the text-based skip-gram objective $\sum_{-c\leq j\leq c, j\neq 0}\log p(w_{t+j}|w_t)$, whereas the $\mathcal{L}_{vision}(w_t)$ term forces word representations to take visual information into account. Note that if a word w_t is not associated to visual information, as is systematically the case, e.g., for determiners and non-imageable nouns, but also more generally for any word for which no visual data are available, $\mathcal{L}_{vision}(w_t)$ is set to 0.

We now propose two variants of the visual objective, resulting in two distinguished multi-modal versions of the skip-gram model.

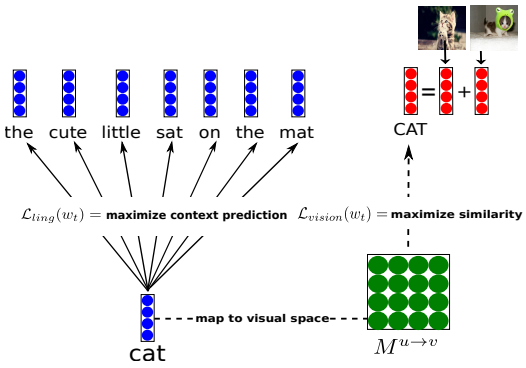

Figure 1: "Cartoon" of MMSKIP-GRAM-B. Linguistic context vectors are actually associated to classes of words in a tree, not single words. SKIP-GRAM is obtained by ignoring the visual objective, MMSKIP-GRAM-A by fixing $M^{u\to v}$ to the identity matrix.

3.3 Multi-modal Skip-gram Model A

One way to force word embeddings to take visual representations into account is to try to directly increase the similarity (expressed, for example, by the *cosine*) between linguistic and visual rep-

resentations, thus aligning the dimensions of the linguistic vector with those of the visual one (recall that we are inducing the first, while the second is fixed), and making the linguistic representation of a concept "move" closer to its visual representation. We maximize similarity through a max-margin framework commonly used in models connecting language and vision (Weston et al., 2010; Frome et al., 2013). More precisely, we formulate the visual objective $\mathcal{L}_{vision}(w_t)$ as:

$$-\sum_{w' \sim P_n(w)} \max(0, \gamma - cos(u_{w_t}, v_{w_t}) + cos(u_{w_t}, v_{w'})) \quad (4)$$

where the minus sign turns a loss into a cost, γ is the margin, u_{w_t} is the target multimodally-enhanced word representation we aim to learn, v_{w_t} is the corresponding visual vector (fixed in advance) and $v_{w'}$ ranges over visual representations of words (featured in our image dictionary) randomly sampled from distribution $P_n(w_t)$. These random visual representations act as "negative" samples, encouraging u_{w_t} to be more similar to its own visual representation than to that of other words. The sampling distribution is currently set to uniform, and the number of negative samples controlled by hyperparameter k.

3.4 Multi-modal Skip-gram Model B

The visual objective in MMSKIP-GRAM-A has the drawback of assuming a direct comparison of linguistic and visual representations, constraining them to be of equal size. MMSKIP-GRAM-B lifts this constraint by including an extra layer mediating between linguistic and visual representations (see Figure 1 for a sketch of MMSKIP-GRAM-B). Learning this layer is equivalent to estimating a cross-modal mapping matrix from linguistic onto visual representations, jointly induced with linguistic word embeddings. The extension is straightforwardly implemented by substituting, into Equation 4, the word representation u_{w_t} with $z_{w_t} = M^{u \to v} u_{w_t}$, where $M^{u \to v}$ is the cross-modal mapping matrix to be induced. To avoid overfitting, we also add an L2 regularization term for $M^{u \to v}$ to the overall objective (Equation 3), with its relative importance controlled by hyperparamer λ.

4 Experimental Setup

The parameters of all models are estimated by back-propagation of error via stochastic gradient descent. Our text corpus is a Wikipedia 2009 dump comprising approximately 800M tokens.[1] To train the multimodal models, we add visual information for 5,100 words that have an entry in ImageNet (Deng et al., 2009), occur at least 500 times in the corpus and have concreteness score ≥ 0.5 according to Turney et al. (2011). On average, about 5% tokens in the text corpus are associated to a visual representation. To construct the visual representation of a word, we sample 100 pictures from its ImageNet entry, and extract a 4096-dimensional vector from each picture using the Caffe toolkit (Jia et al., 2014), together with the pre-trained convolutional neural network of Krizhevsky et al. (2012). The vector corresponds to activation in the top (FC7) layer of the network. Finally, we average the vectors of the 100 pictures associated to each word, deriving 5,100 aggregated visual representations.

Hyperparameters For both SKIP-GRAM and the MMSKIP-GRAM models, we fix hidden layer size to 300. To facilitate comparison between MMSKIP-GRAM-A and MMSKIP-GRAM-B, and since the former requires equal linguistic and visual dimensionality, we keep the first 300 dimensions of the visual vectors. For the linguistic objective, we use hierarchical softmax with a Huffman frequency-based encoding tree, setting frequency subsampling option $t = 0.001$ and window size $c = 5$, without tuning. The following hyperparameters were tuned on the text9 corpus:[2] MMSKIP-GRAM-A: k=20, γ=0.5; MMSKIP-GRAM-B: k=5, γ=0.5, λ=0.0001.

5 Experiments

5.1 Approximating human judgments

Benchmarks A widely adopted way to test DSMs and their multimodal extensions is to measure how well model-generated scores approximate human similarity judgments about pairs of words. We put together various benchmarks covering diverse aspects of meaning, to gain insights on the effect of perceptual information on different similarity facets. Specifically, we test on general relatedness (*MEN*, Bruni et al. (2014), 3K pairs), e.g., pickles are related to hamburgers, semantic ($\approx$ taxonomic) simi-

[1] http://wacky.sslmit.unibo.it

[2] http://mattmahoney.net/dc/textdata.html

larity (*Simlex-999*, Hill et al. (2014), 1K pairs; *SemSim*, Silberer and Lapata (2014), 7.5K pairs), e.g., pickles are similar to onions, as well as visual similarity (*VisSim*, Silberer and Lapata (2014), same pairs as SemSim with different human ratings), e.g., pickles look like zucchinis.

Alternative Multimodal Models We compare our models against several recent alternatives. We test the vectors made available by Kiela and Bottou (2014). Similarly to us, they derive textual features with the skip-gram model (from a portion of the Wikipedia and the British National Corpus) and use visual representations extracted from the ESP dataset (von Ahn and Dabbish, 2004) through a convolutional neural network (Oquab et al., 2014). They concatenate textual and visual features after normalizing to unit length and centering to zero mean. We also test the vectors that performed best in the evaluation of Bruni et al. (2014), based on textual features extracted from a 3B-token corpus and SIFT-based Bag-of-Visual-Words visual features (Sivic and Zisserman, 2003) extracted from the ESP collection. Bruni and colleagues fuse a weighted concatenation of the two components through SVD. We further reimplement both methods with our own textual and visual embeddings as CONCATENATION and SVD (with target dimensionality 300, picked without tuning). Finally, we present for comparison the results on *SemSim* and *VisSim* reported by Silberer and Lapata (2014), obtained with a stacked-autoencoders architecture run on textual features extracted from Wikipedia with the Strudel algorithm (Baroni et al., 2010) and attribute-based visual features (Farhadi et al., 2009) extracted from ImageNet.

All benchmarks contain a fair amount of words for which we did not use direct visual evidence. We are interested in assessing the models both in terms of how they fuse linguistic and visual evidence when they are both available, and for their robustness in lack of full visual coverage. We thus evaluate them in two settings. The visual-coverage columns of Table 1 (those on the right) report results on the subsets for which all compared models have access to direct visual information for both words. We further report results on the full sets ("100%" columns of Table 1) for models that can propagate visual information and that, consequently, can meaningfully be tested on words without direct visual representations.

Results The state-of-the-art visual CNN FEATURES alone perform remarkably well, outperforming the purely textual model (SKIP-GRAM) in two tasks, and achieving the best absolute performance on the visual-coverage subset of Simlex-999. Regarding multimodal *fusion* (that is, focusing on the visual-coverage subsets), both MMSKIP-GRAM models perform very well, at the top or just below it on all tasks, with comparable results for the two variants. Their performance is also good on the full data sets, where they consistently outperform SKIP-GRAM and SVD (that is much more strongly affected by lack of complete visual information). They're just a few points below the state-of-the-art MEN correlation (0.8), achieved by Baroni et al. (2014) with a corpus 3 larger than ours and extensive tuning. MMSKIP-GRAM-B is close to the state of the art for Simlex-999, reported by the resource creators to be at 0.41 (Hill et al., 2014). Most impressively, MMSKIP-GRAM-A reaches the performance level of the Silberer and Lapata (2014) model on their SemSim and VisSim data sets, despite the fact that the latter has full visual-data coverage and uses attribute-based image representations, requiring supervised learning of attribute classifiers, that achieve performance in the semantic tasks comparable or higher than that of our CNN features (see Table 3 in Silberer and Lapata (2014)). Finally, if the multimodal models (unsurprisingly) bring about a large performance gain over the purely linguistic model on visual similarity, the improvement is consistently large also for the other benchmarks, confirming that multimodality leads to better semantic models in general, that can help in capturing different types of similarity (general relatedness, strictly taxonomic, perceptual).

While we defer to further work a better understanding of the relation between multimodal grounding and different similarity relations, Table 2 provides qualitative insights on how injecting visual information changes the structure of semantic space. The top SKIP-GRAM neighbours of *donuts* are places where you might encounter them, whereas the multimodal models relate them to other take-away food, ranking visually-similar pizzas at the top. The *owl* example shows how multimodal

tobacco	coffee, cigarette, corn	cigarette, cigar, corn	cigarette, cigar, smoking
depth	size, bottom, meter	sea, underwater, level	sea, size, underwater
chaos	anarchy, despair, demon	demon, anarchy, destruction	demon, anarchy, shadow

Table 2: Ordered top 3 neighbours of example words in purely textual and multimodal spaces. Only *donut* and *owl* were trained with direct visual information.

models pick taxonomically closer neighbours of concrete objects, since often closely related things also look similar (Bruni et al., 2014). In particular, both multimodal models get rid of squirrels and offer other birds of prey as nearest neighbours. No direct visual evidence was used to induce the embeddings of the remaining words in the table, that are thus influenced by vision only by propagation. The subtler but systematic changes we observe in such cases suggest that this indirect propagation is not only non-damaging with respect to purely linguistic representations, but actually beneficial. For the concrete *mural* concept, both multimodal models rank paintings and portraits above less closely related sculptures (they are not a form of painting). For *tobacco*, both models rank cigarettes and cigar over coffee, and MMSKIP-GRAM-B avoids the arguably less common "crop" sense cued by corn. The last two examples show how the multimodal models turn up the embodiment level in their representation of abstract words. For *depth*, their neighbours suggest a concrete marine setup over the more abstract measurement sense picked by the MMSKIP-GRAM neighbours. For *chaos*, they rank a demon, that is, a concrete agent of chaos at the top, and replace the more abstract notion of despair with equally gloomy but more imageable shadows and destruction (more on abstract words below).

5.2 Zero-shot image labeling and retrieval

The multimodal representations induced by our models should be better suited than purely text-based vectors to label or retrieve images. In particular, given that the quantitative and qualitative results collected so far suggest that the models propagate visual information across words, we apply them to image labeling and retrieval in the challenging zero-shot setup (see Section 2 above).[3]

[3]We will refer here, for conciseness' sake, to *image* labeling/retrieval, but, as our visual vectors are aggregated representations of images, the tasks we're modeling consist, more precisely, in labeling a set of pictures denoting the same object and retrieving the corresponding set given the name of the object.

Setup We take out as test set 25% of the 5.1K words we have visual vectors for. The multimodal models are re-trained without visual vectors for these words, using the same hyperparameters as above. For both tasks, the search for the correct word label/image is conducted on the whole set of 5.1K word/visual vectors.

In the image labeling task, given a visual vector representing an image, we map it onto word space, and label the image with the word corresponding to the nearest vector. To perform the vision-to-language mapping, we train a Ridge regression by 5-fold cross-validation on the test set (for SKIP-GRAM only, we also add the remaining 75% of word-image vector pairs used in estimating the multimodal models to the Ridge training data).[4]

In the image retrieval task, given a linguistic/multimodal vector, we map it onto visual space, and retrieve the nearest image. For SKIP-GRAM, we use Ridge regression with the same training regime as for the labeling task. For the multimodal models, since maximizing similarity to visual representations is already part of their training objective, we do not fit an extra mapping function. For MMSKIP-GRAM-A, we directly look for nearest neighbours of the learned embeddings in visual space. For MMSKIP-GRAM-B, we use the $M^{u \to v}$ mapping function induced while learning word embeddings.

Results In image labeling (Table 3) SKIP-GRAM is outperformed by both multimodal models, confirming that these models produce vectors that are directly applicable to vision tasks thanks to visual propagation. The most interesting results however are achieved in image retrieval (Table 4), which is essentially the task the multimodal models have been implicitly optimized for, so that they could be applied to it without any specific training. The strategy of directly querying for the nearest visual vectors of the MMSKIP-GRAM-A word embeddings works remarkably well, outperforming on the higher ranks SKIP-GRAM, which requires an ad-hoc mapping function. This suggests that the multimodal embeddings we are inducing, while general enough to achieve good performance in the semantic tasks discussed above, encode sufficient visual information for direct application to image analysis tasks. This is especially remarkable because the word vectors we are testing were not matched with visual representations at model training time, and are thus multimodal only by propagation. The best performance is achieved by MMSKIP-GRAM-B, confirming our claim that its $M^{u \to v}$ matrix acts as a multimodal mapping function.

[4] We use one fold to tune Ridge λ, three to estimate the mapping matrix and test in the last fold. To enforce strict zero-shot conditions, we exclude from the test fold labels occurring in the LSVRC2012 set that was employed to train the CNN of Krizhevsky et al. (2012), that we use to extract visual features.

5.3 Abstract words

We have already seen, through the *depth* and *chaos* examples of Table 2, that the indirect influence of visual information has interesting effects on the representation of abstract terms. The latter have received little attention in multimodal semantics, with Hill and Korhonen (2014) concluding that abstract nouns, in particular, do not benefit from propagated perceptual information, and their representation is even harmed when such information is forced on them (see Figure 4 of their paper). Still, embodied theories of cognition have provided considerable evidence that abstract concepts are also grounded in the senses (Barsalou, 2008; Lakoff and Johnson, 1999). Since the word representations produced by MMSKIP-GRAM-A, including those pertaining to abstract concepts, can be directly used to search for near images in visual space, we decided to verify, experimentally, if these near images (of concrete things) are relevant not only for concrete words, as

expected, but also for abstract ones, as predicted by embodied views of meaning.

More precisely, we focused on the set of 200 words that were sampled across the USF norms concreteness spectrum by Kiela et al. (2014) (2 words had to be excluded for technical reasons). This set includes not only concrete (*meat*) and abstract (*thought*) nouns, but also adjectives (*boring*), verbs (*teach*), and even grammatical terms (*how*). Some words in the set have relatively high concreteness ratings, but are not particularly imageable, e.g.: *hot, smell, pain, sweet*. For each word in the set, we extracted the nearest neighbour picture of its MMSKIP-GRAM-A representation, and matched it with a random picture. The pictures were selected from a set of 5,100, all labeled with distinct words (the picture set includes, for each of the words associated to visual information as described in Section 4, the nearest picture to its aggregated visual representation). Since it is much more common for concrete than abstract words to be directly represented by an image in the picture set, when searching for the nearest neighbour we excluded the picture labeled with the word of interest, if present (e.g., we excluded the picture labeled *tree* when picking the nearest neighbour of the word *tree*). We ran a CrowdFlower[5] survey in which we presented each test word with the two associated images (randomizing presentation order of nearest and random picture), and asked subjects which of the two pictures they found more closely related to the word. We collected minimally 20 judgments per word. Subjects showed large agreement (median proportion of majority choice at 90%), confirming that they understood the task and behaved consistently.

We quantify performance in terms of proportion of words for which the number of votes for the nearest neighbour picture is significantly above chance according to a two-tailed binomial test. We set significance at $p<0.05$ after adjusting all p-values with the Holm correction for running 198 statistical tests. The results in Table 5 indicate that, in about half the cases, the nearest picture to a word MMSKIP-GRAM-A representation is meaningfully related to the word. As expected, this is more often the case for concrete than abstract words. Still, we also observe a significant preference for the model-predicted nearest picture for about one fourth of the abstract terms. Whether a word was exposed to direct visual evidence during training is of course making a big difference, and this factor interacts with concreteness, as only two abstract words were matched with images during training.[6] When we limit evaluation to word representations that were not exposed to pictures during training, the difference between concrete and abstract terms, while still large, becomes less dramatic than if all words are considered.

Figure 2 shows four cases in which subjects expressed a strong preference for the nearest visual neighbour of a word. *Freedom, god* and *theory* are strikingly in agreement with the view, from embodied theories, that abstract words are grounded in rel-

[5] http://www.crowdflower.com

	global	|*words*|	*unseen*	|*words*|
all	48%	198	30%	127
concrete	73%	99	53%	30
abstract	23%	99	23%	97

Table 5: Subjects' preference for nearest visual neighbour of words in Kiela et al. (2014) vs. random pictures. Figure of merit is percentage proportion of significant results in favor of nearest neighbour across words. Results are reported for the whole set, as well as for words above (*concrete*) and below (*abstract*) the concreteness rating median. The *unseen* column reports results when words exposed to direct visual evidence during training are discarded. The *words* columns report set cardinality.

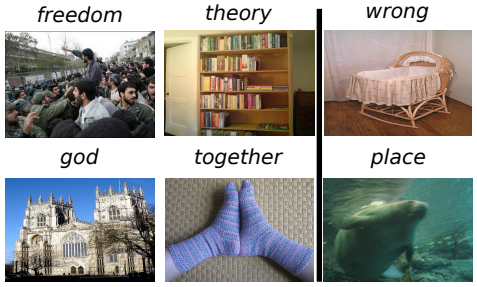

Figure 2: Examples of nearest visual neighbours of some abstract words: on the left, cases where subjects preferred the neighbour to the random foil; on the right, cases where they did not.

[6] In both cases, the images actually depict concrete senses of the words: a memory board for *memory* and a stop sign for *stop*.

evant concrete scenes and situations. The *together* example illustrates how visual data might ground abstract notions in surprising ways. For all these cases, we can borrow what Howell et al. (2005) say about visual propagation to abstract words (p. 260):

> Intuitively, this is something like trying to explain an abstract concept like *love* to a child by using concrete examples of scenes or situations that are associated with love. The abstract concept is never fully grounded in external reality, but it does inherit some meaning from the more concrete concepts to which it is related.

Of course, not all examples are good: the last column of Figure 2 shows cases with no obvious relation between words and visual neighbours (subjects preferred the random images by a large margin).

The multimodal vectors we induce also display an interesting intrinsic property related to the hypothesis that grounded representations of abstract words are more complex than for concrete ones, since abstract concepts relate to varied and composite situations (Barsalou and Wiemer-Hastings, 2005). A natural corollary of this idea is that visually-grounded representations of abstract concepts should be more diverse: If you think of dogs, very similar images of specific dogs will come to mind. You can also imagine the abstract notion of freedom, but the nature of the related imagery will be much more varied. Recently, Kiela et al. (2014) have proposed to measure abstractness by exploiting this very same intuition. However, they rely on manual annotation of pictures via Google Images and define an *ad-hoc* measure of *image dispersion*. We conjecture that the representations naturally induced by our models display a similar property. In particular, the *entropy* of our multimodal vectors, being an expression of how varied the information they encode is, should correlate with the degree of abstractness of the corresponding words. As Figure 3(a) shows, there is indeed a difference in entropy between the most concrete (*meat*) and most abstract (*hope*) words in the Kiela et al. set.

To test the hypothesis quantitatively, we measure the correlation of entropy and concreteness on the 200 words in the Kiela et al. (2014) set.[7] Figure 3(b) shows that the entropies of both the

[7]Since the vector dimensions range over the real number line, we calculate entropy on vectors that are unit-normed after adding a small constant insuring all values are positive.

MMSKIP-GRAM-B*	-0.71

(b)

Figure 3: (a) Distribution of MMSKIP-GRAM-A vector activation for *meat* (blue) and *hope* (red). (b) Spearman ρ between concreteness and various measures on the Kiela et al. (2014) set.

MMSKIP-GRAM-A representations and those generated by mapping MMSKIP-GRAM-B vectors onto visual space (MMSKIP-GRAM-B*) achieve very high correlation (but, interestingly, not MMSKIP-GRAM-B). This is further evidence that multimodal learning is grounding the representations of both concrete and abstract words in meaningful ways.

6 Conclusion

We introduced two multimodal extensions of SKIP-GRAM. MMSKIP-GRAM-A is trained by directly optimizing the similarity of words with their visual representations, thus forcing maximum interaction between the two modalities. MMSKIP-GRAM-B includes an extra mediating layer, acting as a cross-modal mapping component. The ability of the models to *integrate* and *propagate* visual information resulted in word representations that performed well in both semantic and vision tasks, and could be used as input in systems benefiting from prior visual knowledge (e.g., caption generation). Our results with abstract words suggest the models might also help in tasks such as metaphor detection, or even retrieving/generating pictures of abstract concepts. Their incremental nature makes them well-suited for cognitive simulations of grounded language acquisition, an avenue of research we plan to explore further.

Abstract

We address the problem of automatically aligning natural language sentences with corresponding video segments without any direct supervision. Most existing algorithms for integrating language with videos rely on hand-aligned parallel data, where each natural language sentence is manually aligned with its corresponding image or video segment. Recently, fully unsupervised alignment of text with video has been shown to be feasible using hierarchical generative models. In contrast to the previous generative models, we propose three latent-variable discriminative models for the unsupervised alignment task. The proposed discriminative models are capable of incorporating domain knowledge, by adding diverse and overlapping features. The results show that discriminative models outperform the generative models in terms of alignment accuracy.

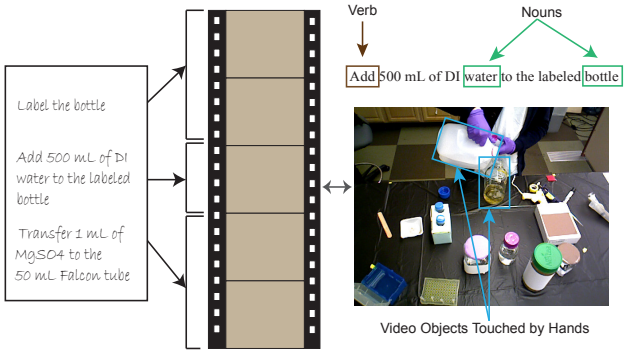

Figure 1: The proposed discriminative learning algorithm aligns protocol sentences to corresponding video frames. We incorporate features that can learn the co-occurrences of nouns and verbs in the sentences with the objects in the video.

1 Introduction

Learning to integrate natural language descriptions with video events is attracting increasing attention in the natural language processing and computer vision communities. The Grounded Language Learning task aims to map the meaning of natural language expressions to their corresponding referents in videos (e.g., objects, actions, and events) without any dictionary. Most existing grounded language learning algorithms are either supervised or weakly-supervised. During the training stage, they assume each video is pre-segmented to chunks of short duration, and each video segment is manually aligned with a natural language sentence that describes that segment. Manually aligning each video segment with a sentence is tedious, especially for long videos. Therefore, it is desirable to automatically align video segments with their corresponding natural language sentences without direct supervision.

Recently, Naim et al. (2014) proposed an unsupervised learning algorithm for automatically aligning sentences in a document with corresponding video segments. Given a sequence of natural language instructions and an unaligned video recording of a person following these instructions, a hierarchical generative model was applied to align each instruc-

Denver, Colorado, May 31 – June 5, 2015.

tion to its corresponding video segment, and to align nouns in each instruction to their corresponding objects in the video. We extend this generative alignment framework by applying several discriminative models with latent variables. Discriminative models are attractive as they can easily incorporate domain knowledge by adding many diverse, overlapping, and complex features. By incorporating a large number of features and regularizing their weights properly, discriminative models have been shown to outperform generative models in many natural language processing tasks (Collins, 2002; Dyer et al., 2011; Yu et al., 2013).

Similar to Naim et al. (2014), we applied our algorithm to align the natural language instructions for biological experiments in "wet laboratories" with recorded videos of people performing these experiments. Typically, each wetlab experiment has a protocol written in natural language, describing the sequence of steps necessary for that experiment. However, these instructions are often incomplete, and do not spell out implicit assumptions and knowledge, causing the results to be difficult to reproduce (Begley and Ellis, 2012). Given a set of such wetlab experiment protocols and associated videos, our initial goal is to infer the correct alignment between the steps mentioned in the protocol and corresponding video segments in which a person performs these steps (Figure 1). The aligned and segmented output of the system described in this paper can eventually be used to learn detailed visual models of correctly performed activities and to identify experimental anomalies.

In this paper, we apply three latent discriminative learning algorithms: latent conditional random field (LCRF), latent structured perceptron (LSP), and latent structured support vector machine (LSSVM) for unsupervised alignment of video with text. We show that discriminative models outperform the existing generative models by incorporating diverse features. While the previous models only considered the mappings of nouns to blobs, and ignored verbs, we incorporated the co-occurrences of verbs with blobs as features in our model. Finally, we propose a constrained variant of the standard LSP and LSSVM update rule, which provided better alignment accuracy and more stable convergence on our datasets.

2 Background Research

2.1 Unsupervised Grounded Language Learning

Most existing grounded language learning algorithms for integrating language with vision rely on either a fully supervised (Kollar et al., 2010; Matuszek et al., 2012) or a weakly supervised training stage (Yu and Ballard, 2004; Kate and Mooney, 2007; Krishnamurthy and Kollar, 2013; Yu and Siskind, 2013; Krishnamoorthy et al., 2013; Rohrbach et al., 2013; Tellex et al., 2013). The fully supervised methods assume that each sentence in the training data is manually paired with the corresponding image or video segment, and furthermore, each word or phrase in a sentence is already mapped to its corresponding blob or action in the image or video segment. Given the detailed annotations, these methods train a set of classifiers to recognize perceptual representations for commonly used words or phrases. After the initial fully supervised training stage, these methods can learn the meaning of new words as they are encountered. Such detailed supervision is difficult to obtain, and as a result most of the recent grounded language learning algorithms rely on weaker supervision (Krishnamurthy and Kollar, 2013; Yu and Siskind, 2013; Krishnamoorthy et al., 2013; Rohrbach et al., 2013; Tellex et al., 2013), where each image or video frame is manually paired with corresponding sentence, but the mapping between objects and words is not provided, and instead learned and inferred automatically as latent variables. Manually pairing each video segment or image frame with the corresponding sentence can be tedious, especially for long videos. Furthermore, these methods can be relatively difficult to extend to new domains, as this may require collecting new annotated data.

Recently, Naim et al. (2014) proposed a fully unsupervised approach for aligning wetlab experiment videos with associated text protocols, without any direct supervision. They proposed a hierarchical generative model to infer the alignment between each video segment with corresponding protocol sentence, and also the mapping of each blob with corresponding noun in that sentence. First, it models the generation of each video segment from one of the sentences in the protocol using a Hidden

Markov Model (HMM) (Rabiner, 1989; Vogel et al., 1996). Next, each tracked object or blob in a video segment is generated from one of the nouns in the corresponding sentence using IBM Model 1 (Brown et al., 1993), a generative model frequently used in machine translation. The IBM Model 1 probabilities are incorporated as emission probabilities in HMM. The transition probabilities are parameterized using the jump size, i.e., the difference between the alignments of two consecutive video segments. They also extended IBM Model 1 by introducing latent variables for each noun, allowing some of the non-object nouns to be unobserved in the video. While the alignment results are encouraging, and show that unsupervised alignment is feasible, they considered the mappings between nouns and blobs only, and ignored the verbs and other relations in the sentences. Moreover, incorporating domain knowledge is not straightforward in these generative models.

2.2 Discriminative Word Alignment

In machine translation, alignment of the words in source language with the words in target language has traditionally been done using the IBM word alignment models (Brown et al., 1993), which are generative models, and typically trained using Expectation Maximization (Dempster et al., 1977). Early attempts (Blunsom and Cohn, 2006; Taskar et al., 2005) towards discriminative word alignment relied on supervised hand-aligned parallel corpora. Dyer et al. (2011) first applied a latent variable conditional random field (LCRF) to perform unsupervised discriminative word alignment. They treated the words' alignments as latent variables, and formulated the task as predicting the target sentence, given the source sentence. We apply similar latent variable discriminative models for unsupervised alignment of sentences with video segments.

3 Problem Formulation and Notations

The input to our system is a dataset containing N pairs of observations $\{(\mathbf{x}_i, \mathbf{y}_i)\}_{i=1}^{N}$, where $\mathbf{x}_i$ represents the i^{th} experiment protocol, and $\mathbf{y}_i$ represents a video of a person carrying out the instructions in that protocol. The protocols are not necessarily unique, as we have multiple videos of different people carrying out the same protocol.

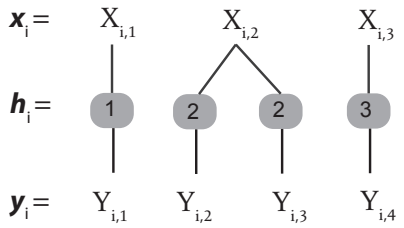

Figure 2: Each $X_{i,m}$ is a sentence in the protocol, consisting of the nouns and verbs in the sentence, and each $Y_{i,n}$ is a video chunk represented by the set of blobs touched by hands in that chunk. The alignment $\mathbf{h}_i = [1, 2, 2, 3]$ maps each video chunk to the corresponding sentence.

We apply similar data preprocessing as Naim et al. (2014). First, we parse each protocol sentence using the two-stage Charniak-Johnson parser (Charniak and Johnson, 2005), and extract the head nouns and verbs from each sentence. Let m_i be the number of sentences in the protocol $\mathbf{x}_i$. We represent $\mathbf{x}_i$ as a sequence of sets $\mathbf{x}_i = [X_{i,1}, \ldots, X_{i,m_i}]$, where $X_{i,m}$ is the set of nouns and verbs in the m^{th} sentence of $\mathbf{x}_i$. Each video $\mathbf{y}_i$ is segmented into a sequence of chunks, each one second long. For each video chunk, we determine the set of objects touched by the participant's hands using automated image segmentation and tracking. We ignore the chunks over which no object is touched by a hand. Let n_i be the number of chunks in $\mathbf{y}_i$. We represent the video $\mathbf{y}_i$ as a sequence of sets: $\mathbf{y}_i = [Y_{i,1}, \ldots, Y_{i,n_i}]$, one for each video chunk, where $Y_{i,n}$ is the set of objects or blobs touched by hands in the n^{th} chunk of $\mathbf{y}_i$. If V_Y is the set of all blobs in the videos, then $Y_{i,n} \subseteq V_Y$.

Our goal is to learn the alignment $\mathbf{h}_i$ between the sentences in $\mathbf{x}_i$ with their corresponding video chunks in $\mathbf{y}_i$ (Figure 2). Formally, $\mathbf{h}_i[n] \in \{1, \ldots, m_i\}$, for $1 \leq n \leq n_i$, where $\mathbf{h}_i[n] = m$ indicates that the video segment $Y_{i,n}$ is aligned to the protocol sentence $X_{i,m}$.

4 Discriminative Alignment

To formulate the alignment problem as a discriminative learning task, we assume the text sequence $\mathbf{x}_i$ as the observed input, and the video sequence $\mathbf{y}_i$ as the output sequence that we aim to predict. Since the alignments are unknown, we treat them

as latent variables. Let $\mathbf{h}_i$ be the hidden alignment vector for an observation pair $(\mathbf{x}_i, \mathbf{y}_i)$. The feature function $\mathbf{\Phi}(\mathbf{x}_i, \mathbf{y}_i, \mathbf{h}_i)$ maps the input observation $(\mathbf{x}_i, \mathbf{y}_i)$, and their latent alignment vector $\mathbf{h}_i$ to a d-dimensional feature vector. Our goal is to learn the weights $\mathbf{w} \in \mathbb{R}^d$ for these features.

4.1 Latent Variable Conditional Random Field

Given a text sequence $\mathbf{x}_i$ and a video sequence $\mathbf{y}_i$ with lengths $|\mathbf{x}_i| = m_i$ and $|\mathbf{y}_i| = n_i$, the conditional probability of the video sequence is:

$$\begin{aligned} p(\mathbf{y}_i|\mathbf{x}_i) &= p(\mathbf{y}_i, n_i|\mathbf{x}_i) \\ &= p(\mathbf{y}_i|\mathbf{x}_i, n_i)\, p(n_i|\mathbf{x}_i) \end{aligned} \quad (1)$$

Since we only aim to learn the alignments given $(\mathbf{x}_i, \mathbf{y}_i)$, we ignore the length probability $p(n_i|\mathbf{x}_i)$, and consider only the first term:

$$p(\mathbf{y}_i|\mathbf{x}_i, n_i) = \sum_{\mathbf{h}_i} p(\mathbf{y}_i, \mathbf{h}_i|\mathbf{x}_i, n_i) \quad (2)$$

We model the conditional probability $p(\mathbf{y}_i, \mathbf{h}_i|\mathbf{x}_i, n_i)$ using a log-linear model:

$$p(\mathbf{y}_i, \mathbf{h}_i|\mathbf{x}_i, n_i) = \frac{\exp \mathbf{w}^T \mathbf{\Phi}(\mathbf{x}_i, \mathbf{y}_i, \mathbf{h}_i)}{Z(\mathbf{x}_i, n_i)}, \quad (3)$$

where $Z(\mathbf{x}_i, n_i) = \sum_{\mathbf{y}} \sum_{\mathbf{h}} \exp \mathbf{w}^T \mathbf{\Phi}(\mathbf{x}_i, \mathbf{y}, \mathbf{h})$. To keep our models tractable, we assume our feature function $\mathbf{\Phi}$ decomposes linearly, similar to a linear-chain graphical model:

$$\mathbf{\Phi}(\mathbf{x}_i, \mathbf{y}_i, \mathbf{h}_i) = \sum_{n=1}^{n_i} \phi(X_{i,m}, Y_{i,n}, m, n, m'),$$

where $\mathbf{h}_i[n] = m$ and $\mathbf{h}_i[n-1] = m'$. Therefore, each factor in our linear chain graph structure depends on the alignment state for the current and the previous video chunk. For any two consecutive alignment states $\mathbf{h}_i[n] = m$ and $\mathbf{h}_i[n-1] = m'$, we represent the factor potential as:

$$\Psi(X_{i,m}, Y_{i,n}, m, n, m') = \exp\left[\mathbf{w}^T \phi(X_{i,m}, Y_{i,n}, m, n, m')\right]$$

Our goal is to maximize the following log-likelihood function:

$$L(\mathbf{w}) = \sum_{i=1}^{N} \log \sum_{\mathbf{h}_i} p(\mathbf{y}_i, \mathbf{h}_i|\mathbf{x}_i, n_i). \quad (4)$$

The gradient of the log-likelihood function with respect to the weight parameters is:

$$\frac{\partial L}{\partial \mathbf{w}} = \sum_{i=1}^{N} \Big[\mathbb{E}_{p(\mathbf{h}|\mathbf{x}_i, n_i, \mathbf{y}_i)} \left[\mathbf{\Phi}(\mathbf{x}_i, \mathbf{y}_i, \mathbf{h})\right] - \mathbb{E}_{p(\mathbf{y}, \mathbf{h}|\mathbf{x}_i, n_i)} \left[\mathbf{\Phi}(\mathbf{x}_i, \mathbf{y}, \mathbf{h})\right] \Big] \quad (5)$$

We apply the stochastic gradient descent algorithm (Vishwanathan et al., 2006) to maximize the conditional log-likelihood. For each observation $(\mathbf{x}_i, \mathbf{y}_i)$, we perform forward-backward dynamic programming to estimate the two expectation terms in equation 5, as discussed next.

4.1.1 Estimation of $\mathbb{E}_{p(\mathbf{h}|\mathbf{x}_i, n_i, \mathbf{y}_i)} \left[\mathbf{\Phi}(\mathbf{x}_i, \mathbf{y}_i, \mathbf{h})\right]$

To estimate the first expectation term in equation 5, we need to sum over all the possible alignment states $h[n] = m$, where $n \in \{1, \ldots, n_i\}$ and $m \in \{1, \ldots, m_i\}$. Since the output sequence $\mathbf{y}_i$ is given, we refer to this stage as "forced" forward-backward stage. The forward messages $\alpha_n^F[m] \propto p(Y_{i,1}, \ldots, Y_{i,n}, \mathbf{h}[n] = m \mid \mathbf{x}_i)$ are estimated using the following recursion:

$$\alpha_n^F(m) = \sum_{m'} \alpha_{n-1}^F(m')\ \Psi(X_{i,m}, Y_{i,n}, m, n, m')$$

where m' is one of the predecessors of the alignment state $h[n] = m$. Assuming no restrictions on the possible alignments, the computational complexity of each iteration on a single observation pair $(\mathbf{x}_i, \mathbf{y}_i)$ is $O(m_i^2 n_i d)$ for m_i sentences, n_i video chunks, and d dimensional features. However, we allow only a constant number of predecessor and successor states for each alignment state, and hence the computational complexity becomes $O(m_i n_i d)$. Similarly, we apply backward recursions, with the same computational complexity.

4.1.2 Estimation of $\mathbb{E}_{p(\mathbf{y}, \mathbf{h}|\mathbf{x}_i, n_i)} \left[\mathbf{\Phi}(\mathbf{x}_i, \mathbf{y}, \mathbf{h})\right]$

While computing the second expectation term, we assume only $\mathbf{x}_i$ and the number of video chunks n_i are observed, and we need to sum probabilities over all possible alignments $h[n] = m$ and all possible video sequences $\mathbf{y}$. Again we apply forward-backward. The computational complexity, however, grows significantly, as we need to sum over all possible set of blobs that may be touched by hands in

each video segment. The forward message $\alpha_n(m)$ is computed as:

$$\alpha_n(m) = \sum_{m'} \alpha_{n-1}(m') \sum_{Y \subseteq V_Y} \Psi(X_{im}, Y, m, n, m')$$

There can be $2^{|V_Y|} - 1$ possible subset of blobs at each of the alignment position, and the overall computational complexity becomes $O(2^{|V_Y|} m_i n_i d)$, which is prohibitively expensive, even for a small number of blobs. In our videos, the hands never touch more than 3 objects at a time. So we considered only the non-empty subsets with 3 or less elements: $P = \{S : S \subseteq V_Y, |S| \leq 3, S \neq \emptyset\}$. The pruning of larger subsets reduces the complexity to $O(|V_Y|^3 m_i n_i d)$. We can further reduce computation by decomposing the forward-backward recursions to the co-occurrence features and alignment path features:

$$\Psi(X_{im}, Y, m, n, m') = \Psi_{co}(X_{im}, Y)\Psi_{ap}(m, n, m')$$

The potential due to alignment path features (Ψ_{ap}) does not depend on the subset of blobs, and only depends on the current and previous alignment states $h[n] = m$ and $h[n-1] = m'$. On the other hand, the co-occurrence potential Ψ_{co} for a given set of blobs Y depends only on the sentence that it is being aligned to, and does not depend on the video chunk index n. Therefore we can decompose the forward recursion as:

$$\alpha_n(m) = \sum_{m'} \alpha_{n-1}(m')\ \Psi_{ap}(m, n, m')\ \delta(m)$$

where $\delta(m) = \sum_{Y \in P} \Psi_{co}(X_{im}, Y)$. We can precompute the values of $\delta(m)$ for each of the m_i sentences, which takes $O(m_i d |V_Y|^3)$ operations. Finally, we run forward recursions over all the alignment states using the precomputed values, and the complexity becomes $O(m_i d |V_Y|^3 + m_i n_i d)$ Similarly the backward recursion becomes:

$$\beta_n(m) = \sum_{m'} \beta_{n+1}(m')\ \Psi_{ap}(m', n{+}1, m)\ \delta(m')$$

The alignment state transition probabilities $\xi_n(m', m)$ represents the probability $p(\mathbf{h}_{n-1} = m', \mathbf{h}_n = m \mid \mathbf{x}_i)$, which can be estimated by marginalizing over all possible sets of blobs:

$$\xi_n(m', m) \propto \alpha_{n-1}(m')\Psi_{ap}(m, n, m')\delta(m)\beta_n(m)$$

4.2 Latent Variable Structured Perceptron

Structured Perceptron (Collins, 2002) has become a popular method for discriminative structured learning due to its relatively fast convergence rate and theoretical convergence guarantee. Since true alignments are unknown, we apply the latent variable structured perceptron algorithm (Liang et al., 2006; Sun et al., 2009; Yu et al., 2013) for our discriminative alignment task.

We iteratively scan through our dataset, one protocol and video pair $(\mathbf{x}_i, \mathbf{y}_i)$ at a time. First, we infer the best alignment $\mathbf{h}_i^{Forced}$ for the given observation pair $(\mathbf{x}_i, \mathbf{y}_i)$ and the current weight vector $\mathbf{w}$:

$$\mathbf{h}_i^{Forced} = \arg\max_{\mathbf{h}} \mathbf{w}^T \mathbf{\Phi}(\mathbf{x}_i, \mathbf{y}_i, \mathbf{h}). \quad (6)$$

This step is known as Forced Decoding, as we are given both the protocol sentences and the associated video chunks. Forced decoding is performed using Viterbi-like dynamic programming (Algorithm 1), where the dynamic programming states are the alignment states (m, n) such that $h[n] = m$.

Algorithm 1 Perceptron Forced-Decoding

Input: Observation pair $(\mathbf{x}_i, \mathbf{y}_i)$ and a weight vector $\mathbf{w}$.
$m_i \leftarrow$ length($\mathbf{x}_i$), and $n_i \leftarrow$ length($\mathbf{y}_i$),
$D[m, n] \leftarrow -\infty$ for $0 \leq m \leq m_i$ and $0 \leq n \leq n_i$
$D[0, 0] \leftarrow 0$
for $m = 1$ to m_i **do**
  for $n = 1$ to n_i **do**
    for each $(m', n-1) \in$ Predecessors(m, n) **do**
      $\mathbf{\Phi} \leftarrow$ create-features$(X_{i,m}, Y_{i,n}, m, n, m')$
      if $D[m', n-1] + \mathbf{w}^T\mathbf{\Phi} > D[m, n]$ **then**
        $D[m, n] \leftarrow D[m', n-1] + \mathbf{w}^T\mathbf{\Phi}$
        Backpointers$[m, n] \leftarrow m'$
$\mathbf{h}_i^{Forced} \leftarrow$ Backtrack(D, Backpointers)
Return $\mathbf{h}_i^{Forced}$

Next, we decode both the highest scoring alignment $\hat{\mathbf{h}}_i$ and video sequence $\hat{\mathbf{y}}_i$, given the protocol $\mathbf{x}_i$ and the number of video chunks n_i.

$$\hat{\mathbf{h}}_i, \hat{\mathbf{y}}_i = \arg\max_{\mathbf{h}, \mathbf{y}} \mathbf{w}^T \mathbf{\Phi}(\mathbf{x}_i, \mathbf{y}, \mathbf{h}) \quad (7)$$

We refer to this step as Full Decoding (Algorithm 2). The dynamic programming is similar to that for forced decoding, except that we need to find the best set of blobs given a set of nouns, for every protocol sentence $X_{i,m}$:

$$B[m] = \arg\max_{S \in P} \mathbf{w}_{co}^T \mathbf{\Phi}_{\mathbf{co}}(X_{i,m}, S) \quad (8)$$

where P is the pruned set of blobs and $\mathbf{\Phi_{co}}(X_{i,m}, S)$ is a vector containing only the co-occurrence features, and $\mathbf{w}_{co}$ contains their corresponding weights. The detailed algorithm is described in Algorithm 2. Finally, we update the weight vector $\mathbf{w}$:

$$\mathbf{w}^{(new)} = \mathbf{w}^{(old)} + \mathbf{\Phi}(\mathbf{x}_i, \mathbf{y}_i, \mathbf{h}_i^{Forced}) - \mathbf{\Phi}(\mathbf{x}_i, \hat{\mathbf{y}}_i, \hat{\mathbf{h}}_i)$$

Algorithm 2 Perceptron Full Decoding

Input: Input protocol $\mathbf{x}_i$, set of all blobs V_Y, number of video chunks n_i, weight vector $\mathbf{w}$.

$m_i \leftarrow \text{length}(\mathbf{x}_i)$
$D[m, n] \leftarrow -\infty$ for $0 \leq m \leq m_i$ and $0 \leq n \leq n_i$
$B[m] \leftarrow \emptyset$ for $0 \leq m \leq m_i$
$D[0, 0] \leftarrow 0$
$P \leftarrow \{S : S \subset V_Y, |S| \leq 3, S \neq \emptyset\}$ // precompute the pruned list of subsets of blobs
for $m = 1$ to m_i **do**
  $B[m] \leftarrow \arg\max_{S \in P} \mathbf{w}_{co}^T \mathbf{\Phi_{co}}(X_{i,m}, S)$
  for $n = 1$ to n_i **do**
    for each $(m', n-1) \in$ Predecessors(m, n) **do**
      $\mathbf{\Phi} \leftarrow$ create-features$(X_{i,m}, B[m], m, n, m')$
      if $D[m', n-1] + \mathbf{w}^T\mathbf{\Phi} > D[m, n]$ **then**
        $D[m, n] \leftarrow D[m', n-1] + \mathbf{w}^T\mathbf{\Phi}$
        Backpointer$[m, n] \leftarrow m'$
$\hat{\mathbf{h}}_i \leftarrow$ Backtrack(D, Backpointers)
$\hat{\mathbf{y}}_i \leftarrow [B[\hat{\mathbf{h}}_{i,1}], \ldots, B[\hat{\mathbf{h}}_{i,n_i}]]$
Return $\hat{\mathbf{h}}_i, \hat{\mathbf{y}}_i$

4.3 Constrained Decoding

During the full decoding of $(\hat{\mathbf{h}}_i, \hat{\mathbf{y}}_i)$, we have no information regarding how many video chunks to assign to each sentence. As a result, the full decoding is unlikely to predict the correct video sequence, no matter how many training iterations performed. In practice, the unconstrained full decoding often ends up aligning too many video chunks to one of the protocol sentences.

To address this problem, we modified the perceptron update rule. Instead of performing unconstrained full decoding, we constrain the alignment $\hat{\mathbf{h}}_i$ to be same as the forced alignment $\mathbf{h}_i^{Forced}$, and infer the best sequence of video chunks $\hat{\mathbf{y}}_i^{Constr}$ under this constraint:

$$\hat{\mathbf{y}}_i^{Constr} = \arg\max_{\mathbf{y}} \mathbf{w}^T \mathbf{\Phi}(\mathbf{x}_i, \mathbf{y}, \mathbf{h}_i^{Forced})$$

We refer to this decoding step as "constrained decoding" (Algorithm 3), and refer to this constrained LSP variant as LSP-C. The modified weight update rule is:

$$\mathbf{w}^{(new)} = \mathbf{w}^{(old)} + \mathbf{\Phi}(\mathbf{x}_i, \mathbf{y}_i, \mathbf{h}_i^{Forced}) - \mathbf{\Phi}(\mathbf{x}_i, \hat{\mathbf{y}}_i^{Constr}, \mathbf{h}_i^{Forced})$$

Algorithm 3 Perceptron Constrained-Decoding

Input: Input protocol $\mathbf{x}_i$, set of all blobs V_Y, number of video chunks n_i, forced alignment $\mathbf{h}_i^{Forced}$, weight vector $\mathbf{w}$.

$P \leftarrow \{S : S \subset V_Y, |S| \leq 3, S \neq \emptyset\}$
for $n = 1$ to n_i **do**
  $m \leftarrow \mathbf{h}_i^{Forced}[n]$
  $\hat{Y}_{i,n}^{Constr} \leftarrow \arg\max_{S \in P} \mathbf{w}_{co}^T \mathbf{\Phi_{co}}(X_{i,m}, S)$
Return $\hat{\mathbf{y}}_i^{Constr} = [\hat{Y}_{i,1}^{Constr}, \ldots, \hat{Y}_{i,n_i}^{Constr}]$

4.4 Latent Structured SVM

Structured SVM can be formulated by extending structured perceptron with two simple modifications: (1) incorporating a large-margin regularization term, and (2) incorporating a general loss function, instead of the zero-one loss of perceptron. The regularization reduces overfitting by keeping feature weights relatively small. Let the loss-augmented full decoding be:

$$(\hat{\mathbf{y}}_i, \hat{\mathbf{h}}_i) = \arg\max_{\mathbf{y}, \mathbf{h}} \mathbf{w}^T \mathbf{\Phi}(\mathbf{x}_i, \mathbf{y}, \mathbf{h}) + \mathcal{L}_i(\mathbf{y}, \mathbf{h}),$$

where $\mathcal{L}_i(\mathbf{y}, \mathbf{h})$ is the loss function for the i^{th} observation. LSSVM minimizes the following objective function:

$$C(w) = \frac{1}{N} \sum_{i=1}^{N} \Big(\mathbf{w}^T \mathbf{\Phi}(\mathbf{x}_i, \hat{\mathbf{y}}_i, \hat{\mathbf{h}}_i) + \mathcal{L}_i(\hat{\mathbf{y}}_i, \hat{\mathbf{h}}_i) - \mathbf{w}^T \mathbf{\Phi}(\mathbf{x}_i, \mathbf{y}_i, \mathbf{h}_i^{Forced}) \Big) + \frac{\lambda}{2} \|w\|^2,$$

which is non-convex and non-differentiable, and optimized utilizing the subgradient method (Ratliff et al., 2007). We perform online learning, and the subgradient in each iteration is:

$$g_i(\mathbf{w}) = \mathbf{\Phi}(\mathbf{x}_i, \hat{\mathbf{y}}_i, \hat{\mathbf{h}}_i) - \mathbf{\Phi}(\mathbf{x}_i, \mathbf{y}_i, \mathbf{h}_i^{Forced}) + \lambda \mathbf{w}.$$

Similar to LSP-C, we can obtain a constrained variant LSSVM-C, by replacing loss-augmented decoding with a constrained variant, where we fix $\hat{\mathbf{h}}_i$ to forced alignment $\mathbf{h}_i^{Forced}$.

4.5 Latent Variables to Map Blobs to Nouns

Given a sentence $X_{i,n}$ and a video segment $Y_{i,m}$, we further introduce additional latent variables to map each blob in $Y_{i,m}$ to one of the nouns in $X_{i,n}$. These latent variables are similar to the IBM Model 1 latent variables of Naim et al. (2014). Instead of turning on the (noun, blob) co-occurrence feature for every noun and blob in $X_{i,n}$ and $Y_{i,m}$, the latent variables map each blob to one of the nouns only. For LCRF, we sum over all the latent variables for estimating the expectations. For LSP and LSSVM, the (noun,blob) feature with maximum feature weight triggers for each blob.

5 Feature Design

The features used in our discriminative models can be grouped in two categories: (1) co-occurrence features, and (2) alignment path features. The co-occurrence features depend only on a protocol sentence and the video segment it aligns to. The alignment path features, on the other hand, do not depend on the co-occurrence of sentence and video segment, and instead capture general alignment properties, e.g., jump size and the distance of an alignment state from the diagonal.

5.1 Co-occurrence Features

The co-occurrence features included in our experiments are:

- *Co-occurrence of Nouns and Blobs:* For each noun in the input protocols and each blob in the videos, we add a boolean feature (noun, blob), which is turned on if we align a sentence containing that noun with a video segment containing that blob.

- *Co-occurrence of Verbs and Blobs:* For each verb in the input protocols and each blob in the videos, we add a boolean feature. This feature captures the observation that certain verbs are more likely to occur with certain objects (e.g., 'write' co-occurs with 'pen', 'aspirate' co-occurs with 'pipette').

We experimented with co-occurrence features of the form: (noun, verb, blob) triplets. However, including these features did not provide any noticeable gain, while significantly increasing the computation time, as the number of features increased drastically. Therefore, we did not include these features in our final experiments.

5.2 Alignment Path Features

Alignment path features depend on the current alignment state $\mathbf{h}[n] = m$, and the previous alignment states $\mathbf{h}[n-1] = m'$. These features do not depend on the nouns and verbs in the sentences and the blobs in the video segments. We used the following alignment path features:

- *Jump Size:* Since we allow monotonic jumps only, the jump sizes can be either zero or one. Therefore, we added two features for these two jump sizes.

- *Positional Features:* we added positional features (Dyer et al., 2011) to discourage alignment states that are too far from the diagonal. For each alignment state (m, n), we estimate normalized distance from the diagonal as $|\frac{m}{m_i} - \frac{n}{n_i}|$. Again we used boolean features by assigning this normalized distance to five equally spaced bins.

The alignment features are not updated by the LSP-C and LSSVM-C methods, as they assume $\mathbf{h}_i^{Forced}$ and $\hat{\mathbf{h}}_i$ to be identical.

6 Results

Our dataset contains 12 wetlab experiment videos, for 3 different protocols (4 videos per protocol). Each protocol contains natural language instructions for an actual biological experiment. On average, each protocol has 9 steps, and 24 sentences. The videos are recorded using an RGB-D Kinect camera, in a mock wetlab setup. The average video length is $\sim$ 5 minutes. There are 34 unique nouns and 25 unique verbs in the protocols, and 22 distinct blobs in the videos.

We follow the same data pre-processing technique as described by Naim et al. (2014). The number of blobs is assumed to be known apriori. We oversegment each frame into many superpixels using the SLIC Superpixels algorithm (Achanta et al., 2012). We combine multiple adjacent superpixels into a blob, based on a pre-trained Gaussian mixture

Dataset	Average Alignment Accuracy (%)							
	LHMM	LCRF	LSP	LSP-C	LSP-H	LSSVM	LSSVM-C	LSSVM-H
Manual-Tracking	75.58	**85.09**	79.64	80.68	80.41	79.64	80.68	80.41
Auto-Tracking	64.04	**65.59**	61.99	63.95	65.27	61.99	63.95	65.27

Table 1: Alignment accuracy ($\%$ of video chunks aligned to the correct protocol step) for both manual and automatic tracking data. LHMM is the existing state-of-the-art generative model. For the variants of latent perceptron (LSP) and latent structured SVM (LSSVM), "C" indicates constrained decoding, and "H" indicates hybrid update.

color model and their boundary maps (Luo and Guo, 2003), and track each blob using a 3D Kalman filter. In order to isolate alignment error from computer vision tracking and segmentation error, we manually tracked and annotated each of the video segments with the set of blobs touched by hands using the video annotation tool Anvil (Kipp, 2012). The alignment accuracies are reported both for the manual and automated tracking datasets. Parsing error is relatively small. The Charniak-Johnson parser correctly identified the nouns and verbs for most sentences, except for several single-word imperative sentences (e.g., Mix.), for which the verbs were mistakenly parsed as nouns.

We experimented with the latent CRF (LCRF), latent perceptron (LSP) and its constrained variant (LSP-C), and latent SVM (LSSVM) and its constrained variant (LSSVM-C). Furthermore, we tried two hybrid variants LSP-H and LSSVM-H, where we started with constrained decoding, and later switched to full decoding. We experimented by incorporating additional latent variables for Blob-to-Noun mapping (Section 4.5), which significantly improved alignment accuracy for LCRF, but decreased accuracy for LSP and LSSVM and their variants. We report the best result for each model. The discriminative algorithms are compared with the state-of-the-art LHMM model (Naim et al., 2014), which is a generative HMM with latent variables for blob-to-noun mapping and the observation states of each noun.

We initialized the weights for co-occurrence and jump size features to the log-probabilities learned by the generative HMM model. All the other features are initialized to zero. For both LHMM and the discriminative models, we used monotonic jumps as they performed better than the non-monotonic jumps. We used the same learning rate $\eta = \frac{0.001}{\sqrt{t}}$ (where t is the iteration number) for all the discriminative models, and the LSSVM regularization constant $\lambda = 0.001$. All the Perceprton and SVM variants performed "weight averaging" (Collins, 2002). The number of iterations are set to 100 for all the algorithms.

Table 1 shows that the discriminative models, especially LCRF and LSP-H/LSSVM-H, outperform the generative model LHMM both on the manual-tracking and auto-tracking datasets. For the manual-tracking dataset, the difference between LHMM and each of the discriminative models is statistically significant (p-value < 0.0001). On the auto-tracking dataset, however, the differences are not significant (p-value > 0.1). Table 2 shows an example of an alignment obtained by LCRF for a short segment of a manually tracked video.

The average running time for each iteration per video is 0.8 seconds for LHMM, 1.1 seconds for LSP and LSSVM, and 2.5 seconds for LCRF on a 2.9 GHz Intel Core-i7 processor and 8GB RAM.

7 Discussions and Future Work

The results show that discriminative methods outperform the generative LHMM model on both the manual and auto-tracking datasets. We achieved the best overall accuracy using the LCRF model. LCRF takes expectations over all possible alignment states and video sequences. On the other hand, LSP and LSSVM consider the highest scoring prediction only, which is similar to the hard-decision decoding. With no information regarding how many video segments to align to each sentence, LSP and LSSVM could not correctly predict the output video sequences during full decoding, and the weight vectors did not converge. By constraining the alignment to the forced alignment, we avoid aggressive updates, which may have helped LSP-C and LSSVM-C to learn better alignments. However, constrained decoding has a limitation that it can not update align-

ment path features. LCRF sums over all possible output and latent variables, which includes the correct solution, and hence constrained decoding is not necessary. While the latent variables for blob-to-noun mappings improved the alignment accuracy for LCRF, it did not improve alignment accuracy for LSP and LSSVM and their variants, presumably because of their hard-decision decoding approach.

Among the different variants of LSP and LSSVM, we obtained the best accuracy with the hybrid variants (LSP-H and LSSVM-H), where we started with constrained decoding, and then switched to standard updates. While these hybird approaches provided better accuracy, they still suffer from the issue of not converging. The feature weights learned by LSSVM and its variants were smaller than that for LSP (due to regularization). However, they always resulted in the same forced decoding alignments in our experiments, and obtained same alignment accuracy.

Unlike the previous models, we considered the co-occurrences of verbs with blobs in the video. The highest weighted features include: *(write, pen)*, *(aspirate, pipette)*, which agree with our intuition. Our immediate next step will be to automatically learn a dictionary of hand motion patterns, and consider the co-occurrence of these patterns with verbs in the sentences. Some of the objects in our video are small and thin (e.g., pen, pipette, spatula, plastic boat), and were not reliably detected by the computer vision segmentation and tracking system. This may be the reason why we achieved relatively smaller improvements on the auto-tracking dataset.

Our alignment models are different from the traditional discriminative approaches in that our cost function is not same as our evaluation criteria. Although our goal is to improve alignment accuracy, the objective function that we minimize is either the negative conditional log-likelihood (LCRF) or the number of mis-predicted video segments (LSSVM). Since the ground truth alignments are unknown, we could not integrate alignment error in our objective function. The proposed discriminative models outperform LHMM despite the fact that the discriminative models are simpler – lacking latent variables for the observation states of nouns. The alignment accuracy of the discriminative models is expected to improve even further once these latent variables are incorporated.

8 Conclusion

We proposed three discriminative unsupervised alignment algorithms and their novel variants using constrained decoding. The proposed algorithms incorporate overlapping features to capture the co-occurrences of nouns and verbs with video blobs, and outperform the state-of-the-art latent HMM model via discriminative training.

Abstract

Content analysis, a widely-applied social science research method, is increasingly being supplemented by topic modeling. However, while the discourse on content analysis centers heavily on reproducibility, computer scientists often focus more on scalability and less on coding reliability, leading to growing skepticism on the usefulness of topic models for automated content analysis. In response, we introduce TopicCheck, an interactive tool for assessing topic model stability. Our contributions are threefold. First, from established guidelines on reproducible content analysis, we distill a set of design requirements on how to computationally assess the stability of an automated coding process. Second, we devise an interactive alignment algorithm for matching latent topics from multiple models, and enable sensitivity evaluation across a large number of models. Finally, we demonstrate that our tool enables social scientists to gain novel insights into three active research questions.

1 Introduction

Content analysis — the examination and systematic categorization of written texts (Berelson, 1952) — is a fundamental and widely-applied research method in the social sciences and humanities (Krippendorff, 2004a), found in one third of all articles published in major communication journals (Wimmer and Dominick, 2010). Initial reading and coding, two labor-intensive steps in the analysis process, are increasingly replaced by computational approaches such as statistical topic modeling (Grimmer, 2013; McFarland et al., 2013; Roberts et al., 2014a).

However, while the discourse on content analysis overwhelmingly centers around the reproducibility and generalizability of a coding scheme (Krippendorff, 2004b; Lombard et al., 2002), computer scientists tend to focus more on increasing the scale of analysis and less on establishing coding reliability. Machine-generated latent topics are often taken on faith to be a truthful and consistent representation of the underlying corpus, but in practice exhibit significant variations among models or modeling runs. These unquantified uncertainties fuel growing skepticism (Schmidt, 2012) and hamper the continued adoption (Grimmer and Stewart, 2011) of topic models for automated content analysis.

In response, we introduce TopicCheck, an interactive tool for assessing the stability of topic models. Our threefold contributions are as follows.

First, from established guidelines on reproducible content analysis, we distill a set of design requirements on how to computationally assess the stability of an automated coding process. We advocate for the use of multiple models for analysis, a user-driven approach to identify acceptable levels of coding uncertainty, and providing users with the capability to inspect model output at all levels of detail.

Second, we devise an interactive *up-to-one* alignment algorithm for assessing topic model stability. Through repeated applications of a topic model to generate multiple outputs, our tool allows users to inspect whether the model consistently uncover the

[*]Work completed while at Stanford University and the University of Washington, and submitted while at the Allen Institute for Artificial Intelligence.

same set of concepts. We allow users to interactively define groupings of matching topics, and present the aligned topics using an informative tabular layout, so that users can quickly identify stable topical groupings as well as any inconsistencies.

Finally, in three case studies, we demonstrate that our tool allows social scientists to gain novel insights into active and ongoing research questions. We provide an in-depth look at the multi-modality of topic models. We document how text pre-processing alters topical compositions, causing shifts in definitions and the removal of select topics. We report on how TopicCheck supports the validity of newly-proposed communication research methods.

2 Background

Manual approaches to extract information from textual data — reading the source documents and codifying notable concepts — do not scale. For example, Pew Research Center produces the News Coverage Index (2014) to measure the quality of news reporting in the United States. Intended to track 1,450 newspapers nationwide, their purely manual efforts only cover 20 stories per day. Researchers stand to lose rich details in their data when their attention is limited to a minuscule fraction of the available texts.

Critical of approaches that "*[make] restrictive assumptions or [are] prohibitively costly*," Quinn et al. (2010) discuss the use of topic models (Blei et al., 2003) to enable large-scale text analysis by using machine-generated latent topics to approximate previously manually-crafted codes. Automated content analysis has enabled groundbreaking massive studies (Grimmer, 2013; McFarland et al., 2013; Roberts et al., 2014a). While this initial uptake of topic models is encouraging, an over-emphasis on scalability and the use of a single model for analysis invites skepticism and threatens continued adoption.

2.1 Coding Reliability & Growing Skepticism

Coding reliability is critical to content analysis. When social scientists devise a coding scheme, they must clearly articulate the definition of their codes in such a way that any person can consistently apply the given codes to all documents in a corpus.

Despite high labor cost, content analysis is typically conducted with multiple coders in order to establish coding reliability; the proper application of reliability measures is heavily discussed and debated in the literature (Krippendorff, 2004b; Lombard et al., 2002). In contrast, software packages (McCallum, 2013; Řehůřek and Sojka, 2010) and graphical tools (Chaney and Blei, 2014; Chuang et al., 2012b) have made topic models accessible, cheap to compute, easy to deploy, but they almost always present users with a single model without any measure of uncertainty; we find few studies on topic model sensitivity and no existing tool to support such analyses.

Schmidt (2012) summarizes the view among digital humanists, a group of early adopters of topic models, on the experience of working with uncertain modeling results: "*A poorly supervised machine learning algorithm is like a bad research assistant. It might produce some unexpected constellations that show flickers of deeper truths; but it will also produce tedious, inexplicable, or misleading results. . . . [Excitement] about the use of topic models for discovery needs to be tempered with skepticism about how often the unexpected juxtapositions. . . will be helpful, and how often merely surprising.*"

Researchers increasingly voice skepticism about the validity of using single models for analysis. In a comprehensive survey of automatic content analysis methods, Grimmer et al. (2011) highlight the need to validate models through close reading and model comparison, and advise against the use of software that "*simply provide the researcher with output*" with no capability to ensure the output is conceptually valid and useful. Chuang et al. (2012a) report that findings from one-off modeling efforts may not sustain under scrutiny. Schmidt (2012) argues that computer-aided text analysis should incorporate competing models or "*humanists are better off applying zero computer programs.*"

2.2 Uncertainties in Topic Models

While topic models remove some issues associated with human coding, they also introduce new sources of uncertainties. We review three factors related to our case studies: multi-modality, text preprocessing, and human judgment of topical quality.

Roberts et al. (2014b) examine the multi-modal distributions of topic models that arise due to the non-convex nature of the underlying optimization. They characterize the various local solutions, and

demonstrate that the spread of topics can lead to contradictory analysis outcomes. The authors note that optimal coding may not necessarily correspond to models that yield the highest value of the objective function, but there is currently a paucity of computational tools to inspect how the various modes differ, help researchers justify why one local mode might be preferred over another on the basis of their domain knowledge, or for an independent researcher to validate another's modeling choices.

Fokkens et al. (2013) report widespread reproducibility failures in natural language processing when they replicate — and fail to reproduce — the results reported on two standard experiments. The authors find that minor decisions in the modeling process can impact evaluation results, including two factors highly relevant to topic modeling: differences in text pre-processing and corpus vocabulary.

The word intrusion test (Chang et al., 2009; Lau et al., 2014) is considered the current state-of-the-art approach to assess topical quality, and captures human judgment more accurately than other topical coherence measures (Stevens et al., 2012; Wallach et al., 2009). However, in this approach, users inspect only a single latent topic at a time without access to the overall set of topics. As a part of this paper, we investigate whether exposure to multiple competing models affects human judgment, and whether model consistency impacts topical coherence.

2.3 Reproducibility of a Coding Process

While no single definition exists for the process of content analysis, a frequently-cited and wide-applied template is provided by Krippendorff (1989; 2004b) who recommends four steps to safeguard the reproducibility of a coding process. Practitioners must demonstrate *coder reliability*, *a decisive agreement coefficient*, *an acceptable level of agreement*, and test *individual variables*.

To the best of our knowledge, our paper is the first to convert guidelines on reproducible human coding into software design requirements on validating automated content analysis. Our interactive alignment algorithm is the first implementation of these guidelines. Our case studies represent the first reports on the impact of computationally quantifying topic model uncertainties, situated within the context of real-world ongoing social science research.

Much of the research on topic modeling focuses on model designs (Blei et al., 2004; Blei and Lafferty, 2006; Rosen-Zvi et al., 2004) or inference algorithms (Anandkumar et al., 2012). Our tool is complementary to this large body of work, and supports real-world deployment of these techniques. Interactive topic modeling (Hu et al., 2014) can play a key role to help users not only verify model consistency but actively curate high-quality codes; its inclusion is beyond the scope of a single conference paper. While supervised learning (Settles, 2011) has been applied to content analysis, it represents the application of a pre-defined coding scheme to a text corpus, which is different from the task of devising a coding scheme and assessing its reliability.

3 Validation Tool Design Requirements

A measure of coding reproducibility is whether a topic model can consistently uncover the same set of latent topics. We assume that users have a large number of topic model outputs, presumed to be identical, and that the users wish to examine unexpected variations among the outputs. To guide tool development, we first identify software design requirements, to meet the standards social scientists need to demonstrate producible coding.

3.1 Topical Mapping & Up-to-One Alignment

A key difference exists between measuring inter-coder agreement and assessing topic model variations. In a manual coding process, human coders are provided code identifiers; responses from different coders can be unambiguously mapped onto a common scheme. No such mapping exists among the output from repeated runs of a topic model. Validation tools must provide users with **effective means to generate topical mapping**.

However, the general alignment problem of optimally mapping *multiple* topics from one model to *multiple* topics in another model is both ill-defined and computationally intractable. Since our tool is to support the comparison of similar — and supposedly identical — model output, we impose the following constraint. A latent topic belonging to a model may align with *up to one* latent topic in another model. We avoid the more restrictive constraint of *one-to-one* alignment. Forcing a topic to always map onto another topic may cause highly dissimilar topics to

be grouped together, obscuring critical mismatches. Instead, up-to-one mapping allows for two potential outcomes, both of which correspond directly to the intended user task: recognize consistent patterns across the models (when alignment occurs) and identify any deviations (when alignment fails).

3.2 Guidelines Adapted for Topic Models

We synthesize the following four requirements from Krippendorff's guidelines (2004b).

To calculate the equivalent of *coder reliability*, we advocate the **use of multiple models to determine modeling consistency**, which may be determined from the repeated applications of the same topic model, a search through the parameter space of a model, or the use of multiple models.

Selecting an appropriate *agreement coefficient* depends on the underlying data type, such as binary, multivariate, ordered, or continuous codes (Cohen, 1960; Holsti, 1969; Krippendorff, 1970; Osgood, 1959; Scott, 1995). No widely-accepted similarity measure exists for aligning latent topics, which are probability distributions over a large vocabulary. We argue that validation tools must be sufficiently modular, in order to **accept any user-defined topical similarity measure** for aligning latent topics.

Acceptable level of agreement depends on the purpose of the analysis, and should account for the costs of drawing incorrect conclusions from a coding scheme. For example, do "*human lives hang on the results of a content analysis?*" (Krippendorff, 2004b). Validation tools must **allow users to set the appropriate acceptable level of agreement**, and help users determine — rather than dictate — when topic models match and what constitutes reasonable variations in the model output.

Finally, Krippendorff points out that aggregated statistics can obscure critical reliability failures, and practitioners must test *individual variables*. We interpret this recommendation as the need to **present users with not a single overall alignment score but details at all levels**: models, topics, and constituent words within each latent topic.

4 Interactive Topical Alignment

We introduce TopicCheck, an implementation of our design specifications. At the core of this tool is an interactive topical alignment algorithm.

4.1 Hierarchical Clustering with Constraints

Our algorithm can be considered as hierarchical agglomerative clustering with up-to-one mapping constraints. As input, it takes in three arguments: a list of topic models, a topical similarity measure, and a matching criterion. As output, it generates a list of topical groups, where each group contains a list of topics with at most one topic from each model.

At initialization, we create a topical group for every topic in every model. We then iteratively merge the two most similar groups based on the user-supplied topical similarity measure, provided that the groups satisfy the user-specified matching criterion and the mapping constraints. When no new groups can be formed, the algorithm terminates and returns a sorted list of final topical groups.

During the alignment process, the following two invariants are guaranteed: Every topic is always assigned to exactly one group; every group contains at most one topic from each model. A topic model m consists of a list of latent topics. A latent topic t is represented by a probability distribution over words. A topical group g also consists of a list of latent topics. Let $|m|$, $|t|$, and $|g|$ denote the number of models, topics, and groups respectively. We create a total of $|g| = |m| \times |t|$ initial topical groups. Although $|g|$ decreases by 1 after each merge, $|g| \geq |t|$ at all times. At the end of alignment, $|g| = |t|$ if and only if perfect alignment occurs and every group contains exactly one topic from each model.

Users may supply any topical similarity measure that best suits their analysis needs. We select cosine similarity for our three case studies, though our software is modular and accepts any input. As a first implementation, we apply single-linkage clustering criteria when comparing the similarity of two topical groups. Single-linkage clustering is computationally efficient (Sibson, 1973), so that users may interact with the algorithm and receive feedback in real-time; our procedure generalizes to other linkage criteria such as complete-linkage or average-linkage.

At each merge step, the most similar pair of topical groups are identified. If they meet the matching criteria and the mapping constraints, the pair is combined into a new group. Otherwise, the algorithm iteratively examines the next most similar pair until either a merge occurs or when all pairs are ex-

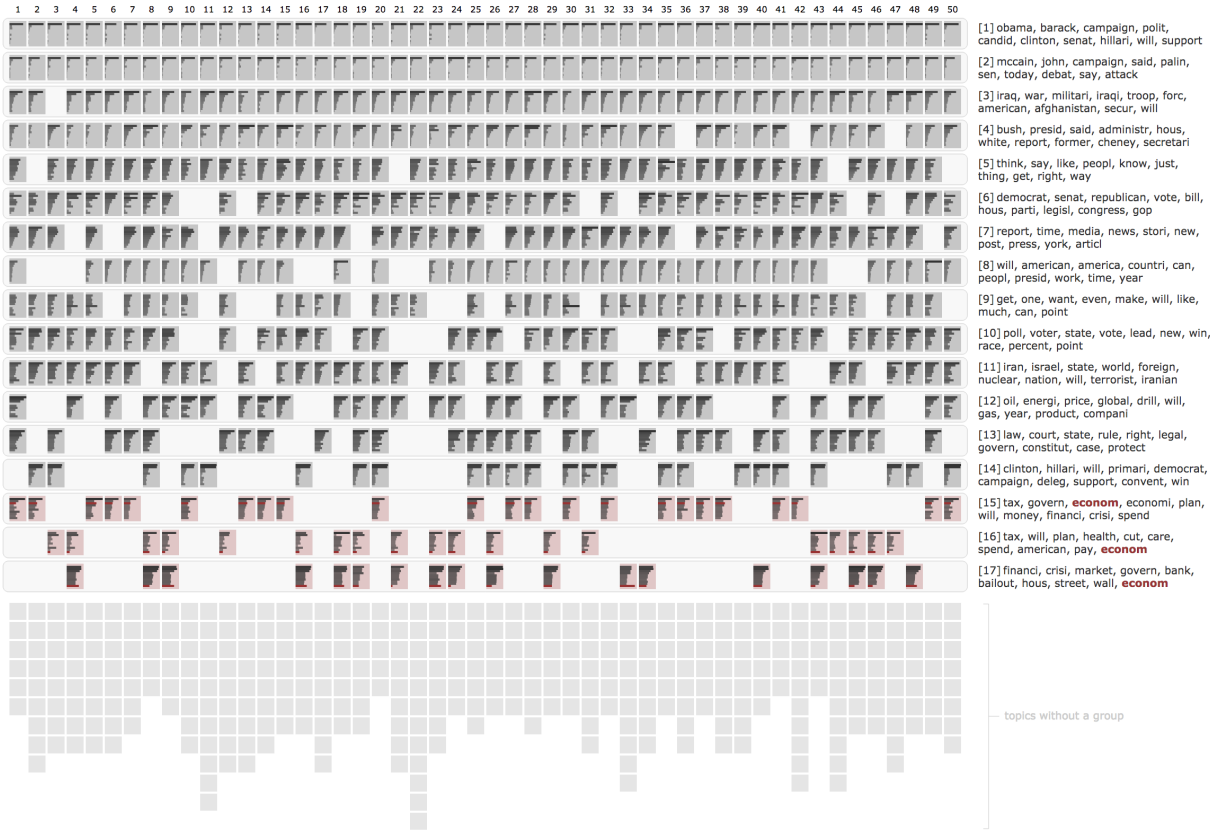

Figure 1: This chart shows topics uncovered from 13,250 political blogs (Eisenstein and Xing, 2010) by 50 structural topic models (Roberts et al., 2013). Latent topics are represented as rectangles; bar charts within the rectangles represent top terms in a topic. Topics belonging to the same model are arranged in a column; topics assigned to the same group are arranged in a row. This chart is completely filled with topics only if perfect alignment occurs. When topics in a model fail to align with topics in other models, empty cells appear in its column. Similarly, when topics in a group are not consistently uncovered by all models, empty cells appear in its row. Hovering over a term highlights all other occurrences of the same term. Top terms belonging to each topical group are shown on the right; they represent the most frequent words over all topics in the group, by summing their probability distributions.

Figure 2: Continued from Figure 1, users may decrease the similarity threshold to generate additional groupings of topics that are less consistent, uncovered by as few as 3 of the 50 modeling runs.

hausted, at which point the procedure terminates.

Users can specify a similarity threshold, below which topical groups are considered to differ too much to be matched. Two groups are allowed to merge only if both of the following conditions are met: their similarity is above the user-defined similarity threshold *and* every topic in the combined group belongs to a different model.

4.2 Tabular Layout and User Interactions

We devise a tabular layout to present the alignment output at all levels of detail: groups, models, topics,

and words. Users can interact with the algorithm, redefine matching criteria, and inspect the aligned models interactively in real-time.

We arrange topical groups as rows and topic models as columns as shown in Figure 1. A topic assigned to group g_i and belonging to model m_j is placed at the intersection of row i and column j. Our up-to-one mapping ensures at most one topic per each cell. A table of size $|g| \times |m|$ will only be completely filled with topics if perfect alignment occurs. When topics in model m_j fail to align with topics in other models, empty cells appear in column j. Similarly, when topics in group g_i are not consistently uncovered by all models, empty cells appear in row i. Within each topic, we show the probability distribution of its constituent words as a bar chart.

Users define three parameters in our tool. First, they may set the matching criteria, and define how aggressively the topics are merged into groups. Second, users may alter the number of topical groups to reveal. Rather than displaying numerous sparse groups, the tool shows only the top groups as determined by their topical weight. Topics in all remaining groups are placed at the bottom of the table and marked as *ungrouped*. Third, users may adjust the number of top terms to show, as a trade-off between details vs. overview. Increasing the number of terms allows users to inspect the topics more carefully, but the cells take up more screen space, reducing the number of visible groups. Decreasing the number of terms reduces the size of each cell, allowing users to see more groups and observe high-level patterns.

The tabular layout enables rapid visual assessment of consistency within a model or a group. We further facilitate comparisons via brushing and linking (Becker and Cleveland, 1987). When users hover over a word on the right hand side or over a bar within the bar charts, we highlight all other occurrences of the same word. For example, in Figure 1, hovering over the term *econom* reveals that the word is common in three topical groups.

5 Deployment and Initial Findings

We implemented our alignment algorithm and user interface in JavaScript, so they are easily accessible within a web browser; topical similarity is computed on a Python-backed web server. We report user responses and initial findings from deploying the tool on three social science research projects. Interactive versions of the projects are available at `http://content-analysis.info/naacl`.

5.1 A Look at Multi-Modal Solutions

We deployed TopicCheck on topic models generated by Roberts et al. (2014b) to examine how model output clusters into local modes. As the models are produced by 50 runs of an identical algorithm with all pre-processing, parameters, and hyper-parameters held constant, we expect minimal variations.

As shown in Figure 1, we observe that the top two topical groups, about Barack Obama and John McCain respectively, are consistently uncovered across all runs. The third topical group, about the Iraqi and Afghani wars (defined by a broader set of terms) is also consistently generated by 49 of the 50 runs.

Toward the bottom of the chart, we observe signs of multi-modality. Topical groups #15 to #17 represent variations of topics about the economy. Whereas group #15 is about the broader economy, groups #16 and #17 focus on taxes and the financial crisis, respectively. Half of the runs produced the broader economy topic; the other runs generated only one or two of the specialized subtopics. No single model uncovered all three, suggesting that the inference algorithm converged to one of two distinct local optimal solutions. In Figure 2, by lowering the matching criteria and revealing additional groups, we find that the model continues to produce interesting topics such as those related to global warming (group #24) or women's rights (group #25), but these topics are not stable across the multiple modes.

5.2 Text Pre-Processing & Replication Issues

We conducted an experiment to investigate the effects of rare word removal using TopicCheck. As a part of our research, we had collected 12,000 news reports from five different international news sources over a period of ten years, to study systematic differences in news coverage on the rise of China, between western and Chinese media.

While many modeling decisions are involved in our analysis, we choose rare word removal for two reasons. First, though the practice is standard, to the best of our knowledge, we find no systematic studies on how aggressively one should cull the vocabulary.

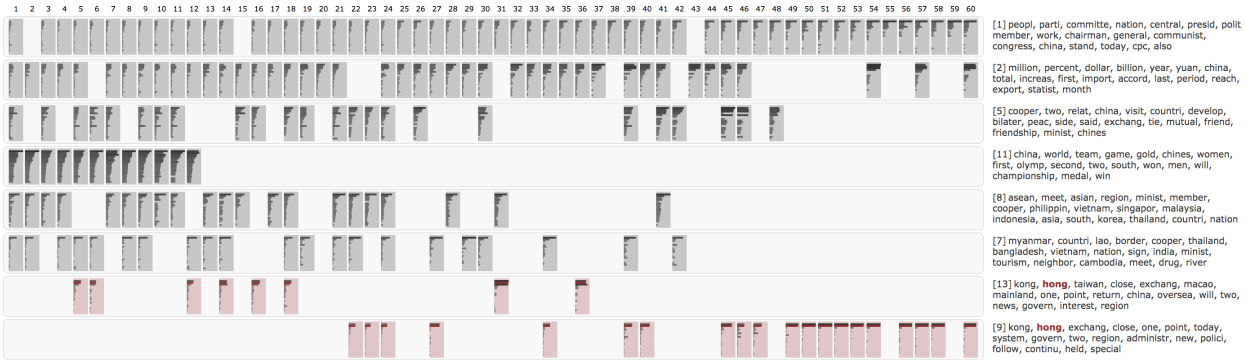

Figure 3: While rare word removal is generally considered to have limited impact on topic model output, we find evidence to the contrary. By varying the removal threshold, for this corpus of international news reports on the rise of China, we observe that topics such as group #11 on the Beijing Olympics begin to disappear. Topics about Hong Kong appear sporadically. On top of the inconsistency issues, different pre-processing settings lead to drifts in topic definitions. For milder removal thresholds (toward the left), group #13 discusses Hong Kong within the context of Taiwan and Macau. With more aggressive filtering (toward the right), group #14 shifts into discussions about Hong Kong itself such as *one country two systems* and the *special administrative region*. Unchecked, these seemingly minor text pre-processing decisions may eventually lead researchers down different paths of analysis.

Second, as latent topics are typically defined through their top words, filtering words that occur only in a small fraction of the documents is generally considered to have limited impact on model output.

We trained structural topic models (Roberts et al., 2013) based on a subset of the corpus with 2,398 documents containing approximately 20,000 unique words. We applied 10 different settings where we progressively removed a greater number of rare terms beyond those already filtered by the default settings while holding all other parameters constant. The number of unique words retained by the models were 1,481 (default), 904, 634, 474, 365, . . ., down to 124 for the 10 settings. We generated 6 runs of the model at each setting, for a total of 60 runs. Removed words are assigned a value of 0 in the topic vector when computing cosine similarity.

We observe significant changes to the model output across the pre-processing settings, as shown in Figure 3. The six models on the far left (columns 1 to 6) represent standard processing; rare word removal ranges from the mildest (columns 7 to 12) to the most aggressive (columns 55 to 60) as the columns move from left to right across the chart.

While some topical groups (e.g., #1 on the communist party) are stable across all settings, many others fade in and out. Group #11 on the Beijing Olympics is consistent under standard processing and the mildest removal, but disappears completely afterward. We find two topical groups about Hong Kong that appear sporadically. On top of the instability issues, we observe that their content drifts across the settings. With milder thresholds, topical group #13 discusses Hong Kong within the context of Taiwan and Macau. With more aggressive filtering, topical group #14 shifts into discussions about Hong Kong itself such as *one country two systems* and the *special administrative region*. Unchecked, these minor text pre-processing decisions may lead researchers down different paths of analysis.

5.3 News Coverage & Topical Coherence

Agenda-setting refers to observations by McCombs et al. (1972) that the media play an important role in dictating issues of importance for voters, and by Iyengar et al. (1993) that news selection bias can determine how the public votes. Studying agenda-setting requires assessing the amount of coverage paid to specific issues. Previous manual coding efforts are typically limited to either a single event or subsampled so thinly that they lose the ability to consistently track events over time. Large-scale analysis (e.g., for an entire federal election) remains beyond the reach of most communication scholars.

As part of our research, we apply topic modeling to closed-captioning data from over 200,000 hours of broadcasts on all mainstream news networks, to track the full spectrum of topics across all media out-

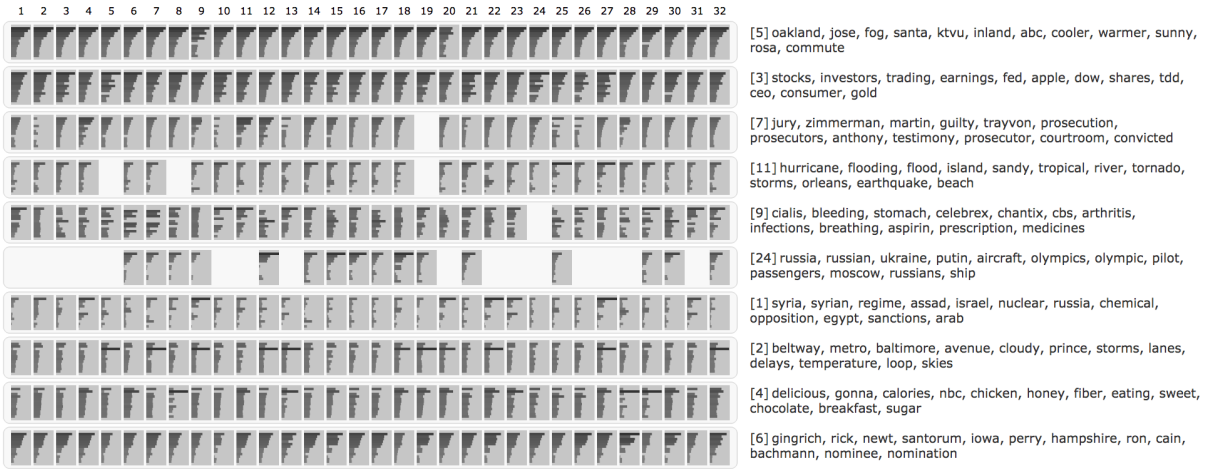

Figure 4: To enable large-scale studies of agenda-setting, we applied topic modeling to closed-captioning of over 200,000 hours of broadcasts, to estimate coverage in mainstream news networks. Through TopicCheck, the researchers find consistent topical groups that correspond to known major news categories. Group #9 represents topics about advertisements and valuable data to study the relationships between broadcasters and advertisers.

lets. We conduct word intrusion tests (Chang et al., 2009) on Amazon Mechanical Turk, and obtain over 50,000 user ratings to identify high quality topics. However, to establish topic modeling as a valid research method, we must demonstrate the reliability of how we include or exclude topics in our analyses.

By applying TopicCheck to 32 runs of the same topic model, as shown in Figure 4, we confirm that the consistent topical groupings capture at least four major known news categories: weather (such as group #5), finance (group #3), major events (group #7 on the Trayvon Martin shooting), and natural disasters (group #11 on Hurricane Katrina). We find additional evidence supporting the use of topic models, including the consistent appearance of advertising topics (group #9 on the sales of prescription medicine to senior citizens, a major demographic of the broadcast news audience). These topics may enable studies on the relationship between broadcasters and advertisers, an important but difficult question to address because few previous studies have the resources to codify advertisement content.

However, event-specific topics tend to appear less consistently (such as group #24 on Russia, its conflict with Ukraine, and the Sochi Olympics). We note the lack of consistent topics on supreme court cases, an expected but missing news category, which warrants more in-depth investigations.

We compare human judgment of topical quality when examining multiple models and those based on word intrusion tests. We calculate the aggregated topical coherence scores for each topical grouping. We find that consistent topical groups tend to receive higher coherence scores. However, topics about natural disasters receive low scores with a high variance (avg 0.5371; stdev 0.2497); many of them would have previously been excluded from analysis.

6 Discussions

To many social scientists, statistical models are measurement tools for inspecting social phenomena, such as probing recurring language use in a text corpus with topic models. In this light, instruments with known performance characteristics — including well-quantified uncertainties and proper coverage — are more valuable than potentially powerful but inconsistent modeling approaches.

Our initial findings suggest that a single topic model may not capture all perspectives on a dataset, as evident in the multiple local solutions about the economy, Hong Kong, and natural disasters in the three case studies respectively. By exposing model stability, our tool can help researchers validate modeling decisions, and caution against making too general a claim about any single modeling result.

We hypothesize that the low coherence scores for topics about natural disasters might derive from two causes. First, news media might cover an event differently (e.g., focusing on economic vs. humanitarian issues during Hurricane Katrina). Second, un-

folding events may naturally have less stable vocabularies. In both cases, detecting and pinpointing reporting bias is central to the study of agenda-setting. These observations suggest that for certain applications, identifying consistent topics across multiple models may be equally critical as, if not more than, enforcing topical coherence within a single model.

Increasingly, text analysis relies on data-dependent modeling decisions. Rare word removal can substantively alter analysis outcomes, but selecting an appropriate threshold requires inspecting the content of a text corpus. TopicCheck can help archive the exact context of analysis, allowing researchers to justify — and readers to verify and challenge — modeling decisions through access to data.

Finally, topic modeling has dramatically lowered the costs associated with content analysis, allowing hundreds of models to be built in parallel. The current intended user task for TopicCheck is to validate the stability of presumably identical models. We plan to develop additional tools to help social scientists design better models, and actively explore the effects of alternative coding schemes.

7 Conclusion

We present TopicCheck for assessing topic model stability. Through its development, we demonstrate that existing research on reproducible manual codification can be transferred and applied to computational approaches such as automated content analysis via topic modeling. We hope this work will help computer scientists and social scientists engage in deeper conversations about research reproducibility for large-scale computer-assisted text analysis.

Inferring latent attributes of Twitter users with label regularization

Abstract

Inferring latent attributes of online users has many applications in public health, politics, and marketing. Most existing approaches rely on supervised learning algorithms, which require manual data annotation and therefore are costly to develop and adapt over time. In this paper, we propose a lightly supervised approach based on label regularization to infer the age, ethnicity, and political orientation of Twitter users. Our approach learns from a heterogeneous collection of soft constraints derived from Census demographics, trends in baby names, and Twitter accounts that are emblematic of class labels. To counteract the imprecision of such constraints, we compare several constraint selection algorithms that optimize classification accuracy on a tuning set. We find that using no user-annotated data, our approach is within 2% of a fully supervised baseline for three of four tasks. Using a small set of labeled data for tuning further improves accuracy on all tasks.

1 Introduction

Data annotation is a key bottleneck in applying supervised machine learning to language processing problems. This is especially problematic in streaming settings such as social media, where models quickly become dated as new linguistic patterns emerge. An attractive alternative is *lightly supervised learning* (Schapire et al., 2002; Jin and Liu, 2005; Chang et al., 2007; Graça et al., 2007; Quadrianto et al., 2009; Mann and McCallum, 2010; Ganchev et al., 2010). In this approach, classifiers are trained from a set of domain-specific *soft* constraints, rather than individually labeled instances. For example, *label regularization* (Mann and McCallum, 2007; Graça et al., 2007) uses prior knowledge of the expected label distribution to fit a model from large pools of unlabeled instances. Similarly, annotating features with their expected class frequency has proven to be an efficient way of bootstrapping from domain knowledge (Druck et al., 2009; Melville et al., 2009; Settles, 2011).

In this paper we use lightly supervised learning to infer the age, ethnicity, and political orientation of Twitter users. Lightly supervised learning provides a natural method for incorporating the rich, declarative constraints available in social media. Our approach pairs unlabeled Twitter data with constraints from county demographics, trends in first names, and exemplar Twitter accounts strongly associated with a class label.

Prior applications of label regularization use a small number of highly-accurate constraints; for example, Mann and McCallum (2007) use a single constraint that is the true label proportions of an unlabeled dataset, and Ganchev and Das (2013) use cross-lingual constraints from aligned text. In contrast, we use hundreds of constraints that are heterogeneous, overlapping, and noisy. For example, we constrain the predicted attributes of users from a county to match those collected by the Census, despite the known non-representativeness of Twitter users (Mislove et al., 2011). Furthermore, users from that county who list first names in their profile have additional constraints imposed upon them, which may conflict with the county constraints.

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 185–195,
Denver, Colorado, May 31 – June 5, 2015.

To deal with such noisy constraints, we explore forward selection algorithms that choose from hundreds of soft constraints to optimize accuracy on a tuning set. We find that this approach is competitive with a fully supervised approach, with the added advantage of being less reliant on labeled data and therefore easier to update over time. Our primary research questions and answers are as follows:

RQ1. What effect do noisy constraints have on label regularization? We find that simply using all constraints, ignoring noise and overlap, results in surprisingly high accuracy, within 2% of a fully-supervised approach on three of four tasks. For age classification, the constraint noise appears to substantially degrade accuracy.

RQ2. How can we select the most useful constraints? Using a small tuning set, we find that our forward selection algorithms improve label regularization accuracy while using fewer than 10% of the available constraints. Constraint selection improves age classification accuracy by nearly 18% (absolute).

RQ3. Which constraints are most informative? We find that follower constraints result in the highest accuracy in isolation, yet the constraint types appear to be complementary. For three of four tasks, combining all constraint types leads to the highest accuracy.

In the following, we first review related work in lightly supervised learning and latent attribute inference, then describe the Twitter data and constraints. Next, we formalize the label regularization problem and our constraint selection algorithms. Finally, we present empirical results on four classification tasks and conclude with a discussion of future work.

2 Related Work

Inferring demographic attributes of users in social media with supervised learning is a growing area of interest, with applications in public health (Dredze, 2012), politics (O'Connor et al., 2010) and marketing (Gopinath et al., 2014). Attributes considered include age (Nguyen et al., 2011; Al Zamal et al., 2012), ethnicity (Pennacchiotti and Popescu, 2011; Rao et al., 2011), and political orientation (Conover et al., 2011; Barberá, 2013).

The main of drawback supervised learning in social media is that human annotation is expensive and error-prone, and collecting pseudo-labeled data by self-identifying keywords is noisy and biased (e.g., searching for profiles that mention political orientation). For these reasons we investigate lightly-supervised learning, which takes advantage of the plentiful unlabeled data.

Previous work in lightly-supervised learning has developed methods to train classifiers from prior knowledge of label proportions (Jin and Liu, 2005; Chang et al., 2007; Musicant et al., 2007; Mann and McCallum, 2007; Quadrianto et al., 2009; Liang et al., 2009; Ganchev et al., 2010; Mann and McCallum, 2010; Chang et al., 2012; Wang et al., 2012; Zhu et al., 2014) or prior knowledge of features-label associations (Schapire et al., 2002; Haghighi and Klein, 2006; Druck et al., 2008; Melville et al., 2009). In addition to standard document categorization tasks, lightly supervised approaches have been applied to named-entity recognition (Mann and McCallum, 2010; Ganchev and Das, 2013; Wang and Manning, 2014), dependency parsing (Druck et al., 2009; Ganchev et al., 2009), language identification (King and Abney, 2013), and sentiment analysis (Melville et al., 2009).

One similarly-motivated work is that of Chang et al. (2010), who infer race/ethnicity of online users using name and ethnicity distributions provided by the U.S. Census Bureau. This external data is incorporated into the model as a prior; however, no linguistic content is used in the model, limiting the coverage of the resulting approach. Oktay et al. (2014) extend the work of Chang et al. (2010) to also include statistics over first names.

Other work has inferred population-level statistics from social media; e.g., Eisenstein et al. (2011) use geolocated tweets to predict zip-code statistics of demographic attributes of users, and Schwartz et al. (2013) predict county health statistics from Twitter. However, no user-level attributes are predicted.

Patrini et al. (2014) build a Learning with Label Proportions (LLP) model with the objective to learn a supervised classifier when, instead of labels, only label proportions for bags of observations

are known. Their empirical results demonstrate that their algorithms compete with or are just percents of AUC away from the supervised learning approach.

In preliminary work (Mohammady and Culotta, 2014), we fit a regression model to predict the ethnicity distribution of a county based on its Twitter usage, then applied the regression model to classify individual users. In contrast, here we use label regularization, which can more naturally be applied to user-level classification and can incorporate a wider range of constraint types.

3 Data

In this section we describe all data and constraints collected for our experiments.

3.1 Labeled Twitter Data

For validation (and for tuning some of the methods) we annotate Twitter users according to age, ethnicity, and political orientation. We collects four disjoint datasets for this purpose:

Race/ethnicity: This data set comes from the research of Mohammady and Culotta (2014). They categorized 770 Twitter profiles into one of four categories (Asian, Black, Latino, White). They used the Twitter Streaming API to obtain a random sample of 1,000 users, filtered to the United States. These were manually categorized by analyzing the profile, tweets, and profile image for each user, discarding those for which race could not be determined (230/1,000; 23%). The category frequency is Asian (22), Black (263), Latino (158), White (327). For each user, they collected the 200 most recent tweets using the Twitter API. We refer to this dataset as the **race** dataset.

Age: Annotating Twitter users by age can be difficult, since it is rarely explicitly mentioned. Similar to prior work (Rao et al., 2010; Al Zamal et al., 2012), we divide users into those below 25 and those above above 25 years old. Using the idea from Al Zamal et al. (2012), we use the Twitter search API to find tweets with phrases like "happy 30th birthday to me," and then we collect those users and download their 200 most recent tweets using the Twitter API. We collect 1,436 users (771 below 25 and 665 above 25). While this sampling procedure introduces some selection bias, it provides a useful form of validation in the absence of expedient alternatives. We refer to this dataset as the **age** dataset.

Politician: Inspired by works of (Cohen and Ruths, 2013), we select the official Twitter accounts of members of the U.S. Congress. We select 189 Democratic accounts and and 188 Republican accounts and download their most recent 200 tweets. We refer to this dataset as the **politician** dataset.

Politician-follower: As the **politician** dataset is not representative of typical users, we collect a separate political datasets. We first collect a list of followers of the official Twitter accounts for both parties ("thedemocrats" and "gop"). We randomly select 598 likely Democrats and 632 likely Republicans, and download the most recent 200 tweets for each user. While the labels for these data may contain moderate noise (since not everyone who follows "gop" is Republican), a manual inspection did not reveal any mis-annotations. We refer to this as the **politician-follower** dataset.[1]

We split each of the datasets above into 40% tuning/training and 60% testing (though not all methods will use the training set, as we describe below).

3.2 Unlabeled Twitter Data

Label regularization depends on a pool of unlabeled data, along with soft constraints over the label proportions in that data. Since many of our constraints involve location, we use the Twitter streaming API to collect 1% of geolocated tweets, using a bounding box of the United States (48 contiguous states plus Hawaii and Alaska). In order to assign each tweet to a county, we use the U.S. Census' center of population data.[2] We use this data to map each geolocated Twitter user to a corresponding county. We use the k-d tree algorithm (Maneewongvatana and Mount, 2002) to find the nearest center of population for each tweet and use a threshold to discard tweets that are not within a specified distance of any county center. In total, we collect 18 million geolocated tweets from 2.7 million unique users.

[1] We were unfortunately unable to obtain the annotated political data of Cohen and Ruths (2013) for direct comparison.

[2] https://www.census.gov/geo/reference/centersofpop.html

3.3 Constraints

Finally, we describe the soft constraints used by label regularization. Each constraint will apply to a (possibly overlapping) subset of users from the unlabeled Twitter data. For all constraints below, we only include the constraint for consideration if at least 1,000 unlabeled Twitter users are matched. For example, if we only have 500 users from a county, we will not use that county's demographics as a constraint. This is to ensure that there is sufficient unlabeled data for learning. We consider three classes of constraints:

County constraints (cnt): The U.S. Census produces annual estimates of the ethnicity and age demographics for each county. We use the most recent decennial census (2010) to compute the proportion of each county that is below and above 25 years old (to match the labels of the annotated data). We additionally use the 2012 updated estimates of ethnicity by county, restricting to Asian, Black, Latino, and White. Each constraint, then, is applied to the users assigned to that county in the unlabeled data. For example, there are 46K unlabeled users from Cook County, which the Census estimates as 45% White. We consider 3,000 total counties as constraints, of which roughly 500 are retained for consideration after filtering those that match fewer than 1,000 users.

Name constraints (nam): Silver and McCanc (2014) recently demonstrated how a person's first name can often indicate their age. The Social Security Administration reports the frequencies of names given to children born in a given year,[3] and its actuarial tables[4] estimate how many people born in a given year are still alive. From these data, one can estimate the age distribution of people with a given name. For example, the median age of someone named "Brittany" is 23. With this approach, we can assign constraints indicating the fraction of people with a given name that are above and below 25 years old.

For each user in the unlabeled Twitter data, we parse the "name" field of the profile, assuming that the first token represents the first name. Constraints are assigned to users with matching names. We consider more than 50K total name constraints, of which we retain 175 that match a sufficient number of users. For example, there are roughly 1,600 unlabeled users with the first name Katherine; the constraint specifies that 86% of them are under 25.

Follower constraints (fol): Our final type of constraint uses Twitter accounts and hashtags strongly associated with a class label. The constraint applies to users that follow such exemplar accounts or use such hashtags. We consider two sources of such constraints. For age and race, we download demographic data for 1K websites from Quantcast.com, an audience measurement company that tracks the demographics of visitors to millions of websites (Kamerer, 2013). We then identify the Twitter accounts for each website. For example, one constraint indicates that 12% of Twitter users who follow "oprah" are Latino. For political constraints, we manually identify 18 Twitter accounts or hashtags that are strongly associated with either Democrats or Republicans.[5] The constraint specifies that 90% of users that follow one of these accounts (or use one of these hashtags) are affiliated with the corresponding party. (We omit constraints use to construct the labeled data for the **politician-follower** data.)

4 Label Regularization

Our goal is to learn a classification model using the unlabeled Twitter data and the constraints described above. The idea of label regularization is to define an objective function that enforces that the predicted label distribution for a set of unlabeled data closely matches the expected distribution according to a constraint.

We select multinomial logistic regression as our classification model. Given a feature vector x, a class label y, and set of parameter vectors $\theta = \{\theta_{y_1} \dots \theta_{y_k}\}$ (one vector per class), the conditional distribution of y given x is defined as follows:

$$p_\theta(y|x) = \frac{\exp(\theta_y \cdot x)}{\sum_{y'} \exp(\theta_{y'} \cdot x)}$$

[3] http://www.ssa.gov/oact/babynames/

[4] http://www.ssa.gov/oact/NOTES/as120/LifeTables_Tbl_7.html

[5] For Democrats: thedemocrats, wegoted, dccc, collegedems, dennis_kucinich, sensanders, repjohnlewis, keithellison, #p2. For Republicans: gop, nrsc, the_rga, repronpaul, senrandpaul, senmikelee, repjustinamash, gopleader, #tcot

Typically, θ is set to maximize the likelihood of a labeled training set. Instead, we will optimize the objective defined in Mann and McCallum (2007), using only unlabeled data and constraints.

Let $U = \{U_1 \dots U_k\}$ be a set of sets, where U_j consists of unlabeled feature vectors x. The elements of U may be overlapping. Let $\tilde{p}_j$ be the expected label distribution of U_j. E.g., $\tilde{p}_j = \{.9, .1\}$ would indicate that 90% of examples in U_j are expected to have class label 0. The combination of $(U_j, \tilde{p}_j)$ is called a **constraint**.

Our goal, then, is to set θ so that the predicted label distribution matches $\tilde{p}_j$, for all j. Since using the predicted class counts results in an objective that is non-differentiable, Mann and McCallum (2007) instead use the model's posterior distribution:

$$\hat{q}_j(y) = \sum_{x \in U_j} p_\theta(y|x)$$

$$\hat{p}_j(y) = \frac{\hat{q}_j(y)}{\sum_{y'} \hat{q}_j(y')}$$

where $\hat{p}_j$ is the normalized form of $\hat{q}_j$. Then, we want to set θ such that $\hat{p}_j$ and $\tilde{p}_j$ are close. Mann and McCallum (2007) use KL-divergence, which is equivalent to augmenting the likelihood with a Dirichlet prior over expectations where values for the priors are proportional to $\tilde{p}_j$. KL-divergence can be factored into two parts:

$$= -\sum_y \tilde{p}_j(y) \log \hat{p}_j(y) + \sum_y \tilde{p}_j(y) \log \tilde{p}_j(y)$$
$$= H(\tilde{p}_j, \hat{p}_j) - H(\tilde{p}_j)$$

where $H(\tilde{p}_j)$ is constant for each j, and so we need to minimize $H(\tilde{p}_j, \hat{p}_j)$ in order to minimize KL-divergence, where $H(\tilde{p}_j, \hat{p}_j)$ is the cross-entropy of the hypothesized distribution and the expected distribution for U_j.

We additionally use L2 regularization, resulting in our final objective function:

$$J(\theta) = \sum_j H(\tilde{p}_j, \hat{p}_j) + \frac{1}{\lambda} \sum_y ||\theta_y||_2^2$$

In practice we find that λ does not need tuning for each data set. We set it simply to:

$$\lambda = \frac{C}{\sum_j |U_j|}$$

We set C to 1.3e10 in our experiments. Mann and McCallum (2007) compute the gradient of cross-entropy as follows:

$$\frac{\partial}{\partial \theta_k} H(\tilde{p}_j, \hat{p}_j) = -\sum_{x \in U_j} \sum_y p_\theta(y|x) x_k$$
$$\times \left(\frac{\tilde{p}_j(y)}{\hat{p}_j(y)} - \sum_{y'} \frac{\tilde{p}_j(y) \times p_\theta(y'|x)}{\hat{p}_j(y)} \right)$$

The gradient for θ_k is then a sum of the gradients for each constraint j. In order to minimize the objective function, we use gradient descent with L-BFGS (Byrd et al., 1995). (While the objective is not guaranteed to be convex, this approximation has worked well in prior work.) To help reduce overfitting, we use early-stopping (10 iterations).

Temperature: Mann and McCallum (2007) find that sometimes label regularization returns a degenerate solution. For example, for a three class problem with constraint $\tilde{p}_j(y) = \{.5, .35, .15\}$, it may find a solution such that $p_\theta(y) = \{.5, .35, .15\}$ for every instance and as a result all of the instances are assigned the same label. To avoid this behavior Mann and McCallum (2007) introduce a temperature parameter T into the classification function as follows:

$$p_\theta(y|x) = \frac{\exp(\theta_y \cdot x / T)}{\sum_y \exp(\theta_y \cdot x / T)}$$

In practice we find that we can set T to two for binary classification and ten for multi-class problems.

While the approach described above closely follows Mann and McCallum (2007), we note two important distinctions: we use no labeled data in our objective, and we consider a set of hundreds of noisy, overlapping constraints (as opposed to only a handful of precise constraints).

4.1 Constraint Selection

As described above, our proposed constraints are undoubtedly inexact. For example, it is generally accepted that social media users are not a representative sample of the population. E.g., younger, urban and minority populations tend to be overrepresented on Twitter (Mislove et al., 2011; Lenhart and Fox, 2009), and Latino users tend to be underrepresented on Facebook (Watkins, 2009). Thus, it is incorrect to

assume that the demographics of Twitter users from a county match those of all people from a county. While it may be possible to directly adjust for these mismatches using techniques from survey reweighting (Gelman, 2007), it is difficult to precisely quantify the proper weights in this context.

Instead, we propose a search-based approach inspired by feature selection algorithms commonly used in machine learning (Guyon and Elisseeff, 2003). The idea is to select the subset of constraints that result in the most accurate model. We first assume the presence of a small set of labeled data $L = \{(x_1, y_1) \dots (x_n, y_n)\}$. Given a set of constraints $C = \{(U_1, \tilde{p}_1) \dots (U_k, \tilde{p}_k)\}$, the search objective is to select a subset of constraints $C^* \subseteq C$ to minimize error on L:

$$C^* \leftarrow \operatorname*{argmin}_{C' \subseteq C} E(p_{C'}(y|x), L)$$

where $E(\cdot)$ is a classification error function, and $p_{C'}(y|x)$ is the model fit by label regularization using constraint set C'.

In our experiments, $|C|$ is in the hundreds, so exhaustive, exponential search is impractical. Instead, we consider the following greedy and pseudo-greedy forward-selection algorithms:

- **Greedy (grdy):** Standard greedy search. At each iteration, we select the constraint that leads to the greatest accuracy improvement on L.
- **Semi-greedy (semi):** Rather than selecting the constraint that improves accuracy the most, we randomly select from the top three constraints (Hart and Shogan, 1987).
- **Improved-greedy (imp):** The same as **grdy**, but after each iteration, optionally remove a single constraint. We consider each currently selected constraint, and compute the accuracy attained by removing this constraint from the set. We remove the constraint that improves accuracy the most (if any exists). This constraint is removed from consideration in future iterations.
- **Grasp (grsp):** Greedy Randomized Adaptive Search Procedures (Feo and Resende, 1995) combines **semi** and **imp**.

We run each selection algorithm for 140 iterations (as we discuss below, accuracy plateaus well before then). Then, we select the constraint set that results in the highest accuracy. While this search procedure is computationally expensive, it is fortunately easily parallelizable (by partitioning by constraint), which we take advantage of in our implementation. All constraint selection algorithms use the 40% of the labeled data reserved for training/tuning. After we finalized all models using the tuning data, we then used them to classify the 60% of labeled data reserved for testing.

5 Baselines

We compare label regularization with standard logistic regression (**logistic**) trained using the 40% of labeled data reserved for training/tuning. We also consider several heuristic baselines:

- **Name heuristic, race classification**: We implement the method proposed by (Mohammady and Culotta, 2014), using the top 1000 most popular last names with their race distribution from the U.S. Census Bureau to infer race/ethnicity of users based of most probable race according last name. If the last name is not among the top 1000 most popular for a given race, we simply predict White (the most frequent class).
- **Name heuristic, age classification**: We use the heuristic described in Section 3.3 that estimates a person's age by their first name. Given the age distribution of a first name, we classify the user according to the more probable class.
- **Follower heuristic, political classification**: We reuse the exemplar accounts used in the follower constraint in Section 3.3. That is, rather than using the fact that a user follows "dennis_kucinich" as a soft constraint, we classify such a user as a Democrat. If a user follows more than one of the exemplar accounts, we select the more frequent party.[6] In case of ties (or if the user does not follow any of the accounts), we classify at random.

[6] For the **politician-follower** data the heuristic does not use "thedemocrats" and "gop," because these were used for the original annotation.

	race	age	pol	pol-f	avg

Table 1: Accuracy on the *testing* set. **all-const** does no constraint selection; **imp-greedy** selects constraints to maximize accuracy on the tuning set using the Improved-greedy algorithm.

Features: For all models, we use a standard bag-of-words representation consisting of a binary term vector for the 200 tweets of each user, their description field, and their name field. We differentiate between terms used in the description, tweet text, and name field, and also indicate hashtags. Finally, we include additional features indicating the accounts followed by each user.

6 Results

Table 1 shows the classification accuracy on the test set for each of the four tasks (F1 results are similar). We begin by comparing **heuristic** and **logistic** to the **all-const** results, which is our proposed label regularization approach using no constraint selection (i.e., no user-labeled data). We can see that for three of the four tasks (**race**, **pol**, **pol-f**), label regularization accuracy is either the same as **logistic** or within 2%. That is, using no user-annotated data, we can obtain accuracy competitive with logistic regression.

For **age**, however, label regularization does quite poorly; only using the **fol** constraints surpasses the heuristic baseline. We suspect that this is in part due to the greater noise in age constraints — Twitter users are particularly non-representative of the overall population according to age. To summarize our answer to **RQ1**, label regularization appears to perform quite well under a moderate amount of constraint noise, but can still fail under excessive noise.

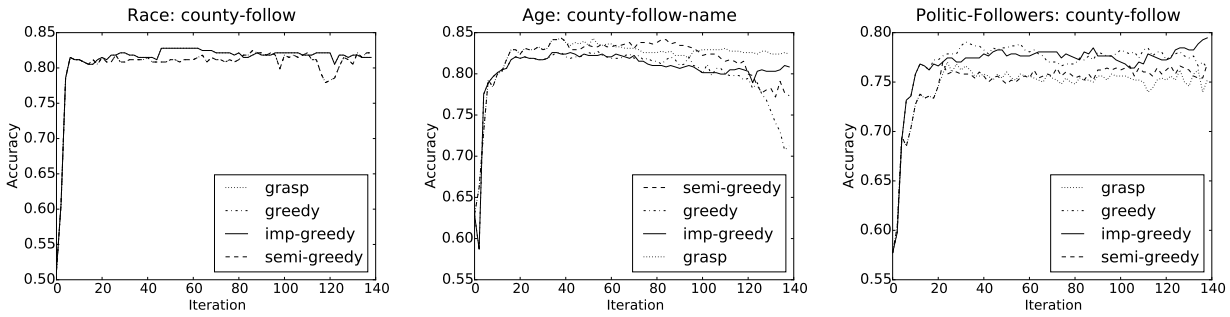
	all	grdy	semi	imp	grsp
Race	77.9	82.5	82.5	**82.8**	**82.8**
Age	48.4	82.8	**84.3**	82.6	**84.3**
Politician	84.0	98.7	96.0	**99.3**	96.7
Politic-fol	61.8	79.1	77.0	**79.5**	77.0
Average	68.0	85.7	85.0	**86.0**	85.2

Table 2: Comparison of the accuracy of constraint selection algorithms on the *tuning* set. **all** uses all possible constraints.

We next consider the effect of the constraint selection algorithms. Table 2 compares the four different constraint selection algorithms, along with the model that selects all constraints. We report the accuracy for each approach considering all constraint types (county, follow, and name, where applicable). Importantly, this accuracy is computed on the *tuning* set, not the test set. The goal here is to determine which search algorithm is able to find the best approximate solution. By comparing with **all**, we can see that constraint selection can significantly improve accuracy on the tuning set (by 18% absolute on average). The differences among the selection algorithms do not appear to be significant.

Figure 1 plots the accuracy at each iteration of constraint select for three of the datasets. The main conclusion we draw from these figures is that high accuracy can be achieved with only a small number of constraints, provided they are carefully chosen. Each method is very close to convergence after using only 20 constraints (selected from hundreds). When examining which constraints are selected, we find that those that apply to many users are often preferred, presumably because there is more data to inform the final model.

Returning to Table 1, we have also listed the accuracy of the **imp-greedy** selection method (which performed best on the tuning set), further strati-



(a) (b) (c)

Figure 1: Accuracy per iteration of constraint selection for three classification tasks.

fied by constraint type. Note that **imp-greedy** selects the constraints that perform best on the tuning set, fits the classification model, and then classifies the testing set. We can see that for three of the four tasks (**race**, **age**, **pol-f**), **imp-greedy** results in higher accuracy than using all the constraints. This is particularly pronounced for **age**: the best result without constraint selection is 61.4, compared with 79.2 for **imp-greedy**. Furthermore, **imp-greedy** outperforms **logistic** on two of four tasks, suggesting that using unlabeled data can improve accuracy. Note that both **imp-greedy** and **logistic** use the same amount of labeled data, though in different ways: **logistic** performs standard supervised classification; **imp-greedy** uses the labeled data to perform constraint selection for label regularization. Thus, to summarize our answer to **RQ2**, we find that **imp-greedy** provides a robust method to select constraints in the presence of noise. While it comes at the cost of a small amount of labeled data, it is less reliant on this data than a traditional supervised approach, and so may be more applicable in streaming settings.

To answer **RQ3**, we can compare the accuracies provided by each of the constraint types in Table 1. For **all-const**, the follower constraints (**fol**) outperform the county constraints (**cnt**) for all tasks, while the name constraint (which only applies to **age**), falls between the two. Including both **cnt** and **fol** improves accuracy on two of the four tasks. These trends change somewhat for **imp-greedy**. The **cnt** constraints are superior for two tasks, while **fol** are superior for the other two. The **nam** constraints again fall between the two. Unlike for **all-const**, using more constraint types improves accuracy on three of four tasks. These differences suggest that the constraint selection algorithms allow label regularization to be more robust to noisy and conflicting constraints. That is, using constraint selection, we can view constraint engineering akin to feature engineering in discriminative, supervised learning methods — developers can add many types of constraints to the model without (much) fear of reducing accuracy. The usual caveat of overfitting applies here as well; indeed, comparing the accuracies on the tuning set (Table 2) with those on the testing set (Table 1) suggests that some over-tuning has occurred, most notably on **age** and **pol**.

We further examined the coefficients of the models trained using each constraint type. We find, for example, that county constraints result in models with large coefficients for location-specific terms (e.g., college names for younger users, southern cities for Republican users), while follower constraints tend to learn models dominated by follower features ("thenation" for Democrats, "glennbeck" for Republicans). Similarly, name constraints result in models dominated by name features. This analysis helps explain how combining constraint types can improve overall accuracy, since each type emphasizes different subsets of features.

This difference between constraint types is further shown in Table 3, which lists the top features for the semi-greedy constraint selection algorithm, fit using different subsets of constraints. In this table, the italicized words are the words from the description field of the user's profile, the underlined words are followed accounts, and the bold words are the words

age	**under 25**	**above 25**
County	athens *tech uga virginia georgia*	airport nashvillescene at theonion *and*
Follow	altpress colourlovers hotnewhiphop planetminecraft me	newsobserver baseballamerica peopleenespanol breakingnews hogshaven
Name	**katherine diana** me my this	**debra lori sandra janet** *No Desc*
politician	**Democratic**	**Republican**
County	*oregon* eugene oregon nesn *university*	colts beach tahoe *indiana* jgfortwayne
Follow	keithellison repjohnlewis sensanders thinkprogres thenation	gopleader senmikelee senrandpaul gop glennbeck

Table 3: Top features learned by label regularization for the age and politician datasets using semi-greedy constraint selection. Models were fit separately for each constraint type (county, follow, name). Italicized words are from the description field, bold words are from the name field, and underlined words are followed accounts.

from the name field of the user profile. In the first row, we display the top features for a model fit using only county constraints. College names appear as top features for younger users, and "airport" and @NashvilleScene (a newspaper) are for older users. The second row of Table 3 shows the top features for following constraints; some news channels are appear for younger (Alternative Press) and older (The News & Observer) users. The third row shows the top features for name constraints, and some names are in the top features for younger (Katherine and Diana) and older (Debra, Lori, Sandra, and Janet). In addition, the absence of a profile description is indicative of older users.

The bottom of Table 3 shows top features for the politician dataset. The first row shows that some colleges, a sports network in New England, and locations in the Pacific Northwest are indicative of Democrats. Indiana-related terms are strong indicators of Republicans: *indiana*, the Indianapolis Colts (an American football team), and 'jgfortwayne' (The Journal Gazette, a newspaper in Fort Wayne, Indiana). This aligns with the strong support of the Republican party in Indiana.[7] The second row shows top-ranked following features. Accounts 'keithellison' and 'repjohnlewis' are top features for Democratic Party; these belong to Keith Ellison and John Robert Lewis, members of the Democratic leadership of the House of Representatives. On other hand, the 'gopleader' (the official account for the Republican's majority leader in the House) and 'senmikelee' (Republican Senator Mike Lee from Utah) are the top features for Republicans.

7 Conclusions and Future work

While label regularization has been used on a number of NLP tasks, we have presented evidence that it is applicable to latent attribute inference even using many noisy, heterogeneous constraints. We have compared a number of constraint selection algorithms and found they can make label regularization more robust to noisy constraints, allowing developers to combine many rich constraint types without reducing accuracy.

There are many avenues for future work. Most pressing is the need to directly address the sampling bias created when constraints derived from the overall population are applied to online users. We plan to explore alternative optimization strategies to explicitly address this issue. Finally, additional research should quantify how responsive label regularization approaches are to the changing linguistic patterns common in online data.

Abstract

We present a novel response generation system that can be trained end to end on large quantities of unstructured Twitter conversations. A neural network architecture is used to address sparsity issues that arise when integrating contextual information into classic statistical models, allowing the system to take into account previous dialog utterances. Our dynamic-context generative models show consistent gains over both context-sensitive and non-context-sensitive Machine Translation and Information Retrieval baselines.

1 Introduction

Until recently, the goal of training open-domain conversational systems that emulate human conversation has seemed elusive. However, the vast quantities of conversational exchanges now available on social media websites such as Twitter and Reddit raise the prospect of building data-driven models that can begin to communicate conversationally. The work of Ritter et al. (2011), for example, demonstrates that a response generation system can be constructed from Twitter conversations using statistical machine translation techniques, where a status post by a Twitter user is "translated" into a plausible looking response.

However, an approach such as that presented in Ritter et al. (2011) does not address the challenge of generating responses that are sensitive to the context of the conversation. Broadly speaking, context may be linguistic or involve grounding in the physical or virtual world, but we here focus on linguistic context. The ability to take into account previous utterances is key to building dialog systems that can keep conversations active and engaging. Figure 1 illustrates a typical Twitter dialog where the contextual information is crucial: the phrase "good luck" is plainly motivated by the reference to "your game" in the first utterance. In the MT model, such contextual sensitivity is difficult to capture; moreover, naive injection of context information would entail unmanageable growth of the phrase table at the cost of increased sparsity, and skew towards rarely-seen context pairs. In most statistical approaches to machine translation, phrase pairs do not share statistical weights regardless of their intrinsic semantic commonality.

Figure 1: Example of three consecutive utterances occurring between two Twitter users A and B.

We propose to address the challenge of context-sensitive response generation by using continuous representations or *embeddings* of words and phrases to compactly encode semantic and syntactic similarity. We argue that embedding-based models af-

Denver, Colorado, May 31 – June 5, 2015.

ford flexibility to model the transitions between consecutive utterances and to capture long-span dependencies in a domain where traditional word and phrase alignment is difficult (Ritter et al., 2011). To this end, we present two simple, context-sensitive response-generation models utilizing the Recurrent Neural Network Language Model (RLM) architecture of (Mikolov et al., 2010). These models first encode past information in a hidden continuous representation, which is then decoded by the RLM to promote plausible responses that are simultaneously fluent and contextually relevant. Unlike typical complex task-oriented multi-modular dialog systems (Young, 2002; Stent and Bangalore, 2014), our architecture is *completely data-driven* and can easily be trained end-to-end using unstructured data without requiring human annotation, scripting, or automatic parsing.

This paper makes the following contributions. We present a neural network architecture for response generation that is both context-sensitive and data-driven. As such, it can be trained from end to end on massive amounts of social media data. To our knowledge, this is the first application of a neural-network model to open-domain response generation, and we believe that the present work will lay groundwork for more complex models to come. We additionally introduce a novel multi-reference extraction technique that shows promise for automated evaluation.

2 Related Work

Our work naturally lies in the path opened by Ritter et al. (2011), but we generalize their approach by exploiting information from a larger context. Ritter et al. and our work represent a radical paradigm shift from other work in dialog. More traditional dialog systems typically tease apart dialog management (Young, 2002) from response generation (Stent and Bangalore, 2014), while our holistic approach can be considered a first attempt to accomplish both tasks jointly. While there are previous uses of machine learning for response generation (Walker et al., 2003), dialog state tracking (Young et al., 2010), and user modeling (Georgila et al., 2006), many components of typical dialog systems remain hand-coded: in particular, the labels and attributes defining dialog states. In contrast, the dialog state in our neural network model is completely latent and directly optimized towards end-to-end performance. In this sense, we believe the framework of this paper is a significant milestone towards more data-driven and less hand-coded dialog processing.

Continuous representations of words and phrases estimated by neural network models have been applied on a variety of tasks ranging from Information Retrieval (IR) (Huang et al., 2013; Shen et al., 2014), Online Recommendation (Gao et al., 2014b), Machine Translation (MT) (Auli et al., 2013; Cho et al., 2014; Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014), and Language Modeling (LM) (Bengio et al., 2003; Collobert and Weston, 2008). Gao et al. (2014a) successfully use an embedding model to refine the estimation of rare phrase-translation probabilities, which is traditionally affected by sparsity problems. Robustness to sparsity is a crucial property of our method, as it allows us to capture context information while avoiding unmanageable growth of model parameters.

Our work extends the Recurrent Neural Network Language Model (RLM) of (Mikolov et al., 2010), which uses continuous representations to estimate a probability function over natural language sentences. We propose a set of conditional RLMs where contextual information (i.e., past utterances) is encoded in a continuous context vector to help generate the response. Our models differ from most previous work in the way the context vector is constructed. For example, Mikolov and Zweig (2012) and Auli et al. (2013) use a pre-trained topic model. In our models, the context vector is learned along with the conditional RLM that generates the response. Additionally, the learned context encodings do not exclusively capture contentful words. Indeed, even "stop words" can carry discriminative power in this task; for example, all words in the utterance "how are you?" are commonly characterized as stop words, yet this is a contentful dialog utterance.

3 Recurrent Language Model

We give a brief overview of the Recurrent Language Model (RLM) (Mikolov et al., 2010) architecture that our models extend. A RLM is a generative model of sentences, i.e., given sentence $s = s_1, \ldots, s_T$, it estimates:

$$p(s) = \prod_{t=1}^{T} p(s_t | s_1, \ldots, s_{t-1}). \quad (1)$$

The model architecture is parameterized by three weight matrices, $\Theta_{\text{RNN}} = \langle W_{in}, W_{out}, W_{hh} \rangle$: an input matrix W_{in}, a recurrent matrix W_{hh} and an output matrix W_{out}, which are usually initialized randomly. The rows of the input matrix $W_{in} \in \mathbb{R}^{V \times K}$ contain the K-dimensional embeddings for each word in the language vocabulary of size V. Let us denote by s_t both the vocabulary token and its one-hot representation, i.e., a zero vector of dimensionality V with a 1 corresponding to the index of the s_t token. The embedding for s_t is then obtained by $s_t^\top W_{in}$. The recurrent matrix $W_{hh} \in \mathbb{R}^{K \times K}$ keeps a history of the subsequence that has already been processed. The output matrix $W_{out} \in \mathbb{R}^{K \times V}$ projects the hidden state h_t into the output layer o_t, which has an entry for each word in the vocabulary V. This value is used to generate a probability distribution for the next word in the sequence. Specifically, the forward pass proceeds with the following recurrence, for $t = 1, \ldots, T$:

$$h_t = \sigma(s_t^\top W_{in} + h_{t-1}^\top W_{hh}), \quad o_t = h_t^\top W_{out} \quad (2)$$

where σ is a non-linear function applied element-wise, in our case the logistic sigmoid. The recurrence is seeded by setting $h_0 = 0$, the zero vector. The probability distribution over the next word given the previous history is obtained by applying the softmax activation function:

$$P(s_t = w | s_1, \ldots, s_{t-1}) = \frac{\exp(o_{tw})}{\sum_{v=1}^{V} \exp(o_{tv})}. \quad (3)$$

The RLM is trained to minimize the negative log-likelihood of the training sentence s:

$$L(s) = -\sum_{t=1}^{T} \log P(s_t | s_1, \ldots, s_{t-1}). \quad (4)$$

The recurrence is unrolled backwards in time using the back-propagation through time (BPTT) algorithm (Rumelhart et al., 1988), and gradients are accumulated over multiple time-steps.

4 Context-Sensitive Models

We distinguish three linguistic entities in a conversation between two users A and B: the context[1] c, the message m and response r. The context c represents a sequence of past dialog exchanges of any length; then B emits a message m to which A reacts by formulating its response r (see Figure 1).

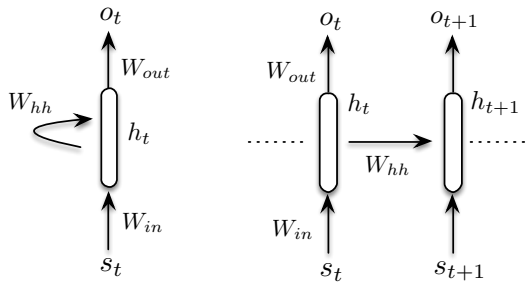

Figure 2: Compact representation of an RLM (left) and unrolled representation for two time steps (right).

We use three context-based generation models to estimate a generation model of the response r, $r = r_1, \ldots, r_T$, conditioned on past information c and m:

$$p(r|c, m) = \prod_{t=1}^{T} p(r_t | r_1, \ldots, r_{t-1}, c, m). \quad (5)$$

These three models differ in the manner in which they compose the context-message pair (c, m).

4.1 Tripled Language Model

In our first model, dubbed RLMT, we straightforwardly concatenate each utterance c, m, r into a single sentence s and train the RLM to minimize $L(s)$. Given c and m, we compute the probability of the response as follows: we perform the forward propagation over the known utterances c and m to obtain a hidden state encoding useful information about previous utterances. Subsequently, we compute the likelihood of the response from that hidden state.

An issue with this simple approach is that the concatenated sentence s will be very long on average, especially if the context comprises multiple utterances. Modelling such long-range dependencies with an RLM is difficult and is still considered an open problem (Pascanu et al., 2013). We will consider RLMT as an additional context-sensitive baseline for the models we present next.

4.2 Dynamic-Context Generative Model I

The above limitation of RLMT can be addressed by strengthening the context bias. In our second model (DCGM-I), the context and the message are encoded

[1] In this work, the context is purely linguistic, but future work might integrate further contextual information, e.g., geographical location, time information, or other forms of grounding.

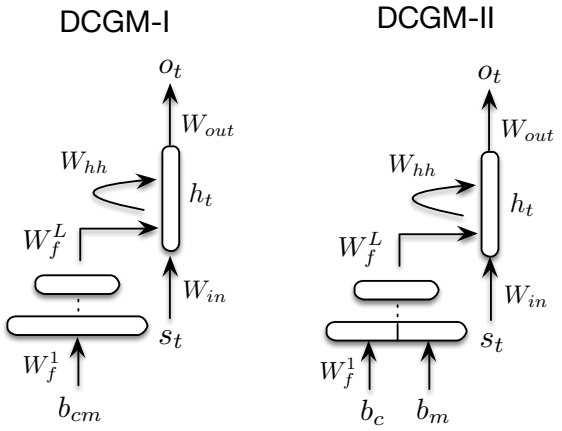

Figure 3: Compact representations of DCGM-I (left) and DCGM-II (right). The decoder RLM receives a bias from the context encoder. In DCGM-I, we encode the bag-of-words representation of both c and m in a single vector b_{cm}. In DCGM-II, we concatenate the representations b_c and b_m on the first layer to preserve order information.

into a fixed-length vector representation the is used by the RLM to decode the response. This is illustrated in Figure 3 (left). First, we consider c and m as a single sentence and compute a single bag-of-words representation $b_{cm} \in \mathbb{R}^V$. Then, b_{cm} is provided as input to a multilayered non-linear forward architecture that produces a fixed-length representation that is used to bias the recurrent state of the decoder RLM. At training time, both the context encoder and the RLM decoder are learned so as to minimize the negative log-probability of the generated response.

The parameters of the model are $\Theta_{\text{DCGM-I}} = \langle W_{in}, W_{hh}, W_{out}, \{W_f^\ell\}_{\ell=1}^L \rangle$, where $\{W_f^\ell\}_{\ell=1}^L$ are the weights for the L layers of the feed-forward context networks. The fixed-length context vector k_L is obtained by forward propagation of the network:

$$\begin{aligned} k_1 &= b_{cm}^\top W_f^1 \\ k_\ell &= \sigma(k_{\ell-1}^\top W_f^\ell) \quad \text{for } \ell = 2, \cdots, L \end{aligned} \tag{6}$$

The rows of W_f^1 contain the embeddings of the vocabulary.[2] These are different from those employed in the RLM and play a crucial role in promoting the specialization of the context encoder to a distinct task. The hidden layer of the decoder RLM takes the following form:

$$h_t = \sigma(h_{t-1}^\top W_{hh} + k_L + s_t^\top W_{in}) \tag{7a}$$

$$o_t = h_t^\top W_{out} \tag{7b}$$

$$p(s_{t+1}|s_1, \ldots, s_{t-1}, c, m) = \text{softmax}(o_t) \tag{7c}$$

This model conditions on the previous utterances via biasing the hidden layer state on the context representation k_L. Note that the context representation does not change through time. This is useful because: (a) it forces the context encoder to produce a representation general enough to be useful for generating all words in the response and (b) it helps the RLM decoder to remember context information when generating long responses.

4.3 Dynamic-Context Generative Model II

Because DCGM-I does not distinguish between c and m, that model has the propensity to underestimate the strong dependency that holds between m and r. Our third model (DCGM-II) addresses this issue by concatenating the two linear mappings of the bag-of-words representations b_c and b_m in the input layer of the feed-forward network representing c and m (see Figure 3 right). Concatenating continuous representations prior to deep architectures is a common strategy to obtain order-sensitive representations (Bengio et al., 2003; Devlin et al., 2014).

The forward equations for the context encoder are:

$$\begin{aligned} k_1 &= [b_c^\top W_f^1, b_m^\top W_f^1], \\ k_\ell &= \sigma(k_{\ell-1}^\top W_f^\ell) \quad \text{for } \ell = 2, \cdots, L \end{aligned} \tag{8}$$

where $[x, y]$ denotes the concatenation of x and y vectors. In DCGM-II, the bias on the recurrent hidden state and the probability distribution over the next token are computed as described in Eq. 7.

5 Experimental Setting

5.1 Dataset Construction

For computational efficiency and to alleviate the burden of human evaluators, we restrict the context sequence c to a single sentence. Hence, our dataset is composed of "triples" $\tau \equiv (c_\tau, m_\tau, r_\tau)$ consisting of three sentences. We mined 127M context-message-response triples from the Twitter FireHose, covering the 3-month period June 2012 through August 2012.

[2] Notice that the first layer of the encoder network is linear. We found that this helps learning the embedding matrix as it reduces the vanishing gradient effect partially due to stacking of squashing non-linearities (Pascanu et al., 2013).

Corpus	# Triples	Avg # Ref	[Min,Max] # Ref
Tuning	2118	3.22	[1, 10]
Test	2114	3.58	[1, 10]

Table 1: Number of triples, average, minimum and maximum number of references for tuning and test corpora.

Only those triples where context and response were generated by the same user were extracted. To minimize noise, we selected triples that contained at least one frequent bigram that appeared more than 3 times in the corpus. This produced a corpus of 29M Twitter triples. Additionally, we hired crowdsourced raters to evaluate approximately 33K candidate triples. Judgments on a 5-point scale were obtained from 3 raters apiece. This yielded a set of 4232 triples with a mean score of 4 or better that was then randomly binned into a tuning set of 2118 triples and a test set of 2114 triples[3]. The mean length of responses in these sets was approximately 11.5 tokens, after cleanup (e.g., stripping of emoticons), including punctuation.

5.2 Automatic Evaluation

We evaluate all systems using BLEU (Papineni et al., 2002) and METEOR (Banerjee and Lavie, 2005), and supplement these results with more targeted human pairwise comparisons in Section 6.3. A major challenge in using these automated metrics for response generation is that the set of reasonable responses in our task is potentially vast and extremely diverse. The dataset construction method just described yields only a single reference for each status. Accordingly, we extend the set of references using an IR approach to mine potential responses, after which we have human judges rate their appropriateness. As we see in Section 6.3, it turns out that by optimizing systems towards BLEU using mined multi-references, BLEU rankings align well with human judgments. This lays groundwork for interesting future correlation studies.

Multi-reference extraction We use the following algorithm to better cover the space of reasonable responses. Given a test triple $\tau \equiv (c_\tau, m_\tau, r_\tau)$, our goal is to mine other responses $\{r_{\tilde{\tau}}\}$ that fit the context and message pair (c_τ, m_τ). To this end, we first select a set of 15 candidate triples $\{\tilde{\tau}\}$ using an IR system. The IR system is calibrated in order to select candidate triples $\tilde{\tau}$ for which both the message $m_{\tilde{\tau}}$ and the response $r_{\tilde{\tau}}$ are similar to the original message m_τ and response r_τ. Formally, the score of a candidate triple is:

$$s(\tilde{\tau}, \tau) = d(m_{\tilde{\tau}}, m_\tau)\,(\alpha\, d(r_{\tilde{\tau}}, r_\tau) + (1-\alpha)\epsilon), \quad (9)$$

where d is the bag-of-words BM25 similarity function (Robertson et al., 1995), α controls the impact of the similarity between the responses and ϵ is a smoothing factor that avoids zero scores for candidate responses that do not share any words with the reference response. We found that this simple formula provided references that were both diverse and plausible. Given a set of candidate triples $\{\tilde{\tau}\}$, human evaluators are asked to rate the quality of the response within the new triples $\{(c_\tau, m_\tau, r_{\tilde{\tau}})\}$. After human evaluation, we retain the references for which the score is 4 or better on a 5 point scale, resulting in 3.58 references per example on average (Table 1). The average lengths for the responses in the multi-reference tuning and test sets are 8.75 and 8.13 tokens respectively.

5.3 Feature Sets

The response generation systems evaluated in this paper are parameterized as log-linear models in a framework typical of statistical machine translation (Och and Ney, 2004). These log-linear models comprise the following feature sets:

MT MT features are derived from a large response generation system built along the lines of Ritter et al. (2011), which is based on a phrase-based MT decoder similar to Moses (Koehn et al., 2007). Our MT feature set includes the following features that are common in Moses: forward and backward maximum likelihood "translation" probabilities, word and phrase penalties, linear distortion, and a modified Kneser-Ney language model (Kneser and Ney, 1995) trained on Twitter responses. For the translation probabilities, we built a very large phrase table of 160.7 million entries by first filtering out Twitterisms (e.g., long sequences of vowels, hashtags), and then selecting candidate phrase pairs using Fisher's exact test (Ritter et al., 2011). We also included MT decoder features specifically motivated by the response generation task: Jaccard distance between source and

[3]The Twitter ids of the tuning and test sets along with the code for the neural network models may be obtained from http://research.microsoft.com/convo/

System	BLEU
RANDOM	0.33
MT	3.21
HUMAN	6.08

Table 2: Multi-reference corpus-level BLEU obtained by leaving one reference out at random.

target phrase, Fisher's exact probability, and a score relating the lengths of source and target phrases.

IR We also use an IR feature built from an index of triples, whose implementation roughly matches the $\text{IR}_{\text{status}}$ approach described in Ritter et al. (2011): For a test triple τ, we choose $r_{\tilde{\tau}}$ as the candidate response iff $\tilde{\tau} = \arg\max_{\tilde{\tau}} d(m_\tau, m_{\tilde{\tau}})$.

CMM Neither MT nor IR traditionally take into account contextual information. Therefore, we take into consideration context and message matches (CMM), i.e., exact matches between c, m and r. We define 8 features as the [1-4]-gram matches between c and the candidate reply r and the [1-4]-gram matches between m and the candidate reply r. These exact matches help capture and promote contextual information in the replies.

RLMT, DCGM-I, DCGM-II We consider the RLM trained on the concatenated triples, denoted as RLMT (Section 4.1), to be a context-sensitive RLM baseline. Each neural network model contributes an additional feature corresponding to the likelihood of the candidate response given context and message.

5.4 Model Training

The proposed models are trained on a 4M subset of the triple data. The vocabulary consists of the most frequent $V = 50K$ words. In order to speed up training, we use the Noise-Contrastive Estimation (NCE) loss, which avoids repeated summations over V by approximating the probability of the target word (Gutmann and Hyvärinen, 2010). Parameter optimization is done using Adagrad (Duchi et al., 2011) with a mini-batch size of 100 and a learning rate $\alpha = 0.1$, which we found to work well on held-out data. In order to stabilize learning, we clip the gradients to a fixed range $[-10, 10]$, as suggested in Mikolov et al. (2010). All the parameters of the neural models are sampled from a normal distribution $\mathcal{N}(0, 0.01)$ while the recurrent weight W_{hh} is initialized as a random orthogonal matrix and scaled by 0.01. To prevent over-fitting, we evaluate performance on a held-out set during training and stop when the objective increases. The size of the RLM hidden layer is set to $K = 512$, where the context encoder is a 512, 256, 512 multilayer network. The bottleneck in the middle compresses context information that leads to similar responses and thus achieves better generalization. The last layer embeds the context vector into the hidden space of the decoder RLM.

5.5 Rescoring Setup

We evaluate the proposed models by rescoring the n-best candidate responses obtained using the MT phrase-based decoder and the IR system. In contrast to MT, the candidate responses provided by IR have been created by humans and are less affected by fluency issues. The different n-best lists will provide a comprehensive testbed for our experiments. First, we augment the n-best list of the tuning set with the scores of the model of interest. Then, we run an iteration of MERT (Och, 2003) to estimate the log-linear weights of the new features. At test time, we rescore the test n-best list with the new weights.

6 Results

6.1 Lower and Upper Bounds

Table 2 shows the expected upper and lower bounds for this task as suggested by BLEU scores for human responses and a random response baseline. The RANDOM system comprises responses randomly extracted from the triples corpus. HUMAN is computed by choosing one reference amongst the multi-reference set for each context-status pair.[4] Although the scores are lower than those usually reported in SMT tasks, the ranking of the three systems is unambiguous.

6.2 BLEU and METEOR

The results of automatic evaluation using BLEU and METEOR are presented in Table 3, where some broad patterns emerge. First, both metrics indicate that a phrase-based MT decoder outperforms a purely IR approach. Second, adding CMM features

[4]For the human score, we compute corpus-level BLEU with a sampling scheme that randomly leaves out one reference - the human sentence to score - for each reference set. This sampling scheme (repeated with 100 trials) is also applied for the MT and RANDOM system so as to make BLEU scores comparable.

Table 3: Context-sensitive ranking results on both MT (left) and IR (right) n-best lists, $n = 1000$. The subscript $_{\text{feat.}}$ indicates the number of features of the models. The log-linear weights are estimated by running one iteration of MERT. We mark by ($\pm\%$) the relative improvements with respect to the reference system ($\triangleright$).

to the baseline systems helps. Third, the neural network models contribute measurably to improvement: RLMT and DCGM models outperform baselines, and DCGM models provide more consistent gains than RLMT.

MT vs. IR BLEU and METEOR scores indicate that the phrase-based MT decoder outperforms a purely IR approach, despite the fact that IR proposes fluent human generated responses. This may be because the IR model only loosely captures important patterns between message and response: It ranks candidate responses solely by the similarity of their message with the message of the test triple (§5.3). As a result, the top ranked response is likely to drift from the purpose of the original conversation. The MT approach, by contrast, more directly models statistical patterns between message and response.

CMM MT+CMM, totaling 17 features (9 from MT + 8 CMM), improves 0.38 BLEU points, a 9.5% relative improvement, over the baseline MT model. IR+CMM, with 10 features (IR + word penalty + 8 CMM), benefits even more, attaining 1.8 BLEU points and 1.5 METEOR points over the IR baseline. Figure 4 (a) and (b) plots the magnitude of the learned CMM feature weights for MT+CMM and IR+CMM. CMM features help in both these hypothesis spaces and especially on the IR n-best list. Figure 4 (b) supports the hypothesis formulated in the previous paragraph: Since IR solely captures inter-message similarities, the matches between message and response are important, while context matches help in providing additional gains. The phrase-based statistical patterns captured by the MT system do a

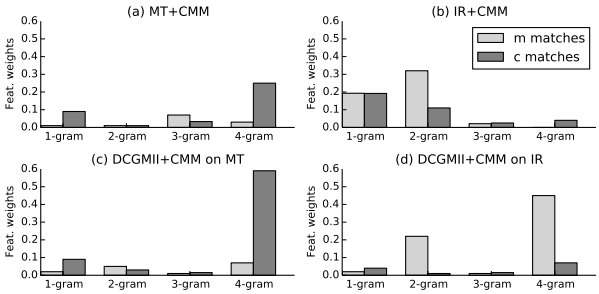

Figure 4: Comparison of the weights of learned CMM features for MT+CMM and IR+CMM systems (a) et (b) and DCGM-II+CMM on MT and IR (c) and (d).

good job in explaining away 1-gram and 2-gram message matches (Figure 4 (a)) and the performance gain mainly comes from context matches. On the other hand, we observe that 4-gram matches may be important in selecting appropriate responses. Inspection of the tuning set reveals instances where responses contain long subsequences of their corresponding messages, e.g., m = "good night best friend, I love you", r = "I love you too, good night best friend". Although infrequent, such higher-order n-gram matches, when they occur, may provide a more robust signal of the quality of the response than 1- and 2-gram matches, given the highly conversational nature of our dataset.

RLMT and DCGM Both RLMT and DCGM models outperform their respective MT and IR baselines. Both models also exhibit similar performance and show improvements over the MT+CMM models, albeit using a lower dimensional feature space. We believe that their similar performance is due to the limited diversity of MT n-best list together with gains in fluency stemming from the strong language

System A	System B	Gain (%)	CI
HUMAN	MT+CMM	13.6*	[12.4,14.8]
DCGM-II	MT	1.9*	[0.8, 2.9]
DCGM-II+CMM	MT	3.1*	[2.0, 4.3]
DCGM-II+CMM	MT+CMM	1.5*	[0.5, 2.5]
DCGM-II	IR	5.2*	[4.0, 6.4]
DCGM-II+CMM	IR	5.3*	[4.1, 6.6]
DCGM-II+CMM	IR+CMM	2.3*	[1.2, 3.4]

Table 4: Pairwise human evaluation scores between System A and B. The first (second) set of results refer to the MT (IR) hypothesis list. The asterisk means agreement between human preference and BLEU rankings.

model provided by the RLM. In the case of IR models, on the other hand, there is more headroom for improvement and fluency is already guaranteed. Any gains must come from context and message matches. Hence, RLMT underperforms with respect to both DCGM and IR+CMM. The DCGM models appear to have better capacity to retain contextual information and thus achieve similar performance to IR+CMM despite their lack of exact n-gram match information.

In the present experimental setting, no striking performance difference can be observed between the two versions of the DCGM architecture. If multiple sequences were used as context, we expect that the DCGM-II model would likely benefit more owing to the separate encoding of message and context.

DCGM+CMM We also investigated whether mixing exact CMM n-gram overlap with semantic information encoded by the DCGM models can bring additional gains. DCGM-{I-II}+CMM systems each totaling 10 features show increases of up to 0.48 BLEU points over MT+CMM and up to 0.88 BLEU over the model based on Ritter et al. (2011). METEOR improvements similarly align with BLEU improvements both for MT and IR lists. We take this as evidence that CMM exact matches and DCGM semantic matches interact positively, a finding that comports with Gao et al. (2014a), who show that semantic relationships mined through phrase embeddings correlate positively with classic co-occurrence-based estimations. Analysis of CMM feature weights in Figure 4 (c) and (d) suggests that 1-gram matches are explained away by the DCGM model, but that higher order matches are important. It appears that DCGM models might be improved by preserving word-order information in context and message encodings.

6.3 Human Evaluation

Human evaluation was conducted using crowd-sourced annotators. Annotators were asked to compare the quality of system output responses pairwise ("Which is better?") in relation to the context and message strings in the 2114 item test set. Identical strings were held out, so that the annotators only saw those outputs that differed. Paired responses were presented in random order to the annotators, and each pair of responses was judged by 5 annotators.

Table 4 summarizes the results of human evaluation, giving the difference in mean scores (pairwise preference margin) between systems and 95% confidence intervals generated using Welch's t-test. Identical strings not shown to raters are incorporated with an automatically assigned score of 0.5. The pattern in these results is clear and consistent: context-sensitive systems (+CMM) outperform non-context-sensitive systems, with preference gains as high as approximately 5.3% in the case of DCGM-II+CMM versus IR, and about 3.1% in the case of DCGM-II+CMM versus MT. Similarly, context-sensitive DCGM systems outperform non-DCGM context-sensitive systems by 1.5% (MT) and 2.3% (IR). These results are consistent with the automated BLEU rankings and confirm that our best performing DCGM models outperform both raw baseline and the context-sensitive baseline using CMM features.

6.4 Discussion

Table 5 provides examples of responses generated on the tuning corpus by the MT-based DCGM-II+CMM system, our best system in terms of both BLEU and human evaluation. Responses from this system are on average shorter (8.95 tokens) than the original human responses in the tuning set (11.5 tokens). Overall, the outputs tend to be generic or commonplace, but are often reasonably plausible in the context as in examples 1-3, especially where context and message contain common conversational elements. Example 2 illustrates the impact of context-sensitivity: the word "book" in the response is not found in the message. Nonetheless, longer generated responses are apt to degrade both syntactically and in terms of content. We notice that longer responses are likely to present

#	Context c	Message m	Generated Response r
1	noone can help this time its just i need a support system	well im here to support you. whenever you need me.	thank you, i appreciate it thank you

8	arresting people over "nasty tweets"? please. i'm not condoning what the lad did but arresting him is a tad silly.	it appears he may have sent death threats to others while all this was kicking off too.	i did! he was armed with nuclear threats? that's what's happening to you.

Table 5: Sample responses produced by the MT-based DCGM-II+CMM system.

information that conflicts either internally within the response itself, or is at odds with the context, as in examples 4-5. This is not unsurprising, since our model lacks mechanisms both for reflecting agent intent in the response and for maintaining consistency with respect to sentiment polarity. Longer context and message components may also result in responses that wander off-topic or lapse into incoherence as in 6-8, especially when relatively low frequency unigrams ("bass", "threat") are echoed in the response. In general, we expect that larger datasets and incorporation of more extensive contexts into the model will help yield more coherent results in these cases. Consistent representation of agent intent is outside the scope of this work, but will likely remain a significant challenge.

7 Conclusion

We have formulated a neural network architecture for data-driven response generation trained from social media conversations, in which generation of responses is conditioned on past dialog utterances that provide contextual information. We have proposed a novel multi-reference extraction technique allowing for robust automated evaluation using standard SMT metrics such as BLEU and METEOR. Our context-sensitive models consistently outperform both context-independent and context-sensitive baselines by up to 11% relative improvement in BLEU in the MT setting and 24% in the IR setting, albeit using a minimal number of features. As our models are completely data-driven and self-contained, they hold the potential to improve fluency and contextual relevance in other types of dialog systems.

Our work suggests several directions for future research. We anticipate that there is much room for improvement if we employ more complex neural network models that take into account word order within the message and context utterances. Direct generation from neural network models is an interesting and potentially promising next step. Future progress in this area will also greatly benefit from thorough study of automated evaluation metrics.

How to Make a Frenemy: Multitape FSTs for Portmanteau Generation

Aliya Deri and Kevin Knight
Information Sciences Institute
Department of Computer Science
University of Southern California
{aderi, knight}@isi.edu

Abstract

A portmanteau is a type of compound word that fuses the sounds and meanings of two component words; for example, "frenemy" (friend + enemy) or "smog" (smoke + fog). We develop a system, including a novel multitape FST, that takes an input of two words and outputs possible portmanteaux. Our system is trained on a list of known portmanteaux and their component words, and achieves 45% exact matches in cross-validated experiments.

W^1	W^2	PM

zeitgeist	ghost	zeitghost

Table 1: Valid component words and portmanteaux.

1 Introduction

Portmanteaux are new words that fuse both the sounds and meanings of their component words. Innovative and entertaining, they are ubiquitous in advertising, social media, and newspapers (Figure 1). Some, like "frenemy" (friend + enemy), "brunch" (breakfast + lunch), and "smog" (smoke + fog), express such unique concepts that they permanently enter the English lexicon.

Portmanteau generation, while seemingly trivial for humans, is actually a combination of two complex natural language processing tasks: (1) choosing component words that are both semantically and phonetically compatible, and (2) blending those words into the final portmanteau. An end-to-end system that is able to generate novel portmanteaux with minimal human intervention would be not only a useful tool in areas like advertising and journalism, but also a notable achievement in creative NLP.

Figure 1: A *New Yorker* headline portmanteau.

Due to the complexity of both component word selection and blending, previous portmanteau generation systems have several limitations. The Nehovah system (Smith et al., 2014) combines words only at exact grapheme matches, making the generation of more complex phonetic blends like "frenemy" or "brunch" impossible. Özbal and Strappavara (2012) blend words phonetically and allow inexact matches but rely on encoded human knowledge, such as sets of similar phonemes and semantically related words. Both systems are rule-based, rather than data-driven, and do not train or test their systems with real-world portmanteaux.

In contrast to these approaches, this paper presents a data-driven model that accomplishes (2) by blending two given words into a portmanteau. That is, with an input of "friend" and "enemy," we want to generate "frenemy."

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 206–210,
Denver, Colorado, May 31 – June 5, 2015.

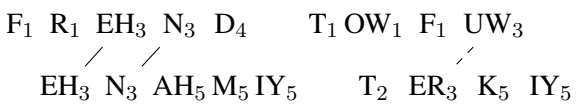

Figure 2: Derivations for friend + enemy → "frenemy" and tofu + turkey → "tofurkey." Subscripts indicate the step applied to each phoneme.

We take a statistical modeling approach to portmanteau generation, using training examples (Table 1) to learn weights for a cascade of finite state machines. To handle the 2-input, 1-output problem inherent in the task, we implement a multitape FST.

This work's contributions can be summarized as:

- a portmanteau generation model, trained in an unsupervised manner on unaligned portmanteaux and component words,
- the novel use of a multitape FST for a 2-input, 1-output problem, and
- the release of our training data.[1]

2 Definition of a portmanteau

In this work, a portmanteau PM and its pronunciation PM_{pron} have the following constraints:

- PM has exactly 2 component words W^1 and W^2, with pronunciations W^1_{pron} and W^2_{pron}.
- All of PM's letters are in W^1 and W^2, and all phonemes in PM_{pron} are in W^1_{pron} and W^2_{pron}.
- All pronunciations use the Arpabet symbol set.
- Portmanteau building occurs at the phoneme level. PM_{pron} is built through the following steps (further illustrated in Figure 2):

1. 0+ phonemes from W^1_{pron} are output.
2. 0+ phonemes from W^2_{pron} are deleted.
3. 1+ phonemes from W^1_{pron} are aligned with an equal number of phonemes from W^2_{pron}. For each aligned pair of phonemes (x, y), either x or y is output.
4. 0+ phonemes from W^1_{pron} are deleted, until the end of W^1_{pron}.
5. 0+ phonemes from W^2_{pron} are output, until the end of W^2_{pron}.

[1] Available at both authors' websites.

3 Multitape FST model

Finite state machines (FSMs) are powerful tools in NLP and are frequently used in tasks like machine transliteration and pronunciation. Toolkits like Carmel and OpenFST allow rapid implementations of complex FSM cascades, machine learning algorithms, and n-best lists.

Both toolkits implement two types of FSMs: finite state acceptors (FSAs) and finite state transducers (FSTs), and their weighted counterparts (wFSAs and wFSTs). An FSA has one input tape; an FST has one input and one output tape.

What if we want a one input and two output tapes for an FST? Three input tapes for an FSA? Although infrequently explored in NLP research, these "multitape" machines are valid FSMs.

In the case of converting $\{\text{W}^1_{\text{pron}}, \text{W}^2_{\text{pron}}\}$ to PM_{pron}, an interleaved reading of two tapes would be impossible with a traditional FST. Instead, we model the problem with a 2-input, 1-output FST (Figure 3). Edges are labeled $x : y : z$ to indicate input tapes W^1_{pron} and W^2_{pron} and output tape PM_{pron}, respectively.

4 FSM Cascade

We include the multitape model as part of an FSM cascade that converts W^1 and W^2 to PM (Figure 4).

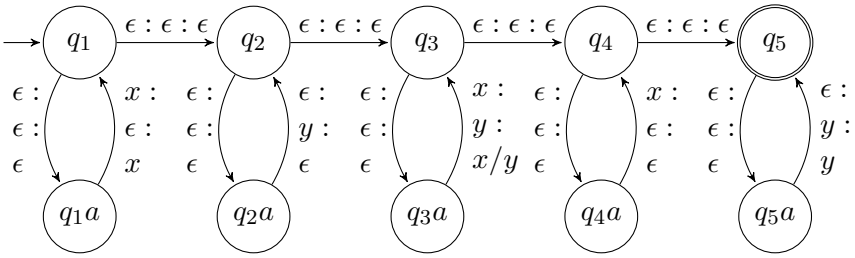

Figure 3: A 2- input, 1-output wFST for portmanteau pronunciation generation.

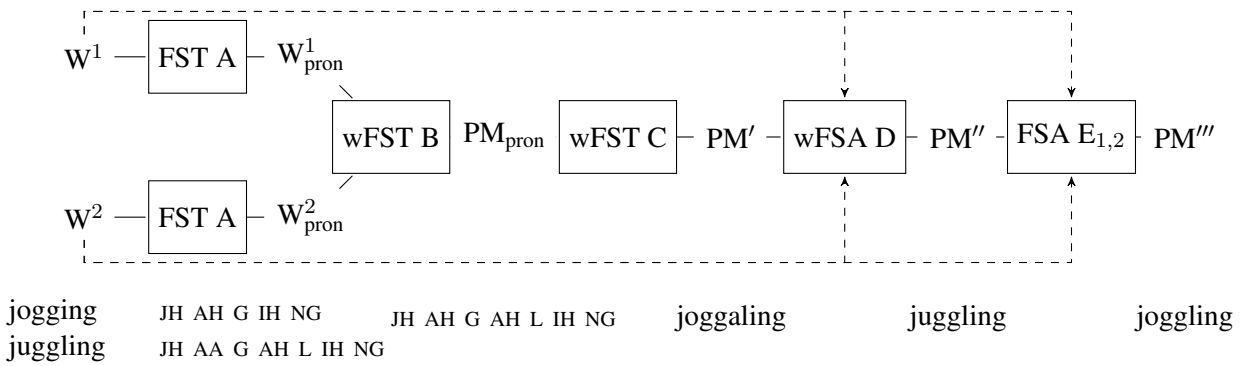

Figure 4: The FSM cascade for converting W^1 and W^2 into a PM, and an illustrative example.

phonemes			$P(x, y \to z)$		
x	y	z	cond.	joint	mixed
AA	AA	AA	1.000	0.017	1.000
AH	ER	AH	0.424	0.007	0.445
AH	ER	ER	0.576	0.009	0.555
P	B	P	0.972	0.002	1.000
P	B	B	0.028	N/A	N/A
Z	SH	SH	1.000	N/A	N/A
JH	AO	JH	1.000	N/A	N/A

Table 2: Sample learned phoneme alignment probabilities for each method.

step k	description	$P(k)$
1	W^1_{pron} keep	0.68
2	W^2_{pron} delete	0.55
3	align	0.74
4	W^1_{pron} delete	0.64
5	W^2_{pron} keep	0.76

Table 3: Learned step probabilities. The probabilities of keeping and aligning are higher than those of deleting, showing a tendency to preserve the component words.

We first generate the pronunciations of W^1 and W^2 with FST A, which functions as a simple look-up from the CMU Pronouncing Dictionary (Weide, 1998).

Next, wFST B, the multitape wFST from Figure 3, translates W^1_{pron} and W^2_{pron} into PM_{pron}. wFST C, built from aligned graphemes and phonemes from the CMU Pronunciation Dictionary (Galescu and Allen, 2001), spells PM_{pron} as PM′.

To improve PM′, we now use three FSAs built from W^1 and W^2. The first, wFSA D, is a smoothed "mini language model" which strongly prefers letter trigrams from W^1 and W^2. The second and third, FSA E_1 and FSA E_2, accept all inputs except W^1 and W^2.

5 Data

We obtained examples of portmanteaux and component words from Wikipedia and Wiktionary lists (Wikipedia, 2013; Wiktionary, 2013). We reject any that do not satisfy our constraints–for example, portmanteaux with three component words ("turkey" + "duck" + "chicken" → "turducken") or without any overlap ("arpa" + "net" → "arpanet"). From 571 examples, this yields 401 $\{W^1, W^2, PM\}$ triples.

We also use manual annotations of PM_{pron} for learning the multitape wFST B weights and for mid-cascade evaluation.

We randomly split the data for 10-fold cross-validation. For each iteration, 8 folds are used for training data, 1 for dev, and 1 for test. Training data is used to learn wFST B weights (Section 6) and dev data is used to learn reranking weights (Section 7).

6 Training

FST A is unweighted and wFST C is pretrained. wFSA D and FSA $E_{1,2}$ are built at runtime.

We only need to learn wFST B weights, which we can reduce to weights on transitions $q_k \to q_k a$ and $q_3 a \to q_3$ from Figure 3. The weights $q_k \to q_k a$ represent the probability of each step, or $P(k)$. The weights $q_3 a \to q_3$ represent the probability of generating phoneme z from input phonemes x and y, or $P(x, y \to z)$.

model	% exact		avg. dist.		% 1k-best

PM″	42.14	1.80	58.10
PM‴	**45.39**	**1.59**	**61.35**

Table 5: PM results on cross-validated test data.

We use expectation maximization (EM) to learn these weights from our unaligned input and output, $\{W^1_{pron}, W^2_{pron}\}$ and PM_{pron}. We use three different methods of normalizing fractional counts. The learned phoneme alignment probabilities $P(x, y \rightarrow z)$ (Table 2) vary across these methods, but the learned step probabilities $P(k)$ (Table 3) do not.

6.1 Conditional Alignment

Our first learning method models phoneme alignment $P(x, y \rightarrow z)$ conditionally, as $P(z|x, y)$. Since $P(z|x, y)$ tends to be larger than step probabilities $P(k)$, the model prefers to align phonemes when possible, rather than keep or delete them separately. This creates longer alignment regions.

Additionally, during training a potential alignment $P(x|x, y)$ can compete only with its pair $P(y|x, y)$, making it more difficult to zero out an alignment's probability. The conditional method therefore also learns more potential alignments between phonemes.

6.2 Joint Alignment

Our second learning method models $P(x, y \rightarrow z)$ jointly, as $P(z, x, y)$. Since $P(z, x, y)$ is relatively low compared to the step probabilities, this method prefers very short alignments–the reverse of the effect seen in the conditional method.

However, the model can also zero out the probabilities of unlikely aligments, so overall it learns fewer possible alignments between phonemes.

tofu	turkey	tofurkey	tofurkey
zeitgeist	ghost	zeitghost	zeitghost

Table 6: Component words and gold and hypothesis PMs.

6.3 Mixed Alignment

Our third learning method initializes alignment probabilities with the joint method, then normalizes them so that $P(x|x, y)$ and $P(y|x, y)$ sum to 1. This "mixed" method, like the joint method, is more conservative in learning phoneme alignments. However, like the conditional method, it has high alignment probabilities and prefers longer alignments.

7 Model Combination and Reranking

Using the methods from sections 6.1, 6.2, and 6.3, we train three models and produce three different 1000-best lists of PM_{pron} candidates for dev data. We combine these three lists into a single one, and compute the following features for each candidate: model scores, PM_{pron} length, percentage of W^1_{pron} or W^2_{pron} in PM_{pron}, and percentage of PM_{pron} in W^1_{pron} or W^2_{pron}. We also include a binary feature for whether PM_{pron} matches W^1_{pron} or W^2_{pron}.

We then compute feature weights using the averaged perceptron algorithm (Zhou et al., 2006), and use them to rerank the candidate list, for both dev and test data. We combine the reranked PM_{pron} lists to generate wFST C's input.

8 Evaluation

We evaluate our model's generation of PM_{pron} pre- and post-reranking against our manually annotated PM_{pron}. We also compare PM′, PM″, and PM‴. For both PM_{pron} and PM, we use three metrics:

- percent of 1-best results that are exact matches,
- average Levenshtein edit distance of 1-bests, and
- percent of 1000-best lists with an exact match.

9 Results and Discussion

We first evaluate the model at PM_{pron}. Table 4 shows that, despite less than 50% exact matches, over 90% of the 1000-best lists contain the correct pronunciation. This motivates our model combination and reranking, which increase exact matches to over 50%.

Next, we evaluate PM (Table 5). A component word mini-LM dramatically improves PM″ compared to PM′. Filtering out component words provides additional gain, to 45% exact matches.

In comparison, a baseline that merges W^1_{pron} and W^2_{pron} at the first shared phoneme achieves 33% exact matches for PM_{pron} and 25% for PM.

Table 6 provides examples of system output. Perfect outputs include "affluenza," "joggling," "tofurkey," and "zeitghost." For others, like "chilax" and "frienemy," the discrepancy is negligible and the hypothesis PM could be considered a correct alternate output. Some hypotheses, like "architecology" and "japanglish," might even be considered superior to their gold counterparts. However, some errors, like "js" and "mman," are clearly unacceptable system outputs.

10 Conclusion

We implement a data-driven system that generates portmanteaux from component words. To accomplish this, we use an FSM cascade, including a novel 2-input, 1-output multitape FST, and train it on existing portmanteaux. In cross-validated experiments, we achieve 45% exact matches and an average Levenshtein edit distance of 1.59.

In addition to improving this model, we are interested in developing systems that can select component words for portmanteaux and reconstruct component words from portmanteaux. We also plan to research other applications for multi-input/output models.

Aligning Sentences from Standard Wikipedia to Simple Wikipedia

University of Washington

Abstract

This work improves monolingual sentence alignment for text simplification, specifically for text in standard and simple Wikipedia. We introduce a method that improves over past efforts by using a greedy (vs. ordered) search over the document and a word-level semantic similarity score based on Wiktionary (vs. WordNet) that also accounts for structural similarity through syntactic dependencies. Experiments show improved performance on a hand-aligned set, with the largest gain coming from structural similarity. Resulting datasets of manually and automatically aligned sentence pairs are made available.

1 Introduction

Text simplification can improve accessibility of texts for both human readers and automatic text processing. Although simplification (Wubben et al., 2012) could benefit from data-driven machine translation, paraphrasing, or grounded language acquisition techniques, e.g. (Callison Burch and Osborne, 2003; Fung and Cheung, 2004; Munteanu and Marcu, 2005; Smith et al., 2010; Ganitkevitch et al., 2013; Hajishirzi et al., 2012; Kedziorski et al., 2014), work has been limited because available parallel corpora are small (Petersen and Ostendorf, 2007) or automatically generated are noisy (Kauchak, 2013).

Wikipedia is potentially a good resource for text simplification (Napoles and Dredze, 2010; Medero and Ostendorf, 2009), since it includes *standard* articles and their corresponding *simple* articles in English. A challenge with automatic alignment is that standard and simple articles can be written independently so they are not strictly parallel, and have very different presentation ordering. A few studies use editor comments attached to Wikipedia edit logs to extract pairs of simple and difficult words (Yatskar et al., 2010; Woodsend and Lapata, 2011). Other methods use text-based similarity techniques (Zhu et al., 2010; Coster and Kauchak, 2011; Kauchak, 2013), but assume sentences in standard and simple articles are ordered relatively.

In this paper, we align sentences in standard and simple Wikipedia using a greedy method that, for every simple sentence, finds the corresponding sentence (or sentence fragment) in standard Wikipedia. Unlike other methods, we do not make any assumptions about the relative order of sentences in standard and simple Wikipedia articles. We also constrain the many-to-one matches to cover sentence fragments. In addition, our method takes advantage of a novel word-level semantic similarity measure that is built on top of Wiktionary (vs. WordNet) which incorporates structural similarity represented in syntactic dependencies. The Wiktionary-based similarity measure has the advantage of greater word coverage than WordNet, while the use of syntactic dependencies provides a simple mechanism for approximating semantic roles.

Here, we report the first manually annotated dataset for evaluating alignments for text simplification, develop and assess a series of alignment methods, and automatically generate a dataset of sentence pairs for standard and simple Wikipedia. Experiments show that our alignment method significantly outperforms previous methods on the hand-aligned

Good	Apple sauce or applesauce is a puree made of apples.	Applesauce (or applesauce) is a sauce that is made from stewed or mashed apples.
Good Partial	Commercial versions of applesauce are really available in supermarkets	It is easy to make at home, and *it is also sold already made in supermarkets as a common food.*
Partial	*Applesauce* is a sauce that is *made from* stewed and mashed apples.	*Applesauce is made by* cooking down apples with water or apple cider to the desired level.

Table 1: Annotated examples: the matching regions for partial and good partial are italicized.

set of standard and simple Wikipedia article pairs. The datasets are publicly available to facilitate further research on text simplification.

2 Background

Given comparable articles, sentence alignment is achieved by leveraging the sentence-level similarity score and the sequence-level search strategy.

Sentence-Level Scoring: There are two main approaches for sentence-level scoring. One approach, used in Wikipedia alignment (Kauchak, 2013), computes sentence similarities as the cosine distance between vector representations of tf.idf scores of the words in each sentence. Other approaches rely on word-level $\sigma(w, w')$ semantic similarity scores $s(W, W') = \frac{1}{Z} \sum_{w \in W} \max_{w' \in W'} \sigma(w, w') idf(w)$. Previous work use WordNet-based similarity (Wu and Palmer, 1994; Mohler and Mihalcea, 2009; Hosseini et al., 2014), distributional similarity (Guo and Diab., 2012), or discriminative similarity (Hajishirzi et al., 2010; Rastegari et al., 2015).

In this paper, we leverage pairwise word similarities, and introduce two novel word-level semantic similarity metrics and show that they outperform the previous metrics.

Sequence-Level Search: There are several sequence-level alignment strategies (Shieber and Nelken, 2006). In (Zhu et al., 2010), sentence alignment between simple and standard articles is computed without constraints, so every sentence can be matched to multiple sentences in the other document. Two sentences are aligned if their similarity score is greater than a threshold. An alternative approach is to compute sentence alignment with a sequential constraint, i.e. using dynamic programming (Coster and Kauchak, 2011; Barzilay and Elhadad, 2003). Specifically, the alignment is computed by a recursive function that optimizes alignment of one or two consecutive sentences in one article to sentences in the other article. This method relies on consistent ordering between two articles, which does not always hold for Wikipedia articles.

3 Simplification Datasets

We develop datasets of aligned sentences in standard and simple Wikipedia. Here, we describe the *manually annotated* dataset and leave the details of the *automatically generated* dataset to Section 5.2.

Manually Annotated: For every sentence in a standard Wikipedia article, we create an HTML survey that lists sentences in the corresponding simple article and allow the annotator to judge each sentence pair as a good, good partial, partial, or bad match (examples in Table 1): *Good:* The semantics of the simple and standard sentence completely match, possibly with small omissions (e.g., pronouns, dates, or numbers). *Good Partial:* A sentence completely covers the other sentence, but contains an additional clause or phrase that has information which is not contained within the other sentence. *Partial:* The sentences discuss unrelated concepts, but share a short related phrase that does not match considerably. *Bad:* The sentences discuss unrelated concepts.

The annotators were native speaker, hourly paid, undergraduate students. We randomly selected 46 article pairs from Wikipedia (downloaded in June 2012) that started with the character 'a'. In total, 67,853 sentence pairs were annotated (277 good, 281 good partial, 117 partial, and 67,178 bad). The kappa value for interannotator agreement is 0.68 (13% of articles were dual annotated). Most disagreements between annotators are confusions between 'partial' and 'good partial' matches. The manually annotated dataset is used as a test set for evaluating alignment methods as well as tuning parameters for generating automatically aligned pairs across standard and simple Wikipedia.

4 Sentence Alignment Method

We use a sentence-level similarity score that builds on a new word-level semantic similarity, described below, together with a greedy search over the article.

4.1 Word-Level Similarity

Word-level similarity functions return a similarity score $\sigma(w_1, w_2)$ between words w_1 and w_2. We introduce two novel similarity metrics: Wiktionary-based similarity and structural semantic similarity.

WikNet Similarity: The Wiktionary-based semantic similarity measure leverages synonym information in Wiktionary as well as word-definition cooccurrence, which is represented in a graph and referred to as WikNet. In our work, each lexical content word (noun, verb, adjective and adverb) in the English Wiktionary is represented by one node in WikNet. If word w_2 appears in any of the sense definitions of word w_1, one edge between w_1 and w_2 is added, as illustrated in Figure 1. We prune the WikNet using the following steps: i) morphological variations are mapped to their baseforms; ii) atypical word senses (e.g. "obsolete," "Jamaican English") are removed; and iii) stopwords (determined based on high definition frequency) are removed. After pruning, there are roughly 177k nodes and 1.15M undirected edges. As expected, our Wiktionary based similarity metric has a higher coverage of 71.8% than WordNet, which has a word coverage of 58.7% in our annotated dataset.

Motivated by the fact that the WikNet graph structure is similar to that of many social networks (Watts and Strogatz, 1998; Wu, 2012), we characterize semantic similarity with a variation on a link-based node similarity algorithm that is commonly applied for person relatedness evaluations in social network studies, the Jaccard coefficient (Salton and McGill, 1983), by quantifying the number of shared neighbors for two words. More specifically, we use the extended Jaccard coefficient, which looks at neighbors within an n-step reach (Fogaras and Racz, 2005) with an added term to indicate whether the words are direct neighbors. In addition, if the words or their neighbors have synonym sets in Wiktionary, then the shared synonyms are used in the extended Jaccard measure. If the two words are in each other's synonym lists, then the similarity is set to 1 otherwise, $\sigma_{wk}(w_1, w_2) = \sum_{l=0}^{n} J_l^s(w_1, w_2)$, for $J_l^s(w_1, w_2) = \frac{\Gamma_l(w_1) \cap_{syn} \Gamma_l(w_2)}{\Gamma_l(w_1) \cup \Gamma_l(w_2)}$ where $\Gamma_l(w_i)$ is the l-step neighbor set of w_i, and $\cap_{syn}$ accounts for synonyms if any. We precomputed similarities between pairs of words in WikNet to make the alignment algorithm more efficient. The WikNet is available at `http://ssli.ee.washington.edu/tial/projects/simplification/`.

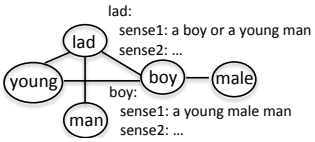

Figure 1: Part of WikNet with words "boy" and "lad".

Structural Semantic Similarity: We extend the word-level similarity metric to account for both semantic similarity between words, as well as the dependency structure between the words in a sentence. We create a triplet for each word using Stanford's dependency parser (de Marneffe et al., 2006). Each triplet $t_w = (w, h, r)$ consists of the given word w, its head word h (governor), and the dependency relationship (e.g., modifier, subject, etc) between w and h. The similarity between words w_1 and w_2 combines the similarity between these three features in order to boost the similarity score of words whose head words are similar and appear in the same dependency structure: $\sigma_{ss_{wk}}(w_1, w_2) = \sigma_{wk}(w_1, w_2) + \sigma_{wk}(h_1, h_2)\sigma_r(r_1, r_2)$ where σ_{wk} is the WikNet similarity and $\sigma_r(r_1, r_2)$ represents dependency similarity between relations r_1 and r_2 such that $\sigma_r = 0.5$ if both relations fall into the same category, otherwise $\sigma_r = 0$.

4.2 Greedy Sequence-level Alignment

To avoid aligning multiple sentences to the same content, we require one-to-one matches between sentences in standard and simple Wikipedia articles using a greedy algorithm. We first compute similarities between all sentences S_j in the simple article and A_i in standard article using a sentence-level similarity score. Then, our method iteratively selects the most similar sentence pair $S^*, A^* = \arg\max s(S_j, A_i)$ and removes all other pairs associated with the respective sentences, repeating until all sentences in the shorter document are aligned. The cost of aligning sentences in two articles S, A is $O(mn)$ where m, n are the number of sentences in

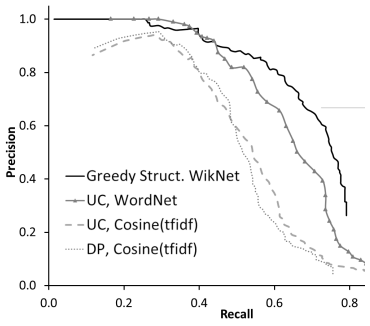

Figure 2: Precision-recall curve for our method vs. baselines.

Good vs. Others	Max F1	AUC
Greedy Struc. WikNet ($sim_G, \sigma_{ss_{wk}}$)	**0.712**	**0.694**
Unconst. WordNet (sim_{UC}, σ_{wd})	0.636	0.651

Good & Good Partial vs. Others		
Greedy Struc. WikNet ($sim_G, \sigma_{ss_{wk}}$)	**0.607**	**0.529**
Unconst. WordNet (sim_{UC}, σ_{wd})	0.515	0.499
Ordered Vec. Space (sim_{DP}, s_{cos})	0.415	0.387
Unconst. Vec. Space (sim_{UC}, s_{cos})	0.431	0.391

Table 2: Max F1, AUC for identifying good matches and identifying good & good partial matches.

articles S and A, respectively. The run time of our method using WikNet is less than a minute for the sentence pairs in our test set.

Many simple sentences only match with a fragment of a standard sentence. Therefore, we extend the greedy algorithm to discover good partial matches as well. The intuition is that two sentences are good partial matches if a simple sentence has higher similarity with a fragment of a standard sentence than the complete sentence. We extract fragments for every sentence from the Stanford syntactic parse tree (Klein and Manning, 2003). The fragments are generated based on the second level of the syntactic parse tree. Specifically, each fragment is a S, SBAR, or SINV node at this level. We then calculate the similarity between every simple sentence S_j with every standard sentence A_i as well as fragments of the standard sentence A_i^k. The same greedy algorithm is then used to align simple sentences with standard sentences or their fragments.

5 Experiments

We test our method on all pairs of standard and simple sentences for each article in the hand-annotated data (no training data is used). For our experiments, we preprocess the data by removing topic names, list markers, and non-English words. In addition, the data was tokenized, lemmatized, and parsed using Stanford CoreNLP (Manning et al., 2014).

5.1 Results

Comparison to Baselines: The baselines are our implementations of previous work: *Unconstrained WordNet* (Mohler and Mihalcea, 2009), which uses an unconstrained search for aligning sentences and WordNet semantic similarity (in particular Wu-Palmer (1994)); *Unconstrained Vector Space* (Zhu et al., 2010), which uses a vector space representation and an unconstrained search for aligning sentences; and *Ordered Vector Space* (Coster and Kauchak, 2011), which uses dynamic programming for sentence alignment and vector space scoring.

We compare our method (*Greedy Structural WikNet*) that combines the novel Wiktionary-based structural semantic similarity score with a greedy search to the baselines. Figure 2 and Table 2 show that our method achieves higher precision-recall, max F1, and AUC compared to the baselines. The precision-recall score is computed for good pairs vs. other pairs (good partial, partial, and bad).

From error analysis, we found that most mistakes are caused by missing good matches (lower recall). As shown by the graph, we obtain high precision (about .9) at recall 0.5. Thus, applying our method on a large dataset yields high quality sentence alignments that would benefit data-driven learning in text simplification.

Table 2 also shows that our method outperforms the baselines in identifying good and good partial matches. Error analysis shows that our fragment generation technique does not generate all possible or meaningful fragments, which suggests a direction for future work. We list a few qualitative examples in Table 3.

Ablation Study: Table 4 shows the results of ablating each component of our method, sequence-level alignments and word-level similarity.

Sequence-level Alignment: We study the contribution of the greedy approach in our method by using word-level structural semantic WikNet similarity $\sigma_{ss(wk)}$ and replacing the sequence-level greedy search strategy with dynamic programming and un-

Good	The castle was later incorporated into the construction of Ashtown Lodge which was to serve as the official residence of the Under Secretary from 1782.	After the building was made bigger and improved, it was used as the house for the Under Secretary of Ireland from 1782.
Good Partial	Mozart's Clarinet Concerto and Clarinet Quintet are both in A major, and generally Mozart was more likely to use clarinets in A major than in any other key besides E-flat major	Mozart used clarinets in A major often.

Table 3: Qualitative examples of the good and good partial matches identified by our method.

Sequence-level	Max F1	AUC
Greedy ($sim_G, \sigma_{ss_{wk}}$)	**0.712**$^+$	**0.694**$^+$
Ordered ($sim_{DP}, \sigma_{ss_{wk}}$)	0.656$^+$	0.610$^+$
Unconstrained ($sim_{UC}, \sigma_{ss_{wk}}$)	0.689	0.689
Word-level	Max F1	AUC
Structural WikNet ($sim_G, \sigma_{ss_{wk}}$)	**0.712**$^+$	**0.694**$^+$
WordNet (sim_G, σ_{wd})	0.665$^+$	0.663$^+$
Structural WordNet ($sim_G, \sigma_{ss_{wd}}$)	0.685	0.679
WikNet (sim_G, σ_{wk})	0.697	0.669

Table 4: Max F1, AUC for ablation study on word-level and sequence-level similarity scores. Values with the $^+$ superscript are significant with p<0.05.

constrained approaches. As expected, the dynamic programming approach used in previous work does not perform as well as our method, even with the structural semantic WikNet similarity, because the simple Wikipedia articles are not explicit simplifications of standard articles.

Word-level Alignment: Table 4 also shows the contribution of the structural semantic WikNet similarity measure $\sigma_{ss_{wk}}$ vs. other word-level similarities (WordNet similarity σ_{wd}, structural semantic WordNet similarity $\sigma_{ss_{wd}}$, and WikNet similarity σ_{wk}). In all the experiments, we use the sequence-level greedy alignment method. The structural semantic similarity measures improve over the corresponding similarity measures for both WordNet and WikNet. Moreover, WikNet similarity outperforms WordNet, and the structural semantic WikNet similarity measure achieves the best performance.

5.2 Automatically Aligned Data

We develop a parallel corpus of aligned sentence pairs between standard and simple Wikipedia, together with their similarity scores. In particular, we use our best case method to align sentences from 22k standard and simple articles, which were download in April 2014. To speed up our method, we index the similarity scores of frequent words and distribute computations over multiple CPUs.

We release a dataset of aligned sentence pairs, with a scaled threshold greater than 0.45.[1] Based on the precision-recall data, we choose a scaled threshold of 0.67 (P = 0.798, R = 0.599, F1 = 0.685) for good matches, and 0.53 (P = 0.687, R = 0.495, F1 = 0.575) for good partial matches. The selected thresholds yield around 150k good matches, 130k good partial matches, and 110k uncategorized matches. In addition, around 51.5 million potential matches, with a scaled score below 0.45, are pruned from the dataset.

6 Conclusion and Future Work

This work introduces a sentence alignment method for text simplification using a new word-level similarity measure (using Wiktionary and dependency structure) and a greedy search over sentences and sentence fragments. Experiments on comparable standard and simple Wikipedia articles outperform current baselines. The resulting hand-aligned and automatically aligned datasets are publicly available.

Future work involves developing text simplification techniques using the introduced datasets. In addition, we plan to improve our current alignment technique with better text preprocessing (e.g., coreference resolution (Hajishirzi et al., 2013)), learning similarities, as well as phrase alignment techniques to obtain better partial matches.

Acknowledgments This research was supported in part by grants from the NSF (IIS-0916951) and (IIS-1352249). The authors also wish to thank Alex Tan and Hayley Garment for annotations, and the anonymous reviewers for their valuable feedback.

Inducing Lexical Style Properties for Paraphrase and Genre Differentiation

Abstract

We present an intuitive and effective method for inducing style scores on words and phrases. We exploit signal in a phrase's rate of occurrence across stylistically contrasting corpora, making our method simple to implement and efficient to scale. We show strong results both intrinsically, by correlation with human judgements, and extrinsically, in applications to genre analysis and paraphrasing.

1 Introduction

True language understanding requires comprehending not just what is said, but how it is said, yet only recently have computational approaches been applied to the subtleties of tone and style. As the expectations on language technologies grow to include tailored search, context-aware inference, and analysis of author belief, an understanding of style becomes crucial.

Lexical features have proven indispensable for the good performance of most applications dealing with language. Particularly, more generalized characterizations of the lexicon (Brown et al., 1992; Wilson et al., 2005; Feng et al., 2013; Ji and Lin, 2009; Resnik, 1995) have become key in overcoming issues with lexical sparseness and in providing practical semantic information for natural language processing systems (Miller et al., 2004; Rutherford and Xue, 2014; Velikovich et al., 2010; Dodge et al., 2012). Most work on stylistic variation, however, has focused on larger units of text (Louis and Nenkova, 2013; Danescu-Niculescu-Mizil et al., 2012; Greene and Resnik, 2009; Xu et al., 2012) and studies of style at the lexical level have been scant. The few recent efforts (Brooke et al., 2010; Brooke and Hirst, 2013b; Brooke and Hirst, 2013a) have been motivated by the need to categorize genre in multiple continuous dimensions and focused on applying standard methods for lexical characterization via graph propagation or crowdsourcing.

Formal/Casual	Complex/Simple
jesus/my gosh	great/a lot
18 years/eighteen	cinema/a movie
respiratory/breathing	a large/a big
yes/yeah	music/the band
decade/ten years	much/many things
1970s/the seventies	exposure/the show
foremost/first of all	relative/his family
megan/you there	matters/the things
somewhere/some place	april/apr
this film/that movie	journal/diary
full/a whole bunch	the world/everybody
otherwise/another thing	burial/funeral
father/my dad	rail/the train
recreation/hobby	physicians/a doctor

Table 1: Paraphrases with large style differences. Our method learns these distinctions automatically.

We propose a simple and flexible method for placing phrases along a style spectrum. We focus on two dimensions: formality and complexity. We evaluate the resulting scores in terms of their correlation with human judgements as well as their utility in two tasks. First, we use the induced dimensions to identify stylistic shifts in paraphrase, allowing us to differentiate stylistic properties in the Paraphrase Database (PPDB) with high accuracy. Second, we test how well the induced scores capture differences between genres, and explore the extent to which these differences are due to topic versus lexical choice between stylistically different expressions for the same content. We show that style alone

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 218–224,
Denver, Colorado, May 31 – June 5, 2015.

does differentiate between genres, and that the combined indicators of style and topic are highly effective in describing genre in a way consistent with human judgements.

2 Method

We focus on two style dimensions: formality and complexity. We define formal language as the way one talks to a superior, whereas casual language is used with friends. We define simple language to be that used to talk to children or non-native English speakers, whereas more complex language is used by academics or domain experts.

We use the Europarl corpus of parliamentary proceedings as an example of formal text and the Switchboard corpus of informal telephone conversations as casual text. We use articles from Wikipedia and simplified Wikipedia (Coster and Kauchak, 2011) as examples of complex and simple language respectively. For each style dimension, we subsample sentences from the larger corpus so that the two ends of the spectrum are roughly balanced. We end up with roughly 300K sentences each for formal/casual text and about 500K sentences each for simple/complex text.[1]

Given examples of language at each end of a style dimension, we score a phrase by the log ratio of the probability of observing the word in the reference corpus (REF) to observing it in the combined corpora (ALL). For formality the reference corpus is Europarl and the combined data is Europarl and Switchboard together. For complexity, the reference corpus is normal Wikipedia and the combined data is normal and simplified Wikipedia together. Specifically, we map a phrase w onto a style dimension via:

$$\text{FORMALITY}(w) = \log\left(\frac{P(w \mid REF)}{P(w \mid ALL)}\right).$$

We assign formality scores to phrases up to three words in length that occur at least three times total in ALL, regardless of whether they occur in both corpora. Phrases which do not occur at all in REF are treated as though they occurred once.

[1]Number of words: casual (2MM), formal (7MM), simple (9MM), complex (12MM).

3 Evaluation

We first assess the intrinsic quality of the scores returned by our method by comparing against subjective human judgements of stylistic properties.

Phrase-level human judgements For each of our style dimensions, we take a random sample of 1,000 phrases from our corpora. We show each phrase to 7 workers on Amazon Mechanical Turk (MTurk) and ask the worker to indicate using a sliding bar (corresponding to a 0 to 100 scale) where they feel each word falls on the given style spectrum (e.g. casual to formal). Workers were given a high-level description of each style (like those given at the beginning of Section 2) and examples to guide their annotation.

	Formal	Casual	Complex	Simple
Low σ	exchange proceedings scrutiny	, uh all that stuff pretty much	per capita referendum proportional	is not the night up
High σ	his speech in return for of the series	radio are really to move into	mid japan os	possible center of sets

Table 2: Phrases with high and low levels of annotator agreement, measured by the variance of the human raters' scores (Low σ = high agreement).

We estimate inter-annotator agreement by computing each rater's correlation with the average of the others. The inter-annotator correlation was reasonably strong on average ($\rho = 0.65$). However, not all phrases had equally strong levels of human agreement. Table 2 shows some examples of phrases which fell "obviously" on one end of a style spectrum (i.e. the variance between humans' ratings was low) and some other examples which were less clear.

Quality of automatic scores We compute the correlation of our method's score with the average human rating for each phrase. The results are summarized in Table 4. The log-ratio score correlates with the human score significantly above chance, even matching inter-human levels of correlation on the formality dimension.

4 Applications

We evaluate the acquired style mappings in two tasks: finding paraphrase pairs with differences in style and characterizing genre variation.

agreed	→	great	→	sure	→	yeah
assumes	→	implies	→	imagine	→	guess
currently	→	today	→	now	→	nowadays
most beautiful	→	very nice	→	really nice	→	really pretty
following a	→	in the aftermath	→	in the wake	→	right after
the man who	→	one who	→	the one that	→	the guy that

Table 3: Groups of paraphrases ordered from most formal (left) to least formal (right), as described in Section 4.1.

	Spearman ρ	
	Formality	Complexity
Inter-annotator	0.654	0.657
Log-ratio score	0.655	0.443

Table 4: First row: mean correlation of each rater's scores with the average of the others. Second row: correlation of our automatic style score with the average human score.

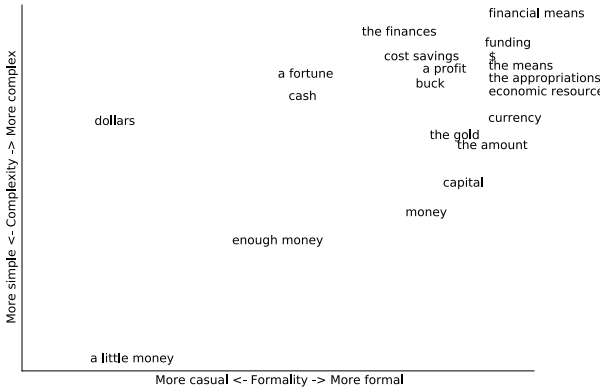

Figure 1: Several paraphrases for *money* ranked according to automatically learned style dimensions.

4.1 Differentiating style in paraphrases

Paraphrases are usually defined as "meaning equivalent" words or phrases. However, many paraphrases, even while capturing the same meaning overall, display subtle differences which effect their substitutability (Gardiner and Dras, 2007).

For example, paraphrasing "I believe that we have..." as "I think we got..." preserves the meaning but causes a clear change in style, from a more formal register to a casual one. It has been proposed that paraphrases are rarely if ever perfectly equivalent, but instead represent *near synonyms* (Edmonds and Hirst, 2002), which contain subtle differences in meaning and connotation.

We test whether our method can tease apart stylistic variation given a set of "equivalent" phrases. We use phrase pairs from the Paraphrase Database (PPDB) (Ganitkevitch et al., 2013). Using the scoring method described in Section 2, we identify paraphrase pairs which display stylistic variation along a particular dimension. We can find pairs $\langle w1, w2 \rangle$ in PPDB for which $\text{FORMALITY}(w1) - \text{FORMALITY}(w2)$ is large; Table 1 gives some examples of pairs identified using this method. We can also view paraphrases along a continuum; Table 3 shows groups of paraphrases ordered from most formal to most casual and Figure 1 shows how paraphrases of the phrase *money* rank along the formality and complexity dimensions. For example, we capture the fact that *money* is more formal but simpler than the idiomatic expression *a fortune*.

Pairwise human judgements To evaluate the goodness of our style-adapted paraphrases, we take a random sample of 3,000 paraphrase pairs from PPDB and solicit MTurk judgements. We show workers each paraphrase pair and ask them to choose which of the words is more casual, or to indicate "no difference." We also carry out the analogous task for the complexity distinction. We take the majority of 7 judgements as the true label for each pair.

In only 9% of the 3,000 paraphrase pairs, turkers decided there was no stylistic difference in the pair, indicating that indeed formality and complexity differences are truly characteristic of paraphrases. In further analysis we ignore the pairs for which the consensus was no difference but note that in further work we need to automate the identification of stylistically equivalent paraphrases.

Automatically differentiating paraphrases Using the human judgements, we compute the accuracy of our method for choosing which word in a pair is more formal (complex). We use the magnitude of the difference in formality (complexity) score as a measure of our method's confidence in its prediction. E.g. the smaller the gap in FORMALITY,

the less confident our method is that there is a true style difference. Table 5 shows pairwise accuracy as a function of confidence: it is well above the 50% random baseline, reaching 90% for the high-confidence predictions in the complexity dimension.

	Pairwise accuracy		
	Top 10%	Top 25%	Overall
Complexity	0.90	0.88	0.74
Formality	0.72	0.73	0.68

Table 5: Pairwise accuracy for paraphrase pairs at varying levels confidence. Top 10% refers to the 10% of pairs with largest difference in log-ratio style score. Random guessing achieves an accuracy of 0.5.

4.2 Genre characterization

Now we explore if the dimensions we learned at the sub-sentential level can be used to capture stylistic variation at the sentence and genre level.

Sentence-level human judgements We gather human ratings of formality and complexity for 900 sentences from the MASC corpus (Ide et al., 2010): 20 sentences from each of 18 genres.[2] Recently data from this corpus has been used to study genre difference in terms of pronoun, named entity, punctuation and part of speech usage (Passonneau et al., 2014). We use the data to test a specific hypothesis that automatically induced scores for lexical style are predictive of perceptions of sentence- and genre-level style.

We average 7 independent human scores to get sentence-level style scores. To get genre-level style scores, we use the the average of the 20 sentence-level scores for the sentences belonging to that genre.

In human perception, the formality and complexity dimensions are highly correlated (Spearman $\rho = 0.7$). However, we see many interesting examples of sentences which break this trend (Table 6). Overall, inter-annotator correlations are reasonably strong ($\rho \approx 0.5$), but as in the phrase-level annotations, we see some sentences for which the judgement seems unanimous among annotators and some sentences for which there is very little consensus (Table 7). We discuss this variation further in Section 5.

Formal/Simple	has dr. miller left the courtroom?
Formal/Simple	i want to thank you for listening tonight.
Casual/Complex	right. cuz if we have a fixed number of neurons-?
Casual/Complex	i was actually thinking we could use the warping factors that we compute for the mfcc's

Table 6: Some examples of sentences for which the generally high correlation between formality and complexity does not hold.

Automatically characterizing genre The extent to which genre is defined by topic versus style is an open question. We therefore look at two methods for genre-level style characterization, which we apply at the sentence-level as well as at the genre-level.

First, we take the average formality (complexity) score of all words in the text, which we refer to as the "all words" method. Using the style score alone in this way will likely to conflate aspects of topic with aspects of style. For example, the word *birthday* receives a very low formality score whereas the phrase *united nations* receives a very high formality score, reflecting the tendency of certain topics to be discussed more formally than others.

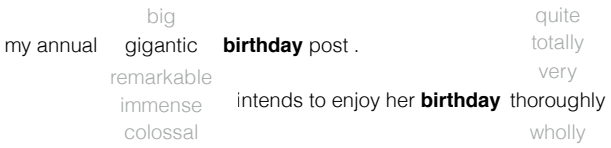

Figure 2: Authors reveal style by choosing casual terms or formal terms for the same concept. Shown is a casual sentence (left) and a formal sentence (right) on the same topic. Alternative paraphrases are ordered casual (top) to formal (bottom).

We therefore use a second method, which we refer to as "PP only", in which we look only at the words in the text which belong to one of our paraphrase sets (as in Figure 3), allowing us to control for topic and focus only on stylistic word choice. In "PP only", we consider a word to be formal if it appears on the formal side of the set (i.e. there are

[2]Court transcripts, debate transcripts, face-to-face conversations, blogs, essays, fiction, jokes, letters, technical writing, newspaper, twitter, email, ficlets (short fan fiction), government documents, journal entries, movie scripts, non-fiction, and travel guides. We omit the "telephone" genre, since it is too similar to the Switchboard corpus and may inflate results.

Formal	Low σ	whereupon, the proceedings were adjourned at 4:20 p.m.
Formal	High σ	mr. president , you have 90 seconds
Casual	Low σ	is she, what grade is she in?
Casual	High σ	they bring to you and your loved ones.
Complex	Low σ	let me abuse the playwright and dismiss the penultimate scene
Complex	High σ	revealing to you my family 's secret because my late dad 's burial is over.
Simple	Low σ	you 're not the only one
Simple	High σ	facebook can get you fired , dumped , and yes , evicted

Table 7: Style ratings of sentences with high and low levels of human agreement, measured by the variance of the human raters' scores (Low σ = high agreement).

more phrases to its left than to its right). We then score the overall formality of the text as the proportion of times a formal phrase was chosen when a more casual paraphrase could have been chosen instead. The intuition is captured in Figure 2: when an author is writing about a given topic, she encounters words for which there exist a range of paraphrases. Her lexical choice in these cases signals the style independent of the topic.

Table 8 shows how well our two scoring methods correlate with the human judgements of sentences' styles. The "all words" method performs very well, correlating with humans nearly as well as humans correlate with each other. Interestingly, when using paraphrases only we maintain significant correlations. This ability to differentiate stylistic variation without relying on cues from topic words could be especially important for tasks such as bias detection (Recasens et al., 2013) and readability (Callan, 2004; Kanungo and Orr, 2009).

	Formality		Complexity	
	Sent.	Genre	Sent.	Genre
Inter-anno.	0.47	–	0.48	–
All words	0.44	0.77	0.43	0.80
PP only	0.18	0.63	0.23	0.45

Table 8: Spearman ρ of automatic rankings with human rankings. Genres are the concatenation of sentences from that genre. In "all words," a text's score is the average log-ratio style score of its words. In "PP only," a text's score is the proportion of times a formal term was chosen when more casual paraphrases existed, effectively capturing style independent of topic.

5 Discussion

Characterization of style at the lexical level is an important first step in complex natural language tasks, capturing style information in a way that is portable across topics and applications. An interesting open question is the extent to which style is defined at the lexical level versus at the sentential level: how strongly are human perceptions of style influenced by topic and context as opposed to by lexical choice? One interesting phenomenon we observe is that inter-annotator correlations are lower at the sentence level ($\rho \approx 0.5$) than at the word- and phrase-level ($\rho \approx 0.65$). Tables 7 offers some insight: for many of the sentences for which human agreement is low, there seems to be some mismatch between the topic and the typical style of that topic (e.g. talking formally about family life, or talking in relatively complex terms about Facebook). When humans are making judgements at the lexical level, such contextual mismatches don't arise, which might lead to higher overall agreements. Interesting future work will need to explore how well humans are able to separate style from topic at the sentence- and document-level, and how the lexical choice of the author/speaker affects this distinction.

6 Conclusion

We present a simple and scalable method for learning fine-grained stylistic variation of phrases. We demonstrate good preliminary results on two relevant applications: identifying stylistic differences in paraphrase, and characterizing variations between genres. Our method offers a simple and flexible way of acquiring stylistic annotations at web-scale, making it a promising approach for incorporating nuanced linguistic information into increasingly complex language applications.[3]

Abstract

Research on entity linking has considered a broad range of text, including newswire, blogs and web documents in multiple languages. However, the problem of entity linking for spoken language remains unexplored. Spoken language obtained from automatic speech recognition systems poses different types of challenges for entity linking; transcription errors can distort the context, and named entities tend to have high error rates. We propose features to mitigate these errors and evaluate the impact of ASR errors on entity linking using a new corpus of entity linked broadcast news transcripts.

1 Introduction

Entity linking identifies for each textual mention of an entity a corresponding entry contained in a knowledge base, or indicates when no such entry exits (NIL). Numerous studies have explored entity linking in a wide range of domains, including newswire (Milne and Witten, 2008; Mcnamee et al., 2009; McNamee and Dang, 2009; Dredze et al., 2010), blog posts (Ji et al., 2010), web pages (Demartini et al., 2012; Lin et al., 2012), social media (Cassidy et al., 2012; Guo et al., 2013a; Shen et al., 2013; Liu et al., 2013), email (Gao et al., 2014) and multi-lingual documents (Mayfield et al., 2011; McNamee et al., 2011; Wang et al., 2012). A common theme across all these settings requires addressing two difficulties in linking decisions: matching the textual name mention to the form contained in the knowledge base, and using contextual clues to disambiguate similar entities. However, all of these studies have focused on written language, while linking of spoken language remains untested. Yet many intended applications of entity linking, such as supporting search (Hachey et al., 2013) and identifying relevant sources for reports (He et al., 2010; He et al., 2011), linking of spoken language is critical. Search results regularly include audio content (e.g. YouTube) and numerous information sources are audio recordings (e.g. media reports.) An evaluation of entity linking for spoken language can help clarify issues and challenges in this domain.

In addition to the two main challenges discussed above, audio entity linking presents two parallel difficulties that arise from automatic transcription (ASR) of speech. First, the context can be both shorter (than newswire formats) and contain ASR errors, which can make the context of the mention less like supporting material in the knowledge base. Second, named entities are often more difficult to recognize (Huang, 2005; Horlock and King, 2003); they are often out-of-vocabulary and less common overall in training data. This can mislead the name matching techniques on which most entity linking systems depend.

In this paper we consider the task of entity linking for spoken language by evaluating linking on transcripts of broadcast news. We select broadcast news as a comparable domain of spoken language to newswire documents, which have been the focus of considerable research for entity linking (Mcnamee et al., 2009; Ji et al., 2010). We chose this comparable domain to focus on issues introduced because of a transition to spoken language from written, as opposed to issues that arise from a general domain shift associated with conversational speech, an issue that has been previously studied in the shift from written news to written conversations (weblogs, social

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 225–230,
Denver, Colorado, May 31 – June 5, 2015.

media, etc.) (Baldwin et al., 2013; Han et al., 2013).

We proceed as follows. We first introduce a new broadcast news dataset annotated for entity linking. We then propose new features based on ASR output to address the two sources of error specific to spoken language: 1) context errors and shortening, 2) name mention transcription errors. We then test our features on the automated output of an ASR system to validate our findings.

2 Entity Linked Spoken Language Data

We created entity linking annotations for HUB4 (Fiscus et al., 1997), a manually-transcribed broadcast news corpus. We used gold named entity annotations from Parada et al. (2011), who manually annotated 9971 utterances with CONLL style (Tjong Kim Sang and De Meulder, 2003) named entities. We selected 2140 person entities and obtained entity linking decisions with regards to the TAC KBP knowledge base (Mcnamee et al., 2009; Ji et al., 2010), which contains 818,741 entries derived from Wikipedia.

Annotations were initially obtained using Amazon Mechanical Turk (Callison-Burch and Dredze, 2010) using the same entity linking annotation scheme as Mayfield et al. (2011). Turkers were asked which of five provided Wikipedia articles matched a person mention highlighted in a displayed utterance. The provided Wikipedia articles were selected based on token overlap between the mention and article title, weighted by TFIDF. In addition to selecting one of the five articles, turkers could select "None of the above", "Not enough information" or "Not a person". We collected one Turker annotation per query and manually verified and corrected each provided label. For mentions that were not matched to an article, we verified that the article was not in the KB, or manually assigned a KB entry otherwise. Because we manually corrected each annotation, mistakes and biases resulting from crowdsourced annotations are not present in this corpus. Of the 2140 annotated mentions, 41% (n=887) were `NIL`, compared to 54.6% in TAC-KBP 2010 (Ji et al., 2010) and 57.1% in TAC-KBP 2009 (Mcnamee et al., 2009). The named entity and linking annotations can be found at `https://github.com/mdredze/speech_ner_entity_linking_data/releases/tag/1.0`.

We divided the 2140 mentions into 60% train ($n = 1283$) and 40% test ($n = 857$.) We ensured that the 1218 unique mention strings were disjoint between the two sets, i.e. no mention in the test data was observed during training.

Each instance is represented by the query (mention string) and document context. Unlike written articles, broadcast news does not indicate where one topic starts and another ends. Therefore, we experimented with different size contexts by including the utterance containing the name mention and up to eight utterances before and after so long as they occurred within 150 seconds of the start of the utterance containing the name mention. We found that five utterances before and after gave the highest average accuracy when using a standard set of features on the reference transcript to perform entity linking; we use this setting in the experiments below.

3 Entity Linking System

For entity linking, we use Slinky (Benton et al., 2014), an entity linking system that uses parallel processing of queries and candidates in a learned cascade to achieve fast and accurate entity linking performance. We use standard features from McNamee et al. (2012) as described in Benton et al. (2014). For a query q composed of a context (multiple utterances) and a named entity string, Slinky first triages (Dredze et al., 2010; McNamee et al., 2012; Guo et al., 2013b) the query to identify a set of candidates C_q in the knowledge base that may correspond to the mention string. Up to 1000 candidates are considered, though its usually much fewer. The system then extracts features based on query and candidate pairs and ranks them using a series of classifiers. The candidates are then ordered by their final scores; the highest ranking candidate is selected as the system's prediction. `NIL` is included as a candidate for every query and is then ranked by the system. For all training settings, we sweep over hyper-parameters using 5-fold cross validation on the training data to find the most accurate system. Reported results are based on the test data.

3.1 Spoken Language Features

ASR transcription errors pose a challenge for standard text processing features, which rely on textual similarity to measure relatedness of both context and entity mention strings. However, ASR errors are not random; incorrectly decoded words may be phonetically similar to the original spoken words. This suggests that similarity can still be captured by considering phonetic similarity.

We experiment with four feature types.

- **Text**: Our baseline system uses features based on the text of the mention string and document. We used the feature set presented by McNamee et al. (2012) and used in Benton et al. (2014), which was the best performing submission in the TAC-KBP 2009 entity linking task. These features include, among others, features that compare the candidate entity name to the mention string as well as the document's terms to those stored in the candidate's description in the KB. These include the dice coefficient, cosine similarity (boolean and weighted), and proportion of candidate tokens in the query document.
- **Phone**: Words in the document, mention string as well as the knowledge base are represented as phone sequences instead of text. We convert all words to phones using a grapheme string to phone (G2P) system.
- **Metaphones**: Two distinct phones can sound similar, yet still appear different when matching phones. Metaphones (Philips, 1990), a more recent version of Soundex, map similar sounding phones to the same representation. We convert the phones used in the previous paragraph to metaphones.
- **Lattice**: Expected word counts of the query document from the ASR lattice. Extracted unigrams are treated as a weighted bag-of-words for the query document. We compute all the features that use the query document's content and weigh them by the term's expectation.

The features in each of the above sets depend on their representation of the text (e.g. text, phone, metaphone, lattice). Additionally, we include the following features in all experiments: *Bias* features that fire for all candidates, only non-`NIL` candidates, and only `NIL` candidates; `NIL` features indicative of being linked to no article in the knowledge base such as the mention string is only 1 or 2 characters/tokens, the number of candidates emitted by the triager; and the *Popularity* (number of Wikipedia in-links) of the candidate.

Triage The above feature sets change the ranking of candidates. We also modified the triage methods that produce C_q based on these new features. For **Text** we used the triage methods of Mcnamee et al. (2009): string similarity based on character/token n-gram overlap, same acronym, exact match, etc. **Phone** triage used the same heuristics but based on phone representations of the mention strings and candidate names. **Metaphone** triage worked as in phone, but used metaphones. When two representations are used we take the union of their candidates.

G2P System For phone features we use a G2P system based on the Sequitur G2P grapheme-phoneme-converter (Bisani and Ney, 2008). We trained the system on version 0.7a of CMUdict[1] (stress omitted from phone sequences, case-insensitive for graphemes), by predicting the phoneme sequence of an English token given its string (G2P). The language model was a 9-gram model with modified Kneser-Ney smoothing applied. For **Phone** features we converted each token to its best phone representation, where each phone, as well as diphthong, is represented by a single character for similarity matching.

4 Experiments

We evaluate reference transcripts and output from two ASR systems run on our dataset (HUB4). We use Kaldi (Povey et al., 2011) trained on the spoken version of the Wall Street Journal corpus (Paul and Baker, 1992).[2] The first system (*mono*) relies on an HMM whose hidden states are context-independent phones. The second system (*tri4b*) uses an HMM that outputs phones dependent on their immediate left and right contexts. These systems respectively achieve 70.6% and 50.7% WER over our training set, where high error rates are likely due to a shift in domain from primarily financial news to the wider

news variety in HUB4. These higher error settings test the limits of entity linking in noisy ASR.

To find the ASR-corrupted mention string used for the query q we align the ASR transcript by token-level edit distance – additions and deletions cost 1, while substitutions cost the Jaccard distance between two tokens. This is done at both training and test time, and allows us to evaluate performance of entity linking features without worrying about errors introduced by a named entity recognizer on the transcripts.

Entity Linking System Training The entity linking system relies on a linear Ranking SVM objective (Joachims, 2006), and the optimal slack parameter C was chosen using 5-fold cross validation over the training set (C varied from 1 and 5 $\times 10^{-5 \ldots 3}$). During cross-validation, mention string types were kept disjoint between the train and development folds. Ranking was performed over the (up to) 1000 candidates produced by triage selected from the TAC-KBP 2009/10 KB (Mcnamee et al., 2009; Ji et al., 2010). Using the selected C we trained over the entire training set and evaluated on the test set.

Table 4: Examples of improved linking accuracy.

5 Results

Table 1 reports both the average accuracy for 5-fold cross validation (CV) on train and for the best tuned system from CV on test data. The reference test accuracy is relatively high, but lags behind person entity linking for written language. When accurate transcripts are available, entity linking for spoken language, while harder, achieves just a little behind written language. However, on ASR transcripts, accuracy drops considerably: 0.77 reference to 0.48 (mono, 71% WER) or 0.55 (tri4b, 51% WER). Our features improve accuracy for both ASR systems. Metaphone features do better than Phone features. Lattice do not show significant improvements, likely because they help with context but not mentions (see below.) When combined with text, both metaphone and phone features do similarly.

The majority of our improvement comes from improvements to recall. Table 3 shows the accuracy of queries for which the triager found the correct candidate in *both* the reference transcript and tri4b, providing a consistent set for comparison. For these queries, tri4b is much closer to the results obtained on reference and much higher than the best results in Table 1. This is encouraging, especially given the 50% WER of tri4b; entity linking accuracy is not seriously impacted by noisy transcripts, provided that

the correct candidate is recalled for ranking.

Table 2 shows the recall of the triager on the reference, tri4b and mono transcripts. Reference recall is quite high, while recall for the ASR systems is much lower. Here, our features dramatically improve the recall, giving the ranker an opportunity to correctly score these queries. The challenge of recall is that many of the mention strings are incorrectly recognized. Table 1 shows the WER of the mention string and the number of mention strings for which the recognition is completely correct. Unsurprisingly, error rates for mentions are higher than the overall WER. In short, success on ASR transcripts is primarily dictated by the effectiveness of finding candidates in triage, which is much harder given the low recognition rate. Our features most benefit overall accuracy by improving recall.

Finally, Table 4 provides example of improved recall: mention strings that are incorrectly recognized by the tri4b ASR system leading to linking failures, but are then correctly linked by our improved features. These examples demonstrate the effectiveness of phonetic matching, retrieving the correct "George W. Bush" when the recognizer output "Georgia the Books."

6 Conclusion

We have conducted the first analysis of entity linking for spoken language. Our new features, which rely on phonetic representations of words and expected counts of the lattice for context, improve the accuracy of an entity linker on ASR output. Our analysis reveals that while the linker is not sensitive to large drops in error rates in the context, it is highly sensitive to error rates in mention strings, due to a drop in triage recall. Our features improve the overall accuracy by improving the recall of the triager. Future work should focus on additional methods for identifying relevant KB candidates given inaccurate transcriptions of mention strings.

Spinning Straw into Gold: Using Free Text to Train Monolingual Alignment Models for Non-factoid Question Answering

peterc@allenai.org

Abstract

Monolingual alignment models have been shown to boost the performance of question answering systems by "bridging the lexical chasm" between questions and answers. The main limitation of these approaches is that they require semistructured training data in the form of question-answer pairs, which is difficult to obtain in specialized domains or low-resource languages. We propose two inexpensive methods for training alignment models solely using free text, by generating artificial question-answer pairs from discourse structures. Our approach is driven by two representations of discourse: a shallow sequential representation, and a deep one based on Rhetorical Structure Theory. We evaluate the proposed model on two corpora from different genres and domains: one from Yahoo! Answers and one from the biology domain, and two types of non-factoid questions: manner and reason. We show that these alignment models trained directly from discourse structures imposed on free text improve performance considerably over an information retrieval baseline and a neural network language model trained on the same data.

1 Introduction

Question Answering (QA) is a challenging task that draws upon many aspects of NLP. Unlike search or information retrieval, answers infrequently contain lexical overlap with the question (e.g. *What should we eat for breakfast? – Zoe's Diner has good pancakes*), and require QA models to draw upon more complex methods to bridge this "lexical chasm" (Berger et al., 2000). These methods range from robust shallow models based on lexical semantics, to deeper, explainably-correct, but much more brittle inference methods based on first order logic.

Berger et al. (2000) proposed that this "lexical chasm" might be partially bridged by repurposing statistical machine translation (SMT) models for QA. Instead of translating text from one language to another, these monolingual alignment models learn to translate from question to answer[1], learning common associations from question terms such as *eat* or *breakfast* to answer terms like *kitchen, pancakes, or cereal*.

While monolingual alignment models have enjoyed a good deal of recent success in QA (see related work), they have expensive training data requirements, requiring a large set of aligned in-domain question-answer pairs for training. For low-resource languages or specialized domains like science or biology, often the only option is to enlist a domain expert to generate gold QA pairs – a process that is both expensive and time consuming. All of this means that only in rare cases are we accorded the luxury of having enough high-quality QA pairs to properly train an alignment model, and so these models are often underutilized or left struggling for resources.

Making use of recent advancements in discourse parsing (Feng and Hirst, 2012), here we address this issue, and investigate whether alignment models for QA can be trained from artificial question-answer pairs generated from discourse structures imposed on free text. We evaluate our methods on two corpora, generating alignment models for an open-domain community QA task using Gigaword[2], and for a biology-domain QA task using a biology textbook.

[1] In practice, alignment for QA is often done from answer to question, as answers tend to be longer and provide more opportunity for association (Surdeanu et al., 2011).

[2] LDC catalog number LDC2012T21

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 231–237,
Denver, Colorado, May 31 – June 5, 2015.

The contributions of this work are:

1. We demonstrate that by exploiting the discourse structure of free text, monolingual alignment models can be trained to surpass the performance of models built from expensive in-domain question-answer pairs.
2. We compare two methods of discourse parsing: a simple sequential model, and a deep model based on Rhetorical Structure Theory (RST) (Mann and Thompson, 1988). We show that the RST-based method captures within and across-sentence alignments and performs better than the sequential model, but the sequential model is an acceptable approximation when a discourse parser is not available.
3. We evaluate the proposed methods on two corpora, including a low-resource domain where training data is expensive (biology).
4. We experimentally demonstrate that monolingual alignment models trained using our method considerably outperform state-of-the-art neural network language models in low resource domains.

2 Related Work

Lexical semantic models have shown promise in bridging Berger et al.'s (2000) "lexical chasm." In general, these models can be classified into alignment models (Echihabi and Marcu, 2003; Soricut and Brill, 2006; Riezler et al., 2007; Surdeanu et al., 2011; Yao et al., 2013) which require structured training data, and language models (Jansen et al., 2014; Sultan et al., 2014; Yih et al., 2013), which operate over free text. Here, we close this gap in resource availability by developing a method to train an alignment model over free text by making use of discourse structures.

Discourse has been previously applied to QA to help identify answer candidates that contain explanatory text (e.g. Verberne et al. (2007)). Jansen et al. (2014) proposed a reranking model that used both shallow and deep discourse features to identify answer structures in large answer collections across different tasks and genres. Here we use discourse to impose structure on free text to create inexpensive knowledge resources for monolingual alignment. Our work is conceptually complementary to that of Jansen et al. – where they explored largely unlexicalized discourse structures to identify explanatory text, we use discourse to learn lexicalized models for semantic similarity.

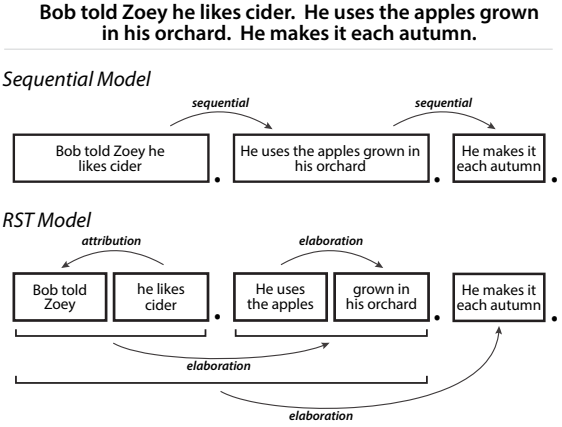

Figure 1: An example of the alignments produced by the two discourse models. The sequential model aligns pairs of consecutive sentences, capturing intersentence associations such as *cider–apples*, and *orchard–autumn*. The RST model generates alignment pairs from participants in all (binary) discourse relations, capturing both intrasentence and intersentence alignments, including *apples–orchard, cider–apples*, and *cider–autumn*.

Our work is conceptually closest to that of Hickl et al. (2006), who created artificially aligned pairs for textual entailment. Taking advantage of the structure of news articles, wherein the first sentence tends to provide a broad summary of the article's contents, Hickl et al. aligned the first sentence of each article with its headline. By making use of automated discourse parsing, here we go further and impose alignment structure over an entire text.

3 Approach

A written text is not simply a collection of sentences, but rather a flowing narrative where sentences and sentence elements depend on each other for meaning – a concept known as cohesion (Halliday and Hasan, 2014). Here we examine two methods for generating alignment training data from free text that make use of cohesion: a shallow method that uses only intersentence structures, and a deep method that uses both intrasentence and intersentence structures. We additionally attempt to separate the contribution of discourse from that of alignment in general by comparing these models against a baseline alignment model which aligns sentences at random.

The first model, the sequential discourse model (SEQ), considers that each sentence continues the

narrative of the previous one, and creates artificial question-answer pairs from all pairs of consecutive sentences. Thus, this model takes advantage of intersentence cohesion by aligning the content words[3] in each sentence with the content words in the following sentence. For example, in the passage in Figure 1, this model would associate *cider* in the first sentence with *apples* and *orchard* in the second sentence.

The second model uses RST to capture discourse cohesion both within and across sentence boundaries. We extracted RST discourse structures using an in-house parser (Surdeanu et al., 2015), which follows the architecture introduced by Hernault et al. (2010) and Feng and Hirst (2012). The parser first segments text into elementary discourse units (EDUs), which may be at sub-sentence granularity, then recursively connects neighboring units with binary discourse relations, such as *Elaboration* or *Contrast*.[4] Our parser differs from previous work with respect to feature generation in that we implement all features that rely on syntax using solely dependency syntax. For example, a crucial feature used by the parser is the dominance relations of Soricut and Marcu (2003), which capture syntactic dominance between discourse units located in the same sentence. While originally these dominance relations were implemented using constituent syntax, we provide an equivalent implementation that relies on dependency syntax. The main advantage to this approach is speed: the resulting parser performs at least an order of magnitude faster than the parser of Feng and Hirst (2012).

Importantly, we generate artificial alignment pairs from this imposed structure by aligning the governing text (nucleus) with its dependent text (satellite).[5] Turning again to the example in Figure 1, this RST-based model captures additional alignments that are both intrasentence, e.g., *apples–orchard*, and intersentence, e.g., *cider–autumn*.

[3]In pilot experiments, we found that aligning only nouns, verbs, adjectives, and adverbs yielded higher performance.

[4]The RST parser performs better on relations which occur more frequently. We use only relations that occurred at least 1% of the time. This amounted to six relations: *elaboration*, *attribution*, *background*, *contrast*, *same-unit*, and *joint*. Using all relations slightly improves performance by 0.3% P@1.

[5]Pilot experiments showed that this direction of alignment performed better than aligning from satellite to nucleus.

4 Models and Features

We evaluate the contribution of these alignment models using a standard reranking architecture (Jansen et al., 2014). The initial ranking of candidate answers is done using a shallow candidate retrieval (CR) component.[6] Then, these answers are reranked using a more expressive model that incorporates alignment features alongside the CR score. As a learning framework we use SVM^{rank}, a Support Vector Machine tailored for ranking.[7] We compare this alignment-based reranking model against one that uses a state-of-the-art recurrent neural network language model (RNNLM) (Mikolov et al., 2010; Mikolov et al., 2013), which has been successfully applied to QA previously (Yih et al., 2013).

Alignment Model: The alignment matrices were generated with IBM Model 1 (Brown et al., 1993) using GIZA++ (Och and Ney, 2003), and the corresponding models were implemented as per Surdeanu et al. (2011) with a global alignment probability. We extend this alignment model with features from Fried et al. (In press) that treat each (source) word's probability distribution (over destination words) in the alignment matrix as a distributed semantic representation, and make use the Jensen-Shannon distance (JSD)[8] between these conditional distributions. A summary of all these features is shown in Table 1.

RNNLM: We learned word embeddings using the `word2vec` RNNLM of Mikolov et al. (2013), and include the cosine similarity-based features described in Table 1.

5 Experiments

We tested our approach in two different domains, open-domain and cellular biology. For consistency we use the same corpora as Jansen et al. (2014), which are described briefly here.

Yahoo! Answers (YA): Ten thousand open-domain *how* questions were randomly chosen from the Ya-

[6]We use the same cosine similarity between question and answer lemmas as Jansen et al. (2014), weighted using *tf.idf*.

[7]`http://www.cs.cornell.edu/people/tj/svm_light/svm_rank.html`

[8]Jensen-Shannon distance is based on Kullback-Liebler divergence but is a distance metric (finite and symmetric).

	Feature Group	Feature Descriptions
Alignment Models	Global Alignment Probability	p(Q|A) according to IBM Model 1 (Brown et al., 1993)
	Jenson-Shannon Distance (JSD)	Pairwise JSDs were found between the probability distribution of each content word in the question and those in the answer. The **mean, minimum, and maximum JSD values** were used as features. Additionally, composite vectors were formed which represented the entire question and the entire answer and the **overall JSD** between these two vectors was also included as a feature. See Fried et. al (In press) for additional details.
RNNLM	Cosine Similarity	Similar to Jansen et al. (2014), we include as features the **maximum and average pairwise cosine similarity** between question and answer words, as well as the **overall similarity** between the composite question and answer vectors.

Table 1: Feature descriptions for alignment models and RNNLM baseline.

hoo! Answers[9] community question answering corpus and divided: 50% for training, 25% for development, and 25% for test. Candidate answers for a given question are selected from the corresponding answers proposed by the community (each question has an average of 9 answers).

Biology QA (Bio): 183 *how* and 193 *why* questions in the cellular biology domain were hand-crafted by a domain expert, and paired with gold answers in the Campbell's Biology textbook (Reece et al., 2011). Each paragraph in the textbook was considered as a candidate answer. As there were few questions, five fold cross-validation was used with three folds for training, one for development, and one for test.

Alignment Corpora: To train the alignment models we generated alignment pairs from two different resources: Annotated Gigaword (Napoles et al., 2012) for YA, and the textbook for Bio. Each was discourse parsed with the RST discourse parser described in Section 3, which is implemented in the FastNLPProcessor toolkit[10], using the MaltParser[11] for syntactic analysis.

5.1 Results and Discussion

Figure 2 shows the performance of the discourse models against the number of documents used to train the alignment model.[12] We used the standard implementation for P@1 (Manning et al., 2008) with the adaptations for Bio described in Jansen et al. (2014). We address the following questions.

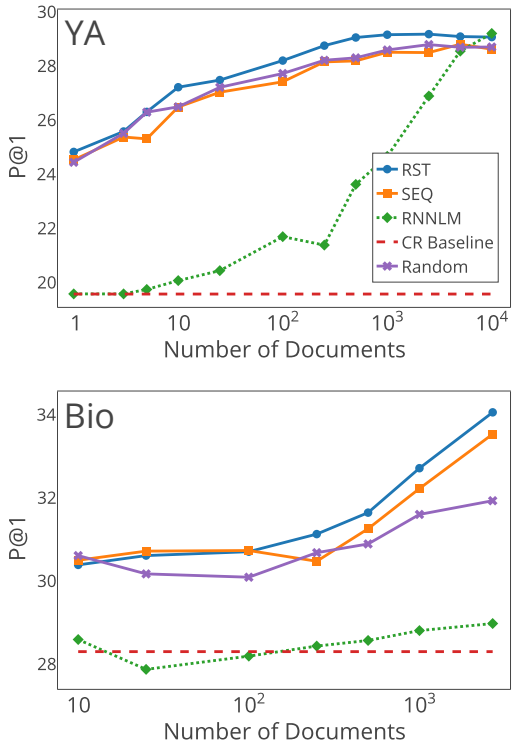

Figure 2: Overall performance for the two discourse-based alignment models, compared against the CR baseline, random baselines, and a RNNLM-based reranker. The x axis indicates the number of training documents used to construct all models. Each point represents the average of 10 samples of training documents.

How does the performance of the RST and SEQ models compare? Comparing the two principal alignment models, the RST-based model significantly outperforms the SEQ model by about 0.5% P@1 in both domains ($p < 0.001$ for Bio and $p < 0.01$ for YA)[13]. This shows that deep discourse anal-

[11] http://www.maltparser.org/

[12] For space reasons the graph for Bio *how* is not shown, but the pattern is essentially identical to Bio *why*.

[13] All reported statistics were performed at the endpoints, i.e., when all training data is used, using bootstrap resampling with

ysis (as imperfect as it is today) is beneficial.

How does the performance of the RST model compare to a model trained on in-domain pairs? Both the RST and SEQ results for YA are *higher* than that of an alignment model trained on explicit in-domain question-answer pairs. Fried et. al (In press) trained an identical alignment model using approximately 65k QA pairs from the YA corpus, and report a performance of 27.24% P@1, or nearly 2 points lower than our model trained using 10,000 Gigaword documents. This is an encouraging result, which further demonstrates that: (a) discourse analysis can be exploited to generate artificial semi-structured data for alignment, and (b) the sequential model, which also outperforms Fried et. al, can be used as a reasonable proxy for discourse when a parser is not available.

How does the performance of the RST model compare to previous work? Comparing our work to Jansen et al. (2014), the most relevant prior work, we notice two trends. First, our discourse-based alignment models outperform their CR + RNNLM model, which peaks at 26.6% P@1 for YA and 31.7% for Bio *why*. While some of this difference can be assigned to implementation differences (e.g., we consider only content words for both alignment and RNNLM, where they used all words), this result again emphasizes the value of our approach. Second, the partially lexicalized discourse structures used by Jansen et. al to identify explanatory text in candidate answers perform better than our approach, which relies solely on lexicalized alignment. However, we expect that our two approaches are complementary, because they address different aspects of the QA task (structure vs. similarity).

How do the RST and SEQ models compare to the non-alignment baselines? In Bio, both the RST and SEQ alignment models significantly outperform the RNNLM and CR baselines ($p < 0.001$). In YA, the RST and SEQ models significantly outperform the CR baseline ($p < 0.001$), and though they considerably outperform the the RNNLM baseline for most training document sizes, when all 10,000 documents are used for training, they do not perform better. This shows that alignment models are more robust to little training data, but RNNLMs catch up when considerable data is available.

How does the SEQ model compare to the RND baseline? In Bio, the SEQ model significantly outperforms the RND baseline ($p < 0.001$) but in YA it does not. This is likely due to differences in the size of the document which was randomized. In YA, the sentences were randomized within Gigaword articles, which are relatively short (averaging 19 sentences), whereas in Bio the randomization was done at the textbook level. In practice, as document size decreases, the RND model approaches the SEQ model.

Why does performance plateau in YA and not in Bio? With Bio, we exploit all of the limited in-domain training data, and continue to see performance improvements. With YA, however, performance asymptotes for the alignment models when trained beyond 10,000 documents, or less than 1% of the Gigaword corpus. Similarly, when trained over the entirety of Gigaword (two orders of magnitude more data), our RNNLM improves only slightly, peaking at approximately 30.5% P@1 (or, a little over 1% P@1 higher). We hypothesize that this limitation comes from failing to take context into account. In open domains, alignments such as *apple – orchard* may interfere with those from different contexts, e.g., *apple – computer*, and add noise to the answer selection process.

6 Conclusion

We propose two inexpensive methods for training alignment models using solely free text, by generating artificial question-answer pairs from discourse structures. Our experiments indicate that these methods are a viable solution for constructing state-of-the-art QA systems for low-resource domains, or languages where training data is expensive and/or limited. Since alignment models have shown utility in other tasks (e.g. textual entailment), we hypothesize that these methods for creating inexpensive and highly specialized training data could be useful for tasks other than QA.

Abstract

The task of Named Entity Disambiguation is to map entity mentions in the document to their correct entries in some knowledge base. We present a novel graph-based disambiguation approach based on Personalized PageRank (PPR) that combines local and global evidence for disambiguation and effectively filters out noise introduced by incorrect candidates. Experiments show that our method outperforms state-of-the-art approaches by achieving 91.7% in micro- and 89.9% in macroaccuracy on a dataset of 27.8K named entity mentions.

1 Introduction

Name entity disambiguation (NED) is the task in which entity mentions in a document are mapped to real world entities. NED is both useful on its own, and serves as a valuable component in larger Knowledge Base Construction systems (Mayfield, 2014).

Since the surge of large, publicly available knowledge bases (KB) such as Wikipedia, the most popular approach has been linking text mentions to KB nodes (Bunescu and Paşca, 2006). In this paradigm, the NED system links text mentions to the KB, and quite naturally utilizes information in the KB to support the linking process. Recent NED systems (Cucerzan, 2007; Ratinov et al., 2011; Alhelbawy and Gaizauskas, 2014) usually exploit two types of KB information: *local* information, which measures the similarity between the text mention and the a candidate KB node; and *global* information, which measures how well the candidate entities in a document are connected to each other, with the assumption that entities appearing in the same document should be coherent. Both types of features have their strengths and drawbacks: local features better encode similarity between a candidate and a KB node, but overlook the coherence between entities; global features are able to exploit interlinking information between entities, but can be noisy if they are used by their own, without considering information from the text and the KB (cf. Section 4).

In this paper, we propose to disambiguate NEs using a Personalized PageRank (PPR)-based random walk algorithm. Given a document and a list of entity mentions within the document, we first construct a graph whose vertices are linking candidates and whose edges reflects links in Wikipedia. We run the PPR algorithm on this graph, with the constraint that we only allow the highest scored candidate for each entity to become the start point of a hop. As all candidates but the correct one are erronous and probably misleading, limiting the random walk to start from the most promising candidates effectively filters out potential noise in the Personalized PageRank process.

Our method has the following properties: 1) as our system is based on a random walk algorithm, it does not require training model parameters ; 2) unlike previous PageRank based approaches in NED (Alhelbawy and Gaizauskas, 2014) which mainly rely on global coherence, our method is able to better utilize the local similarity between a candidate and a KB node (Section 3); and 3) we tailor the Personalized PageRank algorithm to only focus on one high-confidence entity at a time to reduce noise (Section 4).

2 Related Work

Early attempts at the NED tasks use local and surface level information. Bunescu and Paşca

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 238–243,
Denver, Colorado, May 31 – June 5, 2015.

(2006) first utilize information in a knowledge base (Wikipedia) to disambiguate names, by calculating similarity between the context of a name mention and the taxonomy of a KB node.

Later research, such as Cucerzan (2007) and Milne and Witten (2008) extends this line by exploring richer feature sets, such as coherence features between entities. Global coherence features have therefore been widely used in NED research (see e.g. (Ratinov et al., 2011), (Hoffart et al., 2011), and (Cheng and Roth, 2013)) and have been applied successfully in TAC shared tasks (Cucerzan, 2011). These methods often involve optimizing an objective function that contains both local and global terms, and thus requires training on an annotated or distantly annotated dataset.

Our system performs collective NED using a random walk algorithm that does not require supervision. Random walk algorithms such as PageRank (Page et al., 1999) and Personalized PageRank (Jeh and Widom, 2003) have been successfully applied to NLP tasks, such as Word Sense Disambiguation (WSD: (Sinha and Mihalcea, 2007; Agirre and Soroa, 2009)).

Alhelbawy and Gaizauskas (2014) successfully apply the PageRank algorithm to the NED task. Their work is the closest in spirit to ours and performs well without supervision. We try to further improve their model by using a PPR model to better utilize local features, and by adding constraints to the random walk to reduce noise.

3 The Graph Model

We construct a graph representation $G(V, E)$ from the document D with pre-tagged named entity textual mentions $M = \{m_1, ..., m_k\}$. For each entity mention $m_i \in M$ there is a list of candidates in KB $C_i = \{c_1^i, ..., c_{n_i}^i\}$. Vertices V are defined as pairs

$$V = \{\ (m_i, c_j^i)\ |\ \ m_i \in M, c_j^i \in C_i\ \},$$

corresponding to the set of all possible KB candidates for different mentions in M. Edges are undirected and exist between two vertices if the two candidates are directly linked in the knowledge base, but no edge is allowed between candidates for the same named entity. Every vertex (m, c) is associated with an initial similarity score between entity mention m and candidate c (Figure 1).

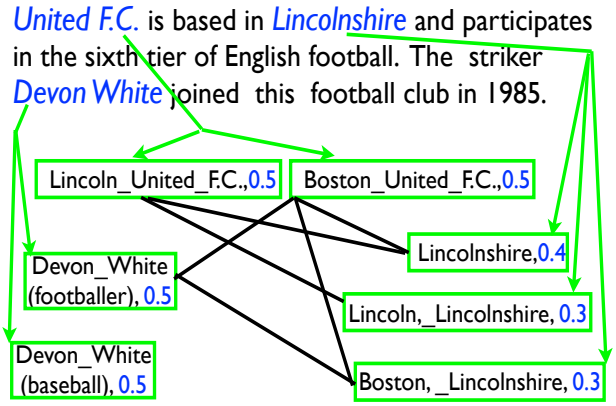

Figure 1: A toy document graph for three entity mentions: *United F.C., Lincolnshire, Devon White*. Candidates and their initial similarity scores are generated for each entity mention.

3.1 Vertices

Candidates. Given named entity mentions M in the document, we need to generate all possible candidates for every mention $m \in M$. We first perform coreference resolution on the whole document and expand m to the longest mention in the coreference chain. We then add a Wikipedia entry c to the candidate set C_i for mention m_i if 1) the title of c is the same as the expanded form of m_i, or 2) string m_i redirects to page c, or 3) c appears in a disambiguation page with title m_i.

Initial Similarity. Initial similarity $iSim$ for vertex (m, c) describes how similar entity mention m to candidate c is. It is independent from other candidates in the graph G. We experiment with the local measure (localSim), based on the local information about the entity in the text, and the global measure (popSim), based on the global importance of the entity. Initial similarity scores of all candidates for a single named entity mention are normalized to sum to 1.

- **localSim**: The local similarity score is produced by a MaxEnt model trained on the TAC2014 EDL training data (LDC2014E15). MaxEnt features include string similarity between the title of the Wikipedia entry and the entity mention, such as edit distance, whether the text mention starts or ends with the Wikipedia title, etc; and whether they have the same type (e.g. person, organization, location, etc).

- **popSim**: We use the Freebase popularity as an alternative similarity measure. The Freebase popularity is a function of entity's incoming and outgoing link counts in Wikipedia and Freebase.[1]

3.2 Edges

Edges in our graph model represent relations between candidates. We insert an edge between two candidates if the Wikipedia entry corresponding to either of the two candidates contains a link to the other candidate. We assume that this relation is bidirectional and thus this edge is undirected.

There is a toy document graph in Figure 1 with three entity mentions and seven candidates: three candidates generated for *Lincolnshire*, and two candidates generated for *United F.C.* and *Devon White* each. Each graph node $e(m, c)$ is a pair of an entity mention m and a candidate c; every node is assigned an initial score, normalized across all candidates for the same entity. An edge is drawn between two candidates for different entities whenever there is a link from the Wikipedia page for one candidate to the Wikipedia page for another. There is no edge between candidates competing for the same entity.

4 The Challenge

A successful entity disambiguation algorithm would benefit from both the initial similarity between candidate and entity, as well as the coherence among entities in the same document. We assume that every entity can refer to at most one in the list of possible candidates, so all candidates except for the correct one for each entity are erroneous and will introduce noise into the document graph. Based on this observation, we contend that the typical random walk approach, which computes coherence of one candidate to the whole graph, is not suitable for our scenario. To address this problem, we propose to consider pairwise relations between every two nodes, given by PPR scores, compute the contribution of every node to the coherence of the other, and impose *aggregation constraints* to avoid redundant contributions.

4.1 Personalized PageRank

The PageRank algorithm considers random walk on a graph, where at each step with probability ϵ (teleport probability) we jump to a randomly selected node on a graph, and with probability $1 - \epsilon$ we follow a random outgoing edge of the current node. Stationary distribution of this walk gives PageRank weights associated with each node. Personalized PageRank is the same as PageRank, except that all teleports are made to the same source node, for which we are personalizing the PageRank.

4.2 Coherence and Constraints

The $coherence$ of the node e to the graph G quantifies how well node e "fits" into this graph. Intuitively, pairwise weights $PPR(s \rightarrow e)$ represent relationships between nodes in the graph: the higher the weight is, the more relevant endpoint e is for the source s. Candidate nodes in the graph have different quality, measured by their initial similarity $iSim$. Thus, coherence of the node e to the graph G due to the presence of node s is given by

$$coh_s(e) = PPR(s \rightarrow e) \cdot iSim(s), \qquad (1)$$

where relevance *e* for *s* is weighted by the $iSim(s)$, which is the similarity between entity e and candidate s. We experiment with a MaxEnt-trained local score and the Freebase popularity as the $iSim$ in Section 5.

We observe that summing the contributions $coh_s(e)$ for all nodes $s \in V$ would accumulate noise, and therefore impose two *aggregation constraints* to take into account this nature of document graph G. Namely, to compute coherence $coh(e)$ of the node $e(m, c)$, corresponding to the entity mention m and the candidate c, to the graph G we enforce:

(c1) ignore contributions from candidate nodes competing for an entity m;
(c2) take only one, highest contribution from candidate nodes, competing for an entity $m' \neq m$;

The first constraint **(c1)** means that alternative candidates $\bar{e}(m, \bar{c})$, generated for the same entity mention m, should not contribute to the coherence of $e(m, c)$, as only one candidate per entity can be correct. For the same reason the second constraint **(c2)** picks the single candidate node $s(m', c')$ for entity $m' \neq m$ with the highest contribution $coh_s(e)$ towards e. So these constraints guarantee that exactly one and the $most\ relevant$ candidate per entity will contribute

[1] https://developers.google.com/freebase/v1/search

to the coherence of the node e. Thus, the set of contributors towards $coh(e)$ is defined as

$$CONTR_{e(m,c)} = \{ (m', \operatorname*{argmax}_c coh_{(m',c)}(e)\ ) \in V,\ m' \neq m \} \quad (2)$$

Then coherence of the node e to graph G is given by

$$coh(e) = \sum_{s \in CONTR_{e(m,c)}} coh_s(e) \quad (3)$$

Consider the example in Figure 1, which has two connected components. Candidate Devon_White_(baseball) is disconnected from the rest of the graph and can neither contribute towards any other candidate nor get contributions from other nodes. So its coherence is zero. All other candidates are connected, i.e. belong to the same connected component. Thus, the random walker, started from any node in this component, will land at any other node in this component with some positive likelihood.

Let us consider the $CONTR_{e(m,c)}$ for entity mention *m = Lincolnshire* and candidate $c =$ Lincolnshire, 0.4,. Without our constraints, nodes Devon_White_(footballer), 0.5, Lincoln_United_F.C., 0.5, Boston_United_F.C., 0.5, Lincoln_Lincolnshire, 0.3, Boston_Lincolnshire, 0.3 can all potentially contribute towards coherence of Lincolnshire, 0.4.

However, **(c1)** and **(c2)** will eliminate contribution from some of the candidates: Constraint **(c1)** does not allow Lincoln_Lincolnshire, 0.3 and Boston_Lincolnshire, 0.3 to contribute, because they compete for the same entity mention as candidate Lincolnshire, 0.4; constraint **(c2)** will allow only one contribution from either Lincoln_United_F.C., 0.5 or Boston_United_F.C., 0.5 whichever is bigger, since they compete for the same entity mention *United F.C.*. Therefore, set $CONTR_{e(m,c)}$ for entity mention *m = Lincolnshire* and candidate $c =$ Lincolnshire, 0.4, will contain only two contributors: candidate Devon_White_(footballer), 0.5, for entity mention *Devon_White,* and exactly one of the candidates for entity mention *United F.C.*

4.3 PPRSim

Our goal is to find the best candidate for every entity given a candidate's coherence and its initial similarity to the entity. To combine the coherence score $coh(e)$ with $iSim(e)$, we weight the latter with an average value of PPR weights used in coherence computation (3) across all nodes in the document graph $G(V, E)$:

$$PPR_{avg} = \frac{\sum_{e \in V} \sum_{s \in CONTR_e} PPR(s \to e)}{|V|} \quad (4)$$

Thus, the final score for node e is a linear combination

$$score(e) = coh(e) + PPR_{avg} \cdot iSim(e) \quad (5)$$

If the document graph has no edges then PPR_{avg} is zero and for any node e its coherence $coh(e)$ is zero as well. In this case we set $score(e)$ to its initial similarity $iSim(e)$ for all nodes e in the graph G. Finally, PPRSim disambiguates entity mention m with the highest scored candidate $c \in C_m$:

$$disambiguate(m) = \operatorname*{argmax}_{c \in C_m} score(m, c) \quad (6)$$

To resolve ties in (6) we pick a candidate with the most incoming wikipedia links.

Thus, candidate Devon_White_(footballer), 0.5 in Figure 1 will get higher overall score than its competitor, Devon_White_(baseball), 0.5. Their initial scores are the same, 0.5, but the latter one is disconnected from other nodes in the graph and thus has a zero coherence. So, entity mention *Devon White* will be correctly disambiguated with the candidate Devon_White_(footballer), 0.5. This candidate is directly connected to Boston_United_F.C., 0.5 and has a shortest path of length 3 to Lincolnshire_United_F.C., 0.5, and therefore contributes more towards Boston_United_F.C., 0.5, and boosts its coherence to make it the correct disambiguation for *United F.C.* Similarly, *Lincolnshire* is correctly disambiguated with Boston_Lincolnshire_F.C., 0.3.

5 Experiments and Results.

Data. For our experiments we use dataset AIDA[2]. All textual entity mentions are manually disambiguated against Wikipedia links (Hoffart et al.,

[2]http://www.mpi-inf.mpg.de/yago-naga/aida/

Models	Cucerzan	Kulkarni	Hoffart	Shirakawa	Alhelbawy	iSim	PPR	PPRSim
Micro	51.03	72.87	81.82	82.29	87.59	62.61	85.56	91.77
Macro	43.74	76.74	81.91	83.02	84.19	72.21	85.86	89.89

Table 1: Performance of PPRSim compared to baselines and state-of-the-art models on AIDA dataset. Baselines iSim and PPR choose a candidate with the highest initial similarity or coherence correspondingly.

2011). There are 34,965 annotated mentions in 1393 documents. Only mentions with a valid entry in the Wikipedia KB are considered (Hoffart et al., 2011), resulting in a total of 27,816 mentions. We use a Wikipedia dump from June 14, 2014, as the reference KB. Our set of candidates is publicly available for experiments[3].

Evaluation. We use two evaluation metrics: (1) Microaccuracy is the fraction of correctly disambiguated entities; (2) Macroaccuracy is the proportion of textual mentions, correctly disambiguated per entity, averaged over all entities.

PPR. We adopt the Monte Carlo approach (Fogaras and Racz, 2004) for computing Personalized PageRank. It performs a number of independent random walks for every source node and takes an empirical distribution of ending nodes to obtain PPR weights with respect to the source. We initialized 2,000 random walks for every source node, performed 5 steps of PPR, and computed PPR weights from all iterations dropping walks from the first one. The teleport probability is set to 0.2.

Baselines. We performed a set of experiments using initial similarity and Personalized PageRank weights. Model iSim uses only Freebase scores and achieves microaccuracy of 62.61% (Table 1). PPR model picks a candidate with highest coherence, computed in (3), where no initial similarity is used ($iSim \equiv 1.0$) and no constraints are applied. It has microaccuracy of 85.56%. This is a strong baseline, proving that coherence (3), solely based on PPR weights, is very accurate. We also reimplemented the most recent state-of-the-art approach by Alhelbawy (2014) based on the PageRank. We ran it on our set of candidates with freebase scores and got 82.2% and 80.2% in micro- and macroaccuracy correspondingy.

[3]https://github.com/masha-p/PPRforNED

PPRSim	Micro	Macro
$iSim \equiv 1.0$	85.56	85.86
$iSim =$ localSim	87.01	86.65
$iSim =$ popSim	90.26	88.98
+(c1)	90.52	89.21
+(c2)	91.68	89.78
+(c1),(c2)	91.77	89.89

Table 2: Performance of PPRSim with different initial similarities and constraints.

Results. We observe that PPR combined with global similarity popSim achieves a microaccuracy of 90.2% (Table 2). Adding constraints into the coherence computation further improves the performance to 91.7%. Interestingly, (c2) is more accurate than (c1). When put together, (c1)+(c2) performs better than each individual constraint (Table 2). Thus, combining coherence and initial similarity via (5) improves both micro- and macroaccuracy, outperforming state-of-the-art models (Table 1).

6 Conclusion and Future Work

In this paper we devise a new algorithm for collective named entity disambiguation based on Personalized PageRank. We show how to incorporate pairwise constraints between candidate entities by using PPR scores and propose a new robust scheme to compute coherence of a candidate entity to a document. Our approach outperforms state-of-the-art models and opens up many opportunities to employ pairwise information in NED. For future work, we plan to explore other strategies and constraints for noise reduction in the document graph.

When and why are log-linear models self-normalizing?

Jacob Andreas and **Dan Klein**
Computer Science Division
University of California, Berkeley
{jda,klein}@cs.berkeley.edu

Abstract

Several techniques have recently been proposed for training "self-normalized" discriminative models. These attempt to find parameter settings for which unnormalized model scores approximate the true label probability. However, the theoretical properties of such techniques (and of self-normalization generally) have not been investigated. This paper examines the conditions under which we can expect self-normalization to work. We characterize a general class of distributions that admit self-normalization, and prove generalization bounds for procedures that minimize empirical normalizer variance. Motivated by these results, we describe a novel variant of an established procedure for training self-normalized models. The new procedure avoids computing normalizers for most training examples, and decreases training time by as much as factor of ten while preserving model quality.

1 Introduction

This paper investigates the theoretical properties of log-linear models trained to make their unnormalized scores approximately sum to one.

Recent years have seen a resurgence of interest in log-linear approaches to language modeling. This includes both conventional log-linear models (Rosenfeld, 1994; Biadsy et al., 2014) and neural networks with a log-linear output layer (Bengio et al., 2006). On a variety of tasks, these LMs have produced substantial gains over conventional generative models based on counting n-grams. Successes include machine translation (Devlin et al., 2014) and speech recognition (Graves et al., 2013). However, log-linear LMs come at a significant cost for computational efficiency. In order to output a well-formed probability distribution over words, such models must typically calculate a normalizing constant whose computational cost grows linearly in the size of the vocabulary.

Fortunately, many applications of LMs remain well-behaved even if LM scores do not actually correspond to probability distributions. For example, if a machine translation decoder uses output from a pre-trained LM as a feature inside a larger model, it suffices to have all output scores on approximately the same scale, even if these do not sum to one for every LM context. There has thus been considerable research interest around training procedures capable of ensuring that unnormalized outputs for every context are "close" to a probability distribution. We are aware of at least two such techniques: noise-contrastive estimation (NCE) (Vaswani et al., 2013; Gutmann and Hyvärinen, 2010) and explicit penalization of the log-normalizer (Devlin et al., 2014). Both approaches have advantages and disadvantages. NCE allows fast training by dispensing with the need to ever compute a normalizer. Explicit penalization requires full normalizers to be computed during training but parameterizes the relative importance of the likelihood and the "sum-to-one" constraint, allowing system designers to tune the objective for optimal performance.

While both NCE and explicit penalization are observed to work in practice, their theoretical properties have not been investigated. It is a classical result that empirical minimization of *classification error* yields models whose predictions generalize well. This paper instead investigates a notion of *normalization error*, and attempts to understand the conditions under which unnormalized model scores are a reliable surrogate for probabilities. While language modeling serves as a motivation and running example, our results apply to any log-linear model, and may be of general use for efficient classification and decoding.

Our goals are twofold: primarily, to provide intuition about how self-normalization works, and why it behaves as observed; secondarily, to back these intuitions with formal guarantees, both about classes of normalizable distributions and parameter estimation procedures. The paper is built around two questions:

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 244–249,
Denver, Colorado, May 31 – June 5, 2015.

When can self-normalization work—for which distributions do good parameter settings exist? And *why* should self-normalization work—how does variance of the normalizer on held-out data relate to variance of the normalizer during training? Analysis of these questions suggests an improvement to the training procedure described by Devlin et al., and we conclude with empirical results demonstrating that our new procedure can reduce training time for self-normalized models by an order of magnitude.

2 Preliminaries

Consider a log-linear model of the form

$$p(y|x;\boldsymbol{\theta}) = \frac{\exp\{\theta_y^\top x\}}{\sum_{y'}\exp\{\theta_{y'}^\top x\}} \quad (1)$$

We can think of this as a function from a *context* x to a probability distribution over *decisions* y_i, where each decision is parameterized by a weight vector θ_y.[1] For concreteness, consider a language modeling problem in which we are trying to predict the next word after the context *the ostrich*. Here x is a vector of features on the context (e.g. $x = \{$`1-2=the_ostrich, 1=the, 2=ostrich, ...`$\}$), and y ranges over the full vocabulary (e.g. $y_1 =$ `the`, $y_2 =$ `runs`, ...).

Our analysis will focus on the standard log-linear case, though later in the paper we will also relate these results to neural networks. We are specifically concerned with the behavior of the normalizer or *partition function*

$$Z(x;\boldsymbol{\theta}) \stackrel{\text{def}}{=} \sum_y \exp\{\theta_y^\top x\} \quad (2)$$

and in particular with choices of $\boldsymbol{\theta}$ for which $Z(x;\boldsymbol{\theta}) \approx 1$ *for most* x.

To formalize the questions in the title of this paper, we introduce the following definitions:

Definition 1. A log-linear model $p(y|x,\boldsymbol{\theta})$ is *normalized* with respect to a set $\mathcal{X}$ if for every $x \in \mathcal{X}$, $Z(x;\boldsymbol{\theta}) = 1$. In this case we call $\mathcal{X}$ *normalizable* and $\boldsymbol{\theta}$ *normalizing*.

Now we can state our questions precisely: What distributions are normalizable? Given data points from a normalizable $\mathcal{X}$, how do we find a normalizing $\boldsymbol{\theta}$?

[1] An alternative, equivalent formulation has a single weight vector and a feature function from contexts and decisions onto feature vectors.

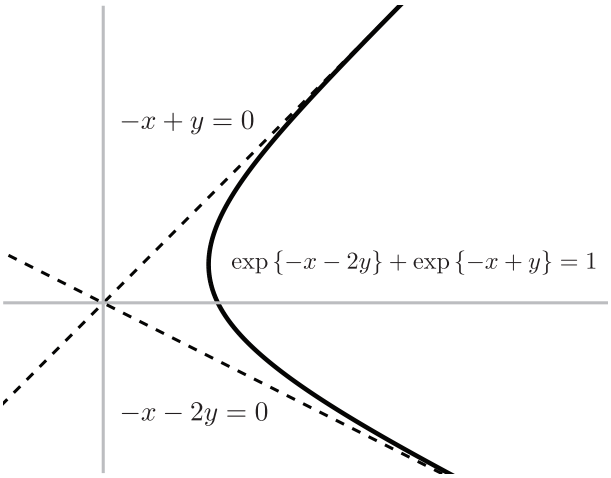

Figure 1: A normalizable set, the solutions $[x, y]$ to $Z([x, y]; \{[-1, 1], [-1, -2]\}) = 1$. The set forms a smooth one-dimensional manifold bounded on either side by the hyperplanes normal to $[-1, 1]$ and $[-1, -2]$.

In sections 3 and 4, we do not analyze whether the setting of $\boldsymbol{\theta}$ corresponds to a good classifier—only a good normalizer. In practice we require both good normalization *and* good classification; in section 5 we provide empirical evidence that both are achievable.

Some notation: Weight vectors θ (and feature vectors x) are d-dimensional. There are k output classes, so the total number of parameters in $\boldsymbol{\theta}$ is kd. $||\cdot||_p$ is the ℓ_p vector norm, and $||\cdot||_\infty$ specifically is the max norm.

3 When should self-normalization work?

In this section, we characterize a large class of datasets (i.e. distributions $p(y|x)$) that are normalizable either exactly, or approximately in terms of their marginal distribution over *contexts* $p(x)$. We begin by noting simple features of Equation 2: it is convex in x, so in particular its level sets enclose convex regions, and are manifolds of lower dimension than the embedding space.

As our definition of normalizability requires the existence of a normalizing $\boldsymbol{\theta}$, it makes sense to begin by fixing $\boldsymbol{\theta}$ and considering contexts x for which it is normalizing.

Observation. *Solutions* x *to* $Z(x;\boldsymbol{\theta}) = 1$*, if any exist, lie on the* boundary *of a convex region in* $\mathbb{R}^d$.

This follows immediately from the definition of a convex function, but provides a concrete example of a set for which $\boldsymbol{\theta}$ is normalizing: the solution set of $Z(x;\boldsymbol{\theta}) = 1$ has a simple geometric interpretation as a particular kind of smooth surface. An example is depicted in Figure 1.

We cannot expect real datasets to be this well behaved, so seems reasonable to ask whether "good-enough" self-normalization is possible for datasets (i.e. distributions $p(x)$) which are only close to some exactly normalizable distribution.

Definition 2. A context distribution $p(x)$ is *D-close* to a set $\mathcal{X}$ if

$$\mathbb{E}_p\left[\inf_{x^* \in \mathcal{X}} ||X - x^*||_\infty\right] = D \tag{3}$$

Definition 3. A context distribution $p(x)$ is *ε-approximately normalizable* if $\mathbb{E}_p|\log Z(X;\boldsymbol{\theta})| \leq \varepsilon$.

Theorem 1. *Suppose $p(x)$ is D-close to $\{x : Z(x;\boldsymbol{\theta}) = 1\}$, and each $||\theta_i||_\infty \leq B$. Then $p(x)$ is dBD-approximately normalizable.*

Proof sketch.[2] Represent each X as $X^* + X^-$, where X^* solves the optimization problem in Equation 3. Then it is possible to bound the normalizer by $\log\exp\{\tilde{\theta}^\top X^-\}$, where $\tilde{\theta}$ maximizes the magnitude of the inner product with X^- over $\boldsymbol{\theta}$.

In keeping with intuition, data distributions that are close to normalizable sets are themselves approximately normalizable on the same scale.[3]

4 Why should self-normalization work?

So far we have given a picture of what approximately normalizable distributions look like, but nothing about how to find normalizing $\boldsymbol{\theta}$ from training data in practice. In this section we prove that any procedure that causes training contexts to approximately normalize will also have log-normalizers close to zero in unseen contexts. As noted in the introduction, this does not follow immediately from corresponding results for *classification* with log-linear models. While the two problems are related (it would be quite surprising to have uniform convergence for classification but not normalization), we nonetheless have a different function class and a different loss, and need new analysis.

Theorem 2. *Consider a sample $(X_1, X_2, \dots)$, with all $||X||_\infty \leq R$, and $\boldsymbol{\theta}$ with each $||\theta_i||_\infty \leq B$. Additionally define $\hat{\mathcal{L}} = \frac{1}{n}\sum_i |\log Z(X_i)|$ and $\mathcal{L} = \mathbb{E}|\log Z(X)|$. Then with probability $1-\delta$,*

$$|\hat{\mathcal{L}} - \mathcal{L}| \leq 2\sqrt{\frac{dk(\log dBR + \log n) + \log\frac{1}{\delta}}{2n}} + \frac{2}{n} \tag{4}$$

Proof sketch. Empirical process theory provides standard bounds of the form of Equation 4 (Kakade, 2011) in terms of the size of a *cover* of the function class under consideration (here $Z(\cdot;\boldsymbol{\theta})$). In particular, given some α, we must construct a finite set of $\hat{Z}(\cdot;\theta)$ such that some $\hat{Z}$ is everywhere a distance of at most α from every Z. To provide this cover, it suffices to provide a cover $\hat{\boldsymbol{\theta}}$ for $\boldsymbol{\theta}$. If the $\hat{\boldsymbol{\theta}}$ are spaced at intervals of length D, the size of the cover is $(B/D)^{kd}$, from which the given bound follows.

This result applies uniformly across choices of $\boldsymbol{\theta}$ regardless of the training procedure used—in particular, $\boldsymbol{\theta}$ can be found with NCE, explicit penalization, or the variant described in the next section.

As hoped, sample complexity grows as the number of features, and not the number of contexts. In particular, skip-gram models that treat context words independently will have sample efficiency multiplicative, rather than exponential, in the size of the conditioning context. Moreover, if some features are correlated (so that data points lie in a subspace smaller than d dimensions), similar techniques can be used to prove that sample requirements depend only on this effective dimension, and not the true feature vector size.

We emphasize again that this result says nothing about the *quality* of the self-normalized model (e.g. the likelihood it assigns to held-out data). We defer a theoretical treatment of that question to future work. In the following section, however, we provide experimental evidence that self-normalization does not significantly degrade model quality.

5 Applications

As noted in the introduction, previous approaches to learning approximately self-normalizing distributions have either relied on explicitly computing the

[2] Full proofs of all results may be found in the Appendix.

[3] Here (and throughout) it is straightforward to replace quantities of the form dB with B by working in ℓ_2 instead of ℓ_∞.

normalizer for each training example, or at least keeping track of an estimate of the normalizer for each training example.

Our results here suggest that it should be possible to obtain approximate self-normalizing behavior without *any* representation of the normalizer on some training examples—as long as a sufficiently large fraction of training examples are normalized, then we have some guarantee that with high probability the normalizer will be close to one on the remaining training examples as well. Thus an unnormalized likelihood objective, coupled with a penalty term that looks at only a small number of normalizers, might nonetheless produce a good model. This suggests the following:

$$l(\boldsymbol{\theta}) = \sum_i \theta_{y_i}^\top x_i + \frac{\alpha}{\gamma} \sum_{h \in H} (\log Z(x_h; \boldsymbol{\theta}))^2 \quad (5)$$

where the parameter α controls the relative importance of the self-normalizing constraint, H is the set of indices to which the constraint should be applied, and γ controls the size of H, with $|H| = \lceil n\gamma \rceil$. Unlike the objective used by Devlin et al. (2014) most examples are *never* normalized during training. Our approach combines the best properties of the two techniques for self-normalization previously discussed: like NCE, it does not require computation of the normalizer on all training examples, but like explicit penalization it allows fine-grained control over the tradeoff between the likelihood and the quality of the approximation to the normalizer.

We evaluate the usefulness of this objective with a set of small language modeling experiments. We train a log-linear LM with features similar to Biadsy et al. (2014) on a small prefix of the Europarl corpus of approximately 10M words.[4] We optimize the objective in Equation 5 using Adagrad (Duchi et al., 2011). The normalized set H is chosen randomly for each new minibatch. We evaluate using two metrics: BLEU on a downstream machine translation task, and *normalization risk* R, the average magnitude of the log-normalizer on held-out data. We measure the response of our training to changes in γ and α. Results are shown in Table 1 and Table 2.

[4]This prefix was chosen to give the fully-normalized model time to finish training, allowing a complete comparison. Due to the limited LM training data, these translation results are far from state-of-the-art.

	Normalized fraction (γ)				
	0	0.001	0.01	0.1	1
R_{train}	22.0	1.7	1.5	1.5	1.5
R_{test}	21.6	1.7	1.5	1.5	1.5
BLEU	1.5	19.1	19.2	20.0	20.0

Table 1: Result of varying normalized fraction γ, with $\alpha = 1$. When no normalization is applied, the model's behavior is pathological, but when normalizing only a small fraction of the training set, performance on the downstream translation task remains good.

	Normalization strength (α)			
α	0.01	0.1	1	10
R_{train}	20.4	9.7	1.5	0.5
R_{test}	20.1	9.7	1.5	0.5
BLEU	1.5	2.6	20.0	16.9

Table 2: Result of varying normalization parameter α, with $\gamma = 0.1$. Normalization either too weak or too strong results in poor performance on the translation task, emphasizing the importance of training procedures with a tunable normalization parameter.

Table 1 shows that with small enough α, normalization risk grows quite large. Table 2 shows that forcing the risk closer to zero is not necessarily desirable for a downstream machine translation task. As can be seen, no noticeable performance penalty is incurred when normalizing only a tenth of the training set. Performance gains are considerable: setting $\gamma = 0.1$, we observe a roughly tenfold speedup over $\gamma = 1$.

On this corpus, the original training procedure of Devlin et al. with $\alpha = 0.1$ gives a BLEU score of 20.1 and R_{test} of 2.7. Training time is equivalent to choosing $\gamma = 1$, and larger values of α result in decreased BLEU, while smaller values result in significantly increased normalizer risk. Thus we see that we can achieve smaller normalizer variance and an order-of-magnitude decrease in training time with a loss of only 0.1 BLEU.

6 Relation to neural networks

Our discussion has focused on log-linear models. While these can be thought of as a class of single-layer neural networks, in practice much of the demand for fast training and querying of log-linear LMs

comes from deeper networks. All of the proof techniques used in this paper can be combined straightforwardly with existing tools for covering the output spaces of neural networks (Anthony and Bartlett, 2009). If optimization of the self-normalizing portion of the objective is deferred to a post-processing step after standard (likelihood) training, and restricted to parameters in the output layers, then Theorem 2 applies exactly.

7 Conclusion

We have provided both qualitative and formal characterizations of "self-normalizing" log-linear models, including what we believe to be the first theoretical guarantees for self-normalizing training procedures. Motivated by these results, we have described a novel objective for training self-normalized log-linear models, and demonstrated that this objective achieves significant performance improvements without a decrease in the quality of the models learned.

A Quality of the approximation

Proof of Theorem 1. Using the definitions of X^*, X^- and $\tilde{\theta}$ given in the proof sketch for Theorem 1,

$$\begin{aligned}
&\mathbb{E}|\log(\sum \exp\{\theta_i^\top X\})| \\
&\quad = \mathbb{E}|\log(\sum \exp\{\theta_i^\top (X^* + X^-)\})| \\
&\quad \leq \mathbb{E}|\log(\exp\{\tilde{\theta}^\top X^-\} \sum \exp\{\theta_i^\top X^*\})| \\
&\quad \leq \mathbb{E}|\log(\exp\{\tilde{\theta}^\top X^-\})| \\
&\quad \leq dDB
\end{aligned}$$

□

B Generalization error

Lemma 3. *For any $\boldsymbol{\theta}_1$, $\boldsymbol{\theta}_2$ with $||\theta_{1,i} - \theta_{2,i}||_\infty \leq D \stackrel{\text{def}}{=} \alpha/dR$ for all i,*

$$||\log Z(x;\boldsymbol{\theta}_1)| - |\log Z(x;\boldsymbol{\theta}_2)|| \leq \alpha \qquad (6)$$

Proof.

$$\begin{aligned}
&||\log Z(x;\boldsymbol{\theta}_1)| - |\log Z(x;\boldsymbol{\theta}_2)|| \\
&\quad \leq |\log Z(x;\boldsymbol{\theta}_1) - \log Z(x;\boldsymbol{\theta}_2)| \\
&\quad \leq \log \frac{Z(x;\boldsymbol{\theta}_1)}{Z(x;\boldsymbol{\theta}_2)} \qquad \text{(w.l.o.g.)} \\
&\quad = \log \frac{\sum_i \exp\left\{(\theta_{1i} - \theta_{2i})^\top x\right\} \exp\left\{\theta_{2i}^\top x\right\}}{\sum_i \exp\left\{\theta_{2i}^\top x\right\}} \\
&\quad \leq dDR + \log \frac{Z(x;\boldsymbol{\theta}_2)}{Z(x;\boldsymbol{\theta}_2)} = \alpha
\end{aligned}$$

□

Corollary 4. *The set of partition functions $\mathcal{Z} = \{Z(\cdot;\boldsymbol{\theta}) : ||\theta||_\infty \leq B \ \forall \theta \in \boldsymbol{\theta}\}$ can be covered on on the ℓ_∞ ball of radius R by a grid of $\hat{\boldsymbol{\theta}}$ with distance D. The size of this cover is*

$$|\hat{\mathcal{Z}}| = \left(\frac{B}{D}\right)^{dk} = \left(\frac{dBR}{\alpha}\right)^{dk} \qquad (7)$$

Proof of Theorem 2. From a standard discretization lemma (Kakade, 2011) and Corollary 4, we immediately have that with probabilty $1 - \delta$,

$$\begin{aligned}
&\sup_{Z \in \mathcal{Z}} |\hat{\mathcal{L}} - \mathcal{L}| \leq \\
&\quad \leq \inf_\alpha 2\sqrt{\frac{dk(\log dBR - \log \alpha) + \log \frac{1}{\delta}}{2n}} + 2\alpha
\end{aligned}$$

Taking $\alpha = 1/n$,

$$\leq 2\sqrt{\frac{dk(\log dBR + \log n) + \log \frac{1}{\delta}}{2n}} + \frac{2}{n}$$

□

Abstract

Word embeddings have been found useful for many NLP tasks, including part-of-speech tagging, named entity recognition, and parsing. Adding multilingual context when learning embeddings can improve their quality, for example via canonical correlation analysis (CCA) on embeddings from two languages. In this paper, we extend this idea to learn *deep non-linear transformations* of word embeddings of the two languages, using the recently proposed deep canonical correlation analysis. The resulting embeddings, when evaluated on multiple word and bigram similarity tasks, consistently improve over monolingual embeddings and over embeddings transformed with linear CCA.

1 Introduction

Learned word representations are widely used in NLP tasks such as tagging, named entity recognition, and parsing (Miller et al., 2004; Koo et al., 2008; Turian et al., 2010; Täckström et al., 2012; Huang et al., 2014; Bansal et al., 2014). The idea in such representations is that words with similar context have similar meaning, and hence should be nearby in a clustering or vector space. Continuous representations are learned with neural language models (Bengio et al., 2003; Mnih and Hinton, 2007; Mikolov et al., 2013) or spectral methods (Deerwester et al., 1990; Dhillon et al., 2011).

The context used to learn these representations is typically the set of nearby words of each word occurrence. Prior work has found that adding **translational context** results in better representations (Diab and Resnik, 2002; Täckström et al., 2012; Bansal et al., 2012; Zou et al., 2013). Recently, Faruqui and Dyer (2014) applied canonical correlation analysis (CCA) to word embeddings of two languages, and found that the resulting embeddings represent word similarities better than the original monolingual embeddings.

In this paper, we follow the same intuition as Faruqui and Dyer (2014) but rather than learning linear transformations with CCA, we permit the correlated information to lie in nonlinear subspaces of the original embeddings. We use the recently proposed deep canonical correlation analysis (DCCA) technique of Andrew et al. (2013) to learn nonlinear transformations of two languages' embeddings that are highly correlated. We evaluate our DCCA-transformed embeddings on word similarity tasks like WordSim-353 (Finkelstein et al., 2001) and SimLex-999 (Hill et al., 2014), and also on the bigram similarity task of Mitchell and Lapata (2010) (using additive composition), obtaining consistent improvements over the original embeddings and over linear CCA. We also compare tuning criteria and ensemble methods for these architectures.

2 Method

We assume that we have initial word embeddings for two languages, denoted by random vectors $\mathbf{x} \in \mathbb{R}^{D_x}$ and $\mathbf{y} \in \mathbb{R}^{D_y}$, and a set of bilingual word pairs. Our goal is to obtain a representation for each language that incorporates useful information from both $\mathbf{x}$ and $\mathbf{y}$. We consider the two input monolingual word embeddings as different views of the same latent semantic signal. There are multiple ways to incorporate multilingual information into word embeddings. Here we follow Faruqui and Dyer (2014) in taking a CCA-based approach, in which we project the original embeddings onto their maximally correlated subspaces. However, instead of relying on linear correlation, we learn more powerful non-linear transformations of each view via deep networks.

Canonical Correlation Analysis A popular method for multi-view representation learning is canonical correlation analysis (CCA; Hotelling, 1936). Its objective is to find two vectors $\mathbf{u} \in \mathbb{R}^{D_x}$

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 250–256,
Denver, Colorado, May 31 – June 5, 2015.

and $\mathbf{v} \in \mathbb{R}^{D_y}$ such that projections of the two views onto these vectors are maximally (linearly) correlated:

$$\max_{\mathbf{u}\in\mathbb{R}^{D_x},\mathbf{v}\in\mathbb{R}^{D_y}} \frac{\mathbb{E}\left[(\mathbf{u}^\top \mathbf{x})(\mathbf{v}^\top \mathbf{y})\right]}{\sqrt{\mathbb{E}\left[(\mathbf{u}^\top \mathbf{x})^2\right]}\sqrt{\mathbb{E}\left[(\mathbf{v}^\top \mathbf{y})^2\right]}} = \frac{\mathbf{u}^\top \mathbf{\Sigma}_{xy}\mathbf{v}}{\sqrt{\mathbf{u}^\top \mathbf{\Sigma}_{xx}\mathbf{u}}\sqrt{\mathbf{v}^\top \mathbf{\Sigma}_{yy}\mathbf{v}}} \quad (1)$$

where $\mathbf{\Sigma}_{xy}$ and $\mathbf{\Sigma}_{xx}$ are the cross-view and within-view covariance matrices. (1) is extended to learn multi-dimensional projections by optimizing the sum of correlations in all dimensions, subject to different projected dimensions being uncorrelated. Given sample pairs $\{(\mathbf{x}_i, \mathbf{y}_i)\}_{i=1}^N$, the empirical estimates of the covariance matrices are $\hat{\mathbf{\Sigma}}_{xx} = \frac{1}{N}\sum_{i=1}^N \mathbf{x}_i\mathbf{x}_i^\top + r_x\mathbf{I}$, $\hat{\mathbf{\Sigma}}_{yy} = \frac{1}{N}\sum_{i=1}^N \mathbf{y}_i\mathbf{y}_i^\top + r_y\mathbf{I}$ and $\hat{\mathbf{\Sigma}}_{xy} = \frac{1}{N}\sum_{i=1}^N \mathbf{x}_i\mathbf{y}_i^\top$ where $(r_x, r_y) > 0$ are **regularization** parameters (Hardoon et al., 2004; De Bie and De Moor, 2003). Then the optimal k-dimensional projection mappings are given in closed form via the rank-k singular value decomposition (SVD) of the $D_x \times D_y$ matrix $\hat{\mathbf{\Sigma}}_{xx}^{-1/2}\hat{\mathbf{\Sigma}}_{xy}\hat{\mathbf{\Sigma}}_{yy}^{-1/2}$.

2.1 Deep Canonical Correlation Analysis

A linear feature mapping is often not sufficiently powerful to faithfully capture the hidden, non-linear relationships within the data. Recently, Andrew et al. (2013) proposed a nonlinear extension of CCA using deep neural networks, dubbed deep canonical correlation analysis (DCCA) and illustrated in Figure 1. In this model, two (possibly deep) neural networks $\mathbf{f}$ and $\mathbf{g}$ are used to extract features from each view, and trained to maximize the correlations between outputs in the two views, measured by a linear CCA step with projection mappings $(\mathbf{u}, \mathbf{v})$. The neural network weights and the linear projections are optimized together using the objective

$$\max_{\mathbf{W_f},\mathbf{W_g},\mathbf{u},\mathbf{v}} \frac{\mathbf{u}^\top \mathbf{\Sigma}_{fg}\mathbf{v}}{\sqrt{\mathbf{u}^\top \mathbf{\Sigma}_{ff}\mathbf{u}}\sqrt{\mathbf{v}^\top \mathbf{\Sigma}_{gg}\mathbf{v}}}, \quad (2)$$

where $\mathbf{W_f}$ and $\mathbf{W_g}$ are the weights of the two networks and $\mathbf{\Sigma}_{fg}$, $\mathbf{\Sigma}_{ff}$ and $\mathbf{\Sigma}_{gg}$ are covariance matrices computed for $\{\mathbf{f}(\mathbf{x}_i), \mathbf{g}(\mathbf{y}_i)\}_{i=1}^N$ in the same way as CCA. The final transformation is the composition of the neural network and CCA projection, e.g., $\mathbf{u}^\top\mathbf{f}(\mathbf{x})$ for the first view. Unlike CCA, DCCA

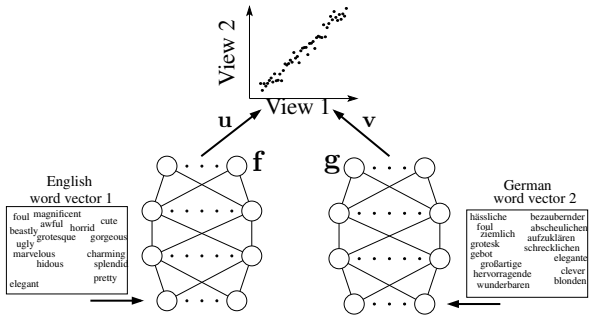

Figure 1: Illustration of deep CCA.

does not have a closed-form solution, but the parameters can be learned via gradient-based optimization, with either batch algorithms like L-BFGS as in (Andrew et al., 2013) or a mini-batch stochastic gradient descent-like approach as in (Wang et al., 2015). We choose the latter in this paper.

An alternative nonlinear extension of CCA is kernel CCA (KCCA) (Lai and Fyfe, 2000; Vinokourov et al., 2003), which introduces nonlinearity through kernels. DCCA scales better with data size, as KCCA involves the SVD of an $N \times N$ matrix. Andrew et al. (2013) showed that DCCA achieves better correlation on held-out data than CCA/KCCA, and Wang et al. (2015) found that DCCA outperforms CCA and KCCA on a speech recognition task.

3 Experiments

We use English and German as our two languages. Our original monolingual word vectors are the same as those used by Faruqui and Dyer (2014). They are 640-dimensional and are estimated via latent semantic analysis on the WMT 2011 monolingual news corpora.[1] We use German-English translation pairs as the input to CCA and DCCA, using the same set of 36K pairs as used by Faruqui and Dyer. These pairs contain, for each of 36K English word types, the single most frequently aligned German word. They were obtained using the word aligner in `cdec` (Dyer et al., 2010) run on the WMT06-10 news commentary corpora and Europarl. After training, we apply the learned CCA/DCCA projection mappings to the original English word embeddings (180K words) and use these transformed embeddings for our evaluation tasks.

3.1 Evaluation Tasks

We compare our DCCA-based embeddings to the original word vectors and to CCA-based em-

[1] `www.statmt.org/wmt11/`

beddings on several tasks. We use WordSim-353 (Finkelstein et al., 2001), which contains 353 English word pairs with human similarity ratings. It is divided into WS-SIM and WS-REL by Agirre et al. (2009) to measure similarity and relatedness. We also use SimLex-999 (Hill et al., 2014), a new similarity-focused dataset consisting of 666 noun pairs, 222 verb pairs, and 111 adjective pairs. Finally, we use the bigram similarity dataset from Mitchell and Lapata (2010) which has 3 subsets, adjective-noun (AN), noun-noun (NN), and verb-object (VN), and dev and test sets for each. For the bigram task, we simply add the word vectors output by CCA or DCCA to get bigram vectors.[2]

All task datasets contain pairs with human similarity ratings. To evaluate embeddings, we compute cosine similarity between the two vectors in each pair, order the pairs by similarity, and compute Spearman's correlation (ρ) between the model's ranking and human ranking.

3.2 Training

We normalize the 36K training pair vectors to unit norm (as also done by Faruqui and Dyer). We then remove the per-dimension mean and standard deviation of this set of training pairs, as is typically done in neural network training (LeCun et al., 1998). We do the same to the original 180K English word vectors (normalize to unit norm, remove the mean/standard deviation of the size-36K training set), then apply our CCA/DCCA mappings to these 180K vectors. The resulting 180K vectors are further normalized to zero mean before cosine similarities between test pairs are computed, as also done by Faruqui and Dyer.

For both CCA and DCCA, we tune the output dimensionality among factors in $\{0.2, 0.4, 0.6, 0.8, 1.0\}$ of the original embedding dimension (640), and regularization (r_x, r_y) from $\{10^{-6}, 10^{-5}, 10^{-4}, 10^{-3}\}$, based on the 7 tuning tasks discussed below.

For DCCA, we use standard deep neural networks with rectified linear units and tune the depth (1 to 4 hidden layers) and layer widths (in $\{128, 256, 512, 1024, 2048, 4096\}$) separately for each language. For optimization, we use stochastic gradient descent (SGD) as described by Wang et al. (2015). We tune SGD hyperparameters on a small grid, choosing a mini-batch size of 3000, learning rate of 0.0001, and momentum of 0.99.

3.3 Tuning

Our main results are based on tuning hyperparameters (of CCA/DCCA) on 7 word similarity tasks.[3] We perform additional experiments in which we tune on the development sets for the bigram tasks. We set aside WS-353, SimLex-999, and the test sets of the bigram tasks as held-out test sets. We consider two tuning criteria:

BestAvg: Choose the hyperparameters with the best average performance across the 7 tuning tasks. This is the only tuning criterion used for CCA.

MostBeat: For DCCA, choose the hyperparameters that beat the best CCA embeddings on a maximum number of the 7 tasks; to break ties here, choose the hyperparameters with the best average performance. The idea is that we want to find a setting that generalizes to many tasks.

We also consider simple ensembles by averaging the cosine similarities from the three best settings under each of these two criteria.

3.4 Results

Table 1 shows our main results on the word and bigram similarity tasks. All values are Spearman's correlation (ρ). We show the original word vector results, the best-tuned CCA setting (CCA-1), the ensemble of the top-3 CCA settings (CCA-Ens), and the same for DCCA (with both tuning criteria). The DCCA results show an overall improvement on most tasks over linear CCA (all of the shaded DCCA results are better than all corresponding CCA results).

Each of our tuning criteria for DCCA performs well, and almost always better than CCA. BestAvg is better on some tasks while MostBeat is better on others; we report both here to bring attention to and promote discussion about the effects of tuning methods when learning representations in the absence of supervision or in-domain tuning data.

In Table 2, we report additional bigram similarity results obtained by tuning on the dev sets of the bi-

[2] We also tried multiplication but it performed worse. In future work, we will directly train on bigram translation pairs.

Table 1: Main results on word and bigram similarity tasks, tuned on 7 development tasks (see text for details). Shading indicates a result that matches or improves the best linear CCA result; boldface indicates the best result in a given column. See Section 3.4 for discussion on NN results.

Embeddings	AN	NN	VN	Avg
CCA	42.4	**48.1**	37.4	42.6
Deep CCA	**45.5**	47.1	**45.1**	**45.9**

Table 2: Bigram results, tuned on bigram dev sets.

gram tasks themselves (as provided by Mitchell and Lapata), since the 7 tuning tasks are not particularly related to the bigram test sets. We see that DCCA can achieve even stronger improvements over CCA and overall using these related dev sets.

We note that the performance on the NN task does not improve. The typical variance of annotator scores for each bigram pair was larger for the NN dataset than for the other bigram datasets, suggesting noisier annotations. Also, we found that the NN annotations often reflected topical relatedness rather than functional similarity, e.g., *television set* and *television programme* are among the most similar noun-noun bigrams. We expect that multilingual information would help embeddings to more closely reflect functional similarity.

For DCCA, we found that the best-performing networks were typically asymmetric, with 1 to 2 layers on the English side and 2 to 4 on the German side. The best network structure on the bigram VN development set is 640-128-128 for the English view and 640-128-512-128 for the German view, with a final CCA projection layer with dimensionality 128 for each language.

4 Discussion

Normalization and Evaluation We note that the cosine similarity (and thus Spearman's ρ) between a pair of words is not invariant to the series of simple (affine) transformations done by the normalizations in our procedure. For their baseline, Faruqui and Dyer (2014) did not remove the standard deviation of the 36K training set for the 180K English vocabulary during testing. We have accidentally found that this normalization step alone greatly improves the performance of the original vectors.

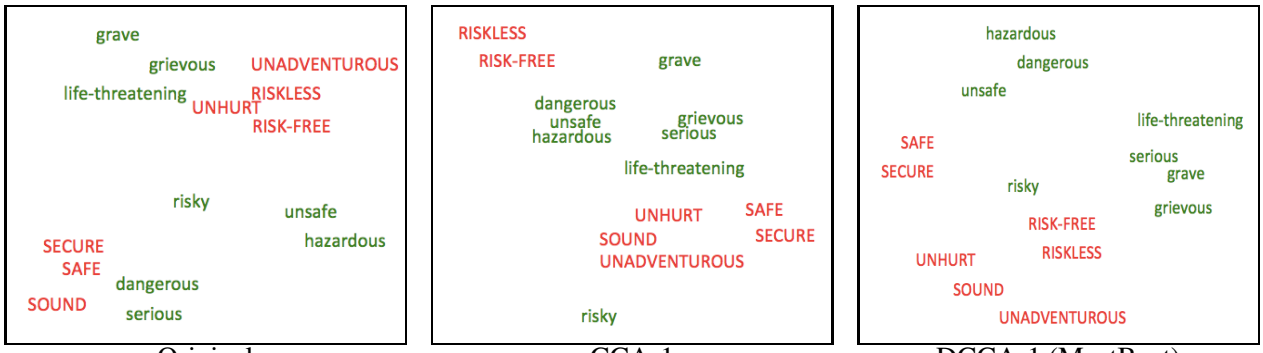
better with DCCA		worse with DCCA	
arrive	come	author	creator
locate	find	leader	manager
way	manner	buddy	companion
recent	new	crowd	bunch
take	obtain	achieve	succeed
boundary	border	attention	interest
win	accomplish	join	add
contemplate	think	mood	emotion

Table 3: Highly-similar pairs in SimLex-999 that improved/degraded the most under DCCA. Pairs are sorted in decreasing order according to the amount of improvement/degradation.

For example, the WS-353 correlation improves from 46.7 to 67.1, essentially matching the linear CCA correlations, though DCCA still outperforms them both. This indicates that the cosine similarity is not stable, and it is likely better to learn a distance/similarity function (using labeled tuning data) atop the learned features such that similarities between selected pairs will match the human similarities, or such that the rankings will match.

Error Analysis We analyze high-similarity word pairs that change the most with DCCA, as compared to both linear CCA and the original vectors.

For a word pair w, we use $r(w)$ to refer to its similarity rank, subscripting it whether it is computed according to human ratings (r_h) or if based on cosine similarity via the original vectors (r_o), CCA-1 (r_c), or DCCA-1 MostBeat (r_d). We define $\delta_a(w) = |r_a(w) - r_h(w)|$ and compute $\Delta(w) =$



Original CCA-1 DCCA-1 (MostBeat)

Figure 2: t-SNE visualization of synonyms (green) and antonyms (red, capitalized) of *dangerous*.

$\delta_d(w) - (\delta_c(w) + \delta_o(w))$. If $\Delta(w) < 0$, then word pair w was closer to the human ranking using DCCA. Table 3 shows word pairs from SimLex-999 with high human similarity ratings (≥ 7 out of 10); column 1 shows pairs with smallest Δ values, and column 2 shows pairs with largest Δ values.

Among pairs in column 1, many contain words with several senses. Using bilingual information is likely to focus on the most frequent sense in the bitext, due to our use of the most frequently-aligned German word in each training pair. By contrast, using only monolingual context is expected to find an embedding that blends the contextual information across all word senses.

Several pairs from column 2 show hypernym rather than paraphrase relationships, e.g., *author-creator* and *leader-manager*. Though these pairs are rated as highly similar by annotators, linear CCA made them less similar than the original vectors, and DCCA made them less similar still. This matches our intuition that bilingual information should encourage paraphrase-like similarity and thereby discourage the similarity of hypernym-hyponym pairs.

Visualizations We visualized several synonym-antonym word lists and often found that DCCA more cleanly separated synonyms from antonyms than CCA or the original vectors. An example of the clearest improvement is shown in Fig. 2.

5 Related work

Previous work has successfully used translational context for word representations (Diab and Resnik, 2002; Zhao et al., 2005; Täckström et al., 2012; Bansal et al., 2012; Faruqui and Dyer, 2014), including via hand-designed vector space models (Peirsman and Padó, 2010; Sumita, 2000) or via unsupervised LDA and LSA (Boyd-Graber and Blei, 2009; Zhao and Xing, 2006).

There have been other recent deep learning approaches to bilingual representations, e.g., based on a joint monolingual and bilingual objective (Zou et al., 2013). There has also been recent interest in learning bilingual representations without using word alignments (Chandar et al., 2014; Gouws et al., 2014; Kočiskỳ et al., 2014; Vulic and Moens, 2013).

This research is also related to early examples of learning bilingual lexicons using monolingual corpora (Koehn and Knight, 2002; Haghighi et al., 2008); the latter used CCA to find matched word pairs. Irvine and Callison-Burch (2013) used a supervised learning method with multiple monolingual signals. Finally, other work on CCA and spectral methods has been used in the context of other types of views (Collobert and Weston, 2008; Dhillon et al., 2011; Klementiev et al., 2012; Chang et al., 2013).

6 Conclusion

We have demonstrated how bilingual information can be incorporated into word embeddings via deep canonical correlation analysis (DCCA). The DCCA embeddings consistently outperform linear CCA embeddings on word and bigram similarity tasks. Future work could compare DCCA to other nonlinear approaches discussed in §5, compare different languages as multiview context, and extend to aligned phrase pairs, and to unaligned data.

Disfluency Detection with a Semi-Markov Model and Prosodic Features

James Ferguson, Greg Durrett and **Dan Klein**
Computer Science Division
University of California, Berkeley
{jferguson,gdurrett,klein}@berkeley.edu

Abstract

We present a discriminative model for detecting disfluencies in spoken language transcripts. Structurally, our model is a semi-Markov conditional random field with features targeting characteristics unique to speech repairs. This gives a significant performance improvement over standard chain-structured CRFs that have been employed in past work. We then incorporate prosodic features over silences and relative word duration into our semi-CRF model, resulting in further performance gains; moreover, these features are not easily replaced by discrete prosodic indicators such as ToBI breaks. Our final system, the semi-CRF with prosodic information, achieves an F-score of 85.4, which is 1.3 F_1 better than the best prior reported F-score on this dataset.

1 Introduction

Spoken language is fundamentally different from written language in that it contains frequent disfluencies, or parts of an utterance that are corrected by the speaker. Removing these disfluencies is desirable in order to clean the input for use in downstream NLP tasks. However, automatically identifying disfluencies is challenging for a number of reasons. First, disfluencies are a syntactic phenomenon, but defy standard context-free parsing models due to their parallel substructures (Johnson and Charniak, 2004), causing researchers to employ other approaches such as pipelines of sequence models (Qian and Liu, 2013) or incremental syntactic systems (Honnibal and Johnson, 2014). Second, human processing of spoken language is complex and mixes acoustic and syntactic indicators (Cutler et al., 1997), so an automatic system must employ features targeting all levels of the perceptual stack to achieve high performance. In spite of this, the primary thread of work in the NLP community has focused on identifying disfluencies based only on lexicosyntactic cues (Heeman and Allen, 1994; Charniak and Johnson, 2001; Snover et al., 2004; Rasooli and Tetreault, 2013). A separate line of work has therefore attempted to build systems that leverage prosody as well as lexical information (Shriberg et al., 1997; Liu et al., 2003; Kim et al., 2004; Liu et al., 2006), though often with mixed success.

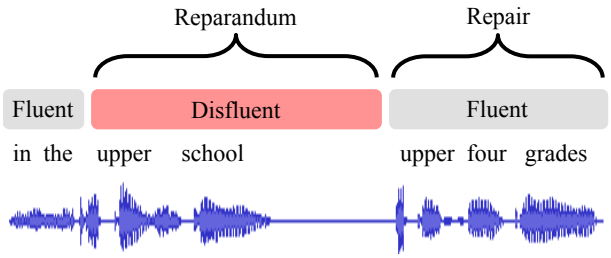

Figure 1: Example of a disfluency where the speaker corrected *upper school*. Our model considers both transcribed text and the acoustic signal and predicts disfluencies as complete chunks using a semi-Markov conditional random field.

In this work, we present a model for disfluency detection that improves upon model structures used in past work and leverages additional prosodic information. Our model is a semi-Markov conditional random field that distinguishes disfluent chunks (to be deleted) from fluent chunks (everything else), as shown in Figure 1. By making chunk-level predictions, we can incorporate not only standard token-level features but also features that can consider the entire reparandum and the start of the repair, enabling our model to easily capture parallelism between these two parts of the utterance.[1] This frame-

[1]The reparandum and repair are important concepts that we will refer to in this paper, but the model does not distinguish the repair from other fluent text which follows.

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 257–262,
Denver, Colorado, May 31 – June 5, 2015.

work also enables novel prosodic features that compute pauses and word duration based on alignments to the speech signal itself, allowing the model to capture acoustic cues like pauses and hesitations that have proven useful for disfluency detection in earlier work (Shriberg et al., 1997). Such information has been exploited by NLP systems in the past via ToBI break indices (Silverman et al., 1992), a mid-level prosodic abstraction that might be indicative of disfluencies. These have been incorporated into syntactic parsers with some success (Kahn et al., 2005; Dreyer and Shafran, 2007; Huang and Harper, 2010), but we find that using features on predicted breaks is ineffective compared to directly using acoustic indicators.

Our implementation of a baseline CRF model already achieves results comparable to those of a high-performance system based on pipelined inference (Qian and Liu, 2013). Our semi-CRF with span features improves on this, and adding prosodic indicators gives additional gains. Our final system gets an F-score of 85.4, which is 1.3 F_1 better than the best prior reported F-score on this dataset (Honnibal and Johnson, 2014).

2 Experimental Setup

Throughout this work, we make use of the Switchboard corpus using the train/test splits specified by Johnson and Charniak (2004) and used in other work. We use the provided transcripts and gold alignments between the text and the speech signal. We follow the same preprocessing regimen as past work: we remove partial words, punctuation, and capitalization to make the input more realistic.[2] Finally, we use predicted POS tags from the Berkeley parser (Petrov et al., 2006) trained on Switchboard.

3 Model

Past work on disfluency detection has employed CRFs to predict disfluencies using a IOBES tag set (Qian and Liu, 2013). An example of this is shown in Figure 2. One major shortcoming of this model is that beginning and ending of a disfluency are not decided jointly: because features in the CRF are local to emissions and transitions, features in this model cannot recognize that a proposed disfluency begins with *upper* and ends before another occurrence of *upper* (see Figure 1). Identifying instances of this parallelism is key to accurately predicting disfluencies. Past work has captured information about repeats using token-level features (Qian and Liu, 2013), but these still apply to either the beginning or ending of a disfluency in isolation. Such features are naturally less effective on longer disfluencies as well, and roughly 15% of tokens occurring in disfluencies are in disfluencies of length 5 or greater. The presence of these longer disfluencies suggests using a more powerful semi-CRF model as we describe in the next section.

3.1 Semi-CRF Model

The model that we propose in this work is a semi-Markov conditional random field (Sarawagi and Cohen, 2004). Given a sentence $x = (x_1, \ldots, x_n)$ the model considers sequences of labeled spans $\bar{s} = ((\ell_1, b_1, e_1), (\ell_2, b_2, e_2), \ldots, (\ell_k, b_k, e_k))$, where $\ell_i \in \{\text{Fluent}, \text{Disfluent}\}$ is a label for each span and $b_i, e_i \in \{0, 1 \ldots n\}$ are fenceposts for each span such that $b_i < e_i$ and $e_i = b_{i+1}$. The model places distributions over these sequences given the sentence as follows:

$$p_\theta(\bar{s}|x) \propto \exp\left(\theta^\top \sum_{i=1}^{k} f(x, (\ell_i, b_i, e_i))\right) \quad (1)$$

where f is a feature function that computes features for a span given the input sentence. In our model we constrain the transitions so that fluent spans can only be followed by disfluent spans. For this task, the spans we are predicting correspond directly to the reparanda of disfluencies, since these are the parts of the input sentences that should be removed. Note that our feature function can jointly inspect both the beginning and ending of the disfluency; we will describe the features of this form more specifically in Section 3.2.2.

To train our model, we maximize conditional log likelihood of the training data augmented with a loss function via softmax-margin (Gimpel and Smith, 2010). Specifically, during training, we maximize $\mathcal{L}(\theta) = \sum_{i=1}^{d} \log p'_\theta(\bar{s}|x)$, where $p'_\theta(\bar{s}|x) = p_\theta(\bar{s}|x) \exp\left(\ell(\bar{s}, \bar{s}^*)\right)$. We take the loss function

[2] As described in Honnibal and Johnson (2014), we computed features over sentences with filler words (*um* and *uh*) and the phrases *I mean* and *you know* removed.

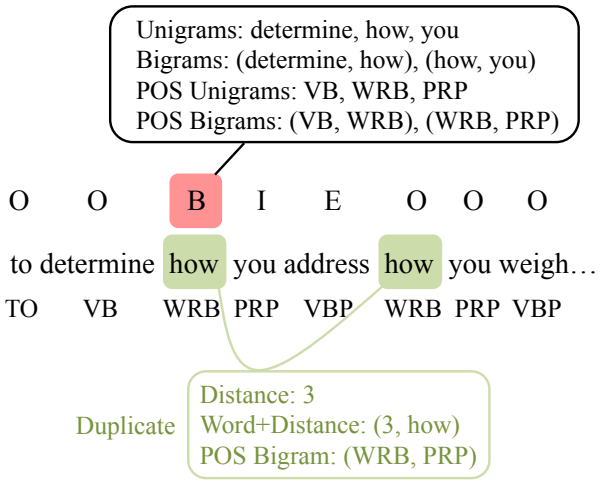

Figure 2: Token features for CRF and semi-CRF models.

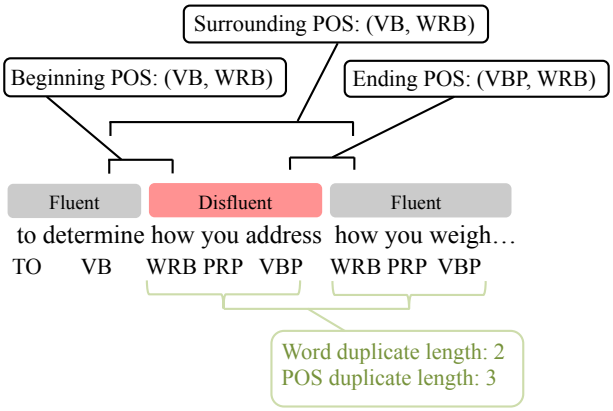

Figure 3: Span features for semi-CRF model.

ℓ to be token-level asymmetric Hamming distance (where the output is viewed as binary edited/non-edited). We optimize with the AdaGrad algorithm of Duchi et al. (2011) with L_2 regularization.

3.2 Features

Features in our semi-CRF factor over spans, which cover the reparandum of a proposed disfluency, and thus generally end at the beginning of the repair. This means that they can look at information throughout the reparandum as well as the repair by looking at content following the span. Many of our features are inspired by those in Qian and Liu (2013) and Honnibal and Johnson (2014). We use a combination of features that are fired for each token within a span, and features that consider properties of the span as a whole.

3.2.1 Token Features

Figure 2 depicts the token-level word features we employ in both our basic CRF and our semi-CRF models. Similar to standard sequence modeling tasks, we fire word and predicted part-of-speech unigrams and bigrams in a window around the current token. In addition, we fire features on repeated words and part-of-speech tags in order to capture the fact that the repair is typically a partial copy of the reparandum, with possibly a word or two switched out. Specifically, we fire features on the distance to any duplicate words or parts-of-speech in a window around the current token, conjoined with the word identity itself or its POS tag (see the *Duplicate* box in Figure 2). We also fire similar features for POS tags since substituted words in the repair frequently have the same tag (compare *address* and *weigh*). Finally, we include a duplicate bigram feature that fires if the bigram formed from the current and next words is repeated later on. When this happens, we fire an indicator for the POS tags of the bigram. In Figure 2, this feature is fired for the word *how* because *how you* is repeated later on, and contains the POS tag bigram (*WRB, PRP*).

Table 1 shows the results for using these features in a CRF model run on the development set.[3]

3.2.2 Span Features

In addition to features that fire for each individual token, the semi-CRF model allows for the inclusion of features that look at characteristics of the proposed span as a whole, allowing us to consider the repair directly by firing features targeting the words following the span. These are shown in Figure 3. Critically, repeated sequences of words and parts-of-speech are now featurized in a coordinated way, making it less likely that spurious repeated content will cause the model to falsely posit a disfluency.

We first fire an indicator of whether or not the entire proposed span is later repeated, conjoined with the length of the span. Because many disfluencies

[3]We created our development set by randomly sampling documents from the training set. Compared to the development set of Johnson and Charniak (2004), this more closely matches the disfluency distribution of the corpus: their development set has 0.53 disfluent tokens per sentence, while our set has 0.38 per sentence, and the training set has 0.37 per sentence.

	Prec.	Rec.	F_1
CRF	84.0	82.1	83.0
Semi-CRF	88.6	81.7	85.0
Semi-CRF + Prosody	89.5	82.7	86.0

Table 1: Disfluency results on the development set. Adding span features on top of a CRF baseline improves performance, and including raw acoustic information gives further performance gains.

are just repeated phrases, and longer phrases are generally not repeated verbatim in fluent language, this feature is a strong indicator of disfluencies when it fires on longer spans. For similar reasons, we fire features for the length of the longest repeated sequences of words and POS tags (the bottom box in Figure 3). In addition to general repeated words, we fire a separate feature for the number of uncommon words (appearing less than 50 times in the training data) contained in the span that are repeated later in the sentence; consider *upper* from Figure 1, which would be unlikely to be repeated on its own as compared to stopwords. Lastly, we include features on the POS tag bigrams surrounding each span boundary (top of Figure 3), as well as the bigram formed from the POS tags immediately before and after the span. These features aim to capture the idea that a disfluency is a mistake with a disjuncture before the repair, so the ending bigram will generally not be a commonly seen fluent pair, and the POS tags surrounding the reparandum should be fluent if the reparandum were removed.

Table 1 shows that the additional features enabled by the CRF significantly improve performance on top of the basic CRF model.

4 Exploiting Acoustic Information

Section 3 discussed a primarily structural improvement to disfluency detection. Henceforth, we will use the semi-CRF model exclusively and discuss two methods of incorporating acoustic duration information that might be predictive of disfluencies. Our results will show that features targeting raw acoustic properties of the signal (Section 4.1) are quite effective, while using ToBI breaks as a discrete indicator to import the same information does not give benefits (Section 4.2)

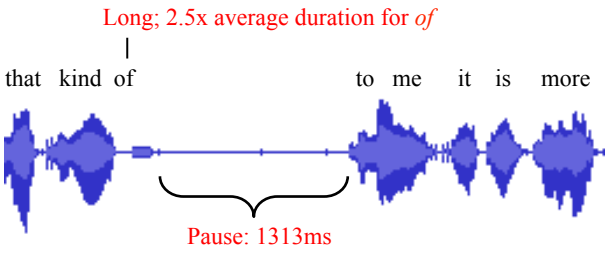

Figure 4: Raw acoustic features. The combination of a long pause and considerably longer than average duration for *of* is a strong indicator of a disfluency.

4.1 Raw Acoustic Features

The first way we implemented this information was in the form of raw prosodic features related to pauses between words and word duration. To compute these features, we make use of the alignment between the speech signal and the raw text. Pauses are then simply identified by looking for pairs of words whose alignments are not flush. The specific features used are indicators of the existence of a pause immediately before or after a span, and the total number of pauses contained within a span. Word duration is computed based on the deviation of a word's length from its average length averaged over all occurrences in the corpus.[4] We fire duration features similar to the pause features, namely indicators of whether the duration of the first and last words in a span deviate beyond some threshold from the average, and the total number of such deviations within a span. As displayed in Table 1, adding these raw features results in improved performance on top of the gains from the semi-CRF model.

4.2 ToBI Features

In addition to the raw acoustic features, we also tried utilizing discrete indicators of acoustic information, specifically ToBI break indices (Silverman et al., 1992). Previous work has shown performance improvements resulting from the use of such discrete information in other tasks, such as parsing (Kahn et al., 2005; Dreyer and Shafran, 2007; Huang and Harper, 2010). We chose to focus specifically on ToBI breaks rather than on ToBI tones because tonal information has appeared relatively less

[4]Note that this averages over multiple speakers as well.

	Disfluency		
	Prec.	Rec.	F_1
Baseline	88.61	81.69	85.01
AuToBI *3*, *4*	88.46	81.92	85.06
CRF ToBI	88.42	81.96	85.07
Raw acoustic	89.53	82.74	**86.00**

Table 2: Disfluency results with predicted ToBI features on the development set. We compare our baseline semi-CRF system (Baseline) with systems that incorporate prosody via predictions from the AuToBI system of Rosenberg (2010) and from our CRF ToBI predictor, as well as the full system using raw acoustic features.

	Prec.	Rec.	F_1
Johnson and Charniak (2004)	–	–	79.7
Qian and Liu (2013)	–	–	83.7
Honnibal and Johnson (2014)	–	–	84.1
CRF	88.7	78.8	83.4
Semi-CRF	90.1	80.0	84.8
Semi-CRF + Prosody	90.0	81.2	85.4

Table 3: Disfluency prediction results on the test set; our base system outperforms that of Honnibal and Johnson (2014), a state-of-the-art system on this dataset, and incorporating prosody further improves performance.

useful for this task (Shriberg et al., 1997). Moreover, the ToBI break specification (Hirschberg and Beckman, 1992) stipulates a category for strong disjuncture with a pause (*2*) as well as a pause marker (*p*), both of which correlate well with disfluencies on gold-annotated ToBI data.

To investigate whether this correlation translates into a performance improvement for a disfluency detection system like ours, we add features targeting ToBI annotations as follows: for each word in a proposed disfluent span, we fire a feature indicating the break index on the fencepost following that word, conjoined with where that word is in the span (beginning, middle, or end).

We try two different ways of generating the break indices used by these features. The first is using the AuToBI system of Rosenberg (2010), a state-of-the-art automatic ToBI prediction systems based on acoustic information which focuses particularly on detecting occurrences of *3* and *4*. Second, we use the subset of Switchboard labeled with ToBI breaks (Taylor et al., 2003) to train a CRF-based ToBI predictor. This model employs both acoustic and lexical features, which are both useful for ToBI prediction despite breaks being a seemingly more acoustic phenomenon (Rosenberg, 2010). The acoustic indicators that we use are similar to the ones described in Section 4 and our lexical features consist of a set of standard surface features similar to those used in Section 3.2.1.

In Table 2 we see that neither source of predicted ToBI breaks does much to improve performance. In particular, the gains from using raw acoustic features are substantially greater despite the fact that the predictions were made in part using similar raw acoustic features. This is somewhat surprising, since intuitively, ToBI should be capturing information very similar to what pauses and word durations capture, particularly when it is predicted based partially on these phenomena. However, our learned ToBI predictor only gets roughly 50 F_1 on break prediction, so ToBI prediction is clearly a hard task even with sophisticated features. The fact that ToBI cannot be derived from acoustic features also indicates that it may draw on information posterior to signal processing, such as syntactic and semantic cues. Finally, pauses are also simply more prevalent in the data than ToBI markers of interest: there are roughly 40,000 pauses on the ToBI-annotated subset of the dataset, yet there are fewer than 10,000 *2* or *p* break indices. The ToBI predictor is therefore trained to ignore information that may be relevant for disfluency detection.

5 Results and Conclusion

Table 3 shows results on the Switchboard test set. Our final system substantially outperforms the results of prior work, and we see that this is a result of both incorporating span features via a semi-CRF as well as incorporating prosodic indicators.

wang.xun,sudoh.katsuhito,nagata.masaaki@lab.ntt.co.jp

Abstract

This paper presents a novel technique for empty category (EC) detection using distributed word representations. A joint model is learned from the labeled data to map both the distributed representations of the contexts of ECs and EC types to a low dimensional space. In the testing phase, the context of possible EC positions will be projected into the same space for empty category detection. Experiments on Chinese Treebank prove the effectiveness of the proposed method. We improve the precision by about 6 points on a subset of Chinese Treebank, which is a new state-of-the-art performance on CTB.

1 Introduction

The empty category (EC) is an important concept in linguistic theories. It is used to describe nominal words that do not have explicit phonological forms (they are also called "covert nouns"). This kind of grammatical phenomenons is usually caused by the omission or dislocation of nouns or pronouns. Empty categories are the "hidden" parts of text and are essential for syntactic parsing (Gabbard et al., 2006; Yang and Xue, 2010). As a basic problem in NLP, the resolution of ECs also has a huge impact on lots of downstream tasks, such as co-reference resolution (Ponzetto and Strube, 2006; Kong and Ng, 2013), long distance dependency relation analysis (Marcus et al., 1993; Xue et al., 2005). Research also uncovers the important role of ECs in machine translation. Some recent work (Chung and Gildea, 2010; Xiang et al., 2013) demonstrates the improvements they manage to obtain through EC detection in Chinese-English translation.

To resolve ECs, we need to decide 1) the position and type of the EC and 2) the content of the EC (to which element the EC is linked to if plausible). Existing research mainly focuses on the first problem which is referred to as EC detection (Cai et al., 2011; Yang and Xue, 2010), and so is this paper. As ECs are words or phrases inferable from their context, previous work mainly designs features mining the contexts of ECs and then trains classification models or parsers using these features (Xue and Yang, 2013; Johnson, 2002; Gabbard et al., 2006; Kong and Zhou, 2010). One problem with these human-developed features are that they are not fully capable of representing the semantics and syntax of contexts. Besides, the feature engineering is also time consuming and labor intensive.

Recently neural network models have proven their superiority in capturing features using low dense vector compared with traditional manually designed features in dozens of NLP tasks (Bengio et al., 2006; Collobert and Weston, 2008; Socher et al., 2010; Collobert et al., 2011; Li and Hovy, 2014; Li et al., 2014).

This paper demonstrates the advantages of distributed representations and neural networks in predicting the locations and types of ECs. We formulate the EC detection as an annotation

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 263–271,
Denver, Colorado, May 31 – June 5, 2015.

task, to assign predefined labels (EC types) to given contexts. Recently, Weston et al. (2011) proposed a system taking advantages of the hidden representations of neural networks for image annotation which is to annotate images with a set of textual words. Following the work, we design a novel method for EC detection. We represent possible EC positions using the word embeddings of their contexts and then map them to a low dimension space for EC detection.

Experiments on Chinese Treebank show that the proposed model obtains significant improvements over the previous state-of-the-art methods based on strict evaluation metrics. We also identify the dependency relations between ECs and their heads, which is not reported in previous work. The dependency relations can help us with the resolution of ECs and benefit other tasks, such as full parsing and machine translation in practice.

2 Proposed Method

We represent each EC as a vector by concatenating the word embeddings of its contexts. As is shown in Fig. 1, we learn a map MAP_A from the annotated data, to project the ECs' feature vectors to a low dimension space K. Meanwhile, we also obtain the distributed representations of EC types in the same low dimension space K. In the testing phase, for each possible EC position, we use MAP_A to project its context feature to the same space and further compare it with the representations of EC types for EC detection.

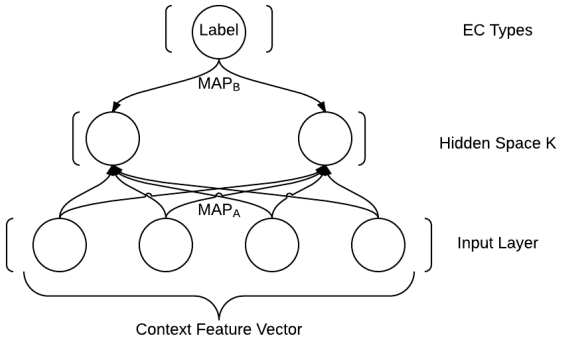

Figure 1: System Architecture

Distributed representations are good at capturing the semantics and syntax of contexts. For example, with word embeddings we are able to tell that "吃/eat" and "喝/drink" have a closer relationship than "吃/eat" and "走/walk" or "喝/drink" and "走/walk". Thus the knowledge we learn from: "EC(你/You)-吃/have-EC(晚饭/supper)-了/past tense marker-么/question marker" could help us to detect ECs in sentences such as "EC(你/You)-饮料/beverage-喝/drink-了/past tense marker-么/question marker", which are similar, though different from the original sentence.

Below is a list of EC types contained in the Chinese Treebank, which are also the types of EC we are to identity in this work.

- pro: small pro, refer to dropped pronouns.
- PRO: big PRO, refer to shared elements in control structures or elements that have generic references.
- OP: null operator, refer to empty relative pronouns.
- T: trace left by A'-movement, e.g., topicalization, relativization.
- RNR: used in right nodes rising.
- *: trace left by passivization, raising.
- Others: other ECs.

According to the reason that one EC is caused, we are able to assign it one of the above categories.

We can formulate EC detection as a combination of a two-class classification problem (is there an EC or not) and a seven-class classification problem (what type the EC is if there is one) following the two-pass method. For one-pass method, EC detection can be formulated as an eight-class (seven EC types listed above plus a dummy "No" type) classification problem. Previous research shows there is no significant differences between their performances (Xue and Yang, 2013). Here we adopt the one-pass method for simplicity.

2.1 System Overview

The proposed system consists of two maps.

MAP_A is from the feature vector of an EC position to a low dimensional space.

$$\begin{aligned} &MAP_A : R^n \rightarrow R^k, k \ll n \\ &f_A(X) \rightarrow W_A X \end{aligned} \tag{1}$$

MAP_A is a linear transformation, and W_A is a $k * n$ matrix.

The other one is from labels to the same low dimensional space.

$$\begin{aligned} &MAP_B : \{Label_1, Label_2, ...\} \in R \rightarrow R^k \\ &f_B(Label_i) \rightarrow W_B^i \end{aligned} \tag{2}$$

MAP_B is also a linear transformation. W_B^i is a k dimensional vector and it is also the distributed representation of $Label_i$ in the low dimensional space.

The two maps are learned from the training data simultaneously. In the testing phase, for any possible EC position to be classified, we extract the corresponding feature vector X, and then map it to the low dimensional space using $f_A(X) = W_A X$. Then we have $g_i(X)$ for each $Label_i$ as follows:

$$g_i(X) = (f_A(X))^T W_B^i \tag{3}$$

For each possible label $Label_i$, $g_i(X)$ is the score that the example having a $Label_i$ and the label predicted for the example is the i that maximizes $g_i(X)$.

Following the method of Weston et al. (2011), we try to minimize a weighted pairwise loss, learned using stochastic gradient descent:

$$\sum_X \sum_{i \neq c} L(rank_c(X)) \max(0, (g_i(X) - g_c(X))) \tag{4}$$

Here c is the correct label for example X, and $rank_c(X)$ is the rank of $Label\ c$ among all possible labels for X. L is a function which reflects our attitude towards errors. A constant function $L = C$ implies we aim to optimize the full ranking list. Here we adopt $L(\alpha) = \sum_{i=1}^{\alpha} 1/i$, which aims to optimize the top 1 in the ranking list, as stated in (Usunier et al., 2009). The learning rate and some other parameters of the stochastic gradient descent algorithm are to be optimized using the development set.

An alternative method is to train a neural network model for multi-class classification directly. It is plausible when the number of classes is not large. One of the advantages of representing ECs and labels in a hidden space is that EC detection usually serves as an intermediate task. Usually we want to know more about the ECs such as their roles and explicit content. Representing labels and ECs as dense vectors will greatly benefit other work such as EC resolution or full parsing. Besides, such a joint embedding framework can scale up to the large set of labels as is shown in the image annotation task (Weston et al., 2011), which makes the identification of dependency types of ECs (which is a large set) possible.

2.2 Context Features Construction

2.2.1 Defining Locations

In a piece of text, possible EC positions can be described with references to tokens, e.g., before the n^{th} token (Yang and Xue, 2010). One problem with such methods is that if there are more than one ECs preceding the n^{th} token, they will occupy the same position and can not be distinguished. One solution is to decide the number of ECs for each position, which complicates the problem. But if we do nothing, some ECs will be ignored.

A compromised solution is to describe positions using parse trees (Xue and Yang, 2013). Adjacent ECs before a certain token usually have different head words, which means they are attached to different nodes (head words) in a parse tree. Therefore it is possible to define positions using "head word, following word" pairs. Thus the problem of EC detection can be formulated as a classification problem: for each "head word, following word" pair, what is the type of the EC? An example is shown in figure 2, in which there are 2 possible EC positions, (吃, 了) and (吃, 。)[1].

[1]Note that there are still problems with the tree based method. As is shown in Fig. 3, the pro and T are attached to the same head word (告别) and share the same

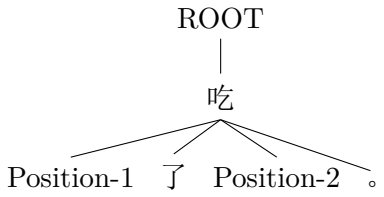

Figure 2: Possible EC Positions in a Dependency Tree

Besides, we keep punctuations in the parse tree so that we can describe all the possible positions using the "head node, following word" pairs, as no elements will appear after a full stop in a sentence.

2.2.2 Feature Extraction

The feature vector is constructed by concatenating the word embeddings of context words that are expected to contribute to the detection of ECs.

1. The head word (except the dummy root node). Suppose words are represented using d dimension vectors, we need d elements to represent this feature. The distributed representations of the head word would be placed at the corresponding positions.

2. The following word in the text. This feature is extracted using the same method with head words.

3. "Nephews", the sons of the following word. We choose the leftmost two.

4. Words in dependency paths. ECs usually have long distance dependencies with words which cannot be fully captured by the above categories. We need a new feature to describe such long distance semantic relations: Dependency Paths. From the training data, we collect all the paths from root nodes to ECs (ECs excluded) together with dependency types. Below we give an example to illustrate the extraction of this kind of features using a complex sentence with a multi-layer hierarchical dependency tree as in Fig. 3. If we have m kinds of such paths with different path types or dependency types, we need md elements to represent this kind of features. The distributed representations of the words would be placed at the corresponding positions in the feature vector and the remaining are set to 0.

following word (德国). But such phenomenas are rare, so here we still adopt the tree based method.

Previous work usually involves lots of syntactic and semantic features. In the work of (Xue and Yang, 2013), 6 kinds of features are used, including those derived from constituency parse trees, dependency parse trees, semantic roles and others. Here we use only the dependency parse trees for the feature extraction. The words in dependency paths we use have proven their potential in representing the meanings of text in frame identification (Hermann et al., 2014).

Take the OP in the sentence shown in Fig. 3 for example. For the OP, its head word is "的", its following word is "告别" and its nephews are "NULL" and "NULL" (ECs are invisible).

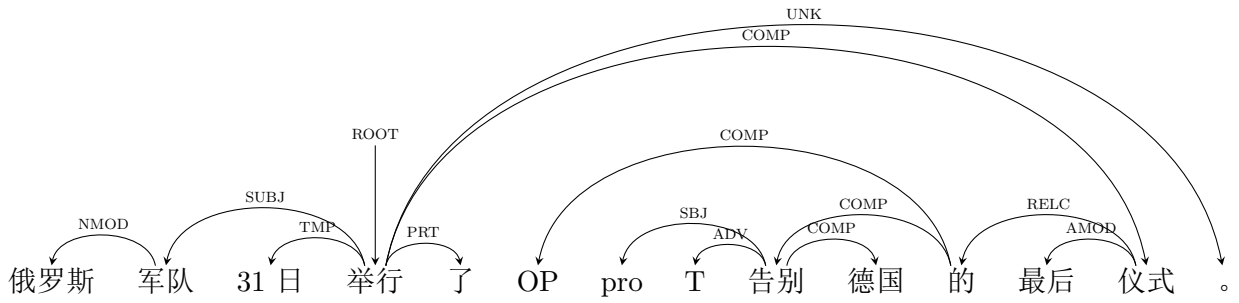
The dependency path from root to OP is:
$Root \xrightarrow{ROOT}$ 举行/hold $\xrightarrow{COMP}$ 仪式/ceremony $\xrightarrow{RELC}$ 的/DE $\xrightarrow{COMP}$ OP

For such a path, we have the following subpaths:

$$Root \xrightarrow{ROOT} . \xrightarrow{COMP} . \xrightarrow{RELC} X$$
$$Root \xrightarrow{ROOT} . \xrightarrow{COMP} X$$
$$Root \xrightarrow{ROOT} X$$

For the position of the OP in the given example, the words with corresponding dependency paths are "的", "仪式" and "举行". Similarly, we collects all the paths from other ECs in the training examples to build the feature template.

In the testing phase, for each possible EC position, we place the distributed representations of the right words at the corresponding positions of its feature vector.



俄罗斯/Russian 军队/troops 31 日/31rd 举行/hold 了/past-tense-marker 告别/farewell 德国/Germany 的/DE 最后/final 仪式/ceremony 。

Table 1: Data Division and EC Distribution

3 Experiments on CTB

3.1 Data

The proposed method can be applied to various kinds of languages as long as annotated corpus are available. In our experiments, we use a subset of Chinese Treebank V7.0.

We split the data set into three parts, training, development and test data. Following the previous research, we use File 1-40 and 901-931 as the test data, File 41-80 as the development data. The training data includes File {81-325, 400-454, 500-554, 590-596, 6000-885, 900}. The development data is used to tune parameters and the final results are reported on the test data. CTB trees are transferred to dependency trees for feature extraction with ECs preserved (Xue, 2007).

The distributed word representation we use is learned using the word2vec toolkit (Mikolov et al., 2013). We train the model on a large Chinese news copora provided by Sogou[2], which contains about 1 billion words after necessary preprocessing. The text is segmented into words using ICTCLAS(Zhang et al., 2003)[3].

3.2 Experiment Settings

Initialization W_A is initialized according to $uniform[-\frac{24}{d_{in}+d_{hidden}}, \frac{24}{d_{in}+d_{hidden}}]$.
And W_B is initialized using $uniform[-\frac{24}{d_{hidden}+d_{out}}, \frac{24}{d_{hidden}+d_{out}}]$.
Here d_{in}, d_{hidden} and d_{out} are the dimensions of the input layer, the hidden space and the label space.

Parameter Tuning To optimize the parameters, firstly, we set the dimension of word vectors to be 80, the dimension of hidden space to be 50. We search for the suitable learning rate in $\{\underline{10^{-1}}, 10^{-2}, 10^{-4}\}$. Then we deal with the dimension of word vectors $\{\underline{80}, 100, 200\}$. Finally we tune the dimension of hidden space in $\{50, 200, \underline{500}\}$ against the F-1 scores. . Those underlined figures are the value of the parameters after optimization. We use the stochastic gradient descent algorithm to optimize the model. The details can be checked here (Weston et al., 2011). The maximum iteration number we used is 10K. In the following experiments,

[2]http://www.sogou.com/labs/dl/cs.html

[3]The word segment standards used by CTB and ICTCLAS are roughly the same with minor differences.

we set the parameters to be learning rate=10^{-1}, word vector dimension=80 and hidden layer dimension=500.

From the experiments for parameter tuning, we find that for the word embeddings in the proposed model, low dimension vectors are better than high dimensions one for low dimension vectors are better in sharing meanings. For the hidden space which represents inputs as uninterpreted vectors, high dimensional vectors are better than low dimensional vectors. The learning rates also have an impact on the performance. If the learning rate is too small, we need more iterations to achieve convergence. If we stop iterations too early, we will suffer under-fitting.

3.3 Results

3.3.1 Metrics and Evaluation

Previous work reports results based on different evaluation metrics. Some work uses linear positions to describe ECs. ECs are judged on a "whether there is an EC of type A before a certain token in the text" basis (Cai et al., 2011). Collapsing ECs before the same token to one, Cai et al. (2011) has 1352 ECs in the test data. Xue and Yang (2013) has stated that some ECs that share adjacent positions have different heads in the parse tree. They judge ECs on a "whether there is an EC of type A with a certain head word and a certain following token in the text" basis. Using this kind of metric, they gets 1765 ECs.

Here we use the same evaluation metric with Xue and Yang (2013). Note that we still cannot describe all the 1838 ECs in the corpora, for on some occasions ECs preceding the same token share the same head word. We also omit some ECs which cause cycles in dependency trees as described in the previous sections. We have 1748 ECs, 95% of all the ECs in the test data, very close to 1765 used by Xue and Yang (2013). The total number of ECs has an impact on the recall. In Table 3, we include results based on each method's own EC count (1748, 1765, 1352 for Ours, Xue's and Cai's respectively) and the real total EC count 1838 (figures in brackets).

Yang and Xue (2010) report an experiment result based on a classification model in a unified parsing frame. We do not include it for it uses different and relativelyThe distributions of ECs in the test data are shown in Table 2.

(Cai)	737	.660	.545 (.401)	.586 (.499)

Table 3: Performance on the CTB Test Data

The results are shown in Table 3. We present the results for each kind of EC and compare our results with two previous state-of-the-art methods(Cai et al., 2011; Xue and Yang, 2013).

The proposed method yields the newest state-of-the-art performances on CTB as far as we know. We also identify the dependency types between ECs and their heads. Some ECs, such as pro and PRO, are latent subjects of sentences. They usually serve as SBJ with very few exceptions. While the others may play various roles. There are 31 possible (EC, Dep) pairs. Using the same model, the overall result is $p = 0.701, r = 0.703, f = 0.702$.

3.3.2 Analysis

We compare the effectiveness of different features by eliminating each kind of features described in the previous section. As Table 4 shows, the most important kind is the dependency paths, which cause a huge drop in performance if eliminated. Dependency paths encode words and path pattern information which is proved essential for the detection of ECs. Besides, headwords are also useful. While for the

	-dep	-head	-following	-nephews
F1	.501	.604	.703	.716
	(-.216)	(-.103)	(-.014)	(-.001)

Table 4: Effectiveness of Features

others, we cannot easily make the conclusion that they are of little usage in the identification of ECs. They are not fully explored in the proposed model, but may be vital for EC detection in reality.

Worth to mention is that of the several kinds of ECs, the proposed method shows the best performance on ECs of type T, which represents ECs that are the trace of "A'"-movement, which moves a word to a position where no fixed grammatical function is assigned. Here we give an example:

"[ ] 看起来/seem A 喜欢/like B."
"A 看起来/seem (EC) 喜欢/like B."

A is moved to the head of the sentence as the topic (topicalization) and left a trace which is the EC. To detect this EC, we need information about the action "喜欢/like", the link verb "看起来/seem" and the arguments "A" and "B". ECs of type T are very common in Chinese, since Chinese is a topic-prominent language. Using distributed representations, it is easy to encode the context information in our feature vectors for EC detection.

We also have satisfying results and significant improvements for the other types except * (trace of A-movement), which make up about 1% of all the ECs in the test data. Partly because there are too few * examples in the training data. We need to further improve our models to detect such ECs.

4 Discussion

The proposed method is capable of handling large set of labels. Hence it is possible to detect EC types and dependency types simultaneously. Besides, some other NLP tasks can also be formulated as annotation tasks, and therefore can be resolved using the same scheme, such as the frame identification for verbs (Hermann et al., 2014).

This work together with some previous work that uses classification methods (Cai et al., 2011; Xue and Yang, 2013; Xue, 2007), regards ECs in a sentence as independent to each other and even independent to words that do not appear in the feature vectors. Such an assumption makes it easier to design models and features but does not reflect the grammatic constraints of languages. For example, simple sentences in Chinese contain one and only one subject, whether it is an EC or not. If it is decided there is an EC as a subject in a certain place, there should be no more ECs as subjects in the same sentence. But such an important property is not reflected in these classification models. Methods that adopt parsing techniques take the whole parse tree as input and output a parse tree with EC anchored. So we can view the sentence as a whole and deal with ECs with regarding to all the words in the sentence. Iida and Poesio (2011) also take the grammar constraints into consideration by formulating EC detection as an ILP problem. But they usually yield poor performances compared with classification methods partly because the methods they use can not fully explore the syntactic and semantic features.

5 Related Work

Empty category is a complex problem (Li and Hovy, 2015). Existing methods for EC detection mainly explores syntactic and semantic features using classification models or parsing techniques.

Johnson (2002) proposes a simple pattern based algorithm to recover ECs, both the positions and their antecedents in phrase structure trees. Gabbard et al. (2006) presents a two stage parser that uses syntactical features to recover Penn Treebank style syntactic analyses, including the ECs. The first stage, sentences are parse as usual without ECs, and in the second stage, ECs are detected using a learned model with rich text features in the tree structures. Kong and Zhou (2010) reports a tree kernel-based model which takes as input parse trees for EC detection. They also deal with EC resolution, to

link ECs to text pieces if possible. They reports their results on Chinese Treebank. Yang and Xue (2010) try to restore ECs from parse trees using a Maximum Entropy model. Iida and Poesio (2011) propose an cross-lingual ILP-based model for zero anaphora detection. Cai et al. (2011) reports a classification model for EC detection. Their method is based on "is there an EC *before* a certain token".

Recently Xue and Yang (2013) further develop the method of Yang and Xue (2010) and explore rich syntactical and semantical features, including paths in parse trees and semantic roles, to train an ME classification model for EC detection and yield the best performance reported using a strict evaluation metric on Chinese Treebank as far as we know.

As we have stated, the traditional features used by above methods are not good at capturing the meanings of contexts. Currently the distributed representations together with deep neural networks have proven their ability not only in representing meaning of words, inferring words from the context, but also in representing structures of text (Socher et al., 2010; Li et al., 2015). Deep neural networks are capable of learning features from corpus, therefore saves the labor of feature engineering and have proven their ability in lots of NLP task (Collobert et al., 2011; Bengio et al., 2006).

The most relevant work to this paper are that of Weston et al. (2011) and that of Hermann et al. (2014). Weston et al. (2011) propose a deep neural network scheme exploring the hidden space for image annotation. They map both the images and labels to the same hidden space and annotate new images according to their representations in the hidden space. Hermann et al. (2014) extend the scheme to frame identification, for which they obtain satisfying results. This paper further uses it for empty category detection with features designed for EC detection.

Compared with previous research, the proposed model simplifies the feature engineering greatly and produces distributed representations for both ECs and EC types which will benefit other tasks.

6 Conclusion

In this paper, we propose a new empty category detection method using distributed word representations. Using the word embeddings of the contexts of ECs as features enables us to employ rich information in the context without much feature engineering. Experiments on CTB have verified the advantages of the proposed method. We successfully beat the existing state-of-the-art methods based on a strict evaluation metric. The proposed method can be further applied to other languages such as Japanese. We will further explore the feasibility of using neural networks to resolve empty categories: to link ECs to their antecedents.

Abstract

A large part of human communication involves referring to entities in the world and often these entities are objects that are visually present for the interlocutors. A system that aims to resolve such references needs to tackle a complex task: objects and their visual features need to be determined, the referring expressions must be recognised, and extra-linguistic information such as eye gaze or pointing gestures need to be incorporated. Systems that can make use of such information sources exist, but have so far only been tested under very constrained settings, such as WOz interactions. In this paper, we apply to a more complex domain a reference resolution model that works incrementally (i.e., word by word), grounds words with visually present properties of objects (such as shape and size), and can incorporate extra-linguistic information. We find that the model works well compared to previous work on the same data, despite using fewer features. We conclude that the model shows potential for use in a real-time interactive dialogue system.

1 Introduction

Referring to entities in the world via definite descriptions makes up a large part of human communication (Poesio and Vieira, 1997). In task-oriented situations, these references are often to entities that are visible in the shared environment. This kind of reference has attracted attention in recent computational research, but the kinds of interactions studied are often fairly restricted in controlled lab situations (Tanenhaus and Spivey-Knowlton, 1995) or simulated human/computer interactions, (Schlangen et al., 2009; Kousidis et al., 2013; Chai et al., 2014). In such task-oriented, co-located settings, interlocutors can make use of extra-linguistic cues such as gaze or pointing gestures. Furthermore, listeners resolve references as they unfold, often identifying the referred entity before the end of the reference (Tanenhaus and Spivey-Knowlton, 1995; Spivey et al., 2002), however research in reference resolution has mostly focused on full, completed referring expressions.

In this paper we make a first move towards addressing somewhat more complex domains. We apply a model of reference resolution, which has been tested in a simpler setup, on more natural data coming from a corpus of human/human interactions. The model is *incremental* in that it does not wait until the end of an utterance to process, rather it updates its interpretation at each word increment. The model can also incorporate other modalities, such as gaze or pointing cues (deixis) incrementally. We also model the saliency of the context, and show that the model can easily take such contextual information into account. The model improves over previous work on reference resolution applied to the same data (Iida et al., 2010; Iida et al., 2011).

The paper is structured as follows: in the following section we discuss related work on incremental resolution of referring expressions. We explain the model that we use in Section 3 and the data we apply it to in Section 4. We then describe the experiments and the results and provide a discussion.

2 Related Work

Reference resolution (RR), which is the task of resolving referring expressions (REs) to what they are

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 272–282,
Denver, Colorado, May 31 – June 5, 2015.

intended to refer to, has been well-studied in various fields such as psychology (Isaacs and Clark, 1987; Tanenhaus and Spivey-Knowlton, 1995), linguistics (Pineda and Garza, 2000), as well as human/human (Iida et al., 2010) and human/machine interaction (Prasov and Chai, 2010; Siebert and Schlangen, 2008; Schlangen et al., 2009). In recent years, multi-modal corpora have emerged which provide RR with important contextual information: collecting dialogue between two humans (Tokunaga et al., 2012; Spanger et al., 2012), between a human and a (simulated) dialogue system (Kousidis et al., 2013; Liu et al., 2013), with gaze, information about the shared environment, and in some cases deixis.

It has been shown that incorporating gaze improves RR in a situated setting because speakers need to look at and distinguish from distractors the objects they are describing: this has been shown in a static scene on a computer screen (Prasov and Chai, 2008), in human-human interactive puzzle tasks (Iida et al., 2010; Iida et al., 2011), in web browsing (Hakkani-tür et al., 2014), and in a moving car where speakers look at objects in their vicinity (Misu et al., 2014). Incorporating pointing (deictic) gestures is also potentially useful in situated RR; as for example Matuszek et al. (2014) have shown in work on resolving objects processed by computer vision techniques. Chen and Eugenio (2012) looked into reference in multi-modal settings, with focus on co-referential pronouns and pointing gestures. However, these approaches were applied in settings in which communication between the two interlocutors was constrained, or the developed systems did not process incrementally. Kehler (2000) presented approach that focused more on interaction in a map task, though the model was not incremental, nor did grounding occur between language and world, as we do here.

Incremental RR has also been studied in a number of papers, including a framework for fast incremental interpretation (Schuler et al., 2009), a Bayesian filtering model approach that was sensitive to disfluencies (Schlangen et al., 2009), a model that used Markov Logic Networks to resolve objects on a screen (Kennington and Schlangen, 2013), a model of RR and incremental feedback (Traum et al., 2012), and an approach that used a semantic representation to refer to objects (Peldszus et al., 2012; Kennington et al., 2014). However, the approaches reported there did not incorporate multi-modal information, were too slow to work in real-time, were evaluated on constrained data, or only focused on a specific type of RR, ignoring pronouns or deixis.

In this paper, we opted to use the model presented in Kennington et al. (2013), the *simple incremental update model* (SIUM). It has been tested extensively against data from a puzzle-playing human/computer interaction domain (the PENTO data, (Kousidis et al., 2013)); it can incorporate multi-modal information, works in real-time, and can resolve definite, exophoric, and deictic references in a single framework, all of which makes it a potential candidate for working in an interactive, multi-modal dialogue system. The model is similar to the one proposed in Funakoshi et al. (2012), which could resolve descriptions, anaphora, and deixis in a unified manner, but that model does not work incrementally.[1]

The main contributions of this paper are the more thorough exposition of the model (in Section 3) and its application and evaluation on much less constrained, more interactive (and hence realistic) data than what it has previously been tested on (Section 4). Moreover, the data set used here is also from a typologically very different language (Japanese) than what the model has been previously tested on (German), and so the robustness of the model against these differences is also investigated.

We will now describe the model, and that will be followed by a description of the corpus we used.

3 The Simple Incremental Update Model

Following Kennington et al. (2013) and Kennington et al. (2014), we model the task at hand as one of recovering I, the intention of the speaker making the RE, where I ranges over the possible alternatives (the objects in the domain). This recovery proceeds incrementally (word by word), for RE of arbitrary length. That is, if U denotes the current word, we are interested in $P(I|U)$, the current hypothesis about

[1] It can be argued that any non-incremental model could be made into an incremental one by applying that model at each word (Khouzaimi et al., 2014), but we would argue that more modeling effort is required in order for the model to work in an interactive dialogue system, see (Schlangen and Skantze, 2009; Aist et al., 2007; Skantze and Schlangen, 2009; Skantze and Hjalmarsson, 1991).

the intended referent, given the observed word. We assume the presence of an unobserved, latent variable R, which models properties of the candidate objects such as colour or shape; explained further below), and so the computation formally is:

$$P(I|U) = \sum_{r \in R} \frac{P(I, U, R)}{P(U)} \quad (1)$$

Which, after making some independence assumptions, can be factored into:

$$P(I|U) = \frac{1}{P(U)} P(I) \sum_{r \in R} P(U|R) P(R|I) \quad (2)$$

This is an update model in the usual sense that the posterior $P(I|U)$ at one step becomes the prior $P(I)$ at the next. $P(R|I)$ provides the link between the intentions (that is, objects) and the properties (e.g., the colour and shape of each object), and $P(U|R)$ the link between properties and (observed) words. Being incremental, this model is computed at each word. As properties play an important role in this model, they will now be explained.

Properties The variable R models visual or abstract properties of entities (such as real-world objects or linguistic entities) and their selection for verbalisation in the referring expression. The simple assumption made by the model is that only such properties can be selected for verbalisation which the candidate object actually has. Hence, the starting point for the model is a representation of the world and the current dialogue context in terms of the properties of the objects. For this paper, this means properties belonging to objects in the shared work space.

We will explain the properties we used in our implementation of this model (henceforth SIUM, i.e., *simple incremental update model*), the motivation for using them, and give an example of applying the model in Section 5.

4 The REX Data

The corpora presented in Iida et al. (2011) and Spanger et al. (2012) are a collection of human/human interaction data where the participants collaboratively solved Tangram puzzles. In this setting, anaphoric references (i.e., pronoun references to entities in an earlier utterance, e.g., "move *it* to the left") and exophoric references via definite descriptions (i.e., references to real-world objects, e.g., "*that* one" or "the big triangle") are common (note that both refer in different ways to objects that are physically present). The corpus also records an added modality: the gaze of the puzzle *solver* (SV) who gives the instructions and that of the *operator* (OP), who moves the tangram pieces. The mouse pointer controlled by the OP could also be considered a modality, used as a kind of pointing gesture that both participants can observe. The goal of the task was to arrange puzzle pieces on a board into a specified shape (example in Figure 1), which was only known to SV and hidden from OP. The language of the dialogues was Japanese.

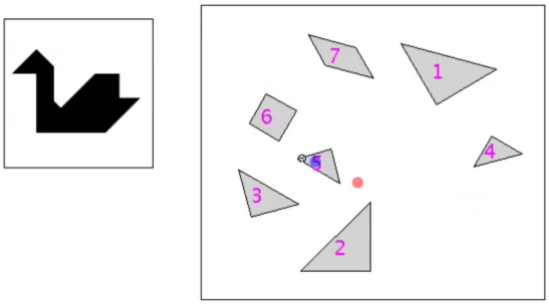

Figure 1: Example Tangram Board; the goal shape is the swan in the top left, the shared work area is the large board on the right, the mouse cursor and OP gaze (blue dot) are on object 5, the SV gaze is the red dot (gaze points were not seen by the participants).

This environment provided frequent use of REs that aimed to distinguish puzzle pieces (and piece groups) from each other. The following are some example REs from the REX corpus:

(1) a. *chicchai sankakkei*
b. small triangle

(2) a. *sono ichiban migi ni shippo ni natte iru sankakkei*
b. that most right tail becoming triangle
'that right-most triangle that is the tail'

Example (1) is a typical example of an RE as found in the corpus. Note that this at the same time constitutes the whole utterance, which hence can be classi-

fied as a non-sentential utterance (Schlangen, 2004). Its transliteration consists of 8 Japanese characters, which could be tokenized into two words. The more difficult RE shown in Example (2) requires the model to learn how spatial placements map to certain descriptions. Moreover, Japanese is a head-final language where comparative landmark pieces are uttered before the referent. Also, because this was a highly interactive setting, many exophoric pronouns were used, e.g., *sore* and *sono*, both meaning *that*.[2] Pronoun references like this made up around 32% of the utterances.

Corpus annotations included (for both participants) transcriptions of utterances, the object being looked at any given time, the object being pointed at or manipulated by the mouse, segmentation of the REs and the corresponding referred object or objects. The spatial layout of the board was recorded each time an object was manipulated. Further details of the corpus can be found in (Iida et al., 2011). In order to directly compare our work with previous work, in our evaluations below we consider the same annotated REs. Iida et al. (2011) applied a support vector machine-based ranking algorithm (Joachims, 2002) to the task of resolving REs in this corpus. They used a total of 36 binary features in the SVM classifier, which predicted the referred object. They further used a separate model for pronoun utterances and non-pronoun utterances, allowing the classifier to learn patterns without confusing utterance types. More details on the results of these models are given below.

The SIU-model has previously been applied to two datasets from the Pentomino domain (Kennington et al., 2013), where the speaker's goal was to identify one out of a set of tetris-like (but consisting of five instead of four blocks) puzzle pieces. However, in these datasets, the references were "one-shot" and not embedded in longer dialogues, as is the case in the REX corpus. A summary of differences between the two tasks is summarised in Table 1. Applying SIUM to data like that found in the REX corpus is a natural next step to test the abilities of the model as a RR component in a dialogue system.

[2]To be precise, *sono* is a demonstrative adjective.

	PENTO	REX
language	**German**	**Japanese**
language type	SVO	SOV
phrase type	head-initial	head-final
avg utt length	7-8	4-5
number of objects	15	7
interactivity	human-wizard	human-human
recorded gaze	SV (speaker)	SV, OP
% of pronoun utts	0%	32%

Table 1: Summary of differences between PENTO and REX tasks.

5 Experiment

Procedure The procedure for this experiment is as follows. In order to compare our results directly with those of Iida et al. (2011), we provide our model with the same training and evaluation data, in a 10-fold cross-validation of the 1192 REs from 27 dialogues (the T2009-11 corpus in Tokunaga et al. (2012)). For development, we used a separate part of the REX corpus (N2009-11) that was structured similarly to the one used in our evaluation.

Task The task is RR. At each increment, SIUM returns a distribution over all objects; the probability for each object represents the strength of the belief that it is the referred one. The argmax of the distribution is chosen as the hypothesised referred object.

P(R|I) $P(R|I)$ models the likelihood of selecting a property of a candidate object for verbalisation; this likelihood is assumed to be uniform for all the properties that the candidate object has.[3] We derive these properties from a representation of the scene; similar to how Iida et al. (2011) computed features to present to their classifier: namely **Ling** (linguistic features), **TaskSp** (task specific features), and **Gaze** (from SV only). Some features were binary, others such as shape and size had more values. Table 2 shows all the properties that were used here. Each will now be explained.

Ling Each object had a shape, size, and relative position to the other pieces. We determined by hand

[3]Uniformity in the likelihood of the properties isn't an ideal approach as certain properties could be more likely to be selected than others; we leave a more principled approach to using saliency to help determine the likelihood of the properties to future work.

Ling	TaskSp
tri/squ/pgram	most_recent_move
small/med/big	mouse_pointed
left/mid/right	
prev_referred	**Gaze**
top/cen/bottom	most_gazed_at
referred_5	gazed_at_in_utt
referred_10	longest_gazed_at
referred_20	recent_fixation

Table 2: List of properties used for each source of information.

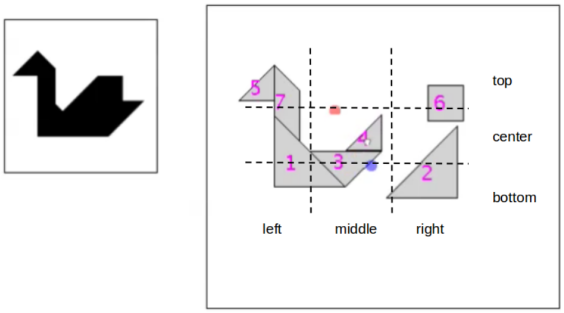

Figure 2: Tangram later in the dialogue; the notion of *right-ness* and other spatial concepts changes throughout the dialogue (compare to Figure 1), the grids are added to show which objects receive which horizontal and which vertical properties.

the shape and size properties which remained static through each dialogue. The position properties were derived from the corpus logs. For each object, the centroid of each object was computed. Then, the vertical and horizontal range for all of the objects was calculated and then split into three even sections in each dimension (see Figure 2). An object with a centroid in the left-most section of the horizontal range received a `left` property, similarly `middle` and `right` properties were calculated for corresponding objects. For vertical placement, `top`, `center` and `bottom` properties were given to objects in the respective vertical segments. Figure 2 shows an example segmentation. Each object had a vertical and a horizontal property at all times, however, moving an object could result in a change of one of these spatial properties as the dialogue progressed. As an example, compare Figure 1, which is a snapshot of the interaction towards the beginning, and Figure 2, which shows a later stage of the game board; spatial layout changes throughout the dialogue.

These properties differ somewhat from the features for the Ling model presented in Iida et al. (2011). Three features that we did use as properties had to do with reference recency: the most recently referred object received the `referred_X` properties, if an object was referred to in the past 5, 10, or 20 seconds.

TaskSp Iida et al. (2011) used 14 task-specific features, three of which they found to be the most informative in their model. Here, we will only use the two most informative features as properties (the third one, whether or not an object was being manipulated at the beginning of the RE, did not improve results in a held-out test): the object that was most recently moved received the `most_recent_move` property and objects that have the mouse cursor over them received the `mouse_pointed` property (see Figure 2; object 4 would receive both of these properties, but only for the duration that the mouse was actually over it). Each of these properties can be extracted directly from the corpus annotations.

Gaze Similar to Iida et al. (2011), we consider gaze during a window of 1500ms before the onset of the RE. The object that was gazed at the longest during that time received a `longest_gazed_at` property, the object which was fixated upon most recently during that interval before the RE onset received a `recent_fixation` property, and the object which had the most fixations received the `most_gazed_at` property. During a RE, an object received the `gazed_at_in_utt` property if it is gazed at during the RE up until that point. These properties can be extracted directly from the corpus annotations. Other gaze features are not really accessible to an incremental model such as this, as gaze features extracted from gaze activity over the RE can only be computed when it is complete. Our Gaze properties are made up of these 4 properties, as opposed to the 14 features in Iida et al. (2011).

P(U|R) $P(U|R)$ is the model that connects the property selected for verbalisation with a way of verbalising it (a value for U). Instead of directly learning this model from data, which would suffer from data sparseness, we trained a naive Bayes model

for $P(R|U)$ (as, according to Bayes' rule, $P(U|R)$ is equal to $P(R|U)P(U)\frac{1}{P(R)}$, which, plugged in into formula (2), cancels out $\frac{1}{P(U)}$; further assuming the $P(R)$ is uniform, we can directly replace $P(U|R)$ with $P(R|U)$ here). On the language side (the variable U in the model), we used n-grams over Japanese characters (we attempted tokenisation of the REs into words, but found that using characters worked just as well in the held-out set).

P(I) The prior $P(I)$ is the posterior of the previously computed increment. In the first increment, it can simply be set to a uniform distribution. Here, we apply a more informative prior based on saliency. We learn a *context model* which is queried when the first word begins, taking information about the context immediately before the beginning of the RE into account, producing a distribution over objects, which becomes $P(I)$ of the first increment in the RE. The context model itself is a simple application of the SIUM, where instead of being a word, U is a token that represents saliency. The context model thus learns what properties are important to the pre-RE context and provides an up-to-date distribution over the objects as a RE begins.

5.1 Example

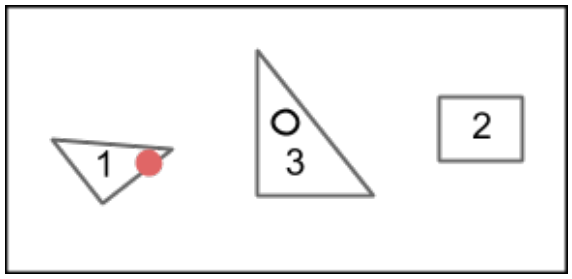

Figure 3: Example scene with two triangles and one square, 1 is being looked at by the SV, 3 was recently moved and the mouse pointer is still over it.

We will now give a simple example of how the model is applied to the REX data using a subset of the above properties for the RE *small triangle*. Table 3 shows a simple normalised co-occurrence count of how many times properties were observed as belonging to a referred object (the basis for $P(U|R)$). Figure 3 shows the current toy scene, and Table 4 shows the properties that each object in the scene has during the utterance. Table 5 shows the full application of the model by summing over the properties for the product $P(U|R)P(R|I)$ and multiplying by the prior $P(I)$, the posterior of the previous step. Included in this example is how the initial prior is computed from the context model.

property	*small*	*triangle*	*square*	⟨*context*⟩
small	.87	.02	.4	.04
big	.01	.08	.02	.05
triangle	.04	.88	.01	.09
square	.04	.01	.9	.09
left	.06	.07	.06	.09
center	.04	.03	.04	.07
right	.04	.06	.05	.03
most_gazed	.07	.09	.07	.6
recent_move	.03	.1	.04	.56
mouse_pointed	.08	.05	.06	.71

Table 3: Applications of $P(U|R)$, for some values of U and R; we assume that this model is learned from data (rows are excerpted from a larger distribution over all the words in the vocabulary)

property	1	2	3
small	0.25	0.33	0
big	0	0	0.2
triangle	0.25	0	0.2
square	0	0.33	0
left	0.25	0	0
center	0	0	0.2
right	0	0.33	0
most_gazed	0.25	0	0
recent_move	0	0	0.2
mouse_pointed	0	0	0.2

Table 4: $P(R|I)$, for our example domain. The probability mass is distributed over the number of properties that a candidate object actually has.

Before the RE even begins, the prior saliency yields that 3 is the most likely object to be referred; it was the most salient in that it was the most recently moved object and the mouse pointer was still over it. However, initial prior information alone is not enough to resolve the intended object; for that the RE is needed. After the word *small* is uttered, 1 is the most likely referred object. After *triangle*, 1 remains the highest in the distribution. With the RE alone, in this case there would have been enough information to infer that 1 was the referred object, but adding the prior information provided additional evidence.

I	U	$\Sigma\, P(U\|R) * P(R\|I)$	$P(I\|U)$
1	⟨*context*⟩	$.25(.04 + .09 + .09 + .6)$	.37
2		$.33(.04 + .09 + .03)$	.095
3		$.2(.05 + .09 + .07 + .56 + .71)$	.535
1	*small*	$.25(.87 + .04 + .06 + .07)$	.65
2		$.33(.87 + .04 + .04)$	.2
3		$.2(.01 + .04 + .04 + .03 + .08)$	.15
1	*triangle*	$.25(.02 + .88 + .07 + .09)$	.81
2		$.33(.02 + .01 + .06)$	.028
3		$.2(.08 + .88 + .03 + .1 + .05)$	.162

Table 5: Application of RE *small triangle*, where 1 is the referred object

Evaluation Metrics We report results of our evaluation in referential accuracy on utterances that were annotated as referring to a single object (references to group objects is left for future work). Going beyond Iida et al. (2011), our model computes a resolution hypothesis incrementally; for the performance of this aspect of the system we followed previously used metrics for evaluation (Schlangen et al., 2009; Kennington et al., 2013):

first correct: how deep into the RE does the model predict the referent for the first time?

first final: how deep into the RE does the model predict the correct referent and keep that decision until the end?

edit overhead: how often did the model unnecessarily change its prediction (the only *necessary* prediction happens when it first makes a correct prediction)?

We compare non-incremental results to three evaluations performed in Iida et al. (2011), namely when Ling is used alone, Ling+TaskSP used together, and Ling+TaskSp+Gaze. Furthermore, they show results of models where a separate part handled REs that used pronouns, as well as a part that handled the non-pronoun REs, and a combined model that handled both types of expressions.

6 Results

6.1 Reference Resolution

Results of our evaluation are shown in Figure 4. The SIUM model performs better than the combined approach of Iida et al. (2011), and performs better than their separated model—when not including gaze (there is a significant difference between SIUM and the separated models for Ling+TaskSp, though

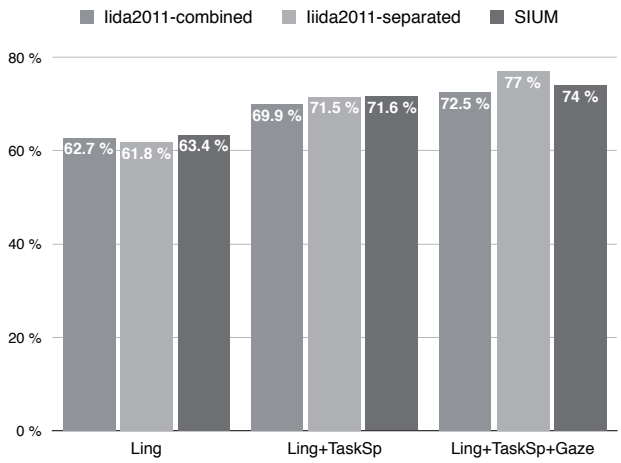

Figure 4: Comparison of model accuracies; our SIUM approach generally performs better over the combined model presented in Iida et al., (2011)

SIUM only got one more correct than the separated model). This is a welcome result, as it shows that our very simple incremental model that uses a basic classifier is comparable to a non-incremental approach that uses a more complicated classifier. It further shows that the SIUM model is robust to using TaskSp and Gaze features as properties, as long as those features are available immediately before the RE begins, or during the RE.

The best-performing approach is the Iida2011-separated model with gaze. This is the case for several reasons: first, their models use features that are not available to our incremental model (e.g., their model uses 14 gaze features, some of which were based on the entire RE, ours only uses 4 properties). Second, and more importantly, separated models means less feature confusion: in Iida et al. (2011) (Section 5.2), the authors give a comparison of the most informative features for each model; task and gaze features were prominent for the pronoun model, whereas gaze and language features were prominent for the non-pronoun model. We also tested SIUM under separated conditions to better compare with the approaches presented here. The separated models, however, did not improve. This, we assume, is because the model grounds *language* with properties (see Discussion below). An interactive dialogue system might not have the luxury of choosing between two models at runtime. We assume that a model that can sufficiently handle both

	1-5	6-8	9-14
first correct (% into RE)	35.47	22.34	14.8
first final (% into RE)	69.0	49.85	48.0
edit overhead (all lengths)	0.88%		
never correct (all lengths)	5.5%		

Table 6: Incremental results for SIUM, numbers represent % into RE.

types of utterances is to be preferred to one that doesn't.

6.2 Incremental Behaviour

Table 6 shows how our model fares using the incremental metrics described earlier. (As this has not been done in Iida et al. (2011), direct comparison is not possible.) For the evaluation, REs are binned into short, normal, and long (1-5, 6-8, 9-14 characters, respectively, based on what the average numbers of words in REs in this corpus is), to make relative statements ("% into the utterance") comparable.

Ideally, a system would make the first correct decision as early as possible without changing that decision. The results in the table show a respectable incremental model; on average it picks the right object early, with some edit overhead (making unnecessary changes in its prediction), finally fixing on a final decision before the end of the RE with low edit overhead, meaning it rarely changes its mind once it has made a decision. In some cases, SIUM never guessed the correct object, labeled *never correct* in the table. These incremental results are consistent with previous work for the SIUM; overall, the model is stable across the RE.

6.3 Discussion

Despite being very simple, there is an important difference that allows SIUM to improve over previous work. It learns to connect object properties selected for verbalisation to ways of verbalising them, and forms a stochastic expectation about which properties might be selected for verbalisation (namely, those that are present). This represents a type of *grounding* (Harnad, 1990; Roy, 2005).[4] In terms of the SIUM formalism, the link between object and words is mediated by the properties the object has

[4]Not to be confused with *building common ground* (Clark, 1996) which is also referred to as *grounding*.

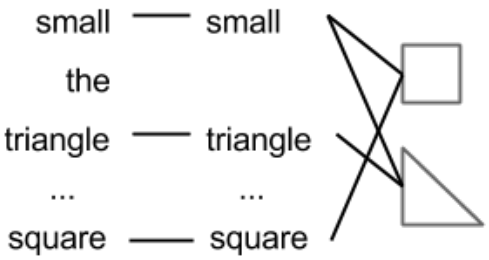

Figure 5: Words that describe objects are linked via a hand-coded `compatibility` function; links from words to multiple properties can exist, provided it is coded.

and by a stochastic process of associating words with properties. Figure 6 visualises this: each word has a stochastic connection between each property and objects have a set of properties. The property names are arbitrary as long as they are consistent. In contrast, previous work in RR (Iida et al., 2011; Chai et al., 2014) used a hand-coded concept-labeled semantic representation and checked if aspects of the RE match that of a particular object. If so, a binary *compatibility* feature was set. Figure 5 shows this; words can only link to objects via hand-crafted rules (e.g., the word or FOL predicate and property string must match). By the way SIUM uses properties, it can also perform (exophoric) pronoun resolution, deixis (the mouse pointer) and definite descriptions, in a single framework. This is a nice feature of the model: adding additional modalities does not require model reformulation.

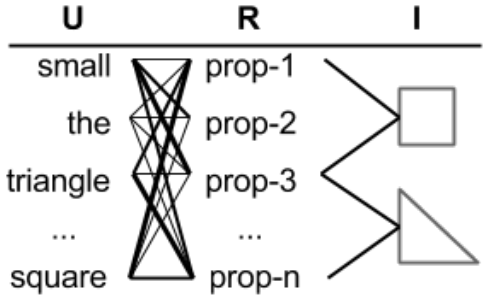

Figure 6: Words that describe objects are linked via properties stochastically: thicker lines between U and R represent higher probabilities. The lines between R and I denote a property belonging to an object. The cardinality of U does not equal R.

Incorporating saliency information via a context model is also a nice feature of the model. In this paper, we computed the initial $P(I)$ using a context model instantiated by SIUM. By considering only this saliency information, the context model can predict the referred object in 41% of the cases. It also learned which properties were important for saliency (that is, these are the properties that the model would most likely select): `recently_fixated`, `most_gaze_at`, `longest_gazed_at`, `prev_ref`, as might be expected. In less than 2% of the cases, the context model referred to the correct object, but was wrongly "overruled" when processing the corresponding RE.

There were shortcomings, however. In previous work, it was shown that SIUM performed well when REs contained pronouns (see Kennington et al. (2013), experiment 2). However, in the current work we observed that REs with pronouns were more difficult for the model to resolve than the model presented in Iida et al. (2011). We surmise that SIUM had a difficult time grounding certain properties, as the Japanese pronoun *sore* can be used anaphorically or demonstratively in this kind of context (i.e., sometimes *sore* refers to previously-manipulated objects, or objects that are newly identified with a mouse pointer over them); the model presented in Iida et al. (2011) made more use of contextual information when pronouns were used, particularly in the combined model which incorporated gaze information, as shown above.

7 Conclusion

The SIUM is a model of RR that grounds language with the world, works incrementally, can incorporate modalities such as gaze and deixis, and can resolve multiple kinds of RRs in a single framework. This paper represents the natural next step in evaluating SIUM in a setting that was less constrained and more interactive, with added knowledge that it can work in more than one language.

There is more to be tested for SIUM. A common form of RR happens collaboratively over multiple utterances (Clark and Wilkes-Gibbs, 1986; Heeman and Hirst, 1995), SIUM has only been tested on isolated REs. Though SIUM required fewer features (realised as properties) than previous work, those properties still need to be computed. We leave for future work investigation of a version of the model that can ground language with raw(er) information from the world (e.g., vision information), eliminating the need to determine properties.

Abstract

Marketing materials such as flyers and other infographics are a vast online resource. In a number of industries, such as the commercial real estate industry, they are in fact the only authoritative source of information. Companies attempting to organize commercial real estate inventories spend a significant amount of resources on manual data entry of this information. In this work, we propose a method for extracting structured data from free-form commercial real estate flyers in PDF and HTML formats. We modeled the problem as text categorization and Named Entity Recognition (NER) tasks and applied a supervised machine learning approach (Support Vector Machines). Our dataset consists of more than 2,200 commercial real estate flyers and associated manually entered structured data, which was used to automatically create training datasets. Traditionally, text categorization and NER approaches are based on textual information only. However, information in visually rich formats such as PDF and HTML is often conveyed by a combination of textual and visual features. Large fonts, visually salient colors, and positioning often indicate the most relevant pieces of information. We applied novel features based on visual characteristics in addition to traditional text features and show that performance improved significantly for both the text categorization and NER tasks.

1 Introduction

Digital flyers are the preferred and sometimes only method of conveying offerings information in a number of broker-based industries. Such industries typically lack a centralized database or an established source of information. Organizing such content typically involves manual data entry, an expensive and labour intensive effort. Further challenge is that available offerings constantly change and manually entered data often results in out-dated inventories.

In particular, the commercial real estate industry in the US (unlike residential real estate[1]) does not have a centralized database or an established source of information. A number of commercial real estate inventories collect commercial real estate data using information from flyers, contacting brokers, or visiting physical sites[2]. The data is manually entered in structured form. At the same time, inventories change on a daily basis. As a result, the collected information is typically sparse and often outdated. In fact, commercial real estate brokers often need to rely on networking and chance in preference to consulting third party listing databases.

While brokers do not often update third party inventory databases, they do create marketing materials (usually PDF flyers and/or HTML emails/web pages) that contain all relevant listing information. Virtually all commercial real estate offerings come with a publicly available marketing material that contains all relevant listing information. Figures 1 and 2 show two typical commercial real estate flyers.

[1]The US Multiple Listing Services (MLS), governed by the National Association of Realtors, represents the US residential real estate.

[2]LoopNet, subsidiary of CoStar Group Inc., is the most heavily trafficked online commercial real estate inventory.

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 283–292,
Denver, Colorado, May 31 – June 5, 2015.

Figure 1: An example of a commercial real estate flyer © Kudan Group Real Estate.

Our goal is to utilize this publicly available information and extract structured data that can be continuously updated for a reliable centralized database of offerings.

Commercial listing information is typically summarized in a structured form suitable for targeted property searches. The most important information consists of the various categories of the offering. For example, the transaction type (*sale*, *lease*, and/or *investment*), the property type (*industrial, retail, office*, etc.), the location of the property (its full geocoded address), the size of the property, the contact information of the brokers representing the property, etc.

This information is typically present in text form within the flyer. However, flyers and similar marketing materials are essentially multi-media documents. In addition to text, information is also conveyed by attributes such as font size, color, positioning, and images. For example, the listing address of the flyer on Figure 1 can be easily identified by its prominent color, size, and positioning (*2834 N. Southport Ave*, upper left corner). While the address of the broker firm shown in the same flyer is considered non-essential information and lacks such visual prominence (*156 North Jefferson St.*, upper right corner). In fact, it is very difficult and sometimes impossible to distinguish between the two address types when considering a text-only version of the flyer. Similarly, the transaction type (*For Sale*) of the property on Figure 2 is prominently shown in a large font and distinctive color. To account for the multi-media nature of the dataset, we attempt to combine textual and visual features for the task of automatic extraction of structured information from free-form commercial real estate flyers.

The problem of extracting structured data from flyers was modeled as text categorization and Named Entity Recognition (NER) tasks as described in Section *Problem Definition* below. Typically, both text categorization and NER approaches are applied to genres with exclusively text-based content (newswires, scientific publications, blogs and other social media texts). As a result, the feature space of NER and text categorization involves purely textual features: word attributes and characteristics, their contexts and frequencies. However, textual information in visually rich formats, such as PDF and HTML, is interlaced with typographic and other visually salient characteristics. In this study, we propose several novel features that take visual characteristics into account and show that performance improves significantly on both the text categorization and NER tasks.

2 Problem Definition

Given a commercial real estate flyer, our task is to extract structured information that can be used as input to a commercial real estate listing service. This information includes categories associated with the property (property type and transaction type) and a list of property attributes (address, space information, and broker information).

The task of identifying a list of categories was modeled as a text categorization task. The categories and associated types are summarized in Table 1. Both text categorization tasks (identifying the Transaction and Property Types) are multi-label classification tasks, i.e. multiple category labels can be assigned to each listing. For example, properties are often offered for both *sale* and *lease* and belong to both transaction types. Similarly, a retail building could offer an associated office unit and belongs to property types *retail* and *office*.

The task of identifying values of specific listing attributes was modeled as a Named Entity Recognition (NER) task. The various NER types and de-

Transaction Type	A listing can have one or more of the following transaction types: *sale, lease, investment*.
Property Type	A listing can have one or more of the following property types: *retail, office, industrial, land, multi-family*.

Table 1: Types and descriptions of flyer categories.

scriptions are summarized in Table 2. The named entities represent a typical set of attributes collected by commercial real estate listing services. They are 1) one or more brokers representing the property and their contact information; 2) the full address of the property broken down into individual address fields; 3) one or more spaces including their sizes and types (e.g. sizes of available units in a shopping mall, the sizes of a warehouse building and associated office building, etc.).

Broker Name Broker Email Broker Phone Company Name	The contact information of all listing brokers, including full name, email address, phone number. The brokerage company name.
Street City Neighborhood State Zip	The address information of the listing address including street or intersection, city, state, and, zip code.
Space Size and Type	Size and attributes of relevant spaces (e.g. *27,042 SF building, 4.44 acres site*, etc.); Includes the numeric value, unit of measure, whether the value is a part of a range (min or max) or exact value, as well as the space type *(unit, building,lot*); Excludes size information of non-essential listing attributes (e.g. basement size or parking lot size).

Table 2: Types and descriptions of named entities relevant to extracting listing information from commercial real estate flyers.

The problem of automatically extracting structured information from real estate flyers was then implemented as a combination of the text categorization and NER tasks.

3 Method

3.1 Dataset

The dataset consists of 2,269 commercial real estate flyers submitted to a listing service[3] over a period of one year. It represents over 450 US locations, over 90 commercial real estate companies and over 800 commercial real estate brokers. The flyers were generated using different tools and formats and represent a wide variety of styles. Typically, the same broker can represent properties of various categories and transaction types. The text categorization was evaluated using the full dataset of 2,269 flyers with 5-fold cross validation. For the NER task, we used 60 percent of the flyers for training (a total of 1,361 flyers), and the remaining 40 percent for testing (a total of 908 flyers).

All flyers (PDF and HTML) were converted to a common format (HTML)[4]. The flyers were converted to text using an HTML parser and extracting DOM[5] text elements while preserving some of the white space formatting. In some cases, text was presented inside embedded images within the flyer. Since the majority of flyers, however, were mostly in text format, OCR[6] was not used and text within images was discarded. The median number of characters, tokens, and sentences for flyers are 2106, 424, and 72 respectively.

3.2 Training Data Transformation

In previous work, we have created a tool used to annotate HTML flyers and evaluated the NER task on a subset of 800 manually annotated flyers. However, the manual annotation proved a laborious task (the same listing attribute typically appears multiple times in the document) and resulted in moderate inter-annotator agreement. In this work, instead of manually annotating the full set of 2,269 flyers, we used listing data entered by professional data en-

[3] © BrokerSavant Inc.

[4] PDFs were converted to HTML using the PDFTOHTML conversion program `http://pdftohtml.sourceforge.net/`. While the open-source tool occasionally misaligned text, performance was satisfactory and the use of more accurate commercial PDF-to-HTML5 conversion tool was deemed unnecessary.

[5] Document Object Model.

[6] Optical Character Recognition.

Figure 2: An example of a commercial real estate flyer and manually entered listing information © ProMaker Commercial Real Estate LLC, © BrokerSavant Inc.

try staff employed by the listing service[7]. Figure 2 shows an example of a real estate flyer and the corresponding manually entered listing data.

To generate a dataset for the text categorization tasks we assigned the list of manually entered labels for transaction and property types to each flyer. For example, the flyer from Figure 2 was assigned to transaction type *sale* and property type *industrial*.

To generate annotated data for the NER task, we had to convert the stand-alone listing information to annotated text in which each occurrence of the field values was marked with the corresponding entity type via string matching. The manually entered listing data, however, introduced some text variations and did not always match the text in the corresponding flyer. For example, the same street and intersection address could be expressed in a variety of ways (e.g. *'Westpark Drive and Main Street' vs 'Westpark Dr & Main St'; '123 North Main Road' vs '123 N Main'*, etc.). Similarly, broker names, phones, and company names could have a variety of alternative representations (e.g. *'Michael R. Smith' vs 'Mike Smith CCIM'; 'Lee and Associates' vs 'Lee & Associates of IL LLC'; '773-777-0000 ext 102' vs '773.777.0000x102'*, etc.). Lastly, space size information was always entered in square feet, while at the same time it could be expressed as both square feet and acres (with various precision points) in the corresponding flyer (e.g. *53796 sf, 1.235 acres, 1.23 acres*, etc.).

To account for the various ways in which an attribute value can be expressed in the text we hand-crafted a small set of rules and regular expressions that allowed us to find most of its alternative representations. In some cases, however, the listing value was not found in the corresponding flyer text. In the case of such a discrepancy, the flyer was simply discarded from the training set used for the corresponding named entity type. Such discrepancies could occur for several reasons. In some cases, the manually hand-crafted rules and regular expressions did not cover all possible variants in which the value could be expressed. On occasion, the text containing the attribute value was in image format (inside embedded images). We also noted a few instances of incorrectly entered manual data. As a result, only a portion of the training data (a total of 1,361 flyers) was used for the training of individual named entity types. We were able to automatically annotate 878 flyers used for training the address named entity recognizer (street or intersection, city, state, zip), 1145 flyers used for training the broker information named entity recognizer (broker name, phone, email, company) and 1242 flyers for training the space named entity recognizer (size and space type).

3.3 Data Pre-processing

As mentioned earlier, all flyers (PDF and HTML) were converted to a common format (HTML). An HTML parser was then used to create a text representation of the flyer. The text was tokenized and tokens were normalized (all tokens were converted to lower case and digits were converted to a common format).

As noted previously, data entry staff were able to quickly spot listing attributes of interest solely because of their visual characteristics. To account for such visual characteristics we included typographic and other visual features associated with tokens or text chunks for both the text categorization and NER tasks. Typographic and visual features were based on the computed HTML style attributes for each DOM element containing text.

Computing the HTML style attributes is a complex task since they are typically defined by a combination of CSS[8] files, in-lined HTML style attributes, and browser defaults. The complexities of style definition, inheritance, and overwriting are handled by

[7] © BrokerSavant Inc.

[8] Cascading Style Sheets.

browsers[9]. We used the Chrome browser to dynamically compute the style of each DOM element and output it as inline style attributes. To achieve this we programmatically inserted a javascript snippet that inlines the computed style and saves the new version of the HTML on the local file system utilizing the HTML5 *saveAs* interface[10]. We then normalized the style attribute values for font size, RGB color, and Y coordinate as described in the following sections.

3.4 Text Categorization

The text categorization task involves labeling all flyers with appropriate transaction types and property types as shown in Table 1. This is a multi-label classification task as in all cases a flyer can have more than one label (e.g. Transaction Type: *sale, lease*; Property Type: *retail, office*).

We applied a supervised Machine Learning approach to the task utilizing Support Vector Machines (SVM) (Vapnik, 2000) using the LibSVM library (Chang and Lin, 2011). SVM was a sensible choice as it has been shown to be one of the top performers on a number of text categorization tasks (Joachims, 1998; Yang and Liu, 1999; Sebastiani, 2002).

Category information such as the transaction type and property type are one of the key pieces of information in a flyer. However, they are not always explicitly mentioned in the flyer and in some cases the data entry person needs to read the full content of the flyer to infer the property type. For example, an *industrial* property might be inferred by a mention of a particular zoning category and description of loading docks; a *retail* property type might be inferred by mentions of retail neighbors (e.g. *Staples, Bed Bath and Beyond*, etc) and traffic counts; an *investment* property type can be inferred by description of NOI (net operating income) and Cap Rates (the ratio between the NOI and capital cost of a property), etc. At the same time, when present, terms indicating the transaction and property types typically appear prominently in large fonts. For example, the property type of the flyer shown on Figure 1 is prominently shown in large font (*Restaurant* indicates *retail* property type). Similarly, the transaction type of the flyer shown on Figure 2 is again prominently displayed in a large font (*For Sale*). The classifiers could then benefit from both the full text of the flyers, combined with some information of the visual prominence of individual words.

We used 'bag-of-words' representation (token unigrams) and modeled the task as a binary classification for each category label. As a term weighting scheme, we first used TF-IDF as one of the most common weighting schemes used for term categorization (Lan et al., 2005; Soucy and Mineau, 2005). This served as a performance baseline. To account for visually prominent characteristics of important document terms we also introduced a term weight that takes into account the relative font size of the term. As a measure of the relative font size, we used the percentile rank of the term font size, compared to all term font sizes in the document. For example, a weight of 0.9 is assigned to terms whose font size is greater than 90% of all tokens within the current document. The font size percentile was then used as a term weighting scheme (instead of TF-IDF). Table 3 summarizes the results of 5-fold cross validation using the full dataset of 2,269 flyers. We used a linear kernel model with the default parameters.

		TF-IDF	Font Size Pctl
Property type	P	79.57	85.04
	R	85.27	84.16
	F	82.32	**84.6**
Transaction type	P	87.56	89.64
	R	92.87	94.60
	F	90.14	**92.05**

Table 3: Results from applying SVM on the task of identifying flyer Property Types (*retail, office, industrial, land, multi-family*) and Transaction Types (*sale, lease, investment*). We used 'bag-of-words' representation (unigrams) applying two different term weight schemes: TF-IDF and the relative percentile rank of the term font size. P=precision, R=recall, F=f1 score.

In both text categorization tasks the Font Size Percentile term weight significantly outperformed the TF-IDF term weight scheme[11].

[9] We attempted to use an HTML renderer from the Cobra java toolkit `http://lobobrowser.org/cobra.jsp` to compute HTML style attributes. However, this renderer produced poor results on our dataset and failed to accurately compute the pixel location of text elements.

[10] `https://github.com/eligrey/FileSaver.js`

[11] The difference is statistically significant with p value $<$ 0.05% using Z-test on two proportions.

3.5 Named Entity Recognition

A supervised machine learning approach was then applied to the task of identifying the named entities shown in Table 2. The task was modeled as a **BIO** classification task, classifiers identify the **B**eginning, the **I**nside, and **O**utside of the text segments. We first used a traditional set of text-based features for the classification task. Table 4 lists the various text-based features used. In all cases, a sliding window including the 6 preceding and 6 following tokens was used as features.

Feature Name	Description
Token	A normalized string representation of the token. All tokens were converted to lower case and all digits were converted to a common format.
Token Orth	The token orthography. Possible values are lowercase (all token characters are lower case), all capitals (all token characters are upper case), upper initial (the first token character is upper case, the rest are lower case), mixed (any mixture of upper and lower case letters not included in the previous categories).
Token Kind	Possible values are word, number, symbol, punctuation.
Regex type	Regex-based rules were used to mark chunks as one of 3 regex types: email, phone number, zip code.
Gazetteer	Text chunks were marked as possible US cities or states based on US Census Bureau city and state data. www.census.gov/geo/maps-data/data/gazetteer2013.html.

Table 4: List of text-based features used for the NER task. A sliding window of the 6 preceding and 6 following tokens was used for all features.

As noted previously, data entry staff were able to quickly spot named entities of interest solely because of their visual characteristics. To account for such visual characteristics, we also included visual features associated with text chunks. We used the computed HTML style attributes for each DOM element containing text. Table 5 lists the computed visual features and shows details on how we normalized the style attribute values for font size, RGB color, and Y coordinate.

We then applied SVM on the NER task using the LibSVM library. We again chose SVMs as they have been shown to perform well on a variety of NER tasks, for example (Isozaki and Kazawa, 2002; Takeuchi and Collier, 2002; Mayfield et al., 2003; Ekbal and Bandyopadhyay, 2008). We used a linear kernel model with the default parameters. The multi-class problem was converted to binary problems using the one-vs-others scheme.

Feature Name	Description
Font Size	The computed *font-size* attribute of the surrounding HTML DOM element, normalized to 7 basic sizes (*xx-small, x-small, small, medium, large, x-large, xx-large*).
Color	The computed *color* attribute of the surrounding HTML DOM element. The RGB values were normalized to a set of 100 basic colors. We converted the RGB values to the YUV color space, and then used Euclidian distance to find the most similar basic color approximating human perception.
Y Coordinate	The computed *top* attribute of the surrounding HTML DOM element, i.e. the y-coordinate in pixels. The pixel locations was normalized to 150 pixel increments (roughly 1/5th of the visible screen for the most common screen resolution.)

Table 5: List of visual features used for the NER task. A sliding window of 6 preceding and 6 following DOM elements were used for all features.

As described earlier, we used a portion of the total training data (a total of 1,361 flyers) for the NER tasks. We were able to automatically annotate and use as training data 878 flyers used for address named entities, 1,145 flyers used for broker information named entities, and 1,242 flyers for space named entities. Results were evaluated against the manually entered data for the full test set of 908 flyers. We first used the trained classifiers to find named entities, including their boundaries and types. The predicted named entities were then used to generate listing data as follows. For attributes that have a single value per flyer, we used the predicted named entity of the corresponding type with the highest probability estimate[12]. Single value listing attributes are the fields of the listing address (street or intersection, city, state, zip). Flyers contain a single list-

[12]We used the LibSVM probability estimates for each predicted named entity.

ing, which in turn has a single address. In contrast, broker information and space information are multi-value attributes. A listing is typically represented by multiple brokers and can contain multiple spaces. To construct listing information in the case of multi-value attributes, we used all predicted named entities of the corresponding types. The predicted listing information was then compared to the gold standard of manually entered listing data.

The construction of listing data (for comparison with manually entered data) resulted in a strict performance measure. We consider an answer to be correct only if both the entity boundaries and entity type are accurately predicted. In addition, in the case of single value attributes, only the highest ranking named entity (based on estimated probabilities) was retained.

Results are shown in Table 6. We compared performance of classifiers using only textual features (first 3 columns), versus performance using both textual and visual features (next 3 columns).

Named Entity	Pt	Rt	Ft	Pv+t	Rv+t	Fv+t
Broker Name	93.3	81.2	86.9	95.9	85.5	90.4
Broker Email	95.6	83.6	89.2	95.8	86.5	90.9
Broker Phone	95.4	82.6	88.6	95.7	83.3	89.1
Company Name	97.6	93.9	95.7	98.2	94.9	96.5
Street	77.0	83.4	80.1	81.4	88.6	84.9
City	88.1	96.1	91.9	92.0	98.3	95.0
State	93.1	98.6	95.8	95.4	99.4	97.3
Zip	92.0	86.7	89.3	96.3	86.4	91.1
Space Size	76.8	57.9	66.0	80.1	65.7	72.2
Space Type	66.7	62.6	64.6	68.8	66.7	67.8
OVERALL	87.7	80.3	83.8	89.7	83.5	86.5

Table 6: Results from applying SVM using the textual features described in Table 4, as well as both the textual and visual features described in Tables 4 and 5. t=textual features only, v+t=visual + textual features, P=Precision, R=Recall, F=F1-score

The addition of visual features significantly[13] increased the overall F1-score from 83.8 to 86.5%. Performance gains are more significant for named entities that are typically visually salient and are otherwise difficult (or impossible) to identify in a text-only version of the flyers. In particular, improvements were most significant for named entities referring to space information. A flyer typically describes multiple spaces, however, only a few of these are considered relevant for the purposes of listing services. For example, the size of an office space is typically entered, while the size of an office associated with a retail or industrial space is typically omitted. Similarly, lot size is included in building and land listings, but excluded when the listing refers to a unit (or multiple units) within a building. Essential space information is usually prominently displayed and as a result easy to identify. Similarly, named entities referring to address information also showed overall significant improvement. As noted earlier, the property address (vs other addresses in the flyer) is typically visually prominent. In both cases, visual features proved useful predictors.

[13]The difference is statistically significant with p value $<$ 0.05% using Z-test on two proportions.

4 Discussion

In both the text categorization and NER tasks performance improved significantly over the baseline with the addition of typographic and visual features. However, in both cases, improvements were somewhat moderate (around 3% on average). Further improvement could be achieved by including features that account for additional visual characteristics, such as a measure of how eye-catching or striking the relative font color differences are, the perceived contrast between foreground and background colors, etc.

In future work, we could also add to the overall system an image classification component. It has been noted that occasionally the only indicator of the property type of a flyer is present in embedded flyer images and not present in the flyer text. For example, a number of flyers display images of the inside and outside of restaurants, gas stations, shopping malls and thus specify the property type as *retail* without giving additional textual clues. Similarly, an image of a warehouse, a land parcel, or an areal photo of a shopping center explicitly identify the listing property type.

Lastly, it should be noted that an overall system performance baseline is one that measures the average performance of data entry staff in commercial real estate listing services. However, the terms and conditions of most listing services prohibit gathering and using data for such purposes. We were able to collect a very small set of listings (100 listings)

from several listing services[14] and evaluate the precision of a limited set of listing fields. We compared the values of manually entered listing fields against the associated flyer (considered to be the gold standard). The precision of property type, transaction type, space type, and space size was measured as 97%, 79%, 72%, and 73% respectively. While results are not conclusive, this preliminary evaluation suggests that machine learning could achieve performance on par with the performance of manual data entry.

5 Related Work

A number of studies survey and compare term weighting schemes and feature selection methods for text categorization, for example (Salton and Buckley, 1988; Yang and Pedersen, 1997; Debole and Sebastiani, 2004; Soucy and Mineau, 2005; Lan et al., 2005; Lan et al., 2009). They describe supervised and traditional term weighting schemes. All, however, are only considering the textual information in documents such as the term frequency, the collection frequency, combined with normalization factors, various information theory functions and statistics metrics.

A number of term weighting schemes have been suggested for web retrieval and classification that rely on the HTML DOM structure. (Cutler et al., 1997; Cutler et al., 1999; Riboni, 2002; Kwon and Lee, 2000). The idea is that terms appearing in different HTML elements of a document may have different significance in identifying the document (e.g. terms in HTML titles and headings vs HTML body). In our dataset, however, visually salient information does not fall into any distinctive HTML element type. Instead all text is typically presented in *div* elements whose style characteristics are defined by a number of css descriptors complicated by external css files, css inlining, style inheritance, and browser defaults.

Nadeau and Satoshi (2007) present a survey of NER and describe the feature space of NER research. While they mention multi-media NER in the context of video/text processing, all described features/approaches focus only on textual representation.

The literature on Information Extraction from HTML resources is dominated by various approaches based on wrapper induction (Kushmerick, 1997; Kushmerick, 2000). Wrapper inductions rely on common HTML structure (based on the HTML DOM) and formatting features to extract structured information from similarly formatted HTML pages. This approach, however, is not applicable to the genres of marketing materials (PDF and HTML) since they typically do not share any common structure that can be used to identify relevant named entities. Laender et al. (2002) present a survey of data extraction techniques and tools from structured or semi-structured web resources.

Cai et al. (2003) present a vision-based segmentation algorithm of web pages that uses HTML layout features and attempts to partition the page at the semantic level. In (Burget and Rudolfova, 2009) authors propose web-page block classification based on visual features. Yang and Zhang (2001) build a content tree of HTML documents based on *visual consistency* inferred semantics. Burget (2007) proposes a layout based information extraction from HTML documents and states that this visual approach is more robust than traditional DOM-based methods.

Changuel et al.(2009a) describe a system for automatically extracting author information from webpages. They use spatial information based on the depth of the text node in the HTML DOM tree. In (Changuel et al., 2009b) and (Hu et al., 2006), the authors proposed a machine learning method for title extraction and utilize format information such as font size, position, and font weight. In (Zhu et al., 2007) authors use layout information based on font size and weight for NER for automated expense reimbursement.

None of the above studies, however, include computed HTML style attributes (as seen in browsers), and as a result are not applicable to the vast majority of web pages which do not rely on HTML layout tags or DOM-structure to describe style.

6 Conclusion

In this study, we generated dataset and features from available commercial real estate flyers and associ-

[14] Due to data usage restrictions we were unable to collect a larger dataset or reveal the identity of the source listing services.

ated manually entered listing data. This approach precludes the need for manual linguistic annotation and instead relies on existing data available from commercial real estate listing services. We modeled the structured data extraction task as text categorization and NER tasks and applied machine learning (SVM) on the automatically generated training datasets. The learned models were then applied on our test set and the predicted values were used to reconstruct listing data matching the manually entered fields. Results suggest that this completely automated approach could substitute or enhance the existing manual data entry workflows.

In addition, we have shown that ubiquitous online formats such as PDF and HTML often exploit the interaction of textual and visual elements. Specifically, in the marketing domain, information is often augmented or conveyed by non-textual features such as positioning, font size, color, and images. We explored the use of novel features capturing the visual characteristics of marketing flyers. Results show that the addition of visual features improved overall performance significantly in the context of text categorization and NER.

Abstract

We propose a method for simultaneously translating from a single source language to multiple target languages T1, T2, etc. The motivation behind this method is that if we only have a weak language model for T1 and translations in T1 and T2 are associated, we can use the information from a strong language model over T2 to disambiguate the translations in T1, providing better translation results. As a specific framework to realize multi-target translation, we expand the formalism of synchronous context-free grammars to handle multiple targets, and describe methods for rule extraction, scoring, pruning, and search with these models. Experiments find that multi-target translation with a strong language model in a similar second target language can provide gains of up to 0.8-1.5 BLEU points.[1]

1 Introduction

In statistical machine translation (SMT), the great majority of work focuses on translation of a single language pair, from the source F to the target E. However, in many actual translation situations, identical documents are translated not from one language to another, but between a large number of different languages. Examples of this abound in commercial translation, and prominent open data sets used widely by the MT community include UN documents in 6 languages (Eisele and Chen, 2010), European Parliament Proceedings in 21 languages (Koehn, 2005), and video subtitles on TED in as many as 50 languages (Cettolo et al., 2012).

Figure 1: An example of multi-target translation, where a second target language is used to assess the quality of the first target language.

However, despite this abundance of multilingual data, there have been few attempts to take advantage of it. One exception is the *multi-source* SMT method of Och and Ney (2001), which assumes a situation where we have multiple source sentences, and would like to combine the translations from these sentences to create a better, single target translation.

In this paper, we propose a framework of *multi-target* SMT. In multi-target translation, we translate F to not a single target E, but to a set of sentences $\mathcal{E} = \langle E_1, E_2, \ldots, E_{|\mathcal{E}|} \rangle$ in multiple target languages (which we will abbreviate T1, T2, etc.). This, in a way, can be viewed as the automated version of the multi-lingual dissemination of content performed by human translators when creating data for the UN, EuroParl, or TED corpora mentioned above.

But what, one might ask, do we expect to gain by generating multiple target sentences at the same time? An illustrative example in Figure 1 shows three potential Chinese T1 translations for an Arabic input sentence. If an English speaker was asked to simply choose one of the Chinese translations, they

[1] Code and data to replicate the experiments can be found at http://phontron.com/project/naacl2015

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 293–302,
Denver, Colorado, May 31 – June 5, 2015.

likely could not decide which is correct. However, if they were additionally given English T2 translations corresponding to each of the Chinese translations, they could easily choose the third as the most natural, even without knowing a word of Chinese.

Translating this into MT terminology, this is equivalent to generating two corresponding target sentences E_1 and E_2, and using the naturalness of E_2 to help decide which E_1 to generate. Language models (LMs) are the traditional tool for assessing the naturalness of sentences, and it is widely known that larger and stronger LMs greatly help translation (Brants et al., 2007). It is easy to think of a situation where we can only create a weak LM for T1, but much more easily create a strong LM for T2. For example, T1 could be an under-resourced language, or a new entrant to the EU or UN.

As a concrete method to realize multi-target translation, we build upon Chiang (2007)'s framework of synchronous context free grammars (SCFGs), which we first overview in Section 2.[2] SCFGs are an extension of context-free grammars that define rules that synchronously generate source and target strings F and E. We expand this to a new formalism of multi-synchronous CFGs (MSCFGs, Section 3) that simultaneously generate not just two, but an arbitrary number of strings $\langle F, E_1, E_2, \ldots, E_N \rangle$. We describe how to acquire these from data (Section 4), and how to perform search, including calculation of LM probabilities over multiple target language strings (Section 5).

To evaluate the effectiveness of multi-target translation in the context of having a strong T2 LM to help with T1 translation, we perform experiments on translation of United Nations documents (Section 6). These experiments, and our subsequent analysis, show that the framework of multi-target translation can, indeed, provide significant gains in accuracy (of up to 1.5 BLEU points), particularly when the two target languages in question are similar.

2 Synchronous Context-Free Grammars

We first briefly cover SCFGs, which are widely used in MT, most notably in the framework of hierarchical phrase-based translation (Hiero; Chiang (2007)). SCFGs are based on synchronous rules defined as tuples of X, γ, and α

$$X \rightarrow \langle \gamma, \alpha \rangle, \tag{1}$$

where X is the head of the rule, and γ and α are strings of terminals and indexed non-terminals on the source and target side of the grammar. Each non-terminal on the right side is indexed, with non-terminals with identical indices corresponding to each-other. For example, a synchronous rule could take the form of[3]

$$X \rightarrow \langle X_0 \text{ of the } X_1,\ X_0 \text{ des } X_1 \rangle. \tag{2}$$

By simply generating from this grammar, it is possible to generate a string in two languages synchronously, as shown in Figure 2 (a). When we are already given a source side sentence and would like to using an SCFG to generate the translation, we find all rules that match the source side and perform search using the CKY+ algorithm (Chappelier et al., 1998). When we would additionally like to consider

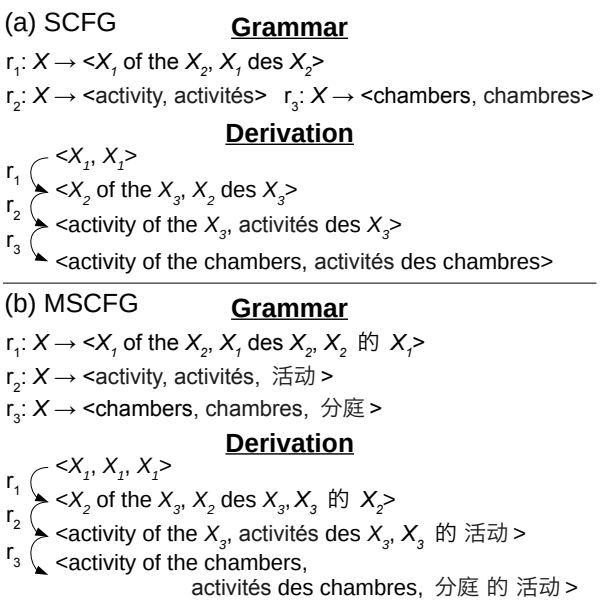

Figure 2: Synchronous grammars and derivations using (a) standard SCFGs and (b) the proposed MSCFGs.

[2] One could also consider a multi-target formulation of phrase-based translation (Koehn et al., 2003), but generating multiple targets while considering reordering in phrase-based search is not trivial. We leave this to future work.

[3] It is possible to use symbols other than X (e.g.: NP, VP) to restrict rule application to follow grammatical structure, but we focus on the case with a single non-terminal.

an LM, as is standard in SMT, we perform a modified version of CKY+ that approximately explores the search space using a method such as cube pruning (Chiang, 2007).

3 Multi-Synchronous CFGs

In this section, we present the basic formalism that will drive our attempts at multi-target translation. Specifically, we propose a generalization of SCFGs, which we will call multi-synchronous context free grammars (MSCFGs). In an MSCFG, the elementary structures are rewrite rules containing not a source and target, but an arbitrary number M of strings

$$X \rightarrow \langle \eta_1, ..., \eta_M \rangle, \quad (3)$$

where X is the head of the rule and η_m is a string of terminal and non-terminal symbols.[4] In this paper, for notational convenience, we will use a specialized version of Equation 3 in which we define a single γ as the source side string, and $\alpha_1, ...\alpha_N$ as an arbitrary number N of target side strings:

$$X \rightarrow \langle \gamma, \alpha_1, ..., \alpha_N \rangle. \quad (4)$$

Therefore, at each derivation step, one non-terminal in γ is chosen and all the nonterminals with same indices in $\alpha_1, ..., \alpha_N$ will be rewritten using a single rule. Figure 2 (b) gives an example of generating sentences in three languages using MSCFGs. Translation can also be performed by using the CKY+ algorithm to parse the source side, and then generate targets in not one, but multiple languages.

It can be noted that this formalism is a relatively simple expansion of standard SCFGs. However, the additional targets require non-trivial modifications to the standard training and search processes, which we discuss in the following sections.

4 Training Multi-Synchronous Grammars

This section describes how, given a set of parallel sentences in N languages, we can create translation models (TMs) using MSCFGs.

[4] We will also make the restriction that indices are linear and non-deleting, indicating that each non-terminal index present in any of the strings will appear exactly once in all of the strings. Thus, MSCFGs can also be thought of as a subset of the "generalized multi-text grammars" of Melamed et al. (2004).

4.1 SCFG Rule Extraction

First, we briefly outline rule extraction for SCFGs in the standard two-language case, as proposed by Chiang (2007). We first start by preparing two corpora in the source and target language, $\mathcal{F}$ and $\mathcal{E}$, and obtaining word alignments for each sentence automatically, using a technique such as the IBM models implemented by GIZA++ (Och and Ney, 2003).

We then extract initial phrases for each sentence. Given a source f_1^J, target e_1^I, and alignment $A = \{\langle i_1, i'_1 \rangle, \ldots, \langle i_{|A|}, i'_{|A|} \rangle\}$ where i and i' represent indices of aligned words in F and E respectively. First, based on this alignment, we extract all pairs of phrases $BP = \{\langle f_{i_1}^{j_1}, e_{i'_1}^{j'_1} \rangle, \ldots, \langle f_{i_{|BP|}}^{j_{|BP|}}, e_{i'_{|BP|}}^{j'_{|BP|}} \rangle\}$, where $f_{i_1}^{j_1}$ is a substring of f_1^J spanning from i_1 to j_1, and $e_{i'_1}^{j'_1}$ is analogous for the target side. The criterion for whether a phrase $\langle f_i^j, e_{i'}^{j'} \rangle$ can be extracted or not is whether there exists at least one alignment in A that falls within the bounds of both f_i^j and $e_{i'}^{j'}$, and no alignments that fall within the bounds of one, but not the other. It is also common to limit the maximum length of phrases to be less than a constant S (in our experiments, 10). The `phrase-extract` algorithm of Och (2002) can be used to extract phrases that meet these criteria.

Next, to create synchronous grammar rules, we cycle through the phrases in BP, and extract all potential rules encompassed by this phrase. This is done by finding all sets of 0 or more non-overlapping sub-phrases of initial phrase $\langle f_i^j, e_{i'}^{j'} \rangle$, and replacing them by non-terminals to form rules. In addition, it is common to limit the number of non-terminals to two and not allow consecutive non-terminals on the source side to ensure search efficiency, and limit the number of terminals to limit model size (in our experiments, we set this limit to five).

4.2 MSCFG Rule Extraction

In this section, we generalize the rule extraction process in the previous section to accommodate multiple targets. We do so by first independently creating alignments between the source corpus $\mathcal{F}$, and each of N target corpora $\{\mathcal{E}_1, \ldots, \mathcal{E}_N\}$.

Given a particular sentence we now have source F, N target strings $\{E_1, \ldots, E_N\}$, and N alignments $\{A_1, \ldots, A_N\}$. We next in-

dependently extract initial phrases for each of the N languages using the standard bilingual `phrase-extract` algorithm, yielding initial phrase sets $\{BP_1, \ldots, BP_N\}$. Finally, we convert these bilingual sets of phrases into a single set of multilingual phrases. This can be done by noting that all source phrases f_i^j will be associated with a set of 0 or more phrases in each target language. We define the set of multilingual phrases associated with f_i^j as the cross product of these sets. In other words, if f_i^j is associated with 2 phrases in T1, and 3 phrases in T2, then there will be a total of $2*3 = 6$ phrase triples extracted as associated with f_i^j.[5]

Once we have extracted multilingual phrases, the remaining creation of rules is essentially the same as the bilingual case, with sub-phrases being turned into non-terminals for the source and all targets.

4.3 Rule Scoring

After we have extracted rules, we assign them feature functions. In traditional SCFGs, given a source and target γ and α_1, it is standard to calculate the log forward and backward translation probabilities $P(\gamma|\alpha_1)$ and $P(\alpha_1|\gamma)$, log forward and backward lexical translation probabilities $P_{lex}(\gamma|\alpha_1)$ and $P_{lex}(\alpha_1|\gamma)$, a word penalty counting the non-terminals in α_1, and a constant phrase penalty of 1.

In our MSCFG formalism, we also add new features regarding the additional targets. Specifically in the case where we have one additional target α_2, we add the log translation probabilities $P(\gamma|\alpha_2)$ and $P(\alpha_2|\gamma)$, log lexical probabilities $P_{lex}(\gamma|\alpha_2)$ and $P_{lex}(\alpha_2|\gamma)$, and word penalty for α_2. In addition, we add log translation probabilities that consider both targets at the same time $P(\gamma|\alpha_1, \alpha_2)$ and $P(\alpha_1, \alpha_2|\gamma)$. As a result, compared to the 6-feature set in standard SCFGs, an MSCFG rule with two targets will have 13 features.

4.4 Rule Table Pruning

In MT, it is standard practice to limit the number of rules used for any particular source γ to ensure realistic search times and memory usage. This limit is generally imposed by ordering rules by the phrase probability $P(\alpha_1|\gamma)$ and only using the top few (in our case, 10) for each source γ. However, in the MSCFG case, this is not so simple. As the previous section mentioned, in the two-target MSCFG, we have a total of three probabilities conditioned on γ: $P(\alpha_1, \alpha_2|\gamma)$, $P(\alpha_1|\gamma)$, $P(\alpha_2|\gamma)$. As our main motivation for multi-target translation is to use T2 to help translation of T1, we can assume that the final of these three probabilities, which only concerns T2, is of less use. Thus, we propose two ways for pruning the rule table based on the former two.

The first method, which we will call *T1+T2*, is based on $P(\alpha_1, \alpha_2|\gamma)$. The use of this probability is straightforward, as it is possible to simply list the top rules based on this probability. However, this method also has a significant drawback. If we are mainly interested in accurate generation of the T1 sentence, there is a possibility that the addition of the T2 phrase α_2 will fragment the probabilities for α_1. This is particularly true when the source and T1 are similar, while T2 is a very different language. For example, in the case of a source of English, T1 of French, and T2 of Chinese, translations of English to French will have much less variation than translastions of English to Chinese, due to less freedom of translation and higher alignment accuracy between English and French. In this situation, the pruned model will have a variety of translations in T2, but almost no variety in T1, which is not conducive to translating T1 accurately.

As a potential solution to this problem, we also test a *T1* method, which is designed to maintain variety of T1 translations for each rule. In order to do so, we first list the top α_1 candidates based only on the $P(\alpha_1|\gamma)$ probability. Each α_1 will be associated with one or more α_2 rule, and thus we choose the α_2 resulting in the highest joint probability of the two targets $P(\alpha_1, \alpha_2|\gamma)$ as the representative rule for α_1. This pruning method has the potential advantage of increasing the variety in the T1 translations, but also has the potential disadvantage of artificially reducing genuine variety in T2. We examine which method is more effective in the experiments section.

5 Search with Multiple LMs

LMs computes the probability $P(E)$ of observing a particular target sentence, and are a fundamental

[5] Taking the cross-product here has the potential for combinatorial explosion as more languages are added, but in our current experiments with two target languages this did not cause significant problems, and we took no preventative measures.

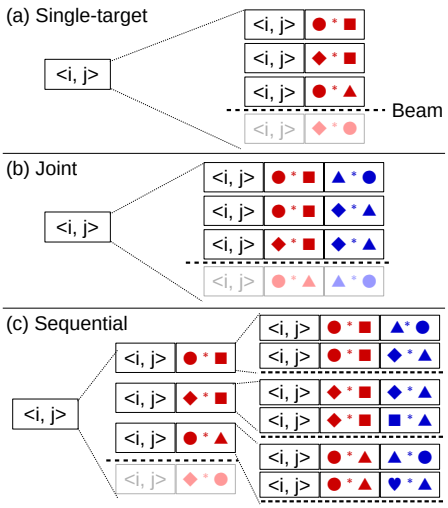

Figure 3: State splitting with (a) one LM, (b) two LMs with joint search, and (c) two LMs with sequential search, where T1 and T2 are the first (red) and second (blue) columns respectively.

part of both standard SMT systems and the proposed method. Unlike the other features assigned to rules in Section 4.3, LM probabilities are non-local features, and cannot be decomposed over rules. In case of n-gram LMs, this probability is defined as:

$$P_{LM}(E) = \prod_{i=1}^{|E|+1} p(e_i|e_{i-n+1}, \ldots, e_{i-2}, e_{i-1}) \quad (5)$$

where the probabilities of the next word e_i depend on the previous $n-1$ words.

When not considering an LM, it is possible to efficiently find the best translation for an input sentence f_1^J using the CKY+ algorithm, which performs dynamic programming remembering the most probable translation rule for each state corresponding to source span f_i^j. When using an LM, it is further necessary split each state corresponding to f_i^j to distinguish between not only the span, but also the strings of $n-1$ boundary words on the left and right side of the translation hypothesis, as illustrated in Figure 3 (a). As this expands the search space to an intractable size, this space is further reduced based on a limit on expanded edges (the pop limit), or total states per span (the stack limit), through a procedure such as cube pruning (Chiang, 2007).

In a multi-target translation situation with one LM for each target, managing the LM state becomes more involved, as we need to keep track of the $n-1$ boundary words for both targets. We propose two methods for handling this problem.

The first method, which we will dub the *joint* search method, is based on consecutively expanding the LM states of both T1 and T2. As shown in the illustration in Figure 3 (b), this means that each post-split search state will be annotated with boundary words from both targets. This is a natural and simple expansion of the standard search algorithm, simply using a more complicated representation of the LM state. On the other hand, because the new state space is the cross-product of all sets of boundary words in the two languages, the search space becomes significantly larger, with the side-effect of reducing the diversity of T1 translations for the same beam size. For example, in the figure, it can be seen that despite the fact that 3 hypotheses have been expanded, we only have 2 unique T1 LM states.

Our second method, which we will dub the *sequential* search method, first expands the state space of T1, then later expands the search space of T2. This procedure can be found in Figure 3 (c). It can be seen that by first expanding the T1 space we ensure diversity in the T1 search space, then additionally expand the states necessary for scoring with the T2 LM. On the other hand, if the T2 LM is important for creating high-quality translations, it is possible that the first pass of search will be less accurate and prune important hypotheses.

6 Experiments

6.1 Experimental Setup

We evaluate the proposed multi-target translation method through translation experiments on the MultiUN corpus (Eisele and Chen, 2010). We choose this corpus as it contains a large number of parallel documents in Arabic (ar), English (en), Spanish (es), French (fr), Russian (ru), and Chinese (zh), languages with varying degrees of similarity. We use English as our source sentence in all cases, as it is the most common actual source language for UN documents. To prepare the data, we first deduplicate the sentences in the corpus, then hold out 1,500 sentences each for tuning and test. In our basic training setup, we use 100k sentences for training both the TM and the T1 LM. This somewhat small

number is to simulate a T1 language that has relatively few resources. For the T2 language, we assume we have a large language model trained on all of the UN data, amounting to 3.5M sentences total.

As a decoder, we use the Travatar (Neubig, 2013) toolkit, and implement all necessary extensions to the decoder and rule extraction code to allow for multiple targets. Unless otherwise specified, we use joint search with a pop limit of 2,000, and T1 rule pruning with a limit of 10 rules per source rule. BLEU is used for both tuning and evaluating all models. In particular, we tune and evaluate all models based on T1 BLEU, simulating a situation similar to that in the introduction, where we want to use a large LM in T2 to help translation in T1. In order to control for optimizer instability, we follow Clark et al. (2011)'s recommendation of performing tuning 3 times, and reporting the average of the runs along with statistical significance obtained by pairwise bootstrap resampling (Koehn, 2004).

6.2 Main Experimental Results

In this section we first perform experiments to investigate the effectiveness of the overall framework of multi-target translation.

We assess four models, starting with standard single-target SCFGs and moving gradually towards our full MSCFG model:

SCFG: A standard SCFG grammar with only the source and T1.

SCFG+T2Al: SCFG constrained during rule extraction to only extract rules that also match the T2 alignments. This will help measure the effect, if any, of being limited by T2 alignments in rule extraction.

MSCFG-T2LM: The MSCFG, without using the T2 LM. Compared to SCFG+T2Al, this will examine the effect caused by adding T2 rules in scoring (Section 4.3) and pruning (Section 4.4) the rule table.

MSCFG: The full MSCFG model with the T2 LM.

The result of experiments using all five languages as T1, and the remaining four languages as T2 for all of these methods is shown in Table 1.

T1	T2	SCFG	SCFG +T2Al	MSCFG -T2LM	MSCFG

	ru		20.50	21.15	21.14

Table 1: Results for standard Hiero (SCFG), SCFG with T2 extraction constraints (SCFG+T2Al), a multi-SCFG minus the T2 LM (MSCFG-T2LM), and full multi-target translation (MSCFG). Bold indicates the highest BLEU score, and daggers indicate statistically significant gains over SCFG (†: $p < 0.05$, ‡: $p < 0.01$)

First, looking at the overall results, we can see that MSCFGs with one of the choices of T2 tends to outperform SCFG for all instances of T1. In particular, the gain for the full MSCFG model is large for the cases where the two target languages are French and Spanish, with en-fr/es achieving a gain of 1.46 BLEU points, and en-es/fr achieving a gain of 0.76 BLEU points over the baseline SCFG. This is followed by Arabic, Russian and Chinese, which all saw small gains of less than 0.3 when using Spanish as T2, with no significant difference for Chinese. This result indicates that multi-target MT has the potential to provide gains in T1 accuracy, particularly in cases where the languages involved are similar to each other.

It should be noted however, that positive results are sensitive to the languages chosen for T1 and T2,

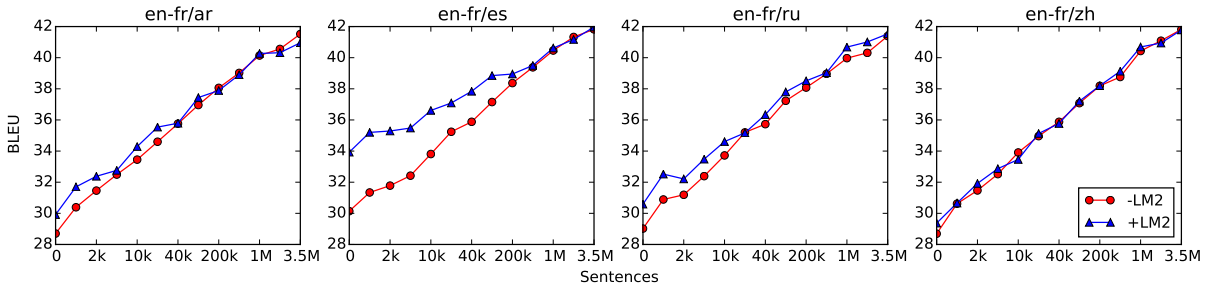

Figure 4: BLEU scores for different T1 LM sizes without (-LM2) or with (+LM2) an LM for the second target.

T2	SCFG	+T2Al
ar	223M	46.5M
es		134M
ru		70.8M
zh		26.0M

Table 2: Differences in rule table sizes for a T1 of French.

and in the cases involving Russian or Chinese, there is often even a drop in accuracy compared to the baseline SCFG. The reason for this can be seen by examining the results for SCFG+T2Al and MSCFG-T2LM. It can be seen that in the cases where there is an overall decrease in accuracy, this decrease can generally be attributed to a decrease when going from SCFG to SCFG+T2Al (indicating that rule extraction suffers from the additional constraints imposed by T2), or a decrease from SCFG+T2Al to MSCFG-LM2 (indicating that rule extraction suffers from fragmentation of the T1 translations by adding the T2 translation). On the other hand, we can see that in the majority of cases, going from MSCFG-LM2 to MSCFG results in at least a small gain in accuracy, indicating that a T2 LM is generally useful, after discounting any negative effects caused by a change in the rule table.

In Table 2 we show additional statistics illustrating the effect of adding a second language on the number of rules that can be extracted. From these results, we can see that all languages reduce the number of rules extracted, with the reduction being greater for languages with a larger difference from English and French, providing a convincing explanation for the drop in accuracy observed between these two settings.

6.3 Effect of T1 Language Model Strength

The motivation for multi-target translation stated in the introduction was that information about T2 may give us hints about the appropriate translation in T1. It is also a reasonable assumption that the less information we have about T1, the more valuable the information about T2 may be. To test this hypothesis, we next show results of experiments in which we vary the size of the training data for the T1 LM in intervals from 0 to 3.5M sentences. For T2, we either use no LM (MSCFG-T2LM) or an LM trained on 3.5M sentences (MSCFG). The results for when French is used as T1 are shown in Figure 4.

From these results, we can see that this hypothesis is correct. When no T1 LM is used, we generally see some gain in translation accuracy by introducing a strong T2 LM, with the exception of Chinese, which never provides a benefit. When using Spanish as T2, this benefit continues even with a relatively strong T1 LM, with the gap closing after we have 400k sentences of data. For Arabic and Russian, on the other hand, the gap closes rather quickly, with consistent gains only being found up to about 20-40k sentences. In general this indicates that the more informative the T2 LM is in general, the more T1 data will be required before the T2 LM is no longer able to provide additional gains.

6.4 Effect of Rule Pruning

Next we examine the effect of the rule pruning methods explained in Section 4.4. We set T1 to either French or Chinese, and use either the naive pruning criterion using T1+T2, or the criterion that picks the top translations in T1 along with their most probable T2 translation. Like previous experiments, we

use the top 10 rules for any particular F.

Results are shown in Table 3. From these results we can see that in almost all cases, pruning using T1 achieves better results. This indicates the veracity of the observation in Section 4.4 that considering multiple T2 for a particular T1 causes fragmentation of TM probabilities, and that this has a significant effect on translation results. Interestingly, the one exception to this trend is T1 of French and T2 of Spanish, indicating that with sufficiently similar languages, the fragmentation due to the introduction of T2 translations may not be as much of a problem.

It should be noted that in this section, we are using the joint search algorithm, and the interaction between search and pruning will be examined more completely in the following section.

6.5 Effect of Search

Next we examine the effect of the search algorithms suggested in Section 5. To do so, we perform experiments where we vary the search algorithm (joint or sequential), the TM pruning criterion (T1 or T1+T2), and the pop limit. For sequential search, we set the pop limit of T2 to be 10, as this value did not have a large effect on results. For reference, we also show results when using no T2 LM.

From the BLEU results shown in Figure 5, we can see that the best search algorithm depends on the pruning criterion and language pair.[6] In general, when trimming using T1, we achieve better results using joint search, indicating that maintaining T1 variety in the TM is enough to maintain search accuracy. On the other hand, when using the T1+T2 pruned model when T2 is Chinese, sequential search is better. This shows that in cases where there are large amounts of ambiguity introduced by T2, sequential search effectively maintains necessary T1 variety before expanding the T2 search space. As there is no general conclusion, an interesting direction for future work is search algorithms that can combine the advantages of these two approaches.

7 Related Work

While there is very little previous work on multi-target translation, there is one line of work by González and Casacuberta (2006) and Pérez et al. (2007), which adapts a WFST-based model to output multiple targets. However, this purely monotonic method is unable to perform non-local reordering, and thus is not applicable most language pairs. It is also motivated by efficiency concerns, as opposed to this work's objective of learning from a T2 language.

Factored machine translation (Koehn and Hoang, 2007) is also an example where an LM over a second

[6] Results for model score, a more direct measure of search errors, were largely similar.

stream of factors (for example POS tags, classes, or lemmas) has been shown to increase accuracy. These factors are limited, however, by the strong constraint of being associated with a single word and not allowing reordering, and thus are not applicable to our setting of using multiple languages.

There has also been work on using multiple languages to improve the quality of extracted translation lexicons or topic models (Mausam et al., 2009; Baldwin et al., 2010; Mimno et al., 2009). These are not concerned with multi-target translation, but may provide us with useful hints about how to generate more effective multi-target translation models.

8 Conclusion

In this paper, we have proposed a method for multi-target translation using a generalization of SCFGs, and proposed methods to learn and perform search over the models. In experiments, we found that these models are effective in the case when a strong LM exists in a second target that is highly related to the first target of interest.

As the overall framework of multi-target translation is broad-reaching, there are a still many challenges left for future work, a few of which we outline here. First, the current framework relies on data that is entirely parallel in all languages of interest. Can we relax this constraint and use comparable data, or apply MSCFGs to pivot translation? Second, we are currently performing alignment independently for each target. Can we improve results by considering all languages available (Lardilleux and Lepage, 2009)? Finally, in this paper we considered the case where we are only interested in T1 accuracy, but optimizing translation accuracy for two or more targets, possibly through the use of multi-metric optimization techniques (Duh et al., 2012) is also an interesting future direction.

Abstract

This paper describes a joint model of word segmentation and phonological alternations, which takes unsegmented utterances as input and infers word segmentations and underlying phonological representations. The model is a Maximum Entropy or log-linear model, which can express a probabilistic version of Optimality Theory (OT; Prince and Smolensky (2004)), a standard phonological framework. The features in our model are inspired by OT's Markedness and Faithfulness constraints. Following the OT principle that such features indicate "violations", we require their weights to be non-positive. We apply our model to a modified version of the Buckeye corpus (Pitt et al., 2007) in which the only phonological alternations are deletions of word-final /d/ and /t/ segments. The model sets a new state-of-the-art for this corpus for word segmentation, identification of underlying forms, and identification of /d/ and /t/ deletions. We also show that the OT-inspired sign constraints on feature weights are crucial for accurate identification of deleted /d/s; without them our model posits approximately 10 times more deleted underlying /d/s than appear in the manually annotated data.

1 Introduction

This paper unifies two different strands of research on word segmentation and phonological rule induction. The *word segmentation task* is the task of segmenting utterances represented as sequences of phones into sequences of words. This is an idealisation of the lexicon induction problem, since the resulting words are phonological forms for lexical entries.

In its simplest form, the data for a word segmentation task is obtained by looking up the words of an orthographic transcript (of, say, child-directed speech) in a pronouncing dictionary and concatenating the results. However, this formulation significantly oversimplifies the problem because it assumes that each token of a word type is pronounced identically in the form specified by the pronouncing dictionary (usually its citation form). In reality there is usually a significant amount of pronunciation variation from token to token.

The Buckeye corpus, on which we base our experiments here, contains manually-annotated surface phonetic representations of each word as well as the corresponding underlying form (Pitt et al., 2007). For example, a token of the word "lived" has the underlying form /l.ih.v.d/ and could have the surface form [l.ah.v] (we follow standard phonological convention by writing underlying forms with slashes and surface forms with square brackets, and use the Buckeye transcription format).

There is a large body of work in the phonological literature on inferring phonological rules mapping underlying forms to their surface realisations. While most of this work assumes that the underlying forms are available to the inference procedure, there is work that induces underlying forms as well as the phonological processes that map them to sur-

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 303–313,
Denver, Colorado, May 31 – June 5, 2015.

face forms (Eisenstat, 2009; Pater et al., 2012).

We present a model that takes a corpus of unsegmented surface representations of sentences and infers a word segmentation and underlying forms for each hypothesised word. We test this model on data derived from the Buckeye corpus where the only phonological variation consists of word-final /d/ and /t/ deletions, and show that it outperforms a state-of-the-art model that only handles word-final /t/ deletions.

Our model is a MaxEnt or log-linear model, which means that it is formally equivalent to a Harmonic Grammar, which is a continuous version of Optimality Theory (OT) (Smolensky and Legendre, 2005). We use features inspired by OT, and show that sign constraints on feature weights result in models that recover underlying /d/s significantly more accurately than models that don't include such contraints. We present results suggesting that these constraints simplify the search problem that the learner faces.

The rest of this paper is structured as follows. The next section describes related work, including previous work that this paper builds on. Section 3 describes our model, while section 4 explains how we prepared the data, presents our experimental results and investigates the effects of design choices on model performance. Section 5 concludes the paper and discusses possible future directions.

2 Background and related work

The *word segmentation task* is the task of segmenting utterances represented as sequences of phones into sequences of words. Elman (1990) introduced the word segmentation task as a simplified form of lexical acquisition, and Brent and Cartwright (1996) and Brent (1999) introduced the *unigram model of word segmentation*, which forms the basis of the model used here. Goldwater et al. (2009) described a non-parametric Bayesian model of word segmentation, and highlighted the importance of contextual dependencies. Johnson (2008) and Johnson and Goldwater (2009) showed that word segmentation accuracy improves when phonotactic constraints on word shapes are incorporated into the model. That model has been extended to also exploit stress cues (Börschinger and Johnson, 2014), the "topics" present in the non-linguistic context (Johnson et al., 2010) and the special properties of function words (Johnson et al., 2014).

Liang and Klein (2009) proposed a simple unigram model of word segmentation much like the original Brent unigram model, and introduced a "word length penalty" to avoid under-segmentation that we also use here. (As Liang et al note, without this the maximum likelihood solution is not to segment utterances at all, but to analyse each utterance as a single word). Berg-Kirkpatrick et al. (2010) extended this model by defining the unigram distribution with a MaxEnt model. The MaxEnt features can capture phonotactic generalisations about possible word shapes, and their model achieves a state-of-the-art word segmentation f-score.

The *phonological learning* task is to learn the phonological mapping from underlying forms to surface forms. Johnson (1984) and Johnson (1992) describe a search procedure for identifying underlying forms and the phonological rules that map them to surface forms given surface forms organised into inflectional paradigms. Goldwater and Johnson (2003) and Goldwater and Johnson (2004) showed how Harmonic Grammar phonological constraint weights (Smolensky and Legendre, 2005) can be learnt using a Maximum Entropy parameter estimation procedure given data consisting of underlying and surface word form pairs. There is now a significant body of work using Maximum Entropy techniques to learn phonological constraint weights (see esp. Hayes and Wilson (2008), as well as the review in Coetzee and Pater (2011)).

Recently there has been work attempting to integrate these two approaches. The word segmentation work generally ignores pronunciation variation by assuming that the input to the learner consists of sequences of citation forms of words, which is highly unrealistic. The phonology learning work has generally assumed that the learner has access to the underlying forms of words, which is also unrealistic.

In the word segmentation area, Elsner et al. (2012) and Elsner et al. (2013) generalise the Goldwater bigram model by assuming that the bigram model generates underlying forms, which a finite state transducer maps to surface forms. While this is an extremely general model, inference in such a model is very challenging, and they restrict attention to

transducers where the underlying to surface mapping consists of simple substitutions, so their model cannot handle the deletion phenomena studied here. Börschinger et al. (2013) also generalise the Goldwater bigram model by including an underlying-to-surface mapping, but their mapping only allows word-final underlying /t/ to be deleted, which enables them to use a straight-forward generalisation of Goldwater's Gibbs sampling inference procedure.

In phonology, Eisenstat (2009) and Pater et al. (2012) showed how to generalise a MaxEnt model so it also learns underlying forms as well as MaxEnt phonological constraint weights given surface forms in paradigm format. The vast sociolinguistic literature on /t/-/d/-deletion is surveyed in Coetzee and Pater (2011), together with prior OT and MaxEnt analyses of the phenomena.

2.1 The Berg-Kirkpatrick et al. model

This section contains a more technical description of the Berg-Kirkpatrick et al. (2010) MaxEnt unigram model of word segmentation, which our model directly builds on. Our model integrates the MaxEnt unigram word segmentation model of Berg-Kirkpatrick et al. with the MaxEnt phonology models developed by Goldwater and Johnson (2003) and Goldwater and Johnson (2004). Because both kinds of models are MaxEnt models, this integration is fairly easy, and the inference procedure requires optimisation of a fairly straight-forward objective function. We use a customised version of the OWLQN-LBFGS procedure (Andrew and Gao, 2007) that allows us to impose sign constraints on individual feature weights.

As is standard in the word-segmentation literature, the model's input is a sequence of utterances $D = (w_1, \ldots, w_n)$, where each utterance $w_i = (w_{i,1}, \ldots, w_{i,m_i})$ is a sequence of (surface) phones. The Berg-Kirkpatrick et al model is a unigram model, so it defines a probability distribution over possible words s, where s is also a sequence of phones. The probability of an utterance w is the sum of the probability of all word sequences that generate it:

$$\mathrm{P}(w \mid \theta) \;=\; \sum_{\substack{s_1 \ldots s_\ell \\ \text{s.t.} s_1 \ldots s_\ell = w}} \prod_{j=1}^{\ell} \mathrm{P}(s_j \mid \theta)$$

Berg-Kirkpatrick et al's model of word probabilities $\mathrm{P}(s \mid \theta)$ is a MaxEnt model with parameters θ, where the features $f(s)$ of surface form s are chosen to encourage the model to generalise appropriately over word shapes. While they don't describe their features in complete detail, they include features for each word s, features for the prefix and suffix of s and features for the CV skeleton of the prefix and suffix of s.

In more detail, $\mathrm{P}(s \mid \theta)$ is a MaxEnt model as follows:

$$\begin{aligned} \mathrm{P}(s \mid \theta) &= \frac{1}{Z} \exp(\theta \cdot f(s)), \text{ where:} \\ Z &= \sum_{s' \in \mathcal{S}} \exp(\theta \cdot f(s')) \end{aligned}$$

The set of possible surface word forms $\mathcal{S}$ is the set of substrings (i.e., sequences of phones) occuring in the training data D that are shorter than a user-specified length bound. We follow Berg-Kirkpatrick in imposing a length bound on possible words; for the Brent corpus the maximum word length is 10 phones, while for the Buckeye corpus the maximum word length is 15 phones (reflecting the fact that words are longer in this adult-directed corpus).

While restricting the set of possible word forms $\mathcal{S}$ to the substrings appearing in D is reasonable for a simple multinomial model like the one in Liang and Klein (2009), it's interesting that this produces good results with a MaxEnt model like Berg-Kirkpatrick et al's, since one might expect such a model would have to learn generalisations about *impossible word shapes* in order to perform well. Because $\mathcal{S}$ only contains a small fraction of the possible phone strings, one might worry that the model would not see enough "impossible words" to learn to distinguish possible words from impossible ones, but the model's good performance suggests this is not the case.[1]

[1] The non-parametric Bayesian approach of Goldwater et al. (2009) and Johnson (2008) can be viewed as setting $\mathcal{S}$ to the set of all possible phone strings (i.e., a possible word can be any string of phones, whether or not it appears in D). The success of Berg-Kirkpatrick et al's approach suggests that these non-parametric methods might not be necessary here, i.e., the set of substrings actually occuring in D is "large enough" to enable the model to learn "implicit negative evidence" generalisations about impossible word shapes.

Berg-Kirkpatrick et al follow Liang et al in using maximum likelihood estimation to estimate their model's parameters (Berg-Kirkpatrick et al actually use L_2-regularised maximum likelihood estimates). As Liang et al note, it's easy to show that the maximum likelihood segmentation leaves each utterance unsegmented, i.e., each utterance is analysed as a single word. To avoid this, Berg-Kirkpatrick et al follow Liang et al by multiplying the word probabilities by a *word length penalty* term. Thus the likelihood L_D they actually maximise is as shown below:

$$L_D(\theta) = \prod_{i=1}^{n} \mathrm{P}(w_i \mid \theta)$$

$$\mathrm{P}(w \mid \theta) = \sum_{\substack{s_1 \ldots s_\ell \\ \text{s.t.} s_1 \ldots s_\ell = w}} \prod_{j=1}^{\ell} \mathrm{P}(s_j \mid \theta) \exp(-|s_i|^d)$$

where d is a constant chosen to optimise segmentation performance. This means that the model is deficient, i.e., $\sum_{s \in \mathcal{S}} \mathrm{P}(s \mid \theta) < 1$. (Because our model uses a word length penalty in the same way, it too is deficient).

As Figure 1 shows, performance is very sensitive to the word length penalty parameter d: the best word segmentation on the Brent corpus is obtained when $d \approx 1.6$, while the best segmentation on the Buckeye corpus is obtained when $d \approx 1.5$. As far as we know there is no principled way to set d in an unsupervised fashion, so this sensitivity to d is perhaps the greatest weakness of this kind of model.

Even so, it's interesting that a unigram model without the kind of inter-word dependencies that Goldwater et al. (2009) argues for can do so well. It's possible that the improvement that Goldwater et al found with the bigram model is because modelling individual bigram dependencies splits the data in a way that reduces overlearning (Börschinger et al., 2012).

3 A MaxEnt unigram model of word segmentation and word-final /d/ and /t/ deletion

This section explains how we extend the Berg-Kirkpatrick et al. (2010) model to handle a set $\mathcal{P}$ of phonological processes, where a phonological process $p \in \mathcal{P}$ is a partial, non-deterministic function

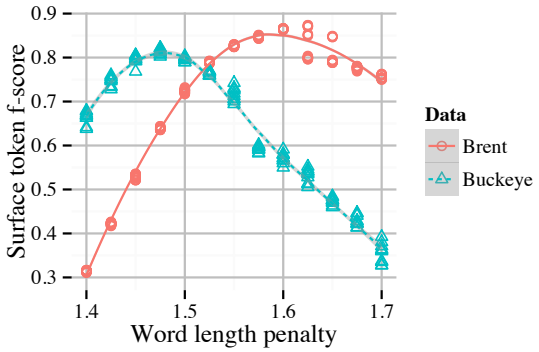

Figure 1: Sensitivity of surface token f-score to word length penalty factor d for the Brent and Buckeye corpora on data with no /d/ or /t/ deletions. Performance is sensitive to the value of the word length penalty d, and the optimal value of d depends on the corpus.

mapping underlying forms to surface forms. For example, word-final /t/ deletion is the function mapping underlying underlying forms ending in /t/ to surface forms lacking that final segment.

Our model is also a unigram model, but it defines a distribution over pairs (s, u) of surface/underlying form pairs, where s is a surface form and u is an underlying form. Below we allow this distribution to condition on phonological properties of the neighbouring surface forms.

The set $\mathcal{X}$ of possible (s, u) surface/underlying form pairs is defined as follows. For each surface form $s \in \mathcal{S}$ (the set of length-bounded phone substrings of the data D), $(s, s) \in \mathcal{X}$. In addition, if $u \in \mathcal{S}$ and some phonological alternation $p \in \mathcal{P}$ maps u to a surface form $s \in p(u) \in \mathcal{S}$, then $(s, u) \in \mathcal{X}$. That is, we require that potential underlying forms appear as surface substrings somewhere in the data D (which means this model cannot handle e.g., absolute neutralisation).

In the experiments below, we let $\mathcal{P}$ be phonological processes that delete word-final /d/ and /t/ phonemes. Given the Buckeye data, ([l.ih.v], /l.ih.v/), ([l.ih.v], /l.ih.v.d/) and ([l.ih.v], /l.ih.v.t/) are all members of $\mathcal{X}$ (i.e., candidate (s, u) pairs), corresponding to "live", "lived" and the non-word "livet" respectively, where the latter two surface forms are generated by final /d/ and /t/ deletion respectively.

Word-final /d/ and /t/ deletion depends on various aspects of the phonological context, such as

whether the following word begins with a consonant or a vowel. Our model handles this dependency by learning a conditional model over surface/underlying form pairs $(s, u) \in \mathcal{X}$ that depends on the phonological context c:

$$\begin{aligned} \mathrm{P}(s, u \mid c, \theta) &= \frac{1}{Z_c} \exp(\theta \cdot f(s, u, c)), \text{ where:} \\ Z_c &= \sum_{(s,u) \in \mathcal{X}} \exp(\theta \cdot f(s, u, c)) \end{aligned}$$

In our experiments below, the set of possible contexts is $\mathcal{C} = \{\mathrm{C}, \mathrm{V}, \#\}$, encoding whether the following word begins with a consonant, a vowel or is the end of the utterance respectively. We leave for future research the exploration of other sorts of contextual conditioning. Note that the set $\mathcal{X}$ is the same for all contexts c; we show below that restricting attention to just those surface/underlying pairs appearing in the context c degrades the model's performance. In other words, the model benefits from the implicit negative evidence provided by underlying/surface pairs that do not occur in a given context.

We define the probability of a surface form $s \in \mathcal{S}$ in a context $c \in \mathcal{C}$ by marginalising out the underlying form:

$$\mathrm{P}(s \mid c, \theta) = \sum_{u:(s,u) \in \mathcal{X}} \mathrm{P}(s, u \mid c, \theta)$$

We optimise a penalised log likelihood $Q_D(\theta)$, with the word length penalty term d applied to the underlying form u.

$$\begin{aligned} Q(s \mid c, \theta) &= \sum_{u:(s,u) \in \mathcal{X}} \mathrm{P}(s, u \mid c, \theta) \exp(-|u|^d) \\ Q(w \mid \theta) &= \sum_{\substack{s_1 \ldots s_\ell \\ \text{s.t.} s_1 \ldots s_\ell = w}} \prod_{j=1}^{\ell} Q(s_j \mid c, \theta) \\ Q_D(\theta) &= \sum_{i=1}^{n} \log Q(w_i \mid \theta) - \lambda \|\theta\|_1 \end{aligned}$$

We are somewhat cavalier about the conditional contexts c here: in our model below the context c for a word is determined by the following word, so one can view our model as a generative model that generates the words in an utterance from right to left.

Because our model is a MaxEnt model, we have considerable freedom in the choice of features, and as Berg-Kirkpatrick et al. (2010) emphasise, the choice of features directly determines the kinds of generalisations the model can learn. The features $f(s, u, c)$ of a surface form s, underlying form u and context c we use here are inspired by OT. We describe our features using an example where $s =$ [l.ih.v], $u =$ /l.ih.v.t/ and $c =$ C (i.e., the word is followed by a consonant).

Underlying form lexical features: A feature for each underlying form u. In our example, the feature is `<U l ih v t>`. These features enable the model to learn language-specific lexical entries. There are 4,803,734 underlying form lexical features (one for each possible substring in the training data).

Surface markedness features: The length of the surface string (`<#L 3>`), the number of vowels (`<#V 1>`) (this is a rough indication of the number of syllables), the surface suffix (`<Suffix v>`), the surface prefix and suffix CV shape (`<CVPrefix CV>` and `<CVSuffix VC>`), and suffix+context CV shape (`<CVContext _C>` and `<CVContext C _C>`). There are 108 surface markedness features.

Faithfulness features: A feature for each divergence between underlying and surface forms (in this case, `<*F t>`). There are two faithfulness features.

We used L_1 regularisation here, rather than the L_2 regularisation used by Berg-Kirkpatrick et al. (2010), in the hope that its sparsity-inducing "feature selection" capabilities would enable it to "learn" lexical entries for the language, as well as precisely which markedness features are required to account for the data. However, we found that the choice of L_1 versus L_2 regression makes little difference, and the model is insensitive to the value of the regulariser constant λ (we set to $\lambda = 1$ in the experiments below).

We developed a specially modified version of the LBFGS-OWLQN optimisation procedure for optimising L_1-regularised loss functions (Andrew and

Gao, 2007) that allows us to constrain certain feature weights θ_k to have a particular sign. This is a natural extension of the LBFGS-OWLQN procedure since it performs orthant-constrained line searches in any case. We describe experiments below where we require the feature weights for the markedness and faithfulness features to be non-positive, and where the underlying lexical form features are required to be non-negative. The requirement that the lexical form features are positive, combined with the sparsity induced by the L_1 regulariser, was intended to force the model to learn an explicit lexicon encoded by the underlying form features with positive weights (although our results below suggest that it did not in fact do this).

The inspiration for the requirement that markedness and faithfulness features are non-positive comes from OT, which claims that the presence of such features can only reduce the "harmony", i.e., the well-formedness, of an (s, u) pair. Versions of Harmonic Grammar that aim to produce OT-like behavior with weighted constraints often bound weights at zero (see e.g. Pater (2009)). The results below are the first to show that these constraints matter for word segmentation.

4 Experimental results

This section describes the experiments we performed to evaluate the model just described. We first describe how we prepared the data on which the model is trained and evaluated, and then we describe the performance of that model. Finally we perform an analysis of how the model's performance varies as parameters of the model are changed.

We ran this model on data extracted from the Buckeye corpus of conversational speech (Pitt et al., 2007) which was modified so the only alternations it contained are final /d/ and /t/ deletions. The Buckeye corpus gives a surface realisation and an underlying form for each word token, and following Börschinger et al. (2013), we prepared the data as follows. We used the Buckeye underlying forms as our underlying forms. Our surface forms were also identical to the Buckeye underlying forms, except when the underlying form ends in either a /d/ or a /t/. In this case, if the Buckeye surface form does not end in an allophonic variant of that segment, then our surface form consists of the Buckeye underlying form with that final segment deleted. Thus the only phonological variation in our data are deletions of word-final /d/ and /t/ appearing in the Buckeye corpus, otherwise our surface forms are identical to Buckeye underlying forms.

For example, consider a token whose Buckeye underlying form is /l.ih.v.d/ "lived". If the Buckeye surface form is [l.ah.v] then our surface form would be [l.ih.v], while if the Buckeye surface form is [l.ah.v.d] then our surface form would be [l.ih.v.d].

We now present some descriptive statistics on our data. The data contains 48,796 sentences and 890,597 segments. The longest sentence has 187 segments. The "gold" data has the following properties. There are 236,996 word boundaries, 285,792 word tokens, and 9,353 underlying word types. The longest word has 17 segments. Of the 41,186 /d/s and 73,392 /t/s in the underlying forms, 24,524 /d/s and 40,720 /t/s are word final, and of these 13,457 /d/s and 11,727 /t/s are deleted (i.e., do not appear on the surface).

Our model considers all possible substrings of length 15 or less as a possible surface form of a word, yielding 4,803,734 possible word types and 5,292,040 possible surface/underlying word type pairs. Taking the 3 contexts derived from the following word into account, there are 4,969,718 possible word+context types. When all possible surface/underlying pairs are considered in all possible contexts there are 15,876,120 possible surface/underlying/context triples.

Table 1 summarises the major experimental results for this model, and compares them to the results of Börschinger et al. (2013). Note that their model only recovers word-final /t/ deletions and was run on data without word-final /d/ deletions, so it is solving a simpler problem than the one studied here. Even so, our model achieves higher overall accuracies.

We also conducted experiments on several of the design choices in our model. Figure 2 shows the effect of the sign constraints on feature weights discussed above. This plot shows that the contraints on the weights of markedness and faithfulness features seems essential for good word segmentation performance. Interestingly, we found that the weight constraints make very little difference if the data does

	Börschinger et al. 2013	Our model
Surface token f-score	0.72	**0.76** (0.01)
Underlying type f-score	—	0.37 (0.02)
Deleted /t/ f-score	0.56	**0.58** (0.03)
Deleted /d/ f-score	—	0.62 (0.19)

Table 1: Results summary for our model compared to that of the Börschinger et al. (2013) model. Surface token f-score is the standard token f-score, while underlying type or "lexicon" f-score measures the accuracy with which the underlying word types are recovered. Deleted /t/ and /d/ f-scores measure the accuracy with which the model recovers segments that don't appear in the surface. These results are averaged over 40 runs (standard deviations in parentheses) with the word length penalty $d = 1.525$ applied to underlying forms; standard deviations are given in parentheses.

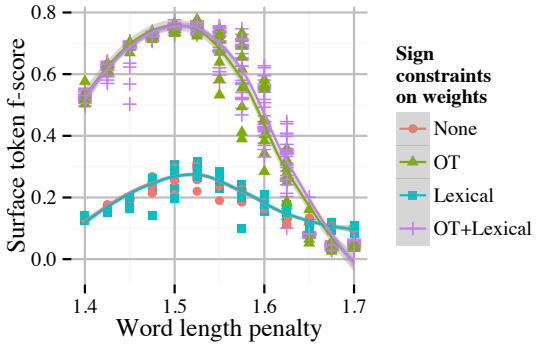

Figure 2: The effect of constraints on feature weights on surface token f-score. "OT" indicates that the markedness and faithfulness features are required to be non-positive, while "Lexical" indicates that the underlying lexical features are required to be non-negative.

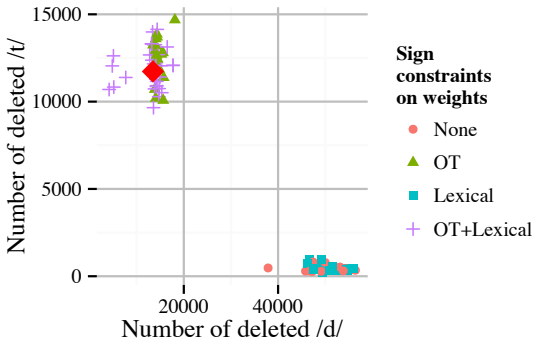

Figure 3: The effect of constraints feature weights on the number of deleted underlying /d/ and /t/ segments posited by the model (d = 1.525). The red diamond indicates the 13,457 deleted underlying /d/ and 11,727 deleted underlying /t/ in the "gold" data.

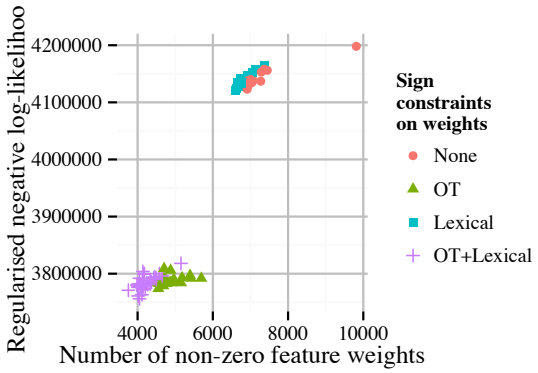

Figure 4: The regularised log-likelihood as a function of the number of non-zero weights for different constraints on feature weights ($d = 1.525$).

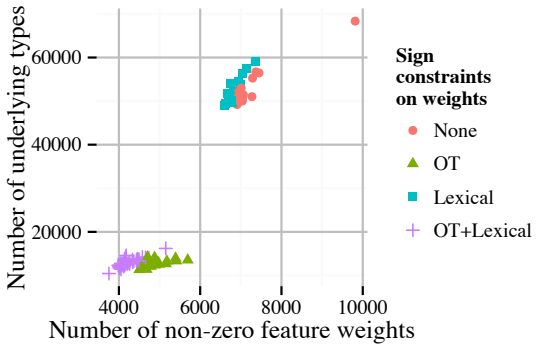

Figure 5: The number of underlying types proposed by the model as a function of the number of non-zero weights, for different constraints on feature weights ($d = 1.525$). There are 9,353 underlying types in the "gold" data.

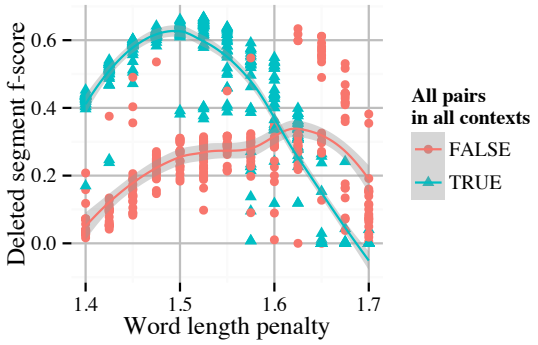

Figure 6: F-score for deleted /d/ and /t/ recovery as a function of word length penalty d and whether all surface/underlying pairs $\mathcal{X}$ are included in all contexts $\mathcal{C}$ ($d = 1.525$).

not any /t/ or /d/ deletions (i.e., the case that Berg-Kirkpatrick et al. (2010) studied).

Investigating this further, we found that the weight constraints on the markedness and faithfulness features has a dramatic effect on the recovery of underlying segments, particularly underlying /d/s. Figure 3 shows that with these constraints the model recovers approximately the correct number of deleted underlying segments, while without this constraint the model posits far too many underlying /d/s. Figure 4 shows that these constraints help the model find higher regularised likelihood sets of feature weights with fewer non-zero feature weights.

We examined how the number of non-zero feature weights (most of which are for underlying type features) relate to the number of underlying types posited by the model. Figure 5 shows that the weight constraints on markedness and faithfulness constraints have great impact on the number of non-zero feature weights and on the number of underlying forms the model posits. In all cases, the model recovers far more underlying forms than it finds non-zero weights.

The lexicon weight constraints have much less impact than the OT weight constraints. As Figure 3 shows, without the OT weight constraints the models posit too many deleted /d/ and essentially no deleted /t/. Figure 4 shows that OT weight constraints enable the model to find higher likelihood solutions, i.e., the OT weight constraints help search. Inspired by a reviewer's comments, we studied type-token ratios and the number of boundaries our models posit. We found that the models without OT weight constraints posit far too few word boundaries compared to the gold data, so the number of surface tokens is too low, so the words are too long, and the number of underlying types is too high. This is consistent with Figures 4–5.

We also examined whether it is necessary to consider all surface/underlying pairs $\mathcal{X}$ in each context $\mathcal{C}$, or whether it is possible to restrict attention to the much smaller sets $\mathcal{X}_c$ that occur in each $c \in \mathcal{C}$ (this dramatically reduces the amount of memory required and speeds the computation). Figure 6 shows that working with the smaller, context-specific sets dramatically decreases the model's ability to recover deleted segments.

5 Conclusions and future work

The MaxEnt unigram model of word segmentation developed by Berg-Kirkpatrick et al. (2010) integrates straight-forwardly with the MaxEnt phonology models of Goldwater and Johnson (2003) to produce a MaxEnt model that jointly models word segmentation and the mapping from underlying to surface forms.

We tested our model on data derived from the manually-annotated Buckeye corpus of conversational speech (Pitt et al., 2007) in which the only phonological alternations are deletions of word-final /d/ and /t/ segments. We demonstrated that our model improves on the state-of-the-art for word seg-

mentation, recovery of underlying forms and recovery of deleted segments for this corpus.

Our model is a MaxEnt or log-linear unigram model over the set of possible surface/underlying form pairs. Inspired by the work of Berg-Kirkpatrick et al. (2010), the set of surface/underlying form pairs our model calculates the partition function over is restricted to those actually appearing in the training data, and doesn't include all logically possible pairs. We found that even with this restriction, the model produces good results.

Because our model is a Maximum Entropy or log-linear model, it is formally an instance of a Harmonic Grammar (Smolensky and Legendre, 2005), so we investigated features inspired by OT, which is a discretised version of Harmonic Grammar that has been extensively developed in the linguistics literature. The features our model uses consist of underlying form features (one for each possible underlying form), together with markedness and faithfulness phonological features inspired by OT phonological analyses. According to OT, these markedness and faithfulness features should always have negative weights (i.e., when such a feature "fires", it should always make the analysis less probable). We found that constraining feature weights in this way dramatically improves the model's accuracy, apparently helping to find higher likelihood solutions.

Looking forwards, a major drawback of the MaxEnt approaches to word segmentation are their sensitivity to the *word length penalty* parameter, which this model shares with the models of Berg-Kirkpatrick et al. (2010) and (Liang and Klein, 2009) on which it is based. It would be very desirable to have a principled way to set this parameter in an unsupervised manner.

Because our goal was to explore the MaxEnt approach to joint segmenation and alternation, we deliberately used a minimal feature set here. As the reviewers pointed out, we did not include any morphological features, which could have a major impact on the model. Investigating the impact of richer feature sets, including a combination of phonotactic and morphological features, would be an excellent topic for future work.

It would be interesting to extend this approach to a wider range of phonological processes in addition to the word-final /t/ and /d/ deletion studied here. Because this model enumerates the possible surface/underlying/context triples before beginning to search for potential surface and underlying words, its memory requirements would grow dramatically if the set of possible surface/underlying alternations were increased. (The fact that we only considered word final /d/ and /t/ deletions means that there are only three possible underlying word forms for each surface word forms). Perhaps there is a way of identifying potential underlying forms that avoids enumerating them. For example, it might be possible to sample possible underlying word forms during the learning process rather than enumerating them ahead of time, perhaps by adapting non-parametric Bayesian approaches (Goldwater et al., 2009; Johnson and Goldwater, 2009; Börschinger et al., 2013).

Abstract

One of the weaknesses of current supervised word sense disambiguation (WSD) systems is that they only treat a word as a discrete entity. However, a continuous-space representation of words (word embeddings) can provide valuable information and thus improve generalization accuracy. Since word embeddings are typically obtained from unlabeled data using unsupervised methods, this method can be seen as a semi-supervised word sense disambiguation approach. This paper investigates two ways of incorporating word embeddings in a word sense disambiguation setting and evaluates these two methods on some SensEval/SemEval lexical sample and all-words tasks and also a domain-specific lexical sample task. The obtained results show that such representations consistently improve the accuracy of the selected supervised WSD system. Moreover, our experiments on a domain-specific dataset show that our supervised baseline system beats the best knowledge-based systems by a large margin.

1 Introduction

Because of the ambiguity of natural language, many words can have different meanings in different contexts. For example, the word "bank" has two different meanings in "the bank of a river" and "a bank loan". While it seems simple for humans to identify the meaning of a word according to the context, word sense disambiguation (WSD) (Ng and Lee, 1996; Lee and Ng, 2002) is a difficult task for computers and thus requires sophisticated means to achieve its goal. Part of this ambiguity may be resolved by considering part-of-speech (POS) tags but the word senses are still highly ambiguous even for the same part-of-speech. Machine translation is probably the most important application of word sense disambiguation. In machine translation, different senses of a word cause a great amount of ambiguity for automated translation and it negatively affects the results. Hence, an accurate WSD system can benefit machine translation significantly and improve the results (Chan et al., 2007; Carpuat and Wu, 2007; Vickrey et al., 2005). Moreover, Zhong and Ng (2012) have shown that word sense disambiguation improves information retrieval by proposing a method to use word senses in a language modeling approach to information retrieval.

The rest of this paper is organized as follows. Section 2 gives a literature review of related work, including a review of semi-supervised word sense disambiguation and distributed word representation called word embeddings. The method and framework used in this paper are explained in Section 3. Finally, we evaluate the system in Section 4 and conclude the paper in Section 5.

2 Related Work

The method that we use in this paper is a semi-supervised learning method which incorporates knowledge from unlabeled datasets by using word embeddings. This section is a literature review of previous work on semi-supervised word sense disambiguation and various methods of obtaining word embeddings.

2.1 Semi-Supervised Word Sense Disambiguation

Among various types of semi-supervised learning approaches, *co-training* and *self-training* are probably the most common. These methods randomly select a subset of a large unlabeled dataset and classify these samples using one (self-training) or two (co-training) classifiers, trained on a smaller set of labeled samples. After assigning labels to the new samples, these methods select the samples that were classified with a high confidence (according to a selection criterion) and add them to the set of labeled data. These methods have been used in the context of word sense disambiguation. Mihalcea (2004) used both co-training and self-training to make use of unlabeled datasets for word sense disambiguation. Mihalcea also introduced a technique for combining co-training and majority voting, called *smoothed co-training*, and reported improved results. Another related study was done by (Pham et al., 2005). In (Pham et al., 2005), some semi-supervised learning techniques were used for word sense disambiguation. Pham et al. employed co-training and spectral graph transduction methods in their experiments and obtained significant improvements over a supervised method.

Another semi-supervised learning method used for word sense disambiguation is Alternating Structure Optimization (ASO), first introduced by (Ando and Zhang, 2005) and later applied to word sense disambiguation tasks by (Ando, 2006). This algorithm learns a predictive structure shared between different problems (disambiguation of a target word). Semi-supervised application of the ASO algorithm was shown to be useful for word sense disambiguation and improvements can be achieved over a supervised predictor (Ando, 2006).

This paper uses a different method proposed by (Turian et al., 2010) that can be applied to a wide variety of supervised tasks in natural language processing. This method uses distributed word representations (word embeddings) as additional feature functions in supervised tasks and is shown to improve the accuracy of named-entity recognition (NER) and chunking. In this paper, we also follow the same approach for word sense disambiguation. The key idea is that a system without a continuous-space representation of words ignores the similarity of words completely and relies only on their discrete form. However, when a distributed representation for words is added to the system, the classifier can make use of the notion of *similarity* of words and learn the relationships between class labels and words.

In addition to using *raw* word embeddings, we also propose a method to *adapt* embeddings for each classification task. Since word embeddings do not include much task-specific discriminative information, we use a neural network to modify word vectors to tune them for our WSD tasks. We show that this process results in improved accuracy compared to raw word embeddings.

Recently, obtaining word embeddings in an unsupervised manner from large text corpora has attracted the attention of many researchers (Collobert and Weston, 2008; Mnih and Hinton, 2009; Mikolov et al., 2013a; Mikolov et al., 2013b). Subsequently, there have been some published word embeddings and some software for training word embeddings.

For word sense disambiguation, there are very few open source programs. Since we are interested in a fully supervised WSD tool, IMS (It Makes Sense) (Zhong and Ng, 2010) is selected in our work. This system allows addition of extra features in a simple way and hence is a good choice for testing the effect of word embeddings as additional features. Moreover, the scores reported for IMS are competitive with or better than state-of-the-art systems (Zhong and Ng, 2010).

2.2 Word Embeddings

There are several types of word representations. A *one-hot* representation is a vector where all components except one are set to zero and the component at the index associated with a word is set to one. This type of representation is the sparsest word representation and does not carry any information about word similarity. Another popular approach is to use the methods mainly applied in information retrieval. Latent Semantic Analysis (LSA) and Latent Dirichlet Allocation (LDA) are such examples, and word representations produced by these methods can also be used in other applications. However, a dense distributed representation for words (word embeddings) can learn more complex relationships

between words and hence, it can be useful in a wide range of applications. We only focus on word embeddings in this paper and apply them to word sense disambiguation.

Word embeddings are distributed representations of words and contain some semantic and syntactic information (Mikolov et al., 2013c). Such representations are usually produced by neural networks. Examples of such neural networks are (log-)linear networks (Mikolov et al., 2013a), deeper feed-forward neural networks (Bengio et al., 2003; Collobert and Weston, 2008), or recurrent neural networks (Mikolov et al., 2010). Moreover, it has been shown that deep structures may not be needed for word embeddings estimation (Lebret et al., 2013) and shallow structures can obtain relatively high quality representations for words (Mikolov et al., 2013b).

In this paper, we have used the word embeddings created and published by (Collobert and Weston, 2008). Throughout this paper, we refer to these word embeddings as 'CW'. This method is proposed in (Collobert and Weston, 2008) and explained further in (Collobert et al., 2011). The authors use a feed-forward neural network to produce word representations. In order to train the neural network, a large text corpus is needed. Collobert and Weston (2008) use Wikipedia (Nov. 2007 version containing 631 million words) and Reuters RCV1 (containing 221 million words) (Lewis et al., 2004) as their text corpora and Stochastic Gradient Descent (SGD) as the training algorithm. The training algorithm selects a window of text randomly and then replaces the middle word with a random word from the dictionary. Then the original window of text and the corrupted one is given to the neural network. The neural network computes $f(x)$ and $f(x^{(w)})$, where x is the original window of text, $x^{(w)}$ is the same window of text with the middle word replaced by word w, and $f(.)$ is the function that the neural network represents. After computing $f(x)$ and $f(x^{(w)})$, the training algorithm uses a *pairwise ranking* cost function to train the network. The training algorithm minimizes the cost function by updating the parameters (including word embeddings) and as a consequence of using the pairwise ranking cost function, this neural network tends to assign higher scores to *valid* windows of texts and lower scores to *incorrect* ones. After training the neural network, the word vectors in the lookup table layer form the word embeddings matrix. Collobert et al. (2011) have made this matrix available for public use and it can be accessed online[1].

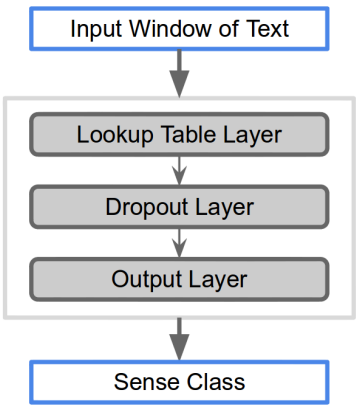

Figure 1: The neural network architecture for adaptation of word embeddings.

3 Method

In this section, we first explain our novel task-specific method of *adapting* word embeddings and then describe our framework in which raw or adapted word embeddings are included in our word sense disambiguation system. To the best of our knowledge, the use of word embeddings for semi-supervised word sense disambiguation is novel.

3.1 Adaptation of Word Embeddings

Word embeddings capture some semantic and syntactic information and usually similar words have similar word vectors in terms of distance measures. However, in a classification task, it is better for word embeddings to also include some task specific discriminative information. In order to add such information to word embeddings, we modify word vectors using a neural network (Figure 1) to obtain *adapted* word embeddings. This section explains this process in detail.

The neural network that we used to adapt word embeddings is similar to the *window approach* network introduced by (Collobert and Weston, 2008). This neural network includes the following layers:

[1] http://ml.nec-labs.com/senna

- Lookup table layer: This layer includes three lookup tables. The first lookup table assigns a vector to each input word, as described earlier. The second lookup table maps each word to a vector with respect to the capitalization feature. Finally, the third lookup table maps each word to its corresponding vector based on the word's POS tag.

- Dropout layer: In order to avoid overfitting, we added a dropout layer (Hinton et al., 2012) to the network to make use of its regularization effect. During training, the dropout layer copies the input to the output but randomly sets some of the entries to zero with a probability p, which is usually set to 0.5. During testing, this layer produces the output by multiplying the input vector by $1 - p$ (see (Hinton et al., 2012) for more information).

- Output layer: This layer linearly maps the input vector X to a C-dimensional vector Y (equation 1) and then applies a SoftMax operation (Bridle, 1990) over all elements of Y (equation 2):

$$Y = WX + b \quad (1)$$

$$p(t|I) = \frac{\exp(Y_t)}{\sum_{j=1}^{C} \exp(Y_j)} \qquad 1 \leq t \leq C \quad (2)$$

  where I is the input window of text and t is a class label (sense tag in WSD). The output of the output layer can be interpreted as a conditional probability $p(t|I)$ over tags given the input text.

This architecture is similar to the network used by (Collobert and Weston, 2008) but it does not include a hidden layer. Since the number of training samples for each word type in WSD is relatively small, we did not use a hidden layer to decrease the model size and consequently overfitting, as much as possible. Moreover, we added the dropout layer and observed increased generalization accuracy subsequently.

In order to train the neural network, we used Stochastic Gradient Descent (SGD) and error back-propagation to minimize negative log-likelihood cost function for each training example (I, t) (equation 3).

$$-\log p(t|I) = \log(\sum_{j=1}^{C} exp(Y_j)) - Y_t \quad (3)$$

During the training process, the inputs are the windows of text surrounding the target word with their assigned POS tags. We used fixed learning rate (0.01) during training, with no momentum.

Since the objective is to adapt word embeddings using the neural network, we initialized the lookup table layer parameters using pre-trained word embeddings and trained a model for each target word type. After the training process completes, the modified word vectors form our adapted word embeddings, which will be used in exactly the same way as the original embeddings. Section 3.2 explains the way we use word embeddings to improve a supervised word sense disambiguation system.

3.2 Framework

The supervised system that we used for word sense disambiguation is an open source tool named IMS (Zhong and Ng, 2010). This software extracts three types of features and then uses Support Vector Machines (SVM) as the classifier. The three types of features implemented in IMS are explained below.

- POS tags of surrounding words: IMS uses the POS tags of all words in a window size of 7, surrounding the target ambiguous word. POS tag features are limited to the current sentence and neighboring sentences are not considered.

- Surrounding words: Additionally, the surrounding words of a target word (after removing stop words) are also used as features in IMS. However, unlike POS tags, the words occurring in the immediately adjacent sentences are also included.

- Local collocations: Finally, 11 local collocations around the target word are considered as features. These collocations also cover a window size of 7, where the target word is in the middle.

All mentioned features are binary features and will be used by the classifier in the next phase. After extracting these features, the classifier (SVM) is

used to train a model for each target word. In the test phase, the model is used to classify test samples and assign a sense tag to each sample.

This supervised framework with separate feature extraction and classification phases makes it easy to add any number of features and in our case, word embeddings. In order to make use of word embeddings trained by a neural network, we follow the approach of (Turian et al., 2010) and include word embeddings for all words in the surrounding window of text, given a target ambiguous word. We use the words from immediately adjacent sentences if the window falls beyond the current sentence boundaries. Since each word type has its own classification model, we do not add the word embeddings for the target word because the same vector will be used in all training and test samples and will be useless.

After extraction of the three mentioned types of features, $d.(w-1)$ features will be added to each sample, where d is the word embeddings dimension and w is the number of words in the window of text surrounding the target word (window size). w is one of the hyper-parameters of our system that can be tuned for each word type separately. However, since the training sets for some of the benchmark tasks are small, tuning the window size will not be consistent over different tuning sets. Thus, we decided to select the same window size for all words in a task and tune this parameter on the whole tuning set instead. After augmenting the features, a model is trained for the target word and then the classifier can be used to assign the correct sense to each test sample.

However, since the original three types of features are binary, newly added real-valued word embeddings do not fit well into the model and they tend to decrease performance. This problem is addressed in (Turian et al., 2010) and a simple solution is to scale word embeddings. The following conversion is suggested by (Turian et al., 2010):

$$E \leftarrow \sigma \cdot E / stddev(E) \tag{4}$$

where σ is a scalar hyper-parameter denoting the desired standard deviation, E is the word embeddings matrix and $stddev(.)$ is the standard deviation function, which returns a scalar for matrix E. However, different dimensions of word embedding vectors may have different standard deviations and Equation 4 may not work well. In this case, per-dimension scaling will make more sense. In order to scale the word embeddings matrix, we use Equation 5 in our experiments:

$$E_i \leftarrow \sigma \cdot E_i / stddev(E_i), \quad i : 1, 2, ..., d \tag{5}$$

where E_i denotes the i^{th} dimension of word embeddings. Like (Turian et al., 2010), we also found that $\sigma = 0.1$ is a good choice for the target standard deviation and works well.

4 Results and Discussion

We evaluate our word sense disambiguation system experimentally by using standard benchmarks. The two major tasks in word sense disambiguation are *lexical sample task* and *all-words task*. For each task, we explain our experimental setup first and then present the results of our experiments for the two mentioned tasks. Although most benchmarks are general domain test sets, a few domain-specific test sets also exist (Koeling et al., 2005; Agirre et al., 2010).

4.1 Lexical Sample Tasks

We have evaluated our system on SensEval-2 (SE2) and SensEval-3 (SE3) lexical sample tasks and also the domain-specific test set (we call it DS05) published by (Koeling et al., 2005). This subsection describes our experiments and presents the results of these tasks.

4.1.1 Experimental Setup

Most lexical sample tasks provide separate training and test sets. Some statistics about these tasks are given in Table 1.

	SE2	**SE3**	**DS05**
#Word types	73	57	41
#Training samples	8,611	8,022	-
#Test samples	4,328	3,944	10,272

Table 1: Statistics of lexical sample tasks

The DS05 dataset does not provide any training instances. In order to train models for DS05 (and later for the SE3 all-words task), we generated training samples for the top 60% most frequently occurring polysemous content words in Brown Corpus,

using the approach described in (Ng et al., 2003; Chan and Ng, 2005). This dataset is automatically created by processing parallel corpora without any manual sense annotation effort. We used the following six English-Chinese parallel corpora: Hong Kong Hansards, Hong Kong News, Hong Kong Laws, Sinorama, Xinhua News, and the English translations of Chinese Treebank. Similar to (Zhong and Ng, 2010), we obtained word alignments using GIZA++ (Och and Ney, 2000). Then, for each English word, the aligned Chinese word is used to find the corresponding sense tag for the English word. Finally, we made use of examples from the DSO corpus (Ng and Lee, 1996) and SEMCOR (Miller et al., 1994) as part of our training data. Table 2 shows some statistics of our training data.

POS	#word types
Adj.	5,129
Adv.	28
Noun	11,445
Verb	4,705
Total	21,307

Table 2: Number of word types in each part-of-speech (POS) in our training set

Since the dataset used by (Zhong and Ng, 2010) does not cover the specific domains of DS05 (Sports and Finance), we added a few samples from these domains to improve our baseline system. For each target word, we *randomly* selected 5 instances (a sentence including the target word) for Sports domain and 5 instances for Finance domain from the Reuters (Rose et al., 2002) dataset's Sports and Finance sections and manually sense annotated them. Annotating 5 instances per word and domain takes about 5 minutes. To make sure that these instances are not the same samples in the test set, we filtered out all documents containing at least one of the test instances and selected our training samples from the rest of the collection. After removing samples with *unclear* tags, we added the remaining instances (187 instances for Sports domain and 179 instances for Finance domain) to our original training data (Zhong and Ng, 2010). We highlight this setting in our experiments by 'CC' (concatenation).

We used the published CW word embeddings and set the word embeddings dimension to 50 in all our experiments. Finally, in order to tune the window size hyper-parameter, we randomly split our training sets into two parts. We used 80% for training models and the remaining 20% for evaluation. After tuning the window size, we used the original complete training set for training our models.

4.1.2 Results

In order to select a value for the window size parameter, we performed two types of tuning. The first method, which (theoretically) can achieve higher accuracies, is per-word tuning. Since each word type has its own model, we can select different window sizes for different words. The second method, on the other hand, selects the same value for the window size for all word types in a task, and we call it per-task tuning.

Although, per-word tuning achieved very high accuracies on the held-out development set, we observed that it performed poorly on the test set. Moreover, the results of per-word tuning are not stable and different development sets lead to different window sizes and also fluctuating accuracies. This is because the available training sets are small and using 20% of these samples as the development set means that the development set only contains a small number of samples. Thus the selected development sets are not proper representatives of the test sets and the tuning process results in overfitting the parameters (window sizes) to the development sets, with low generalization accuracy. However, per-task tuning is relatively stable and performs better on the test sets. Thus we have selected this method of tuning in all our experiments. Mihalcea (2004) also reports that per-word tuning of parameters is not helpful and does not result in improved performance.

We also evaluated our system separately on the word types in each part-of-speech (POS) for SE2 and SE3 lexical sample tasks. The results are included in Table 3 and Table 4. According to these tables, word embeddings do not affect all POS types uniformly. For example, on SE2, the improvement achieved on verbs is much larger than the other two POS types and on SE3, adjectives benefited from word embeddings more than nouns and verbs. However, this table also shows that improvements from word embeddings are consistent over POS types and

both lexical sample tasks.

	SE2		
POS	**#word types**	**baseline**	**CW (17)**
Adj.	15	67.45%	67.72%
Noun	29	69.39%	69.38%
Verb	29	60.45%	61.89%

Table 3: The scores for each part-of-speech (POS) on SE2 lexical sample tasks. The window size is shown inside brackets.

	SE3		
POS	**#word types**	**baseline**	**CW (9)**
Adj.	5	45.93%	47.81%
Noun	32	73.44%	73.83%
Verb	20	74.12%	74.17%

Table 4: The scores for each part-of-speech (POS) on SE3 lexical sample tasks. The window size is shown inside brackets.

Finally, we evaluated the effect of word embeddings and the adaptation process. Table 5 summarizes our findings on SE2 and SE3 lexical sample tasks. According to this table, both types of word embeddings lead to improvements on lexical sample tasks. We also performed a one-tailed paired t-test to see whether the improvements are statistically significant over the baseline (IMS). The improvements obtained using CW word embeddings over the baseline are significant ($p < 0.05$) in both lexical sample tasks. Furthermore, the results show that adapted word embeddings achieve higher scores than raw word embeddings. We have included the scores obtained by the first and the second best participating systems in these lexical sample tasks and also the Most Frequent Sense (MFS) score. The results also show that the Dropout layer increases performance significantly. The reason behind this observation is that without Dropout, word embeddings are overfitted to the training data and when they are used as extra features in IMS, the classifier does not generalize well to the test set. Since adaptation without Dropout leads to worse performance, we include Dropout in all other experiments and only report results obtained using Dropout.

Similarly, Table 6 presents the results obtained from our experiments on the DS05 dataset. In this table, as explained earlier, 'CC' denotes the additional manually tagged instances. For comparison purposes, we included the results reported by two state-of-the-art knowledge-based systems, namely PPR_{w2w} (Agirre et al., 2014) and Degree (Ponzetto and Navigli, 2010).

	SE2	SE3
IMS (baseline)	65.3%	72.7%
IMS + CW	66.1%* (17)	73.0%* (9)
IMS + adapted CW	**66.2%* (5)**	**73.4%* (7)**
– Dropout	65.4% (7)	72.7% (7)
Rank 1 system	64.2%	72.9%
Rank 2 system	63.8%	72.6%
MFS	47.6%	55.2%

Table 5: Lexical sample task results. The values inside brackets are the selected window sizes and statistically significant ($p < 0.05$) improvements are marked with '*'.

Table 6 shows that IMS performs worse than PPR_{w2w} on Sports and Finance domains but IMS + CC outperforms PPR_{w2w}. One of the reasons behind this observation is *unseen* sense tags. For example, in the sentence "the winning goal came with less than a minute left to play[2]", the sense tag for word 'goal' is 'goal%1:04:00::'. However, the training data for IMS does not contain any sample with this sense tag and so it is impossible for IMS to assign this tag to any test instances. On the other hand, the manually annotated instances (CC) include samples with this tag and therefore IMS + CC is able to associate a target word with this sense tag.

According to Table 6, adding word embeddings results in improved performance over the baseline (IMS + CC). Moreover, adapting word embeddings is found to increase accuracy in most cases.

4.2 All-Words Task

We also evaluated the performance of our system on the SensEval-3 (SE3) all-words task. Next, we explain our setup and then present the results of our evaluation.

[2]This example is taken from WordNet v3.1.

	BNC	Sports	Finance	Total
IMS	48.7%	41.4%	53.4%	47.8%
IMS + CC (baseline)	51.7%	55.7%	62.1%	56.4%
IMS + CC + CW (3)	51.9%	56.1%*	**62.3%**	56.7%*
IMS + CC + adapted CW (3)	**52.3%***	**57.1%***	62.0%	**57.1%***
PPR_{w2w}	37.7%	51.5%	59.3%	49.3%
Degree	-	42.0%	47.8%	-

Table 6: DS05 task results. The values inside brackets are the selected window sizes and statistically significant ($p < 0.05$) improvements over 'IMS + CC' are marked with '*'.

4.2.1 Experimental Setup

All-words tasks do not provide any training samples and only include a test set (see Table 7). In order to train our system for SE3 all-words task, we used the automatically labeled training samples used earlier for training models for DS05 (see section 4.1.1). Table 2 shows some statistics about our training set.

	SE3
#Word types	963
#Test samples	2,041

Table 7: Statistics of SE3 all-words task

Similar to the lexical sample tasks, we tune our system on 20% of the original training set. After obtaining window size parameter via tuning, we train on the whole training set and test on the given standard test set.

4.2.2 Results

The results of the evaluation on SE3 all-words task are given in Table 8. This table shows that CW word embeddings improve the accuracy. Similar to the results obtained for the lexical sample tasks, we observe some improvement by adapting word embeddings for SE3 all-words task as well. For comparison purposes, we have included the official scores of rank 1 and rank 2 participating systems in SE3 all-words task and the WordNet first sense (WNs1) score.

	SE3
IMS (baseline)	67.6%
IMS + CW	68.0%* (9)
IMS + adapted CW	**68.2%* (9)**
Rank 1 system	65.2%
Rank 2 system	64.6%
WNs1	62.4%

Table 8: SE3 all-words task results. The values inside brackets are the selected window sizes and statistically significant ($p < 0.05$) improvements over the IMS baseline are marked with '*'.

5 Conclusion

Supervised word sense disambiguation systems usually treat words as discrete entities and consequently ignore the concept of *similarity* between words. However, by adding word embeddings, some of the samples that cannot be discriminated based on the original features (surrounding words, collocations, POS tags) have more chances to be classified correctly. Moreover, word embeddings are likely to contain valuable linguistic information too. Hence, adding continuous-space representations of words can provide valuable information to the classifier and the classifier can learn better discriminative criteria based on such information.

In this paper, we exploited a type of word embeddings obtained by feed-forward neural networks. We also proposed a novel method (i.e., adaptation) to add discriminative information to such embeddings. These word embeddings were then added to a supervised WSD system by augmenting the original binary feature space with real-valued representations for all words occurring in a window of text. We evaluated our system on two general-domain lexical sample tasks, an all-words task, and also a domain-specific dataset and showed that word embeddings consistently improve the accuracy of a supervised word sense disambiguation system, across different datasets. Moreover, we observed that adding dis-

criminative information by adapting word embeddings further improves the accuracy of our word sense disambiguation system.

Continuous Space Representations of Linguistic Typology and their Application to Phylogenetic Inference

Yugo Murawaki
Graduate School of Information Science and Electrical Engineering
Kyushu University
Fukuoka, Japan
murawaki@ait.kyushu-u.ac.jp

Abstract

For phylogenetic inference, linguistic typology is a promising alternative to lexical evidence because it allows us to compare an arbitrary pair of languages. A challenging problem with typology-based phylogenetic inference is that the changes of typological features over time are less intuitive than those of lexical features. In this paper, we work on reconstructing typologically natural ancestors To do this, we leverage dependencies among typological features. We first represent each language by continuous latent components that capture feature dependencies. We then combine them with a typology evaluator that distinguishes typologically natural languages from other possible combinations of features. We perform phylogenetic inference in the continuous space and use the evaluator to ensure the typological naturalness of inferred ancestors. We show that the proposed method reconstructs known language families more accurately than baseline methods. Lastly, assuming the monogenesis hypothesis, we attempt to reconstruct a common ancestor of the world's languages.

1 Introduction

Linguistic typology is a cross-linguistic study that classifies the world's languages according to structural properties such as complexity of syllable structure and object-verb ordering. The availability of a large typology database (Haspelmath et al., 2005) makes it possible to take computational approaches to this area of study (Daumé III and Campbell, 2007; Georgi et al., 2010; Rama and Kolachina, 2012). In this paper, we consider its application to phylogenetic inference. We aim at reconstructing evolutionary trees that illustrate how modern languages have descended from common ancestors.

Typological features have two advantages over other linguistic traits. First, they allow us to compare an arbitrary pair of languages. By contrast, historical linguistics has worked on regular sound changes (see (Bouchard-Côté et al., 2013) for computational models). Glottochronology and computational phylogenetics make use of the presence and absence of lexical items (Swadesh, 1952; Gray and Atkinson, 2003). All these approaches require that certain sets of cognates, or words with common etymological origins, are shared by the languages in question. For this reason, it is hardly possible to use lexical evidence to search for external relations involving language isolates and tiny language families such as Ainu, Basque, and Japanese. For these languages, typology can be seen as the last hope.

The second advantage is that typological features are potentially capable of tracing evolutionary history on the order of 10,000 years because they change far more slowly than lexical traits. A glottochronological study indicates that even if Japanese is genetically related to Korean, they diverged from a common ancestor no earlier than 6,700 years ago (Hattori, 1999). Even the basic vocabulary vanishes so rapidly that after some 6,000 years, the retention rate becomes comparable to chance similarity. By contrast, the word order of Japanese, for example is astonishingly stable. It remains intact from the earliest attested data. Thus we argue that if we manage to develop a statistical model of typological

word order	head-last, OV, postpositional	head-first, VO, prepositional
affixation	pre/infixing, suffixing	pre/infixing or isolating
fusion	agglutinative	fusional
consonants	stable/assimilative	shifting/dissimilative
vowels	harmonizing/stable	reducing/diphthongizing

Table 1: Typological comparison of the Munda and Mon-Khmer branches of the Austroasiatic languages. An abridged version of Table 1 of (Donegan and Stampe, 2004).

changes with predictive power, we can understand a much deeper past.

A challenging problem with typology-based inference is that the changes of typological features over time are less intuitive than those of lexical features. Regular sound changes have been well known since the time of the Neogrammarians. The binary representations of lexical items commonly used in computational phylogenetics correspond to their their presence and absence. The alternations of each feature value can be straightforwardly interpreted as the birth and death (Le Quesne, 1974) of a lexical item. By contrast, it is difficult to understand how a language switches from SOV to SVO.

Practically speaking, since each language is represented by a vector of categorical features, we can easily perform distance-based hierarchical clustering. Still, the extent to which the resultant tree reflects evolutionary history is unclear. Teh et al. (2008) proposed a generative model for hierarchical clustering, which straightforwardly explains evolutionary history. However, features used in their experiments were binarized in a one-versus-rest manner (i.e., expanding a feature with K possible values into K binary features) (Daumé III and Campbell, 2007) although the model itself had an ability to handle categorical values. With the independence assumption of binary features, the model was likely to reconstruct ancestors with logically impossible states.

Typological studies have shown that dependencies among typological features are not limited to the categorical constraints. For example, object-verb ordering is said to imply adjective-noun ordering (Greenberg, 1963). A natural question arises as to what would happen to adjective-noun ordering if object-verb ordering were altered. While dependencies among feature *pairs* were discussed in previous studies (Greenberg, 1978; Dunn et al., 2011), dependencies among more than two features are yet to be exploited.

To gain a better insight into typological changes, we take Austroasiatic languages as an example. Table 1 compares some typological features of the Munda and Mon-Khmer branches. Although their genetic relationship was firmly established, they are almost opposite in structure. Their common ancestor is considered to have been Mon-Khmer-like. This indicates that the holistic changes have happened in the Munda branch (Donegan and Stampe, 2004). To generalize from this example, we suggest the following hypotheses:

1. The holistic polarization can be explained by latent components that control dependencies among observable features.
2. Typological changes can occur in a way such that typologically unnatural intermediate states are avoided.

To incorporate these hypotheses, we propose continuous space representations of linguistic typology. Specifically, we use an autoencoder (see (Bengio, 2009) for a review) to map each language into the latent space. In analogy with principal component analysis (PCA), each element of the encoded vector is referred to as a component. We combine the autoencoder with a typology evaluator that distinguishes typologically natural languages from other possible combinations of features.

Armed with the typology evaluator, we perform phylogenetic inference in the continuous space. The evaluator ensures that inferred ancestors are also typologically natural. The inference procedure is guided by known language families so that each component's stability with respect to evolutionary history can be learned. To evaluate the proposed method, we hide some trees to see how well they are reconstructed.

Lastly, we build a binary tree on top of known language families. This experiment is based on a controversial assumption that the world's languages descend from one common ancestor. Our goal here is not to address the validity of the monogenesis hypothesis. Rather, we address the questions of how the common ancestor looked like if it existed and how modern languages have evolved from it.

2 Related Work

In linguistic typology, much attention has been given to non-tree-like evolution (Trubetzkoy, 1928). Daumé III (2009) incorporated linguistic areas into a phylogenetic model and reported that the extended model outperformed a simple tree model. This result motivates us to use known language families for supervision rather than to perform phylogenetic inference in purely unsupervised settings.

Dunn et al. (2011) applied a state-process model to reference phylogenetic trees to test if a pair of features is independent. The model they adopted can hardly be extended to handle multiple features. They separately applied the model to each language family and claimed that most dependencies were lineage-specific rather than universal tendencies. However, each known language family is so shallow in time depth that few feature changes can be observed in it (Croft et al., 2011). We mitigate data sparsity by letting our model share parameters among language families all over the world.

3 Data and Preprocessing

3.1 Typology Database and Phylogenetic Trees

The typology database we used is the *World Atlas of Language Structures* (WALS) (Haspelmath et al., 2005). As of 2014, it contains 2,679 languages and 192 typological features. It covers less than 15% of the possible language/feature pairs, however.

WALS provides phylogenetic trees but they only have two layers above individual languages: family and genus. Language families include Indo-European, Austronesian and Niger-Congo, and genera within Indo-European include Germanic, Indic and Slavic. For more detailed trees, we used hierarchical classifications provided by Ethnologue (Lewis et al., 2014). The mapping between WALS and Ethnologue was done using ISO 639-3 language codes. We manually corrected some obsolete language codes used by WALS and dropped languages without language codes. We also excluded languages labeled by Ethnologue as Deaf sign language, Mixed language, Creole or Unclassified. For both WALS and Ethnologue trees, we removed intermediate nodes that had only one child. Language isolates were treated as family trees of their own. We obtained 193 family trees for WALS and 189 for Ethnologue.

We made no further modifications to the trees although we were aware that some language families and their subgroups were highly controversial. In the future work, the Altaic language family, for example, should be disassembled into Turkic, Mongolic and Tungusic to test if the Altaic hypothesis is valid (Vovin, 2005).

Next, we removed features with low coverage. Some features such as "Inclusive/Exclusive Forms in Pama-Nyungan" (39B) and "Irregular Negatives in Sign Languages" (139A) were not supposed to cover the world. We selected 98 features that covered at least 10% of languages.[1]

We used the original, categorical feature values. The mergers of some fine-grained feature values seem desirable (Daumé III and Campbell, 2007; Greenhill et al., 2010; Dunn et al., 2011). Some features like "Consonant Inventories" might be better represented as real-valued features. We leave them for future work.

In the end, we created two sets of data. The first set PARTIAL was used to train the typology evaluator. We selected 887 languages that covered at least 30% of features. The second set FULL was for phylogenetic inference. We chose language families in each of which at least 30% of features were covered by one or more languages in the family. The numbers of language families (including language isolates) were reduced to 103 for WALS and 110 for Ethnologue.

3.2 Missing Data Imputation

We imputed missing data using the `R` package *missMDA* (Josse et al., 2012). It handled missing values using multiple correspondence analysis (MCA). Specifically, we used the imputeMCA function to

[1] Additional cleanup is needed. For example, the high-coverage feature "The Position of Negative Morphemes in SOV Languages" (144L) is not defined for non-SOV languages. A natural solution is to add another feature value (*Undefined*).

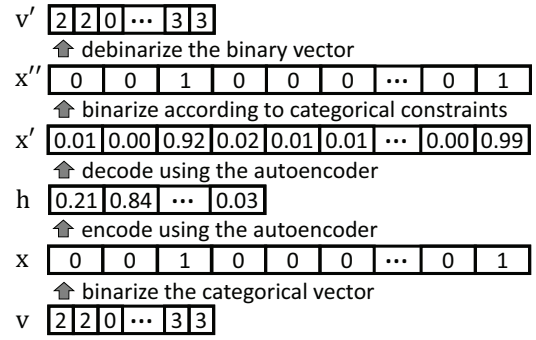

Figure 1: Representations of a language.

predict missing feature values. The substituted data are used (1) to train the typology evaluator and (2) to initialize phylogenetic inference.

To evaluate the performance of missing data imputation, we hid some known features to see how well they were predicted. A 10-fold cross-validation test using the PARTIAL dataset showed that 64.6% of feature values were predicted correctly. It considerably outperformed (1) the random baseline of 22.4% and (2) the most-frequent-value baseline of 28.1%. Thus our assumption of dependencies among features was confirmed.

4 Typology Evaluator

We use a combination of an autoencoder to transform typological features into continuous latent components, and an energy-based model to evaluate how a given feature vector is typologically natural.

We begin with the autoencoder. Figure 1 shows various representations of a language. The original feature representation v is a vector of categorical features. v is binarized into $\mathrm{x} \in \{0,1\}^{d_0}$ in a one-versus-rest manner. x is mapped by an encoder to a latent representation $\mathrm{h} \in [0,1]^{d_1}$, in which d_1 is the dimension of the latent space:

$$\mathrm{h} = s(\mathrm{W_e x} + \mathrm{b_e}),$$

where s is the sigmoid function, and matrix $\mathrm{W_e}$ and vector $\mathrm{b_e}$ are weight parameters to be estimated. A decoder then maps h back to x' through a similar transformation:

$$\mathrm{x}' = s(\mathrm{W_d h} + \mathrm{b_d}).$$

We use tied weights: $\mathrm{W_d} = \mathrm{W_e}^T$. Note that x' is a real vector. To recover a categorical vector, we need to first binarize x' according to categorical constraints and then to debinarize the resultant vector.

The training objective of the autoencoder alone is to minimize cross-entropy of reconstruction:

$$L_{\mathrm{AE}}(\mathrm{x}, \mathrm{x}') = -\sum_{k=1}^{d} x_k \log x'_k + (1-x_k)\log(1-x'_k),$$

where x_k is the k-th element of x.

Next, we plug an energy-based model into the autoencoder. It gives a probability to x.

$$\begin{aligned} p(\mathrm{x}) &= \frac{\exp(\mathrm{W_s}^T \mathrm{g})}{\sum_{\mathrm{x}'} \exp(\mathrm{W_s}^T \mathrm{g}')}, \\ \mathrm{g} &= s(\mathrm{W_l h} + \mathrm{b_l}), \end{aligned}$$

where vector $\mathrm{W_s}$, matrix $\mathrm{W_l}$ and bias term $\mathrm{b_l}$ are the weights to be estimated. h is mapped to $\mathrm{g} \in [0,1]^{d_2}$ before evaluation. This transformation is motivated by our speculation that typologically natural languages may not be linearly separable from unnatural ones in the latent space since biplots of principal components of PCA often show sinusoidal waves (Novembre and Stephens, 2008). The denominator sums over all possible states of x', including those which violate categorical constraints. By maximizing the average log probability of training data, we can distinguish typologically natural languages from other possible combinations of features.

Given a set of N languages with missing data imputed,[2] our training objective is to maximize the following:

$$\sum_{i=1}^{N} (-L_{\mathrm{AE}}(\mathrm{x}_i, \mathrm{x}'_i) + C \log p(\mathrm{x}_i))),$$

where C is some constant. Weights are optimized by the gradient-based AdaGrad algorithm (Duchi et al., 2011) with a mini-batch. A problem with this optimization is that the derivative of the second term contains an expectation that involves a summation over all possible states of x', which is computationally intractable. Inspired by contrastive divergence (Hinton, 2002), we do not compute the expectation exactly but approximate it by few negative samples collected from Gibbs samplers.

4.1 Mixing Languages: An Experiment

To analyze the continuous space representations, we generated mixtures of two languages, which were

[2] We tried a joint inference of weight optimization and missing data imputation but dropped it for its instability. A cross-validation test revealed that the joint inference caused a big accuracy drop in missing data imputation.

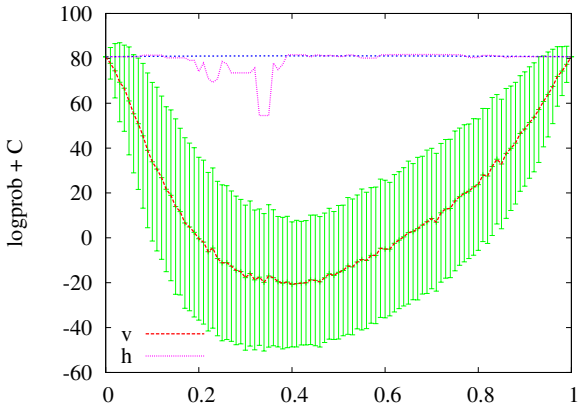

Figure 2: Mixtures of Mundari (a Munda language) and Khmer (a Mon-Khmer language). The transitions from Mundari (leftmost) to Khmer (rightmost). The vertical axis denotes typological naturalness $\log p(\mathrm{x}) + C$.

potential candidates for their common ancestor. The pair of languages A and B was mixed in two ways. First, we replaced elements of A's categorical vector v_A with v_B, with the specified probability. We repeated this procedure 1,000 times to obtain a mean and a standard deviation. Second, we applied linear interpolation of two vectors h_A and h_B and mapped the resultant vector to v'. In this experiment, $d_0 = 539$ and we set $d_1 = 100$ and $d_2 = 10$.

Figure 2 shows the case of the Austroasiatic languages. In the original, categorical representations, the mixtures of two languages form a deep valley (i.e., typologically unnatural intermediate states). By contrast, the continuous space representations allow a language to change into another without harming typological naturalness. This indicates that in the continuous space, we can easily reconstruct typologically natural ancestors. The major feature changes include "postpositional" to "prepositional" (0.46–0.47), "strongly suffixing" to "little affixation" (0.53–0.54) and "SOV" to "SVO" (0.60–0.61).

5 Phylogenetic Inference

5.1 Tree Model

We use continuous space representations and the typology evaluator for phylogenetic inference. Our strategy is to find a tree in which (1) nodes are typologically natural and (2) edges are shorter by the principle of Occam's razor. The first point is realized by applying the typology evaluator. To implement the second point, we define a probability distribution over a parent-to-child move in the continuous space.

We assume that latent components are independent. For the k-th component, the node's value h_k is drawn from a Normal distribution with mean h_k^{P} (its parent's value) and precision λ_k (inverse variance). The further the node moves, the smaller probability it receives. Precision controls each component's stability with respect to evolutionary history.

We set a gamma prior over λ_k, with hyperparameters α and β.[3] Taking advantage of the conjugacy property, we marginalize out λ_k. Suppose that we have drawn n samples and let m_i be the difference between the i-th node and its parent, $h_k - h_k^{\mathrm{P}}$. Then the posterior hyperparameters are $\alpha_n = \alpha + n/2$ and $\beta_n = \beta + \frac{1}{2}\sum_{i=1}^{n} m_i^2$. The posterior predictive distribution is Student's t-distribution (Murphy, 2007):

$$p_k(h_k|h_k^{\mathrm{P}}, M_{\mathrm{hist}}, \alpha, \beta) = t_{2\alpha_n}(h_k|h_k^{\mathrm{P}}, \sigma^2 = \beta_n/\alpha_n),$$

where M_{hist} is a collection of α, β and a history of previously observed differences. The probability of a parent-to-child move is a product of the probabilities of its component moves:

$$p_{\textsc{Move}}(\mathrm{h}|\mathrm{h}^{\mathrm{P}}, M_{\mathrm{hist}}) = \prod_{k=1}^{d} p_k(h_k|h_k^{\mathrm{P}}, M_{\mathrm{hist}}).$$

The root node is drawn from a uniform distribution.

To sum up, the probability of a phylogenetic tree $\boldsymbol{\tau}$ is given by $p_{\textsc{Eval}}(\mathrm{tree}) \times p_{\textsc{Cont}}(\mathrm{tree})$, where

$$\begin{aligned} p_{\textsc{Eval}}(\mathrm{tree}) &= \mathrm{Uniform}(\mathrm{tree}) \prod_{\mathrm{x} \in \mathrm{nodes}(\boldsymbol{\tau})} p(\mathrm{x}), \\ p_{\textsc{Cont}}(\mathrm{tree}) &= \mathrm{Uniform}(\mathrm{root}) \\ &\quad \times \prod_{(\mathrm{h},\mathrm{h}^{\mathrm{P}}) \in \mathrm{edges}(\boldsymbol{\tau})} p_{\textsc{Move}}(\mathrm{h}|\mathrm{h}^{\mathrm{P}}, M_{\mathrm{hist}}). \end{aligned}$$

$\mathrm{nodes}(\boldsymbol{\tau})$ is the set of nodes in $\boldsymbol{\tau}$, and $\mathrm{edges}(\boldsymbol{\tau})$ is the set of edges in $\boldsymbol{\tau}$, We abuse notation as M_{hist} is updated each time a node is observed.

5.2 Inference

Given observed data, we aim at reconstructing the best phylogenetic tree. The data observed are (1) leaves (with some missing feature values) and (2) some tree topologies. We need to infer (1) the missing feature values of leaves, (2) the latent components of internal nodes including the root and (3) the remaining portion of tree topologies. Since leaves

[3] In the experiments, we set $\alpha = \beta = 0.1$.

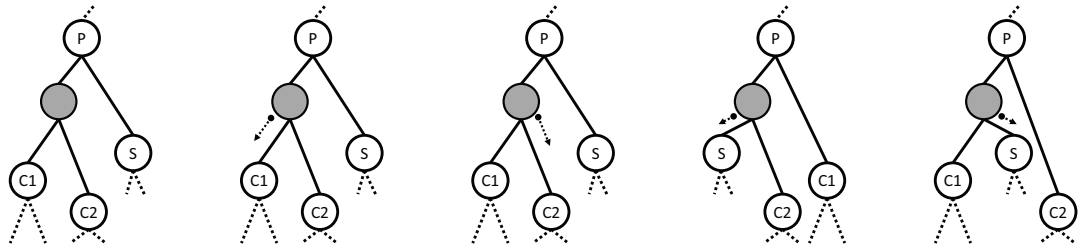

Figure 3: SWAP operator. The gray circle is the target node. Its parent P, sibling S and two children C1 and C2 are shown. (a) The current state. (b–e) The proposed states. (b–c) The topology remains the same but the target is moved toward C1 and C2, respectively. (d) C1 is swapped for S. (e) C2 is swapped for S.

are tied to observed categorical vectors, our inference procedures also work on them. We map categorical vectors into the latent space every time we attempt to change a feature value. By contrast, we adopt latent vectors as the primary representations of internal nodes.

Take the Indo-European language family for example. Its tree topology is given but the states of its internal nodes such as Indo-European, Germanic and Indic need to be inferred. Dutch has some missing feature values. Although they have been imputed with multiple correspondence analysis, its close relatives such as Danish and German might be helpful for better estimation.

We need to infer portions of tree topologies even though a set of trees (language families) is given. To evaluate the performance of phylogenetic inference, we hide some trees to see how well they are reconstructed. To reconstruct a common ancestor of the world's languages, we build a binary tree on top of the set of trees. Note that while we only infer binary trees, a node may have more than two children in the fixed portions of tree topologies.

We use Gibbs sampling for inference. We define four operators, CAT, COMP, SWAP and MOVE. The first tree operators correspond to missing feature values, latent components and tree topologies, respectively.

CAT – For the target categorical feature of a leaf node, we sample from K possible values. Let x' be a binary feature representation with the target feature value altered, let h^{P} be the state of the node's parent, and let $\mathrm{h}' = s(\mathrm{W_e x}' + \mathrm{b_e})$. The probability of choosing x' is proportional to $p(\mathrm{x}')\, p_{\textsc{Move}}(\mathrm{h}'|\mathrm{h}^{\mathrm{P}}, M_{\mathrm{hist}})$, where h is removed from the history. The second term is omitted if the target node has no parent.[4]

COMP – For the target k-th component of an internal node, we choose its new value using the Metropolis algorithm. It stochastically proposes a new state and accepts it with some probability. If the proposal is rejected, the current state is reused as the next state. The proposal distribution $Q(h'_k|h_k)$ is a Gaussian distribution centered at h_k. The acceptance probability is $a(h_k, h'_k) = \min(1, P(h'_k)/P(h_k))$, where $P(h'_k)$ is defined as

$$P(h'_k) = p(\mathrm{x}')\, p_{\textsc{Move}}(\mathrm{h}'|\mathrm{h}^{\mathrm{P}}, M_{\mathrm{hist}}) \prod_{\mathrm{h}^{\mathrm{C}} \in \mathrm{children}(\mathrm{h}')} p_{\textsc{Move}}(\mathrm{h}^{\mathrm{C}}|\mathrm{h}', M_{\mathrm{hist}})$$

where $\mathrm{children}(\mathrm{h}')$ is the set of the target node's children.

SWAP – For the target internal node (which cannot be the root), we use the Metropolis-Hastings algorithm to locally rearrange its neighborhood in a way similar to Li et al. (2000). We first propose a new state as illustrated in Figure 3. The target node has a parent P, a sibling S and two children C1 and C2. From among S, C1 and C2, we choose two nodes. If C1 and C2 are chosen, the topology remains the same; otherwise S is swapped for one of the node's children. It is shown that one topology can be transformed into any other topology in a finite number of steps (Li et al., 2000).

To improve mobility, we also move the target node toward C1, C2 or S, depending on the proposed topology. Here the selected node is denoted by $*$. We first draw r' from a log-normal distribution whose underlying Gaussian distribution has

[4] It is easy to extend the operator to handle internal nodes supplied with some categorical features.

mean -1 and variance 1. The target's proposed state is $\mathrm{h}' = (1 - r')\mathrm{h} + r'\mathrm{h}^*$. r' can be greater than 1, and in that case, the proposed state h' is more distant from h^* than the current state h. This ensures that the transition is reversible because $r = 1/r'$. The acceptance probability can be calculated in a similar manner to that described for COMP.

MOVE – Propose to move the target internal node, without swapping its neighbors.

For initialization, missing feature values are imputed by *missMDA*. The initial tree is constructed by distance-based agglomerative clustering. The state of an internal node is set to the average of those of its children.

6 Experiments

6.1 Reconstruction of Known Family Trees

6.1.1 Data and Method

We first conducted a quantitative evaluation of phylogenetic inference, using known family trees. We ran 5-fold cross-validations. For each of WALS and Ethnologue, we subdivided a set of language families into 5 subsets with roughly the same number of leaves. Because of some huge language families, the number of language families per subset was uneven. We disassembled family trees in the target subset and to let the model reconstruct a binary tree for each language family. Unlike ordinary held-out evaluation, this experiment used all data for inference at once.

6.1.2 Model Settings

We used the parameter settings described in Section 4.1. For phylogenetic inference, we ran 9,000 burn-in iterations after which we collected 100 samples at an interval of 10 iterations.

For comparison, we performed average-link agglomerative clustering (ALC). It has two variants, ALC-CAT and ALC-CONT. ALC-CAT worked on categorical features and used the ratio of disagreement as a distance metric. ALC-CONT performed clustering in the continuous space, using cosine distance. In other words, we can examine the effects of the typology evaluator and precision parameters. For these models, missing feature values are imputed by *missMDA*.

6.1.3 Evaluation Measures

We present purity (Heller and Ghahramani, 2005), subtree (Teh et al., 2008) and outlier fraction scores (Krishnamurthy et al., 2012). All scores are between 0 and 1 and higher scores are better. We calculated these scores for each language family and

	WALS						Ethnologue	
	purity		subtree		outlier		outlier	
ALC-CAT	.500	.557	.608	.626	.343	.330	**.358**	**.398**
ALC-CONT	.503	.557	**.630**	.630	.343	.330	.353	.395
Proposed	**.522**	**.572**	.603	**.651**	**.351**	**.346**	.356	.394

Table 2: Results of the reconstruction of known family trees. Macro-averages are followed by micro-averages.

report macro- and micro-averages. Only non-trivial family trees (trees with more than two children) were considered.

Purity and subtree scores compare inferred trees with gold-standard class labels. In WALS, genera were treated as class labels because they were the only intermediate layer between families and leaves. By contrast, Ethnologue provided more complex trees and we were unable to assign one class label to each language. For this reason, only outlier fraction scores are reported for Ethnologue.

6.1.4 Results

Table 2 shows the scores for reconstructed family trees. The proposed method outperformed the baselines in 5 out of 8 metrics. Three methods performed almost equally for Ethnologue. We suspect that typological features reflect long term trends in comparison to Ethnologue's fine-grained classification. For WALS, the proposed method was beaten by average-link agglomerative clustering only in the macro-average of subtree scores. One possible explanation is randomness of the proposed method. Apparently, random sampling distributed errors more evenly than deterministic clustering. It was penalized more often by subtree scores because they required that all leaves of an internal node belonged to the same class.

6.2 Reconstruction of a Common Ancestor of the World's Languages

We reconstructed a single tree that covers the world. To do this, we build a binary tree on top of known language families, a product of historical linguistics. It is generally said that historical linguistics cannot go far beyond 6,000–7,000 years (Nichols, 2011). Here we attempt to break the brick wall.

It is no surprise that this experiment is full of problems and difficulties. No quantitative evaluation is possible. Underlying assumptions are questionable. No one knows for sure if there was such a thing as one common ancestor of all modern languages. Moreover, *language capacity* of humans, in addition to languages themselves, is likely to have evolved over time (Nichols, 2011). This casts doubt on the applicability of the typology evaluator, which is trained on modern languages, to languages of far distant past. Nevertheless, it is fascinating to make inference on the world's ancestral languages.

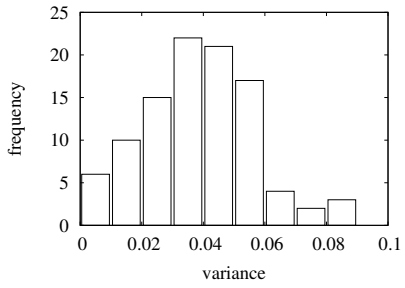

Figure 5: Histogram of posterior variances $\sigma^2 = \beta_n/\alpha_n$ of the 4,000th sample.

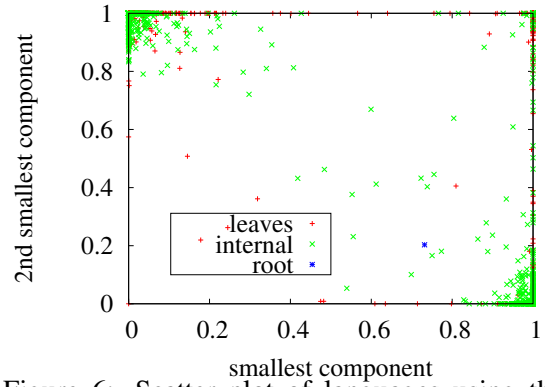

Figure 6: Scatter plot of languages using the components with the two smallest variances.

We used Ethnologue as the known tree topologies. For Gibbs sampling, we ran 3,000 burn-in iterations after which we collected 100 samples at an interval of 10 iterations.

Figure 4 shows a reconstructed tree. To summarize multiple sample trees, we constructed a maximum clade credibility tree. For each clade (a set of all leaves that share a common ancestor), we calculated the fraction of times it appears in the collected samples, which we call a *support* in this pa-

Features	Frequencies/Values
Consonant Inventories	95 Average

per. A tree was scored by the product of supports of all clades within it, and we created a tree that maximized the score. Each edge label shows the support of the corresponding clade. As indicated by generally low supports, the sample trees were very unstable. Some geographically distant groups of languages were clustered near the bottom. We partially attribute this to the *underspecificity* of linguistic typology: even if a pair of languages shares the same feature vector, they are not necessarily the same language. This problem might be eased by incorporating geospatial information into phylogenetic inference (Bouckaert et al., 2012).

Table 3 shows some features of the root. The reconstructed ancestor is moderate in phonological typology, uses suffixing in morphology and prefers the SOV word order. The inferred word order agrees with speculations given by previous studies (Maurits and Griffiths, 2014).

Figure 5 shows the histogram of variance parameters. Some latent components had smaller variances and thus were more stable with respect to evolutionary history. Figure 6 displays languages using the components with the two smallest variances. Unlike PCA plots, data concentrated at the edges.

We used a geometric mean of p_{MOVE} of multiple samples to calculate how a modern language is similar to another. The case of Japanese is shown in Table 4. This ranked list is considerably different from that of disagreement rates of categorical vectors (Spearman's $\rho = 0.76$). When features' stability with respect to evolutionary history is considered, Japanese is less closer to Korean and Ainu than to some Tibeto-Burman languages south of the Himalayas. As the importance of these minor languages of Northeast India is recognized, the Sino-Tibetan tree might be drastically revised in the future (Blench and Post, 2013). The least similar languages include the Malayo-Polynesian and Nilo-Saharan languages.

Rank	Language	Classificatoin	Logprob.
1	(Japanese)	Japonic	76.8

7 Conclusion

In this paper, we proposed continuous space representations of linguistic typology and used them for phylogenetic inference. Feature dependencies are a major focus of linguistic typology, and typology data have occasionally been used for computational phylogenetics. To our knowledge, however, we are the first to integrate the two lines of research. In addition, the continuous space representations underlying interdependent discrete features are applicable to other data including phonological inventories (Moran et al., 2014).

We believe that typology provides important clues for long-term language change. The currently available database only contains modern languages, but we expect that data of some ancestral languages could greatly facilitate computational approaches to diachronic linguistics.

Interpreting Compound Noun Phrases Using Web Search Queries

mars@google.com

Abstract

A weakly-supervised method is applied to anonymized queries to extract lexical interpretations of compound noun phrases (e.g., *"fortune 500 companies"*). The interpretations explain the subsuming role (*"listed in"*) that modifiers (*fortune 500*) play relative to heads (*companies*) within the noun phrases. Experimental results over evaluation sets of noun phrases from multiple sources demonstrate that interpretations extracted from queries have encouraging coverage and precision. The top interpretation extracted is deemed relevant for more than 70% of the noun phrases.

1 Introduction

Motivation: Semantic classes of interest to Web users are often expressed as lexical class labels (e.g., *"fortune 500 companies"*, *"italian composers"*, *"victorinox knives"*). Each class label hints at the implicit properties shared among its instances (e.g., *general electric*, *gaetano donizetti*, *swiss army jetsetter* respectively). Class labels allow for the organization of instances into hierarchies, which in turn allows for the systematic development of knowledge repositories. This motivates research efforts to acquire as many relevant class labels of instances as possible, which have received particular emphasis (Wang and Cohen, 2009; Dalvi et al., 2012; Flati et al., 2014). The efforts are part of the larger area of extracting open-domain facts and relations (Banko et al., 2007; Hoffart et al., 2013; Yao and Van Durme, 2014), ultimately delivering richer results in Web search.

Different methods can associate instances (*general electric*) with both class labels (*"fortune 500 companies"*) and facts (<*general electric*, *founded in*, *1892*>) extracted from text. But the class labels tend to be extracted, maintained and used separately from facts. Beyond organizing the class labels hierarchically (Kozareva and Hovy, 2010), the meaning of a class label is rarely explored (Nastase and Strube, 2008), nor is it made available downstream to applications using the extracted data.

Contributions: The method introduced in this paper is the first to exploit Web search queries to uncover the semantics of open-domain class labels in particular; and of compound noun phrases in general. The method extracts candidate, lexical interpretations of compound noun phrases from queries. The interpretations turn implicit properties or subsuming roles (*"listed in"*, *"from"*, *"made by"*) that modifiers (*fortune 500*, *italian*, *victorinox*) play within longer noun phrases (*"fortune 500 companies"*, *"italian composers"*, *"victorinox knives"*) into explicit strings. The roles of modifiers relative to heads of noun phrase compounds cannot be characterized in terms of a finite list of possible compounding relationships (Downing, 1977). Hence, the interpretations are not restricted to a closed, pre-defined set. Experimental results over evaluation sets of noun phrases from multiple sources demonstrate that interpretations can be extracted from queries for a significant fraction of the input noun phrases. Without relying on syntactic analysis, extracted interpretations induce implicit bracketings over the interpreted noun phrases. The bracketings reveal the multiple senses, some of which are more rare but still plausible, in which the same noun phrase can be sometimes explained. The quality of interpretations is encouraging, with at least one interpretation deemed relevant among the top 3 retrieved for 77% of the

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 335–344,
Denver, Colorado, May 31 – June 5, 2015.

noun phrases with extracted interpretations. The top interpretation is deemed relevant for more than 70% of the noun phrases.

Applications: The extracted interpretations can serve as a bridge connecting class labels and facts. Relevant interpretations allow one to potentially derive missing facts (<*general electric*, *listed in*, *fortune 500*>) from existing class labels (<*general electric*, *fortune 500 companies*>) and vice versa. In addition, relevant interpretations of class labels are themselves class labels inferred for the same instances. Examples are <*general electric*, *companies listed in fortune 500*>, or <*general electric*, *companies in fortune 500*>, based on <*general electric*, *fortune 500 companies*>. If the input class labels are organized hierarchically (<*fortune 500 companies*, *companies*>), interpretations explain why more specific class labels (*"fortune 500 companies"*, *"german companies"*, *"dow jones industrial average companies"*, *"french companies"*) do not merely belong under more general ones (*"companies"*), but do so along shared interpretations (*companies*→*listed in*→{*fortune 500*, *dow jones industrial average companies*}; vs. {*companies*→*from*→{*germany*, *france*}); and, more generally, aid in the better understanding of noun phrases.

2 Interpreting Noun Phrases

Hypothesis: Let N be a compound noun phrase, containing a head H preceded by modifiers M. Each of H and M may contain one or multiple tokens. Being a compound, the sequence of modifiers and head in N act as a single noun (Downing, 1977; Hendrickx et al., 2013). If N is relevant and of interest to Web users, then in a sufficiently large corpus it will eventually be referred to in relatively more verbose search queries, which explain the implicit role that modifiers M play relative to the head H.

Acquisition from Queries: To illustrate the intuition above, consider the noun phrases *"water animals"* and *"zone 7 plants"*. If enough Web users are interested in the concepts represented by these noun phrases, then the phrases are likely to be submitted as search queries. In addition, some Web users seeking similar information are likely to submit queries that make the role of the modifiers *water* and *zone 7* explicit, such as *"animals living in water"* or *"plants that grow in zone 7"*.

As illustrated in Figure 1, the extraction method

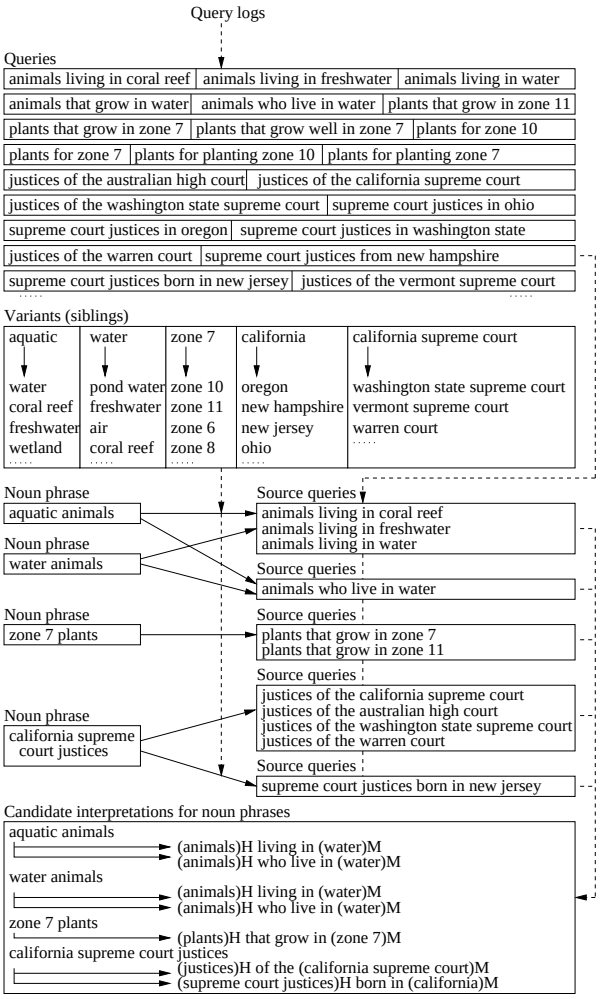

Figure 1: Overview of extraction of interpretations of noun phrases from Web search queries

proposed in this paper takes as input a vocabulary of noun phrases, as well as a set of anonymized queries from which possible interpretations for the noun phrases must be extracted. The extraction consists of several steps: (1) the selection of a subset of queries that may be candidate interpretations of some yet-to-be-specified noun phrases; (2) the matching of the selected queries to the noun phrases to interpret; and (3) the aggregation of matched queries into candidate interpretations extracted for a noun phrase.

Queries as Candidate Interpretations: The input queries are matched against the extraction patterns from Table 1. The use of targeted patterns in information extraction has been suggested before (Hearst, 1992; Fader et al., 2011). In our case, the patterns match queries that start with an arbitrary ngram H, followed by what is likely a

Extraction Pattern → Examples of Matched Queries
Passive constructs:
H [VBN|VBD|VBG] [<anything>] M [<anything>] → (plants)$_H$ grown in (zone 7)$_M$ → (supreme court justices)$_H$ born in (new jersey)$_M$ → (medicinal plants)$_H$ used as (ayurvedic)$_M$ drugs → (manipulatives)$_H$ used in (elementary math)$_M$
Prepositional constructs:
H [IN|TO] [<anything>] M [<anything>] → (plants)$_H$ for (zone 7)$_M$ → (justices)$_H$ of the (california supreme court)$_M$ → (medicinal plants)$_H$ in (ayurvedic)$_M$ products → (math manipulatives)$_H$ for (elementary)$_M$ level
Relative pronoun constructs:
H [that|who|which] [<anything>] M [<anything>] → (plants)$_H$ that grow in (zone 7)$_M$ → (animals)$_H$ who live in (water)$_M$ → (medicinal plants)$_H$ that are used in (ayurveda)$_M$ → (math manipulatives)$_H$ that are taught in the (elementary)$_M$ classroom

Table 1: Extraction patterns matched against queries to identify candidate interpretations (H, M=head and modifier of a hypothetical noun phrase)

passive, prepositional or relative-pronoun construct, followed by another ngram M, and optionally followed by other tokens. The ngrams H and M contain one or more tokens. The patterns effectively split matching queries into four consecutive sequences of tokens Q=[Q_1 Q_2 Q_3 Q_4], where H and M correspond to Q_1 and Q_3, and Q_4 may be empty. For example, the pattern in the lower portion of Table 1 matches the query *"(plants)$_H$ that grow in (zone 7)$_M$"*, which is one of the queries shown in the upper portion of Figure 1.

Mapping Noun Phrases to Interpretations: Each noun phrase to interpret is split into all possible decompositions of two consecutive sequences of tokens N=[N_1 N_2], where the two sequences correspond to a hypothetical modifier and a hypothetical head of the noun phrase. For example, the noun phrase *"zone 7 plants"* is split into [*"zone"*, *"7 plants"*] and separately into [*"zone 7"*, *"plants"*]. If N_1 and Q_3, and N_2 and Q_1 respectively, match, then the matching query Q (e.g., *"(plants)$_H$ that grow in (zone 7)$_M$"*) is retained as a candidate interpretation of the noun phrase N (*"(zone 7)$_M$ (plants)$_H$"*), as shown in the middle portion of Figure 1.

Mapping via Modifier Variants: At its simplest, the matching of the hypothetical modifier relies on strict string matching. Alternatively, original modifiers in the noun phrases to interpret may be matched to queries via expansion variants. Variants are phrases that likely play the same role, and therefore share interpretations, as modifiers relative to the head in a noun phrase. Variants allow for the extraction of candidate interpretations that may otherwise not be available in the input data. For example, in Figure 1, the variant *new jersey* available for *california* allows for the matching of *california* in the noun phrase *"(california)$_M$ (supreme court justices)$_H$"*, with *new jersey* in the query *"(supreme court justices)$_H$ born in (new jersey)$_M$"*. The candidate interpretation *"(supreme court justices)$_H$ born in (california)$_M$"* is extracted for the noun phrase *"(california)$_M$ (supreme court justices)$_H$"*, even though the query *"supreme court justices born in california"* is not present among the input queries.

Possible sources of variants include distributionally similar phrases (Lin and Wu, 2009), where the phrases most similar to a modifier would act as its variants. Mappings from adjectival modifiers in noun phrases (e.g., *aquatic* in *"aquatic animals"* in Figure 1) into the nominal counterparts (e.g., *water*) that are likely to occur in interpretations (e.g., *"(animals)$_H$ who live in (water)$_M$"*) are also useful. Concretely, as described later in Section 3, variants are generated using WordNet (Fellbaum, 1998), distributional similarities and Wikipedia.

Aggregation of Candidate Interpretations: Candidate interpretations of a noun phrase are aggregated from source queries that matched the noun phrase. The frequency score of a candidate interpretation is the weighted sum of the frequencies of source queries from which the candidate interpretation is collected, possibly via variants of modifiers. In the weighted sum, the weights are similarity scores between the original modifier from the noun phrase, on one hand, and the variant from the source query into which the modifier was mapped, on the other hand. For example, in Figure 1, the frequency score of the candidate interpretation *"(plants)$_H$ that grow in (zone 7)$_M$"* for the noun phrase *"(zone 7)$_M$ (plants)$_H$"* is the weighted sum of the frequencies of the source queries *"plants that grow in zone 7"* and *"plants that grow in zone 11"*. The weights for the variants *zone 7* and *zone 11* relative to the original modifier *zone 7* may be 1.0 (identity) and 0.8 (distributional similarity), whereas the weights of adjectival modifiers such as *water* for *aquatic* may be 1.0. Separately from the frequency score, a penalty score is computed that penalizes interpretations containing extraneous tokens. Specifically, the penalty counts

the number of nouns or adjectives located outside the modifier and head. Candidate interpretations extracted for a noun phrase are ranked in increasing order of their penalty scores or, in case of ties, in decreasing order of their frequency scores.

3 Experimental Setting

Sources of Textual Data: The experiments rely on a random sample of around 1 billion fully-anonymized Web search queries in English. The sample is drawn from queries submitted to a general-purpose Web search engine. Each query is available independently from other queries, and is accompanied by its frequency of occurrence in the query logs.

Sources of Variants: The original form of the modifiers is denoted as **orig-phrase**. Three types of variant phrases are collected for the purpose of matching modifiers within noun phrases to interpret, with phrases from queries. Relations encoded as Value-Of, Related-Noun and Derivationally-Related relations in WordNet (Fellbaum, 1998) are the source of **adj-noun** variants. They map around 6,000 adjectives into one or more nouns (e.g., (*french*→*france*), (*electric*→*electricity*), (*aquatic*→*water*)). A repository of distributionally similar phrases, collected in advance (Lin and Wu, 2009) from a sample of around 200 million Web documents in English, is the source of **dist-sim** variants. For each of around 1 million phrases, the variants consist of their 50 most similar phrases (e.g., *art garfunkel*→{*carly simon*, *melissa manchester*, *aaron neville*, ..}).

A snapshot of all Wikipedia articles in English, as available in June 2014, is the source of **wiki-templ** variants. For each of around 50,000 phrases, their wiki-templ variants are collected from Wikipedia categories sharing a common parent Wikipedia category (e.g., *"albums by artist"*) and having a common head (*"art garfunkel albums"*, *"black sabbath albums"*, *"metallica albums"*). The different modifiers (*art garfunkel*, *black sabbath*, *metallica*) that accompany the shared head are collected as variants of one another. Among the four types of variants, wiki-templ variants are applied only when the noun phrase to interpret, and the source Wikipedia category names from which the variants were collected, have the same head. For example, *X=art garfunkel*→{*black sabbath*, *metallica*, *50 cent*, ..} is applied only in the context of the noun phrase *"X albums"*.

Vocabularies of Noun Phrases: The extraction method acquires interpretations from queries, for noun phrases from three vocabularies. **ListQ** is a set of phrases *X* (e.g., *"aramaic words"*) from queries in the form [*list of X*], where the frequency of the query [*X*] is at most 100 times higher than the frequency of the query [*list of X*], and the frequency of the latter is at least 5. **IsA** is a set of class labels (e.g., *"academy award nominees"*), originally extracted from Web documents via Hearst patterns (Hearst, 1992), and associated with at least 25 instances each (e.g., *zero dark thirty*). **WikiC** is a set of Wikipedia categories that contain some tokens in lowercase beyond prepositions and determiners, and whose heads are plural-form nouns (e.g., *"french fiction writers"*). Only phrases that are one of the full-length queries from the input set of Web search queries are retained in the respective sets, as vocabularies of noun phrases to interpret; other phrases are discarded.

Vocabulary	Relative Coverage			
	R	Q	I	I / Q
ListQ	406,249	406,249	277,193	0.682
IsA	613,148	405,262	282,927	0.698
WikiC	248,615	87,878	63,518	0.723

Table 2: Relative coverage of noun phrase interpretation, over noun phrases from various vocabularies (R=number of raw noun phrases; Q=subset of noun phrases from R that are queries; I=subset of noun phrases from Q with some extracted interpretation(s); I/Q=fraction of noun phrases from Q that are present in I)

Parameter Settings: The noun phrases to interpret and queries are both part-of-speech tagged (Brants, 2000). From among candidate interpretations extracted for a noun phrase, interpretations whose penalty score is higher than 1 are discarded. When computing the frequency score of a candidate interpretation as the weighted sum of the frequencies of source queries, the weights assigned to various variants are 1.0, for orig-phrase, adj-noun and wiki-templ variants; and the available distributional similarity scores within [0.0, 1.0], for dist-sim variants.

4 Evaluation Results

Relative Coverage: Because it is not feasible to manually compile the exhaustive sets of all string forms of valid interpretations of all (or many) noun phrases, we compute relative instead of absolute coverage. As illustrated in Table 2, some interpretations are extracted from queries for more than 500,000 of the noun phrases from all input vocabu-

Gold Set: Sample of Noun Phrases
ListQ: 1911 pistols, 2009 movies, alabama sororities, alaskan towns, american holidays, aramaic words, argumentative essays, arm loans, army ranks, .., yugioh movies
IsA: academy award nominees, addicting games, advanced weapons systems, android tablet, application layer protocols, astrological signs, automotive parts, .., zip code
WikiC: 2k sports games, aaliyah songs, advertising slogans, airline tickets, alan jackson songs, ancient romans, andrea bocelli albums, athletic shoes, .., wii accessories

Table 3: Gold sets of 100 noun phrases per vocabulary

laries, or around 70% of all input noun phrases.

Precision of Interpretations: From an input vocabulary, an initial weighted sample of 150 noun phrases with some extracted interpretations is manually inspected. The sampling weight is the frequency of the noun phrases as queries. A noun phrase from the selected sample is either retained, or discarded if deemed to be a non-interpretable phrase. A noun phrase is not interpretable if it is in fact an instance (*"new york"*, *"alicia keys"*) rather than a class; or it is not a properly formed noun phrase (*"watch movies"*); or does not refer to a meaningful class (*"3 significant figures"*). The manual inspection ends, once a sample of 100 noun phrases has been retained. The procedure gives weighted random samples of 100 noun phrases, drawn from each of the ListQ, IsA and WikiC vocabularies. The samples, shown in Table 3, constitute the gold sets of phrases ListQ, IsA and WikiC, over which precision of interpretations is computed. Note that, since the samples are random, Wikipedia categories that contribute to the automatic construction of wiki-templ variants may be selected as gold phrases in WikiC. This is the case for three of the gold phrases in WikiC.

The top 20 interpretations extracted for each gold phrase are manually annotated with correctness labels. As shown in Table 4, an interpretation is annotated as: correct and generic, or correct and specific, if relevant; okay, if useful but containing non-essential information; or wrong. To compute the precision score over a gold set of phrases, the correctness labels are converted to numeric values. Precision of a ranked list of extracted interpretations is the average of the correctness values of the interpretations in the list.

Table 5 provides a comparison of precision scores at various ranks in the extracted lists of interpretations, as an average over all phrases from a gold set.

Label (Score) → Examples of (Noun Phrase: Interpretation)
cg (1.0) → (good short stories: short stories that are good), (bay area counties: counties in the bay area), (fourth grade sight words: sight words in fourth grade), (army ranks: ranks from the army), (who wants to be a millionaire winners: winners of who wants to be a millionaire), (us visa: visa for us)
cs (1.0) → (brazilian dances: dances of the brazilian culture), (tsunami charities: charities that gave to the tsunami), (stephen king books: books published by stephen king), (florida insurance companies: insurance companies headquartered in florida), (florida insurance companies: insurance companies operating in florida), (us visa: visa required to enter us)
qq (0.5) → (super smash bros brawl characters: characters meant to be in super smash bros brawl), (carribean islands: islands by the carribean), (pain assessment tool: tool for recording pain assessment)
xw (0.0) → (periodic functions: functions of periodic distributions), (simpsons episodes: episodes left of simpsons), (atm card: card left in wachovia atm)

Table 4: Examples of interpretations manually annotated with each correctness label (cg=correct generic; cs=correct specific; qq=okay; xw=incorrect)

Gold Set	Precision@N				
	@1	@3	@5	@10	@20
ListQ	0.770	0.708	0.655	0.568	0.465
IsA	0.730	0.598	0.530	0.423	0.329
WikiC	0.780	0.647	0.561	0.455	0.357

Table 5: Average precision, at various ranks in the ranked lists of interpretations extracted for noun phrases from various sets of gold phrases

At ranks 1, 5 and 20, precision scores vary between 0.770, 0.655 and 0.465 respectively, for the ListQ gold set; and between 0.730, 0.530 and 0.329 respectively, for the IsA gold set.

Presence of Relevant Interpretations: Sometimes it is difficult to even manually enumerate as many as 20 distinct, relevant string forms of interpretations for a given noun phrase. Measuring precision at a particular rank (e.g., 20) in a ranked list of interpretations may be too conservative. Table 6 summarizes a different type of scoring metric, namely the presence of any relevant interpretation, among the interpretations extracted up to a particular rank. Relevance is flexibly defined, by requiring the interpretations to have been assigned a certain correctness label, then computing the average number of gold phrases for which such interpretations are present up to a particular rank. When considering only interpretations annotated as correct and generic or correct and specific, in the second row of each vertical

Gold Set	Selected Correctness Labels			Average presence of any interpretations with any of the selected correctness labels				
	cg	cs	qq	@1	@3	@5	@10	@20
ListQ	√	√	√	0.790	0.860	0.870	0.880	0.880
	√	√		0.750	0.810	0.830	0.840	0.840
	√			0.720	0.780	0.790	0.800	0.800
		√		0.030	0.160	0.360	0.450	0.460
IsA	√	√	√	0.750	0.800	0.810	0.830	0.830
	√	√		0.710	0.770	0.790	0.800	0.800
	√			0.650	0.690	0.710	0.710	0.720
		√		0.060	0.220	0.350	0.480	0.520
WikiC	√	√	√	0.810	0.900	0.920	0.930	0.930
	√	√		0.750	0.830	0.860	0.860	0.870
	√			0.640	0.730	0.750	0.750	0.760
		√		0.110	0.210	0.370	0.520	0.560

Table 6: Average of scores indicating the presence or absence of any interpretations annotated with a correctness label from a particular subset of correctness labels. Computed over interpretations extracted up to various ranks in the ranked lists of extracted interpretations (cg=correct generic; cs=correct specific; qq=okay)

Noun Phrase → Multiple-Bracketing Interpretations
african american women writers → (writers)$_H$ who wrote about (african american)$_M$ women, (women writers)$_H$ who are (african american)$_M$, (writers)$_H$ who cover (african american)$_M$ women struggles
chinese traditional instruments → (traditional instruments)$_H$ of (china)$_M$, (instruments)$_H$ used in (chinese traditional)$_M$ music
elementary math manipulatives → (manipulatives)$_H$ for (elementary math)$_M$, (math manipulatives)$_H$ in the (elementary)$_M$ classroom, (manipulatives)$_H$ used in (elementary math)$_M$, (math manipulatives)$_H$ for (elementary)$_M$ level
global corporate tax rates → (corporate tax rates)$_H$ around the (world)$_M$, (tax rates)$_H$ on (global corporate)$_M$ profits

Table 7: Sample of noun phrases from the ListQ gold set, whose top 10 extracted interpretations induce multiple pairs of a head and a modifier of the noun phrases (H=head; M=modifier)

portion in Table 6, the scores at rank 5 are 0.830 for ListQ, 0.790 for IsA and 0.860 for WikiC. Alternatively, in the fourth rows of each vertical portion, the scores at rank 5 are 0.360, 0.350 and 0.370 respectively. The scores indicate that at least one of the top 5 interpretations is correct and specific for about a third of the noun phrases in the gold sets.

Induced Modifiers, Heads and Interpretations: When a candidate interpretation is extracted for a noun phrase, the interpretation effectively induces a particular bracketing over the noun phrase, as it splits it into a modifier and a head. For an ambiguous

Presence of Multiple Bracketings			
Vocabulary	ListQ	IsA	WikiC
Fraction of Noun Phrases	0.110	0.124	0.051

Table 8: Fraction of noun phrases that have some extracted interpretation(s) and contain at least 3 tokens, whose interpretations induce multiple (rather than single) bracketings over interpreted noun phrases. The presence of multiple bracketings for a noun phrase is equivalent to the presence of multiple pairs of a head and a modifier, as induced by the top 10 interpretations extracted for the noun phrase

Noun Phrase → Extracted Interpretations
beatles songs → (songs)$_H$ sung by the (beatles)$_M$, (songs)$_H$ about the (beatles)$_M$
company accounts → (accounts)$_H$ maintained by the (company)$_M$, (accounts)$_H$ owed to a (company)$_M$
florida insurance companies → (insurance companies)$_H$ headquartered in (florida)$_M$, (insurance companies)$_H$ insuring in (florida)$_M$
german food → (food)$_H$ eaten in (germany)$_M$, (food)$_H$ produced in (germany)$_M$, (food)$_H$ that originated in (germany)$_M$
math skills → (skills)$_H$ needed for (math)$_M$, (skills)$_H$ learned in (math)$_M$, (skills)$_H$ gained from studying (math)$_M$
michael jackson song → (song)$_H$ written by (michael jackson)$_M$, (song)$_H$ sung by (michael jackson)$_M$, (song)$_H$ about (michael jackson)$_M$

Table 9: Sample of alternative relevant interpretations extracted among the top 20 interpretations for noun phrases from the ListQ gold set (H=head; M=modifier)

noun phrase, multiple bracketings may be possible, each corresponding to a different interpretation. Interpretations extracted from queries do capture such multiple bracketings, even for phrases from the gold sets, as illustrated in Table 7. Over all noun phrases from the input vocabularies that have some extracted interpretations and contain at least 3 tokens, about 10% (ListQ and IsA) and 5% (WikiC) of the noun phrases have multiple bracketings induced by their top 10 interpretations, as shown in Table 8.

Table 9 shows examples of noun phrases with multiple extracted interpretations that induce identical bracketings, but capture distinct interpretations.

Impact of Variants: Variants of modifiers provide alternatives in extracting candidate interpretations, even when the modifiers from the noun phrases are not present in their original form in the interpretations. For example, the adj-noun variant *ethiopia* of the modifier *ethiopian* leads to the extraction of the interpretation *"runners from ethiopia"* for the noun phrase *"ethiopian runners"*. Similarly, wiki-

Vocab	Variant Type			
	orig-phrase	adj-noun	dist-sim	wiki-templ
Interpretations produced by variant type (not exclusive):				
ListQ	0.453	0.089	0.642	0.017
IsA	0.389	0.121	0.597	0.003
WikiC	0.191	0.097	0.603	0.425
Interpretations produced only by variant type (exclusive):				
ListQ	0.281	0.069	0.450	0.005
IsA	0.299	0.099	0.491	0.001
WikiC	0.086	0.076	0.351	0.225

Table 10: Impact of various types of variants of modifiers, on the coverage of noun phrase interpretations. Computed as the fraction of the top 10 extracted interpretations produced by a particular variant type, and possibly by other variant types (upper portion); or produced only by a particular variant type, and by no other variant types (lower portion) (Vocab=vocabulary of noun phrases)

templ variants *metallica* and *50 cent* of the modifier *art garfunkel*, in the context *"X albums"*, allow for the extraction of the interpretation *"albums sold by art garfunkel"* for the noun phrase *"art garfunkel albums"*, via the interpretations *"albums sold by metallica"* and *"albums sold by 50 cent"*.

Table 10 quantifies the impact of various types of variants, on the coverage of noun phrase interpretations. The scores provided for each variant type correspond to either non-exclusive (upper portion of the table) or exclusive (lower portion) contribution of that variant type towards some extracted interpretations. In other words, in the lower portion, the scores capture the fraction of the top 10 interpretations that are produced only by that particular variant type. Three conclusions can be drawn from the results. First, all variant types contribute to increasing coverage, relative to using only orig-phrase variants. Second, dist-sim variants have a particularly strong impact. Third, wiki-templ variants have a strong impact, but only when the contexts from which they were collected match the context of the noun phrase being interpreted. On the WikiC vocabulary in the lower portion of Table 10, the scores for wiki-templ illustrate the potential that contextual variants have in extracting additional interpretations.

Table 11 again quantifies the impact of variant types, but this time on the coverage and, more importantly, accuracy of interpretations extracted for phrases from the gold sets. The scores are computed over the ranked lists of interpretations from the ListQ gold set, as certain types of variants are temporarily disabled in ablation experiments. The upper portion of the table shows results when only

Variant Types				Impact on Precision

Table 11: Impact of various types of variants of modifiers, on the precision of noun phrase interpretations. Computed over the ListQ gold set, at rank 5 in the ranked lists of extracted interpretations, when various variant types are allowed (√) or temporarily not allowed (-) to produce interpretations (O=orig-phrase variant type; A=adj-noun variant type; D=dist-sim variant type; W=wiki-templ variant type; Cvg=number of noun phrases from the gold set with some interpretation(s) produced by the allowed variant types; P@5=precision at rank 5; C@5=average presence of any interpretations annotated as correct and generic (cg) or correct and specific (cs), among interpretations up to rank 5)

one of the variant types is enabled. It shows that none of the variant types, taken in isolation, can match what they achieve when combined together, in terms of both coverage and accuracy. The middle portion of the table shows results when all but one of the variant types are enabled. Each of the variant types incrementally contributes to higher coverage and accuracy over the combination of the other variant types. The incremental contribution of wiki-templ variants is the smallest. The lower portion of Table 11 gives the incremental contribution of the variant types, relative to using only the orig-phrase variant type. The last row of Table 11 corresponds to all variant types being enabled.

Discussion: Independently of the choice of the textual data source (e.g., documents, queries) from which interpretations are extracted, a noun phrase is intuitively more difficult to interpret if it is relatively more rare or more complex (i.e., longer). Additional experiments quantify the effect, by measuring the correlation between the presence of some extracted interpretations for an input noun phrase, on one hand; and the frequency of the noun phrase as a query (in Table 12), on the other hand. In Table 12,

Vocabulary	Noun Phrases With : Without Interpretation(s)		
	I : ¬I	A_I : $A_{\neg I}$	M_I : $M_{\neg I}$
ListQ	2.14 : 1	2.93 : 1	2.65 : 1
IsA	2.31 : 1	5.76 : 1	3.26 : 1
WikiC	2.60 : 1	3.72 : 1	3.63 : 1

Table 12: Correlation between coverage, measured as the presence of some extracted interpretation(s) for a noun phrase, on one hand; and frequency of the noun phrase as a query, on the other hand (I=number of noun phrases that are queries and have some extracted interpretation(s); ¬I=number of noun phrases that are queries and do not have any extracted interpretation(s); A=average query frequency of noun phrases as queries; M=median query frequency of noun phrases as queries)

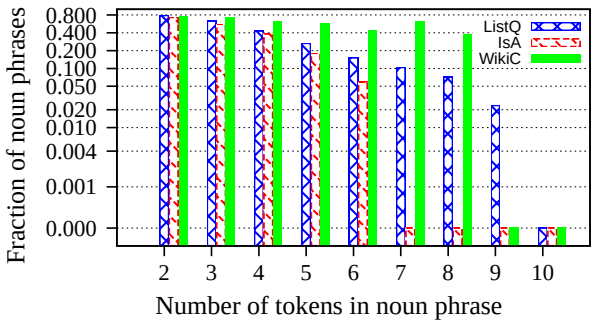

Figure 2: Ability to extract interpretations for noun phrases, as a function of the length of noun phrases. Computed as the fraction of noun phrases from an input vocabulary with a particular number of tokens, for which there are some extracted interpretation(s)

the effect is visible in that query frequency is higher for noun phrases with some extracted interpretations vs. noun phrases with none. For example, the average query frequency is almost three times higher for the former than for the latter, for the ListQ vocabulary. Similarly, in Figure 2, a larger fraction of the input noun phrases with a particular number of tokens have some extracted interpretations, when the number of tokens is lower rather than higher. The effect is somewhat less pronounced for, but still applicable to, the WikiC vocabulary, with some extracted interpretations being present for 75%, 71%, 63%, and 37% of the noun phrases containing 2, 3, 4 and 8 tokens respectively. That a larger fraction of the longer noun phrases can be interpreted in the WikiC vocabulary is attributed to the role of wiki-templ variants in extracting interpretations that would otherwise not be available.

Interpretations from Queries vs. Documents: For completeness, additional experiments evaluate the interpretations extracted from queries, relative to a gold standard introduced in (Hendrickx et al., 2013). The gold standard consists of a gold set of 181 compound noun phrases (e.g., *"accounting principle"* and *"application software"*), their manually-assembled gold paraphrases (e.g., *"principle of accounting"*, *"software to make applications"*), and associated scoring metrics referred to as non-isomorphic and isomorphic. Note that, in comparison to the ListQ, IsA and WikiC evaluation sets, the gold standard in (Hendrickx et al., 2013) may contain relatively less popular gold phrases. As many as 45 gold paraphrases are available per gold phrase on average. They illustrate the difficulty of any attempt to manually assemble exhaustive sets of all strings that are valid interpretations of a noun phrase. For example, the gold paraphrases of the gold phrase *blood cell* include *"cell that is found in the blood"*, but not the arguably equally-relevant *"cell found in the blood"*. In addition, more than one human annotators independently provide the same gold paraphrase for only a tenth of all gold paraphrases. See (Hendrickx et al., 2013) for details on the gold standard and scoring metrics. The gold set is added as another input vocabulary to the method proposed here. After inspection of a training set of compound noun phrases also introduced in (Hendrickx et al., 2013), the parameter settings are modified to only retain interpretations whose penalty score is 0.

The isomorphic and non-isomorphic scores reward coverage and accuracy respectively. For the ranked candidate interpretations extracted from queries for the gold set, they are 0.037 and 0.556 respectively. In comparison to previous methods that operate over documents instead of queries, the isomorphic score is much lower for our method (e.g., 0.037 vs. 0.130 (Van de Cruys et al., 2013)). It suggests that queries cannot reliably provide an exhaustive list of all possible strings available in the gold standard for each gold phrase. However, the non-isomorphic score is higher for our method than for the best method operating over documents (i.e., 0.556 vs. 0.548 (Hendrickx et al., 2013)). In fact, the non-isomorphic score using queries would be 0.745 instead of 0.556, if it were computed over only the 135 gold noun phrases with some extracted interpretations. The results suggests that the method proposed here extracts more accurate interpretations from queries, than previous methods extract from

documents. Higher accuracy is preferable in scenarios like Web search, where it is important to accurately trigger structured results.

Error Analysis: The relative looseness of the extraction patterns applied to queries causes interpretations containing undesirable tokens to be extracted. In addition, part-of-speech tagging errors lead to interpretations receiving artificially low penalty scores, and therefore being considered to be of higher quality than they should be. For example, *phd* in the interpretation *"job for phd in chemistry"* is incorrectly tagged as a past participle verb. As a result, the computed penalty score is too low.

Occasionally, the presence of additional tokens within an interpretation is harmless (e.g., *"issues of controversy in society"* for *"controversial issues"*, *"foods allowed on a high protein low carb diet"* for *"high protein low carb foods"*), if not necessary (e.g., *"dances with brazilian origin"* for *"brazilian dances"*, *"artists of the surrealist movement"* for *"surrealist artists"*, *"options with weekly expirations"* for *"weekly options"*). But often it leads to incorrect interpretations (e.g., *"towns of alaska map"* for *"alaska towns"*, *"processes in chemical vision"* for *"chemical processes"*).

Variants of modifiers occasionally lead to incorrect interpretations for a noun phrase, even if the interpretations may be correct for the individual variants. The phenomenon is an instance of semantic drift, wherein variants do share many properties but still diverge in others. Examples are *"words that are bleeped similarly"* extracted for *"bleeped words"* via the variant *bleeped→spelled*. Separately, linguistic constructs that negate or at least alter the desired meaning affect the understanding of text in general and also affect the extraction of interpretations in particular. Examples are *"heaters with no electricity"* for *"electric heaters"*, and *"animal that used to be endangered"* for *"endangered animal"*.

5 Related Work

Relevant interpretations extracted from queries act as a potential bridge between facts, on one hand, and class labels, on the other hand, available for instances. The former might be inferred from the latter and vice versa. There are two previous studies that are relevant to the task of extracting facts from existing noun phrases. First, (Yahya et al., 2014) extract facts for attributes of instances, without requiring the presence of the verbal predicates usually employed (Fader et al., 2011) in open-domain information extraction. Second, in (Nastase and Strube, 2008), relations encoded implicitly within Wikipedia categories are converted into explicit relations. As an example, the relation <*deconstructing harry*, *directed*, *woody allen*> is obtained from the fact that *deconstructing harry* is listed under *"movies directed by woody allen"* in Wikipedia. The method in (Nastase and Strube, 2008) relies on manually-compiled knowledge, and does not attempt to interpret compound noun phrases.

Since relevant interpretations paraphrase the noun phrases which they interpret, a related area of research is paraphrase acquisition (Madnani and Dorr, 2010; Ganitkevitch et al., 2013). Previous methods for the acquisition of paraphrases of compound noun phrases (Kim and Nakov, 2011; Van de Cruys et al., 2013) operate over documents, and may rely on text analysis tools including syntactic parsing (Nakov and Hearst, 2013). In contrast, the method proposed here extracts interpretations from queries, and applies part of speech tagging. Queries were used as a textual data source in other tasks in open-domain information extraction (Jain and Pennacchiotti, 2010; Pantel et al., 2012).

6 Conclusion

Interpretations extracted from queries explain the roles that modifiers play within longer noun phrases. Current work explores the interpretation of noun phrases containing multiple modifiers (e.g., *"(french)$_{M1}$ (healthcare)$_{M2}$ (companies)$_{H}$"* by separately interpreting *"(french)$_{M1}$ (companies)$_{H}$"* and *"(healthcare)$_{M2}$ (companies)$_{H}$"*); the grouping of lexically different but semantically equivalent interpretations (e.g., *"dances of brazilian origin"*, *"dances from brazil"*); the collection of more variants from Wikipedia and other resources; the incorporation of variants of heads (*physicists→scientists* for interpreting the phrase *"belgian physicists"*), which likely need to be more conservatively applied than for modifiers; and the use of query sessions, as an alternative to sets of disjoint queries.

Abstract

We present an approach to speech recognition that uses only a neural network to map acoustic input to characters, a character-level language model, and a beam search decoding procedure. This approach eliminates much of the complex infrastructure of modern speech recognition systems, making it possible to directly train a speech recognizer using errors generated by spoken language understanding tasks. The system naturally handles out of vocabulary words and spoken word fragments. We demonstrate our approach using the challenging Switchboard telephone conversation transcription task, achieving a word error rate competitive with existing baseline systems. To our knowledge, this is the first entirely neural-network-based system to achieve strong speech transcription results on a conversational speech task. We analyze qualitative differences between transcriptions produced by our lexicon-free approach and transcriptions produced by a standard speech recognition system. Finally, we evaluate the impact of large context neural network character language models as compared to standard n-gram models within our framework.

1 Introduction

Users increasingly interact with natural language understanding systems via conversational speech interfaces. Google Now, Microsoft Cortana, and Apple Siri are all systems which rely on *spoken language understanding* (SLU), where transcribing speech is a single step within a larger system. Building such systems is difficult because spontaneous, conversational speech naturally contains repetitions, disfluencies, partial words, and out of vocabulary (OOV) words (De Mori et al., 2008; Huang et al., 2001). Moreover, SLU systems must be robust to transcription errors, which can be quite high depending on the task and domain.

Modern systems for large vocabulary continuous speech recognition (LVCSR) use hidden Markov models (HMMs) to handle sequence processing, word-level language models, and a pronunciation lexicon to map words into phonetic pronunciations (Saon and Chien, 2012). Traditional systems use Gaussian mixture models (GMMs) to build a mapping from sub-phonetic states to audio input features. The resulting speech recognition system contains many sub-components, linguistic assumptions, and typically over ten thousand lines of source code. Within the past few years LVCSR systems improved by replacing GMMs with deep neural networks (DNNs) (Dahl et al., 2011; Hinton et al., 2012), drawing on early work on with hybrid GMM-NN architectures (Bourlard and Morgan, 1993). Both HMM-GMM and HMM-DNN systems remain difficult to build, and nearly impossible to efficiently optimize for downstream SLU tasks. As a result, SLU researchers typically operate on an n-best list of possible transcriptions and treat the LVCSR system as a black box.

Recently Graves and Jaitly (2014) demonstrated an approach to LVCSR using a neural network trained with the connectionist temporal classification (CTC) loss function (Graves et al., 2006). Us-

[*]Authors contributed equally.

Denver, Colorado, May 31 – June 5, 2015.

ing the CTC loss function the authors built a neural network which directly maps audio input features to a sequence of characters. By re-ranking word-level n-best lists generated from an HMM-DNN system the authors obtained competitive results on the Wall Street Journal corpus.

Our work builds upon the foundation introduced by Graves and Jaitly (2014). Rather than reasoning at the word level, we train and decode our system by reasoning entirely at the character-level. By reasoning over characters we eliminate the need for a lexicon, and enable transcribing new words, fragments, and disfluencies. We train a deep bidirectional recurrent neural network (DBRNN) to directly map acoustic input to characters using the CTC loss function introduced by Graves and Jaitly (2014). We are able to efficiently and accurately perform transcription using only our DBRNN and a character-level language model (CLM), whereas previous work relied on n-best lists from a baseline HMM-DNN system. On the challenging Switchboard telephone conversation transcription task, our approach achieves a word error rate competitive with existing baseline HMM-GMM systems. To our knowledge, this is the first entirely neural-network-based system to achieve strong speech transcription results on a conversational speech task.

Section 2 reviews the CTC loss function and describes the neural network architecture we use. Section 3 presents our approach to efficiently perform first-pass decoding using a neural network for character probabilities and a character language model. Section 4 presents experiments on the Switchboard corpus to compare our approach to existing LVCSR systems, and evaluates the impact of different language models. In Section 5, we offer insight on how the CTC-trained system performs speech recognition as compared to a standard HMM-GMM model, and finally conclude in Section 6.

2 Model

We address the complete LVCSR problem. Our system trains on utterances which are labeled by word-level transcriptions and contain no indication of when words occur within an utterance. Our approach consists of two neural networks which we integrate during a beam search decoding procedure. Our first neural network, a DBRNN, maps acoustic input features to a probability distribution over characters at each time step. Our second system component is a neural network character language model. Neural network CLMs enable us to leverage high order n-gram contexts without dramatically increasing the number of free parameters in our language model. To facilitate further work with our approach we make our source code publicly available. [1]

2.1 Connectionist Temporal Classification

We train neural networks using the CTC loss function to do maximum likelihood training of letter sequences given acoustic features as input. This is a direct, discriminative approach to building a speech recognition system in contrast to the generative, noisy-channel approach which motivates HMM-based speech recognition systems. Our application of the CTC loss function follows the approach introduced by Graves and Jaitly (2014), but we restate the approach here for completeness.

CTC is a generic loss function to train systems on sequence problems where the alignment between the input and output sequence are unknown. CTC accounts for time warping of the output sequence relative to the input sequence, but does not model possible re-orderings. Re-ordering is a problem in machine translation, but is not an issue when working with speech recognition – our transcripts provide the exact ordering in which words occur in the input audio.

Given an input sequence X of length T, CTC assumes the probability of a length T character sequence C is given by,

$$p(C|X) = \prod_{t=1}^{T} p(c_t|X). \tag{1}$$

This assumes that character outputs at each timestep are conditionally independent given the input. The distribution $p(c_t|X)$ is the output of some predictive model.

CTC assumes our ground truth transcript is a character sequence W with length τ where $\tau \leq T$. As a result, we need a way to construct possibly shorter output sequences from our length T sequence of

[1] Available at: `deeplearning.stanford.edu/lexfree`

character probabilities. The CTC *collapsing function* achieves this by introducing a special *blank* symbol, which we denote using "_", and collapsing any repeating characters in the original length T output. This output symbol contains the notion of *junk* or *other* so as to not produce a character in the final output hypothesis. Our transcripts W come from some set of symbols ζ' but we reason over $\zeta = \zeta' \cup \_$.

We denote the collapsing function by $\kappa(\cdot)$ which takes an input string and produces the unique collapsed version of that string. As an example, here are the set of strings Z of length $T = 3$ such that $\kappa(z) = \texttt{hi},\ \forall z \in Z$:

$$Z = \{\texttt{hhi}, \texttt{hii}, \texttt{\_hi}, \texttt{h\_i}, \texttt{hi\_}\}.$$

There are a large number of possible length T sequences corresponding to a final length τ transcript hypothesis. The CTC objective function $\mathcal{L}_{\text{CTC}}(X, W)$ is a likelihood of the correct final transcript W which requires integrating over the probabilities of all length T character sequences $C_W = \{C : \kappa(C) = W\}$ consistent with W after applying the collapsing function,

$$\begin{aligned} \mathcal{L}_{\text{CTC}}(X, W) &= \sum_{C_W} p(C|X) \\ &= \sum_{C_W} \prod_{t=1}^{T} p(c_t|X). \end{aligned} \tag{2}$$

Using a dynamic programming approach we can exactly compute this loss function efficiently as well as its gradient with respect to our probabilities $p(c_t|X)$.

2.2 Deep Bi-Directional Recurrent Neural Networks

Our loss function requires at each time t a probability distribution $p(c|x_t)$ over characters c given input features x_t. We model this distribution using a DBRNN because it provides an expressive model which explicitly accounts for the sequential relationships that should exist in our task. Moreover, the DBRNN is a relatively straightforward neural network architecture to specify, and allows us to learn parameters from data rather than more explicitly specifying how to convert audio features into characters. Figure 1 shows a DBRNN with two hidden layers.

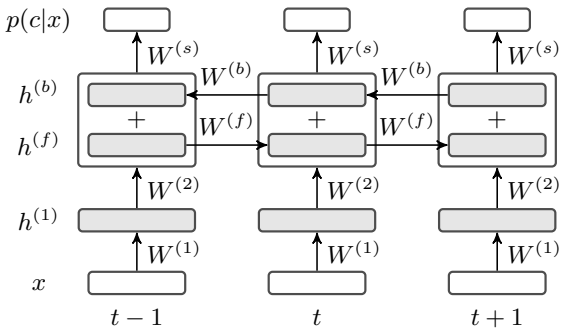

Figure 1: Deep bi-directional recurrent neural network to map input audio features X to a distribution $p(c|x_t)$ over output characters at each timestep t. The network contains two hidden layers with the second layer having bi-directional temporal recurrence.

A DBRNN computes the distribution $p(c|x_t)$ using a series of hidden layers followed by an output layer. Given an input vector x_t the first hidden layer activations are a vector computed as,

$$h^{(1)} = \sigma(W^{(1)T} x_t + b^{(1)}), \tag{3}$$

where the matrix $W^{(1)}$ and vector $b^{(1)}$ are the weight matrix and bias vector. The function $\sigma(\cdot)$ is a point-wise nonlinearity. We use $\sigma(z) = \min(\max(z, 0), \mu)$. This is a rectified linear activation function clipped to a maximum possible activation of μ to prevent overflow. Rectified linear hidden units have been show to work well in general for deep neural networks, as well as for acoustic modeling of speech data (Glorot et al., 2011; Zeiler et al., 2013; Dahl et al., 2013; Maas et al., 2013)

We select a single hidden layer j of the network to have temporal connections. Our temporal hidden layer representation $h^{(j)}$ is the sum of two partial hidden layer representations,

$$h_t^{(j)} = h_t^{(f)} + h_t^{(b)}. \tag{4}$$

The representation $h^{(f)}$ uses a weight matrix $W^{(f)}$ to propagate information forwards in time. Similarly, the representation $h^{(b)}$ propagates information backwards in time using a weight matrix $W^{(b)}$. These partial hidden representations both take input from the previous hidden layer $h^{(j-1)}$ using a weight

matrix $W^{(j)}$,

$$h_t^{(f)} = \sigma(W^{(j)T} h_t^{(j-1)} + W^{(f)T} h_{t-1}^{(f)} + b^{(j)}),$$
$$h_t^{(b)} = \sigma(W^{(j)T} h_t^{(j-1)} + W^{(b)T} h_{t+1}^{(b)} + b^{(j)}). \quad (5)$$

Note that the recurrent forward and backward hidden representations are computed entirely independently from each other. As with the other hidden layers of the network we use $\sigma(z) = \min(\max(z, 0), \mu)$.

All hidden layers aside from the first hidden layer and temporal hidden layer use a standard dense weight matrix and bias vector,

$$h^{(i)} = \sigma(W^{(i)T} h^{(i-1)} + b^{(i)}). \quad (6)$$

DBRNNs can have an arbitrary number of hidden layers, but we assume that only one hidden layer contains temporally recurrent connections.

The model outputs a distribution $p(c|x_t)$ over a set of possible characters ζ using a *softmax* output layer. We compute the softmax layer as,

$$p(c = c_k|x_t) = \frac{\exp(-(W_k^{(s)T} h^{(:)} + b_k^{(s)}))}{\sum_{j=1}^{|\zeta|} \exp(-(W_j^{(s)T} h^{(:)} + b_j^{(s)}))}, \quad (7)$$

where $W_k^{(s)}$ is the k'th column of the output weight matrix $W^{(s)}$ and $b_k^{(s)}$ is a scalar bias term. The vector $h^{(:)}$ is the hidden layer representation of the final hidden layer in our DBRNN.

We can directly compute a gradient for all weights and biases in the DBRNN with respect to the CTC loss function and apply batch gradient descent.

3 Decoding

Our decoding procedure integrates information from the DBRNN and language model to form a single cohesive estimate of the character sequence in a given utterance. For an input sequence X of length T our DBRNN produces a set of probabilities $p(c|x_t),\ t = 1, \ldots, T$. Again, the character probabilities are a categorical distribution over the symbol set ζ.

3.1 Decoding Without a Language Model

As a baseline, we use a simple, greedy approach to decoding the DBRNN outputs (Graves and Jaitly, 2014). The simplest form of decoding does not employ the language model and instead finds the highest probability character transcription given only the DBRNN outputs. This process selects a transcript hypothesis W^* by making a greedy approximation,

$$W^* = \arg\max_W p(W|X) \approx \kappa(\arg\max_C p(C|X))$$
$$= \kappa(\arg\max_C \prod_{t=1}^{T} p(c_t|X)). \quad (8)$$

This decoding procedure ignores the issue of many time-level character sequences mapping to the same final hypothesis, and instead considers only the most probable character at each point in time. Because our model assumes the character labels for each timestep are conditionally independent, C^* is simply the most probable character at each timestep in our DBRNN output. As a result, this decoding procedure is very fast to compute, requiring only time $O(T|\zeta|)$.

3.2 Beam Search Decoding

To decode while taking language model probabilities into account, we use a beam search to combine a character language model and the outputs of our DBRNN. This search-based decoding method does not make a greedy approximation and instead assigns probability to a final hypothesis by integrating over all character sequences consistent with the hypothesis under our collapsing function $\kappa(\cdot)$. Algorithm 1 outlines our decoding procedure.

We note that our decoding procedure is significantly simpler, and in practice faster, than previous decoding procedures applied to CTC models. This is due to reasoning at the character level without a lexicon so as to not introduce difficult multi-level constraints to obey during the decoding search procedure. While a softmax over words is typically the bottleneck in neural network language models, a softmax over possible characters is comparatively cheap to compute. Our character language model is applied at every time step, while word models can only be applied when we consider adding a space or by computing the likelihood of a sequence being the prefix of a word in the lexicon (Graves and Jaitly, 2014). Additionally, our lexicon-free approach re-

Algorithm 1 Beam Search Decoding: Given the likelihoods from our DBRNN and our character language model, for each time step t and for each string s in our current previous hypothesis set Z_{t-1}, we consider extending s with a new character. Blanks and repeat characters with no separating blank are handled separately. For all other character extensions, we apply our character language model when computing the probability of s. We initialize Z_0 with the empty string $\varnothing$. Notation: ζ': character set excluding "_", $s + c$: concatenation of character c to string s, $|s|$: length of s, $p_{\text{b}}(c|x_{1:t})$ and $p_{\text{nb}}(c|x_{1:t})$: probability of s ending and not ending in blank conditioned on input up to time t, $p_{\text{tot}}(c|x_{1:t})$: $p_{\text{b}}(c|x_{1:t}) + p_{\text{nb}}(c|x_{1:t})$

Inputs CTC likelihoods $p_{\text{ctc}}(c|x_t)$, character language model $p_{\text{clm}}(c|s)$
Parameters language model weight α, insertion bonus β, beam width k
Initialize $Z_0 \leftarrow \{\varnothing\}$, $p_{\text{b}}(\varnothing|x_{1:0}) \leftarrow 1$, $p_{\text{nb}}(\varnothing|x_{1:0}) \leftarrow 0$

moves the difficulties of handling OOV words during decoding, which is typically a troublesome issue in speech recognition systems.

4 Experiments

We perform LVCSR experiments on the 300 hour Switchboard conversational telephone speech corpus (LDC97S62). Switchboard utterances are taken from approximately 2,400 conversations among 543 speakers. Each pair of speakers had never met, and converse no more than once about a given topic chosen randomly from a set of 50 possible topics. Utterances exhibit many rich, complex phenomena that make spoken language understanding difficult. Table 2 shows example transcripts from the corpus.

For evaluation, we report word error rate (WER) and character error rate (CER) on the HUB5 Eval2000 dataset (LDC2002S09). This test set consists of two subsets, Switchboard and CallHome. The CallHome subset represents a mismatched test condition as it was collected from phone conversations among family and friends rather than strangers directed to discuss a particular topic. The mismatch makes the CallHome subset quite difficult overall. The Switchboard evaluation subset is substantially easier, and represents a better match of test data to our training corpus. We report WER and CER on the test set as a whole, and additionally report WER for each subset individually.

4.1 Baseline Systems

We build two baseline LVCSR systems to compare our approach to standard HMM-based approaches.

Method	CER	EV	CH	SWBD
HMM-GMM	23.0	29.0	36.1	21.7
HMM-DNN	17.6	21.2	27.1	15.1
HMM-SHF	NR	NR	NR	12.4
CTC no LM	27.7	47.1	56.1	38.0
CTC+5-gram	25.7	39.0	47.0	30.8
CTC+7-gram	24.7	35.9	43.8	27.8
CTC+NN-1	24.5	32.3	41.1	23.4
CTC+NN-3	24.0	30.9	39.9	21.8
CTC+RNN	24.9	33.0	41.7	24.2
CTC+RNN-3	24.7	30.8	40.2	21.4

Table 1: Character error rate (CER) and word error rate results on the Eval2000 test set. We report word error rates on the full test set (EV) which consists of the Switchboard (SWBD) and CallHome (CH) subsets. As baseline systems we use an HMM-GMM system and HMM-DNN system. We evaluate our DBRNN trained using CTC by decoding with several character-level language models: 5-gram, 7-gram, densely connected neural networks with 1 and 3 hidden layers (NN-1, and NN-3), as well as recurrent neural networks s with 1 and 3 hidden layers. We additionally include results from a state-of-the-art HMM-based system (HMM-DNN-SHF) which does not report performance on all metrics we evaluate (NR).

First, we build an HMM-GMM system using the Kaldi open-source toolkit[2] (Povey et al., 2011). The baseline recognizer has 8,986 sub-phone states and 200K Gaussians trained using maximum likelihood. Input features are speaker-adapted MFCCs. Overall, the baseline GMM system setup largely follows the existing `s5b` Kaldi recipe, and we defer to previous work for details (Vesely et al., 2013).

We additionally built an HMM-DNN system by training a DNN acoustic model using maximum likelihood on the alignments produced by our HMM-GMM system. The DNN consists of five hidden layers, each with 2,048 hidden units, for a total of approximately 36 million (M) free parameters in the acoustic model.

Both baseline systems use a bigram language model built from the 3M words in the Switchboard transcripts interpolated with a second bigram language model built from 11M words on the Fisher English Part 1 transcripts (LDC2004T19). Both LMs are trained using interpolated Kneser-Ney smoothing. For context we also include WER results from a state-of-the-art HMM-DNN system built with quinphone phonetic context and Hessian-free sequence-discriminative training (Sainath et al., 2014).

[2] `http://kaldi.sf.net`

4.2 DBRNN Training

We train a DBRNN using the CTC loss function on the entire 300hr training corpus. The input features to the DBRNN at each timestep are MFCCs with context window of ± 10 frames. The DBRNN has 5 hidden layers with the third containing recurrent connections. All layers have 1824 hidden units, giving about 20M trainable parameters. In preliminary experiments we found that choosing the middle hidden layer to have recurrent connections led to the best results.

The output symbol set ζ consists of 33 characters including the special blank character. Note that because speech recognition transcriptions do not contain proper casing or punctuation, we exclude capital letters and punctuation marks with the exception of "–", which denotes a partial word fragment, and "′", as used in contractions such as "`can′t`."

We train the DBRNN from random initial parameters using the gradient-based Nesterov's accelerated gradient (NAG) algorithm as this technique is sometimes beneficial as compared with standard stochastic gradient descent for deep recurrent neural network training (Sutskever et al., 2013). The NAG algorithm uses a step size of 10^{-5} and a momentum of 0.95. After each epoch we divide the learning rate by 1.3. Training for 10 epochs on a single GTX 570 GPU takes approximately one week.

4.3 Character Language Model Training

The Switchboard corpus transcripts alone are too small to build CLMs which accurately model general orthography in English. To learn how to spell words more generally we train our CLMs using a corpus of 31 billion words gathered from the web (Heafield et al., 2013). Our language models use sentence start and end tokens, `<s>` and `</s>`, as

well as a <null> token for cases when our context window extends past the start of a sentence.

We build 5-gram and 7-gram CLMs with modified Kneser-Ney smoothing using the KenLM toolkit (Heafield et al., 2013). Building traditional n-gram CLMs is for $n > 7$ becomes increasingly difficult as the model free parameters and memory footprint become unwieldy. Our 7-gram CLM is already 21GB; we were not able to build higher order n-gram models to compare against our neural network CLMs.

Following work illustrating the effectiveness of neural network CLMs (Sutskever et al., 2011) and word-level LMs for speech recognition (Mikolov et al., 2010), we train and evaluate two variants of neural network CLMs: standard feedfoward deep neural networks (DNNs) and a recurrent neural network (RNN). The RNN CLM takes one character at a time as input, while the non-recurrent CLM networks use a context window of 19 characters. All neural network CLMs use the rectified linear activation function, and the layer sizes are selected such that each has about 5M parameters (20MB).

The DNN models are trained using standard backpropagation using Nesterov's accelerated gradient with a learning rate of 0.01 and momentum of 0.95 and a batch size of 512. The RNN is trained using backpropagation through time with a learning rate of 0.001 and batches of 128 utterances. For both model types we halve the learning rate after each epoch. The DNN models were trained for 10 epochs, and the RNN models for 5 epochs.

All neural network CLMs were trained using a combination of the Switchboard and Fisher training transcripts which in total contain approximately 23M words. We also performed experiments with CLMs trained from a large corpus of web text, but found these CLMs to perform no better than transcript-derived CLMs for our task.

4.4 Results

After training the DBRNN and CLMs we run decoding on the Eval2000 test set to obtain CER and WER results. For all experiments using a CLM we use our beam search decoding algorithm with $\alpha = 1.25$, $\beta = 1.5$ and a beam width of 100. We found that larger beam widths did not significantly improve performance. Table 1 shows results for the DBRNN as well as baseline systems.

The DBRNN performs best with the 3 hidden layer DNN CLM. This DBRNN+NN-3 attains both CER and WER performance comparable to the HMM-GMM baseline system, albeit substantially below the HMM-DNN system. Neural networks provide a clear gain as compared to standard n-gram models when used for DBRNN decoding, although the RNN CLM does not produce any gain over the best DNN CLM.

Without a language model the greedy DBRNN decoding procedure loses relatively little in terms of CER as compared with the DBRNN+NN-3 model. However, this 3% difference in CER translates to a 16% gap in WER on the full Eval2000 test set. Generally, we observe that small CER differences translate to large WER differences. In terms of character-level performance it appears as if the DBRNN alone performs well using only acoustic input data. Adding a CLM yields only a small CER improvement, but guides proper spelling of words to produce a large reduction in WER.

5 Analysis

To better see how the DBRNN performs transcription we show the output probabilities $p(c|x)$ for an example utterance in Figure 2. The model tends to output mostly blank characters and only spike long enough for a character to be the most likely symbol for a few frames at a time. The dominance of the blank class is not forced, but rather learned by the DBRNN during training. We hypothesize that this spiking behavior results in more stable results as the DBRNN only produces a character when its confidence of seeing that character rises above a certain threshold. Note that this a dramatic contrast to HMM-based LVCSR systems, which, due to the nature of generative models, attempt to explain almost all timesteps as belonging to a phonetic substate.

Next, we qualitatively compare the DBRNN and HMM-GMM system outputs to better understand how the DBRNN approach might interact with SLU systems. This comparison is especially interesting because our best DBRNN system and the HMM-GMM system have comparable WERs, removing the confound of overall quality when comparing hypotheses. Table 2 shows example test set utterances along with transcription hypotheses from the HMM-

#	Method	Transcription
(1)	Truth	yeah i went into the i do not know what you think of *fidelity* but
	HMM-GMM	yeah when the i don't know what you think of fidel it even them
	CTC+CLM	yeah i went to i don't know what you think of fidelity but um
(2)	Truth	no no speaking of weather do you carry a altimeter slash *barometer*
	HMM-GMM	no i'm not all being the weather do you uh carry a uh helped emitters last brahms her
	CTC+CLM	no no beating of whether do you uh carry a uh a time or less barometer
(3)	Truth	i would ima- well yeah it is i know you are able to stay home with them
	HMM-GMM	i would amount well yeah it is i know um you're able to stay home with them
	CTC+CLM	i would ima- well yeah it is i know uh you're able to stay home with them

Table 2: Example test set utterances with a ground truth transcription and hypotheses from our method (CTC+CLM) and a baseline HMM-GMM system of comparable overall WER. The words *fidelity* and *barometer* are not in the lexicon of the HMM-GMM system.

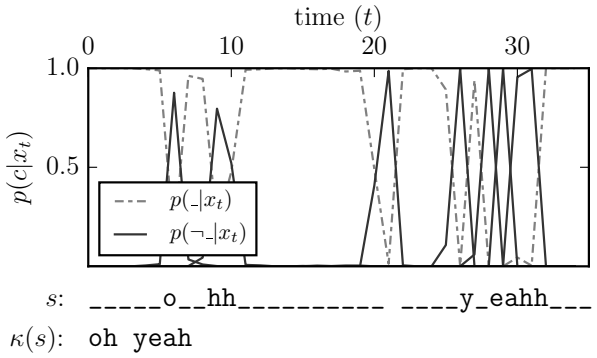

Figure 2: DBRNN character probabilities over time for a single utterance along with the per-frame most likely character string s and the collapsed output $\kappa(s)$. Due to space constraints we only show a distinction in line type between the blank symbol _ and non-blank symbols.

GMM and DBRNN+NN-3 systems.

The DBRNN sometimes correctly transcribes OOV words with respect to our audio training corpus. We find that OOVs tend to trigger clusters of errors in the HMM-GMM system, an observation that has been systematically explored in previous work (Goldwater et al., 2010). As shown in example utterance (3), HMM-GMM errors can introduce word substitution errors which may alter meaning whereas the DBRNN system outputs word fragments or non-words which are phonetically similar and may be useful input features for SLU systems. Unfortunately the Eval2000 test set does not offer a rich set of utterances containing OOVs or fragments to perform a deeper analysis. The HMM-GMM and best DBRNN system achieve identical WERs on the subset of test utterances containing OOVs and the subset of test utterances containing fragments.

Finally, we quantitatively compare how character probabilities from the DBRNN align with phonetic segments from the HMM-GMM system. We generate HMM-GMM forced alignments on a large sample of the training set, and separate utterances into monophone segments. For each monophone, we compute the average character probabilities from the DBRNN by aligning the beginning of each monophone segment, treating it as time 0. We measure time using feature frames rather than seconds. Figure 3 shows character probabilities over time for the phones *k*, *sh*, *w*, and *uw*.

Although the CTC model does not explicitly compute a forced alignment as part of training, we see significant rises in character probabilities corresponding to particular phones during HMM-GMM-aligned monophone segments. This indicates that the CTC model automatically learns a reasonable alignment of characters to the audio. Generally, the CTC model tends to produce character spikes towards the beginning of monophone segments. This is especially evident in plosive consonants such as *k* and *t*. For liquids and glides (*r*, *l*, *w*, *y*), the CTC model does not produce characters until later in the monophone segment. For vowels the CTC character

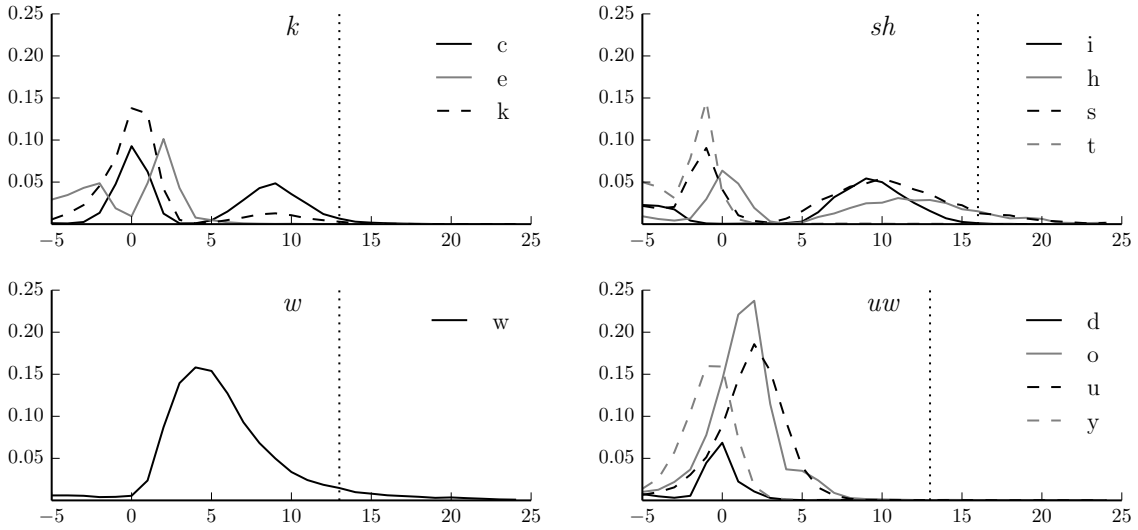

Figure 3: Character probabilities from the CTC-trained neural network averaged over monophone segments created by a forced alignment of the HMM-GMM system. Time is measured in frames, with 0 indicating the start of the monophone segment. The vertical dotted line indicates the average duration of the monophone segment. We show only characters with non-trivial probability for each phone while excluding the blank and space symbols.

probabilities generally rise slightly later in the phone segment as compared to consonants. This may occur to avoid the large contextual variations in vowel pronunciations at phone boundaries. For certain consonants we observe CTC probability spikes before the monophone segment begins, as is the case for *sh*. The probabilities for *sh* additionally exhibit multiple modes, suggesting that CTC may learn different behaviors for the two common spellings of the sibilant *sh*: the letter sequence "sh" and the letter sequence "ti".

6 Conclusion

We presented an LVCSR system consisting of two neural networks integrated via beam search decoding that matches the performance of an HMM-GMM system on the challenging Switchboard corpus. We built on the foundation of Graves and Jaitly (2014) to vastly reduce the overall complexity required for LVCSR systems. Our method yields a complete first-pass LVCSR system with about 1,000 lines of code — roughly an order of magnitude less than high performance HMM-GMM systems. Operating entirely at the character level yields a system which does not require assumptions about a lexicon or pronunciation dictionary, instead learning orthography and phonics directly from data. We hope the simplicity of our approach will facilitate future research in improving LVCSR with CTC-based systems and jointly training LVCSR systems for SLU tasks. DNNs have already shown great results as acoustic models in HMM-DNN systems. We free the neural network from its complex HMM infrastructure, which we view as the first step towards the next wave of advances in speech recognition and language understanding.

Acknowledgments

We thank Awni Hannun for his contributions to the software used for experiments in this work. We also thank Peng Qi and Thang Luong for insightful discussions, and Kenneth Heafield for help with the KenLM toolkit. Our work with HMM-GMM systems was possible thanks to the Kaldi toolkit and its contributors. Some of the GPUs used in this work were donated by the NVIDIA Corporation. AM was supported as an NSF IGERT Traineeship Recipient under Award 0801700. ZX was supported by an NDSEG Graduate Fellowship.

I Can Has Cheezburger?
A Nonparanormal Approach to Combining Textual and Visual Information for Predicting and Generating Popular Meme Descriptions

William Yang Wang and **Miaomiao Wen**
School of Computer Science
Carnegie Mellon University
Pittsburgh, PA 15213

Abstract

The advent of social media has brought Internet memes, a unique social phenomenon, to the front stage of the Web. Embodied in the form of images with text descriptions, little do we know about the "language of memes". In this paper, we statistically study the correlations among popular memes and their wordings, and generate meme descriptions from raw images. To do this, we take a multimodal approach—we propose a robust nonparanormal model to learn the stochastic dependencies among the image, the candidate descriptions, and the popular votes. In experiments, we show that combining text and vision helps identifying popular meme descriptions; that our nonparanormal model is able to learn dense and continuous vision features jointly with sparse and discrete text features in a principled manner, outperforming various competitive baselines; that our system can generate meme descriptions using a simple pipeline.

1 Introduction

In the past few years, Internet memes become a new, contagious social phenomenon: it all starts with an image with a witty, catchy, or sarcastic sentence, and people circulate it from friends to friends, colleagues to colleagues, and families to families. Eventually, some of them go viral on the Internet.

Meme is not only about the funny picture, the Internet culture, or the emotion that passes along, but also about the richness and uniqueness of its language: it is often highly structured with special written style, and forms interesting and subtle connotations that resonate among the readers. For example, the LOL cat memes (e.g., Figure 1) often include superimposed text with broken grammars and/or spellings.

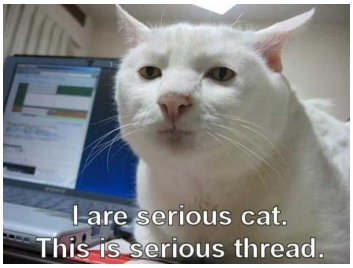

Figure 1: An example of the LOL cat memes.

Even though the memes are popular over the Internet, the "language of memes" is still not well-understood: there are no systematic studies on predicting and generating popular Internet memes from the Natural Language Processing (NLP) and Computer Vision (CV) perspectives.

In this paper, we take a multimodal approach to predict and generate popular meme descriptions. To do this, we collect a set of original meme images, a list of candidate descriptions, and the corresponding votes. We propose a robust nonparanormal approach (Liu et al., 2009) to model the multimodal stochastic dependencies among images, text, and votes. We then introduce a simple pipeline for generating meme descriptions combining reverse image search and traditional information retrieval approaches. In empirical experiments, we show that our model outperforms strong discriminative baselines by very large margins in the regression/ranking experiments, and that in the generation experiment, the nonparanormal outperforms the second-best supervised baseline by 4.35 BLEU points, and obtains a BLEU score improvement of 4.48 over an unsupervised recurrent neural network language model

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 355–365,
Denver, Colorado, May 31 – June 5, 2015.

trained on a large meme corpus that is almost 90 times larger. Our contributions are three-fold:

- We are the first to study the "language of memes" combining NLP, CV, and machine learning techniques, and show that combining the visual and textual signals helps identifying popular meme descriptions;
- Our approach empowers Internet users to select better wordings and generate new memes automatically;
- Our proposed robust nonparanormal model outperforms competitive baselines for predicting and generating popular meme descriptions.

In the next section, we outline related work. In Section 3, we introduce the theory of copula, and our nonparanormal approach. In Section 4, we describe the datasets. We show the prediction and generation results in Section 5 and Section 6. Finally, we conclude in Section 7.

2 Related Work

Although the language of Internet memes is a relatively new research topic, our work is broadly related to studies on predicting popular social media messages (Hong et al., 2011; Bakshy et al., 2011; Artzi et al., 2012). Most recently, Tan et al. (2014) study the effect on wordings for Tweets. However, none of the above studies have investigated multimodal approaches that combine text and vision.

Recently, there has been growing interests in inter-disciplinary research on generating image descriptions. Gupta el al. (2009) have studied the problem of constructing plots from video understanding. The work by Farhadi et al. (2010) is among the first to generate sentences from images. Kulkarni et al. (2011) use linguistic constraints and a conditional random field model for the task, whereas Mitchell et al. (2012) leverage syntactic information and co-occurrence statistics and Dodge et al. (2012) use a large text corpus and CV algorithms for detecting visual text. With the surge of interests in deep learning techniques in NLP (Socher et al., 2013; Devlin et al., 2014) and CV (Krizhevsky et al., 2012; Oquab et al., 2013), there have been several unrefereed manuscripts on parsing images and generating text descriptions lately (Vinyals et al., 2014; Chen and Zitnick, 2014; Donahue et al., 2014; Fang et al., 2014; Karpathy and Fei-Fei, 2014) using neural network models. Although the above studies have shown interesting results, our task is arguably more complex than generating text descriptions: in addition to the visual and textual signals, we have to model the popular votes as a third dimension for learning. For example, we cannot simply train a convolutional neural network image parser on billions of images, and use recurrent neural networks to generate texts such as *"There is a white cat sitting next to a laptop."* for Figure 1. Additionally, since not all images are suitable as meme images, collecting training images is also more challenging in our task.

In contrast to prior work, we take a very different approach: we investigate copula methods (Schweizer and Sklar, 1983; Nelsen, 1999), in particular, the nonparanormals (Liu et al., 2009), for joint modeling of raw images, text descriptions, and popular votes. Copula is a statistical framework for analyzing random variables from Statistics (Liu et al., 2012), and often used in Economics (Chen and Fan, 2006). Only until very recently, researchers from the machine learning and information retrieval communities (Ghahramani et al., 2012; Han et al., 2012; Eickhoff et al., 2013). start to understand the theory and the predictive power of copula models. Wang and Hua (2014) are the first to introduce semiparametric Gaussian copula (a.k.a. nonparanormals) for text prediction. However, their approach may be prone to overfitting. In this work, we generalize Wang and Hua's method to jointly model text and vision features with popular votes, while scaling up the model using effective dropout regularization.

3 Our Approach

A key challenge for joint modeling of text and vision is that, because textual features are often relatively sparse and discrete, while visual features are typically dense and continuous, it is difficult to model them jointly in a principled way.

To avoid comparing "apple and oranges" in the same probabilistic space, we propose the nonparanormal approach, which extends the Gaussian graphical model by transforming its variables by smooth functions. More specifically, for each dimension of textual and visual features, instead of

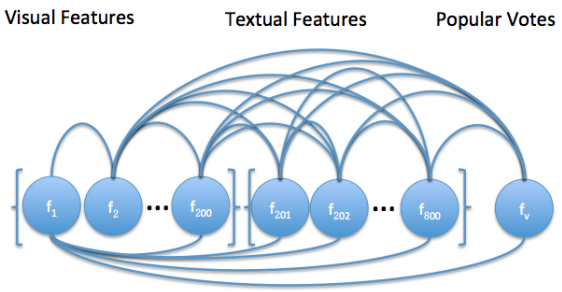

Figure 2: Our nonparanormal method extends Gaussian by transforming each dimension with a smooth function, and jointly models the stochastic dependencies among textual and visual features, as well as the popular votes by the crowd.

using raw counts or histograms, we first use *probability integral transform* to generate empirical cumulative density functions (ECDF): now instead of the probability density function (PDF) space, we are working in the ECDF space where the value of each feature is based on the rank, and is strictly restricted between 0 and 1. Then, we use kernel density estimation to smooth out the zeroing features[1]. Finally, now textual and visual features are compatible, and we then build a parametric Gaussian copula model to estimate the pair-wise correlations among the covariate and the dependent variable.

In this section, we first explain the visual and textual features used in this study. Then, we introduce the theory of copula, and describe the robust nonparanormal. Finally, we show a simple pipeline for generating meme descriptions.

3.1 Features

Textual Features To model the meme descriptions, we take a broad range of textual features into considerations:

- **Lexical Features**: we extract unigrams and bigrams from meme descriptions as surface-level lexical features.
- **Part-of-Speech Features**: to model shallow syntactic cues, we extract lexicalized part-of-speech features using the Stanford part-of-speech tagger (Toutanova et al., 2003).
- **Dependency Triples**: to better understand the deeper syntactic dependencies of keywords in memes, we have also extracted typed dependency triples (e.g., *subj(I,are)*) using the MaltParser (Nivre et al., 2007).
- **Named Entity Features**: after browsing the dataset, we notice that certain names are often mentioned in memes (e.g. "Drake", "Kenye West", and "Justin Bieber"), so we utilize the Stanford named entity recognizer (Finkel et al., 2005) to extract lexicalized named entities.
- **Frame-Semantics Features**: SEMAFOR (Das et al., 2010) is a state-of-the-art frame-semantics parser that produces FrameNet-style semantic annotation. We use SEMAFOR to extract frame-level semantic features.

[1]This is necessary for the normal inversion of the ECDFs, which we will describe in Section 3.2.

Figure 3: An example of the standard SIFT keypoints detected on the "doge" meme.

Visual Features A key insight on viral memes is that the images producing a shared social signal are typically inter-related in style. For example, LOLcats are an early series of memes involving funny cat photos. Similarly, "Bieber memes" involve modified pictures of Bieber.

Therefore, we hypothesize that, by extracting visual features, it is of crucial importance to capture the entities, objects, and styles as visual words in these inter-related meme images. The popular visual bag-of-words representation (Sivic and Zisserman, 2003) is used to describe images:

1. **PHOW Features Extraction**: unlike text features, SIFT first detects the Harris keypoints from an image, and then describes each keypoint with a vector. An example of the SIFT frames are shown in Figure 3. PHOW (Bosch et al., 2007) is a dense and multi-scale variant of the Scale Invariant Feature Transform (SIFT) descriptors. Using PHOW, we obtain about 20K keypoints for each image.

2. **Elkan K-means Clustering** is the clustering method (Elkan, 2003) that we use to obtain the vocabulary for visual words. Comparing to other variants of K-means, this method quickly constructs the codebook from PHOW keypoints.
3. **Bag-of-Words Histograms** are used to represent each image. We match the PHOW keypoints of each image with the vocabulary that we extract from the previous step, and generate a 1×200 sized visual bag-of-words vector.

3.2 The Theory of Copula

In the Statistics literature, copula is widely known as a family of distribution function. The idea behind copula theory is that the cumulative distribution function (CDF) of a random vector can be represented in the form of uniform marginal cumulative distribution functions, and a copula that connects these marginal CDFs, which describes the correlations among the input random variables. However, in order to have a valid multivariate distribution function regardless of n-dimensional covariates, not every function can be used as a copula function. The central idea behind copula, therefore, can be summarize by the Sklar's theorem and the corollary.

Theorem 1 (Sklar's Theorem (1959)) *Let F be the joint cumulative distribution function of n random variables $X_1, X_2, ..., X_n$. Let the corresponding marginal cumulative distribution functions of the random variable be $F_1(x_1), F_2(x_2), ..., F_n(x_n)$. Then, if the marginal functions are continuous, there exists a unique copula C, such that*

$$F(x_1, ..., x_n) = C[F_1(x_1), ..., F_n(x_n)]. \quad (1)$$

Furthermore, if the distributions are continuous, the multivariate dependency structure and the marginals might be separated, and the copula can be considered independent of the marginals (Joe, 1997; Parsa and Klugman, 2011). Therefore, the copula does not have requirements on the marginal distributions, and any arbitrary marginals can be combined and their dependency structure can be modeled using the copula. The inverse of Sklar's Theorem is also true in the following:

Corollary 1 *If there exists a copula $C : (0,1)^n$ and marginal cumulative distribution functions $F_1(x_1), F_2(x_2), ..., F_n(x_n)$, then $C[F_1(x_1), ..., F_n(x_n)]$ defines a multivariate cumulative distribution function.*

3.3 The Nonparanormal

To model multivariate text and vision variables, we choose the nonparanormal (NPN) as the copula function in this study, which can be explained in the following two parts.

The Nonparametric Estimation

Assume we have n random variables of vision and text features $X_1, X_2, ..., X_n$. The problem is that text features are sparse, so we need to perform nonparametric kernel density estimation to smooth out the distribution of each variable. Let $f_1, f_2, ..., f_n$ be the unknown density, we are interested in deriving the shape of these functions. Assume we have m samples, the kernel density estimator can be defined as:

$$\hat{f}_h(x) = \frac{1}{m}\sum_{i=1}^{m} K_h(x - x_i) \quad (2)$$

$$= \frac{1}{mh}\sum_{i=1}^{m} K\left(\frac{x - x_i}{h}\right) \quad (3)$$

Here, $K(\cdot)$ is the kernel function, where in our case, we use the Box kernel[2] $K(z)$:

$$K(z) = \frac{1}{2}, |z| \leq 1, \quad (4)$$

$$= 0, |z| > 1. \quad (5)$$

Comparing to the Gaussian kernel and other kernels, the Box kernel is simple, and computationally inexpensive. The parameter h is the bandwidth for smoothing[3].

Now, we can derive the empirical cumulative distribution functions

$$\hat{F}_{X_1}(\hat{f}_1(X_1)), \hat{F}_{X_2}(\hat{f}_2(X_2)), ..., \hat{F}_{X_n}(\hat{f}_n(X_n))$$

of the smoothed covariates, as well as the dependent variable y (which is the reciprocal rank of the popular votes of a meme) and its CDF $\hat{F}_y(\hat{f}(y))$. The

[2]It is also known as the original Parzen windows (Parzen, 1962).

[3]In our implementation, we use the default h of the Box kernel in the *ksdensity* function in Matlab.

empirical cumulative distribution functions are defined as:

$$\hat{F}(\nu) = \frac{1}{m}\sum_{i=1}^{m}\mathbf{I}\{x_i \leq \nu\} \tag{6}$$

where $\mathbf{I}\{\cdot\}$ is the indicator function, and ν indicates the current value that we are evaluating. Note that the above step is also known as *probability integral transform* (Diebold et al., 1997), which allows us to convert any given continuous distribution to random variables having a uniform distribution. This is crucial for text: instead of using the raw counts, we are now working with uniform marginal CDFs, which helps coping with the overfitting issue due to noise and data sparsity. We also use the same procedure to transform the vision features into CDF space to be compatible with text features.

The Robust Estimation of Copula

Now that we have obtained the marginals, and then the joint distribution can be constructed by applying the copula function that models the stochastic dependencies among marginal CDFs:

$$\begin{aligned}&\hat{F}(\hat{f}_1(X_1), ..., \hat{f}_1(X_n), \hat{f}(y))\\ &= C[\hat{F}_{X_1}\big(\hat{f}_1(X_1)\big), ..., \hat{F}_{X_n}\big(\hat{f}_n(X_n)\big), \hat{F}_y\big(\hat{f}_y(y)\big)]\end{aligned} \tag{7}$$

In this work, we apply the parametric Gaussian copula to model the correlations among the text features and the label. Assume x_i is the smoothed version of random variable X_i, and y is the smoothed label, we have:

$$\begin{aligned}&F(x_1, ..., x_n, y)\\ &= \Phi_\Sigma\Big(\Phi^{-1}[F_{x_1}(x_1)], ..., , \Phi^{-1}[F_{x_n}(x_n)], \Phi^{-1}[F_y(y)]\Big)\end{aligned} \tag{8}$$

where Φ_Σ is the joint cumulative distribution function of a multivariate Gaussian with zero mean and Σ variance. Φ^{-1} is the inverse CDF of a standard Gaussian. In this parametric part of the model, the parameter estimation boils down to the problem of learning the covariance matrix Σ of this Gaussian copula. In this work, we perform standard maximum likelihood estimation (MLE) for the Σ matrix, where we follow the details from prior work (Wang and Hua, 2014).

To avoid overfitting, traditionally, one resorts to classic regularization techniques such as Lasso (Tibshirani, 1996). While Lasso is widely used, the non-differentiable nature of the L_1 norm often make the objective function difficult to optimize. In this work, we propose dropout training (Hinton et al., 2012) as copula regularization. Dropout was proposed by Hinton et al. as a method to prevent feature co-adaptation in the deep learning framework, but recently studies (Wager et al., 2013) also show that its behaviour is similar to L_2 regularization, and can be approximated efficiently (Wang and Manning, 2013) in many other machine learning tasks. Another advantage of dropout training is that, unlike Lasso, it does not require all the features for training, and training is "embarrassingly" parallelizable.

In Gaussian copula estimation context, we can introduce another dimension ℓ: the number of dropout learners, to extend the Σ into a dropout tensor. Essentially, the task becomes the estimation of

$$\Sigma_1, \Sigma_2, ..., \Sigma_\ell$$

where the input feature space for each dropout component is randomly corrupted by $(1-\delta)$ percent of the original dimension. In the inference time, we use geometric mean to average the predictions from each dropout learner, and generate the final prediction. Note that the final Σ matrix has to be symmetric and positive definite, so we apply tiny random Gaussian noise ϵ to maintain the property.

Computational Complexity

One important question regarding the proposed nonparanormal model is the corresponding computational complexity. This boils down to the estimation of the $\hat{\Sigma}$ matrix (Liu et al., 2012): one only needs to calculate the correlation coefficients of $n(n-1)/2$ pairs of random variables. Christensen (2005) shows that sorting and balanced binary trees can be used to calculate the correlation coefficients with complexity of $O(n \log n)$. Therefore, the computational complexity of MLE for the proposed model is $O(n \log n)$.

Efficient Approximate Inference

In this prediction task, in order to perform the exact inference of the conditional probability distribution $p(F_y(y)|F_{x_1}(x_1), ..., F_{x_n}(x_n))$, one needs to solve the mean response $\hat{\mathbf{E}}(F_y(y)|F_{x_1}(x_1), ..., F_{x_1}(x_1))$ from a joint distribution of high-dimensional Gaussian copula. Unfortunately, the exact inference can be

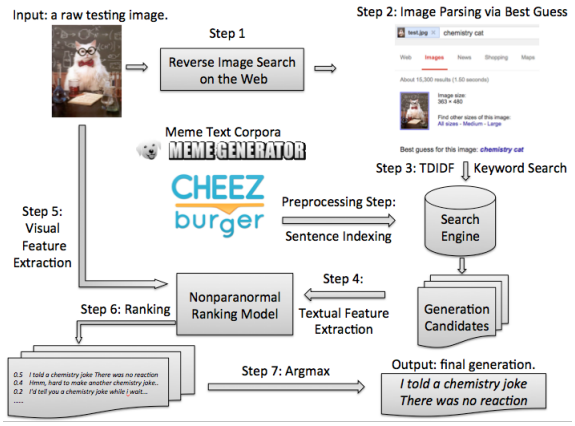

Figure 4: Our pipeline for generating memes from raw images.

intractable in the multivariate case, and approximate inference, such as Markov Chain Monte Carlo sampling (Gelfand and Smith, 1990; Pitt et al., 2006) is often used for posterior inference. In this work, we propose an efficient sampling method to derive y given the text features — we sample $\hat{F_y(y)}$ s.t. it maximizes the joint high-dimensional Gaussian copula density:

$$\underset{\hat{F_y(y)} \in (0,1)}{\arg\max} \frac{1}{\sqrt{\det \Sigma}} \exp\left(-\frac{1}{2}\Delta^T \cdot (\Sigma^{-1} - \mathbf{I}) \cdot \Delta\right) \tag{9}$$

where

$$\Delta = \begin{pmatrix} \Phi^{-1}(F_{x_1}(x_1)) \\ \vdots \\ \Phi^{-1}(F_{x_n}(x_n)) \\ \Phi^{-1}(F_y(y)) \end{pmatrix}$$

This approximate inference scheme using maximum density sampling from the Gaussian copula significantly relaxes the complexity of inference. Finally, to derive $\hat{y}$, the last step is to compute the inverse CDF of $\hat{F_y(y)}$. A detailed description of the inference algorithm can be found in our prior work (Wang and Hua, 2014).

3.4 A Simple Meme Generation Pipeline

Now after we train a nonparanormal model for ranking meme descriptions, we show the simple meme generation pipeline in Figure 4.

Given a test image, we disguise as the Internet Explorer, and query Google's "Search By Image" inverse image search service[4]. By comparing the query image with all possible images with their captions in Google's database, a "Best Guess" of the keywords in the image is then revealed.

Using the extracted image keywords, we further query a TF-IDF based Lucene[5] meme search engine, which we indexed with a large number of Web-crawled meme descriptions. After we obtain the candidate generations, we then extract all the text and vision features that we described in Section 3.1. Finally, our nonparanormal model ranks all possible candidates, and selects the final generation with the highest posterior.

4 Datasets

We collected meme images and text descriptions[6] from two popular meme websites[7]. In the prediction experiment, we use 3,008 image-description pairs for training, and 526 image-description pairs for testing. In the generation experiment, we use 269,473 meme descriptions to index the meme search engine, and 50 randomly selected images for testing. During training, we convert the raw counts of popular votes into reciprocal ranks (e.g., the most popular text descriptions will all have a reciprocal rank of 1, and n-th popular one will have a score of $1/n$).

5 Prediction Experiments

In the first experiment, we compare the proposed NPN with various baselines in a prediction task, since prior literature (Hodosh et al., 2013) also suggests using ranking based evaluation for associating images with text descriptions. Throughout the experiment sections, we set $\ell = 10$, and $\delta = 80$ as the dropout hyperparameters.

Baselines:

The baselines are standard squared-loss linear regression, linear kernel SVM, and non-linear (Gaussian) kernel SVM. In a recent empirical study (Fernández-Delgado et al., 2014) that evaluates 179 classifiers from 17 families on 121 UCI datasets, the authors find that Gaussian SVM is one of the top performing classifiers. We use the Statistical Toolbox's linear regression implementation in Matlab, and LibSVM (Chang and Lin, 2011) for

[4]http://www.google.com/imghp/

[5]http://lucene.apache.org/

[6]http://www.cs.cmu.edu/~yww/data/meme_dataset.zip.

[7]memegenerator.net and cheezburger.com

training and testing the SVM models. The hyperparameter C in linear SVM, and the γ and C hyperparameters in Gaussian SVM are tuned on the training set using 10-fold cross-validation.

Evaluation Metrics:

Spearman's correlation (Hogg and Craig, 1994) and Kendall's tau (Kendall, 1938) have been widely used in many real-valued prediction (regression) problems in NLP (Albrecht and Hwa, 2007; Yogatama et al., 2011), and here we use them to measure the quality of predicted values $\hat{\mathbf{y}}$ by comparing to the vector of ground truth $\mathbf{y}$. Kendall's tau is a nonparametric statistical metric that have shown to be inexpensive, robust, and representation independent (Lapata, 2006). We use paired two-tailed t-test to measure the statistical significance.

5.1 Comparison with Various Baselines

The first two figures in Figure 5 show the learning curve of our system, comparing other baselines. We see that when increasing the amount of training data, our approach clearly dominates all other methods by a large margin. Linear and Gaussian SVMs perform similarly, and have good performances with only 25% of the training data, but the improvements are not large when increasing the amount of training data.

In the last two figures in Figure 5, we increase the amount of features, and compare various models. We see that the linear regression model overfits with 600 features, and Gaussian SVM outperforms the linear SVM. We see that our NPN model clearly outperforms all baselines by a big gap, and does not overfit.

5.2 Combination of Text and Vision

In Table 1, we systematically compare the contributions of each feature set. First, we see that bigram features clearly improve the performance on top of unigram features. Second, named entities are crucial for further boosting the performance. Third, adding the shallow part-of-speech features does not benefit all models, but the dependency triples are shown to be useful for all methods. Finally, we see that using semantic features helps increasing the performances for most of the cases, and combining text and vision features in our NPN framework doubles the performance for associating popular votes, meme images, and text descriptions.

Feature Sets	LR	LSVM	GSVM	NPN
Unigrams	0.152	0.158	0.176	**0.241***
+ Bigrams	0.163	0.248	0.279	**0.318***
+ Named Entities	0.188	0.296	0.312	**0.339***
+ Part-of-Speech	0.184	0.318	0.337	**0.343**
+ Dependency	0.191	0.322	0.348	**0.350**
+ Semantics	0.183	0.368	**0.388**	0.367
All Text + Vision	0.413	0.415	0.451	**0.754***
Unigrams	0.102	0.105	0.118	**0.181***
+ Bigrams	0.115	0.164	0.187	**0.237***
+ Named Entities	0.127	0.202	0.213	**0.248***
+ Part-of-Speech	0.125	0.218	0.232	**0.239**
+ Dependency	0.130	0.223	0.242	**0.255**
+ Semantics	0.124	0.257	**0.270**	**0.270**
All Text + Vision	0.284	0.288	0.314	**0.580***

Table 1: The Spearman correlation (top table) and Kendall's τ (bottom table) for comparing various text features and combining with vision features. The best results of each row are highlighted in **bold**. * indicates $p < .001$ comparing to the second best result.

5.3 The Effects of Dropout Training for Nonparanormals

As we mentioned before, because NPNs model the complex network of random variables, a key issue for training NPN is to prevent the model from overfitting to the training data. So far, none of the prior work have investigated dropout training for regularizing the nonparanormals or even copula in general. To empirical test the effects of dropout training for nonparanormals, in addition to our datasets, we also compare with the unregularized copula from Wang and Hua (2014) on predicting financial risks from earnings calls. Table 2 clearly suggests that dropout training for NPNs significant improves the performances on various datasets.

5.4 Qualitative Analysis

Table 3 shows the top ranked text features that are highly correlated with popular votes. We see that the named entity features are useful: Paul Walker, UPS, Bruce Willis, Pencil Guy, Amy Winehouse are recognized as entities in the meme dataset. Dependency triples, as a less-understood feature set, also perform well in this task. For example, *xcomp(tell,mean)*

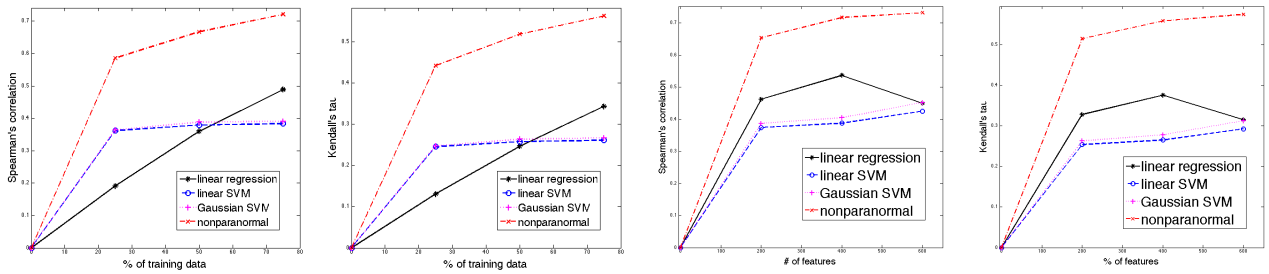

Figure 5: Two figures on the left: varying the amount of training data. L(1): Spearman. L(2): Kendall. Two figures on the right: varying the amount of features. R(1): Spearman. R(2): Kendall.

Datasets	No Dropout	With Dropout

Table 3: Top-30 linguistic features that are highly correlated with the popular votes.

captures the dependency relation of the popular meme series "You mean to tell me...". Interestingly, the transitional dependency feature *dep(when,but)* plays an important role in the language of memes. The object of a preposition, such as *pobj(vegas,in)* and *pobj(life,of)*, also made the list.

Bigrams are shown to be important features as usual. For example, "Yo daw" is a popular meme based on rapper Xzibit's famous reality car show "Pimp My Ride", where the rapper customizes people's car according to personal preferences. This viral meme follows the pattern[8] of "Yo daw(g), I herd you like X (noun), so I put an X in your Y (noun) so you can W (verb) while you Z (verb)."

The use of pronouns, captured by frame semantics features, is associated with popular memes. We hypothesize that by using pronouns such as "i", "you", "we", and "they", the meme recalls personal experiences and emotions, thus connects better with the audience. Finally, we see that the punctuation bigram "...._:" is an important feature in the language of memes, and Web dialect such as "y" (why) also exhibits high correlation with the popular votes.

6 Generation Experiments

In this section, we investigate the performance of our meme generation system using 50 test meme images. To quantitatively evaluate our system, we compare with both unsupervised and supervised baselines. For the unsupervised baselines, we compare with a compact recurrent neural network language model (RNNLM) (Mikolov, 2012) trained on the 3,008 text descriptions of our meme training set, as well as a full model of RNNLM trained on a large meme corpus of 269K sentences[9]. For the supervised baselines, all models are trained on the 3,008 training image-description pairs with labels. All these models can be viewed as different re-ranking methods for the retrieved candidate descriptions. We use BLEU score (Papineni et al., 2002) as the evaluation metric, since the generation task can be viewed as translating raw images into sentences, and it is

[8] http://knowyourmeme.com/memes/xzibit-yo-dawg

[9] Note that there are no image features feeding to the unsupervised RNN models.

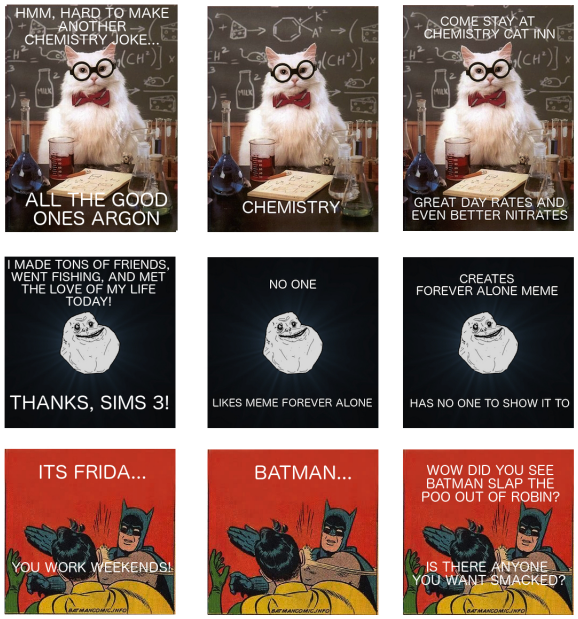

Figure 6: Examples from the meme generation experiment. First row: the chemistry cat meme. Second row: the forever alone meme. Third row: the Batman slaps Robin meme. Left column: human generated top-voted meme descriptions on memegenerator.net at the time of writing. Middle column: generated output from RNNLM. Right column: generated output from NPNs.

used in many caption generation studies (Vinyals et al., 2014; Chen and Zitnick, 2014; Donahue et al., 2014; Fang et al., 2014; Karpathy and Fei-Fei, 2014).

The generation result is shown in Table 4. Note that when combining B-1 to B-4 scores, BLEU includes a brevity penalty as described in the original BLEU paper. We see that our NPN model outperforms the best supervised baseline by 4.35 BLEU points, while also obtaining an advantage of 4.48 BLEU points over the full RNNLM, which is trained on a corpus that is $\sim$90 times larger, in an unsupervised fashion. When breaking down the results, we see that our NPN's advantage is on generating longer phrases, typically trigrams and four-grams, comparing to the other models. This is very interesting, because generating high-quality long phrases is difficult, since the memes are often short.

Systems	BLEU	B-1	B-2	B-3	B-4
RNN-C	19.52	62.2	21.2	12.1	9.0
RNN-F	23.76	72.2	**31.4***	16.2	8.7
LR	23.89	**72.3**	28.3	15.0	10.6
LSVM	21.06	65.0	24.8	13.1	9.3
GSVM	20.63	66.2	22.8	12.8	9.3
NPN	**28.24***	66.9	29.0	**19.7***	**16.6***

Table 4: The BLEU scores for generating memes from images. B-1 to B-4: BLEU unigram to four-grams. The best BLEU results are highlighted in **bold**. * indicates $p < .001$ comparing to the second best system.

We show some generation examples in Figure 6. We see that on the left column, the reference memes are the ones with top votes by the crowd. The first *chemistry cat* meme includes puns, the second *forever alone* meme includes reference to the life simulation video game, while the last *Batman* meme has interesting conversations. In the second column, we see that the memes generated by the full RNNLM model are short, which corresponds to the quantitative results in Table 4. In the third column, our NPN meme generator was able to generate longer descriptions. Interestingly, it also creates a pun for the *chemistry cat* meme. Our generation on the *forever alone* meme is also accurate. In the Batman example, we show that the NPN model makes a sentence-image-mismatch type of error: although the generated sentence includes the entities Batman and Robin, as well as their slapping activity, it was originally created for the "overly attached girlfriend" meme[10].

7 Conclusions

In this paper, we study the language of memes by jointly learning the image, the description, and the popular votes. In particular, we propose a robust nonparanormal approach to transform all vision and text features into the cumulative density function space. By learning the stochastic dependencies, we show that our model significantly outperforms various competitive baselines in the prediction experiments. In addition, we also propose a simple pipeline for generating memes from raw images, drawing the wisdom from reverse image search and traditional information retrieval perspectives. Finally, we show that our model obtains significant BLEU point improvements over an unsupervised RNNLM baseline trained on a larger corpus, as well as other strong supervised baselines.

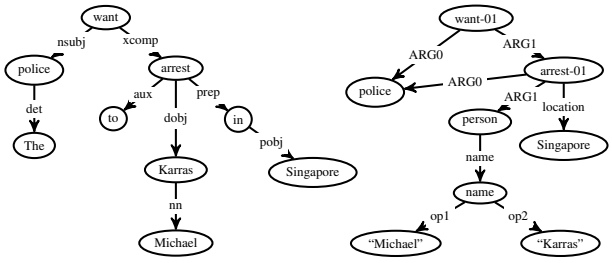
Abstract

We present a two-stage framework to parse a sentence into its Abstract Meaning Representation (AMR). We first use a dependency parser to generate a dependency tree for the sentence. In the second stage, we design a novel transition-based algorithm that transforms the dependency tree to an AMR graph. There are several advantages with this approach. First, the dependency parser can be trained on a training set much larger than the training set for the tree-to-graph algorithm, resulting in a more accurate AMR parser overall. Our parser yields an improvement of 5% absolute in F-measure over the best previous result. Second, the actions that we design are linguistically intuitive and capture the regularities in the mapping between the dependency structure and the AMR of a sentence. Third, our parser runs in nearly linear time in practice in spite of a worst-case complexity of $O(n^2)$.

1 Introduction

Abstract Meaning Representation (AMR) is a rooted, directed, edge-labeled and leaf-labeled graph that is used to represent the meaning of a sentence. The AMR formalism has been used to annotate the AMR Annotation Corpus (Banarescu et al., 2013), a corpus of over 10 thousand sentences that is still undergoing expansion. The building blocks for an AMR representation are concepts and relations between them. Understanding these concepts and their relations is crucial to understanding the meaning of a sentence and could potentially benefit a number of natural language applications such as Information Extraction, Question Answering and Machine Translation.

The property that makes AMR a graph instead of a tree is that AMR allows reentrancy, meaning that the same concept can participate in multiple relations. Parsing a sentence into an AMR would seem to require graph-based algorithms, but moving to graph-based algorithms from the typical tree-based algorithms that we are familiar with is a big step in terms of computational complexity. Indeed, quite a bit of effort has gone into developing grammars and efficient graph-based algorithms that can be used to parse AMRs (Chiang et al., 2013).



(a) Dependency tree (b) AMR graph

Figure 1: Dependency tree and AMR graph for the sentence, "The police want to arrest Micheal Karras in Singapore."

Linguistically, however, there are many similarities between an AMR and the dependency structure of a sentence. Both describe relations as holding between a head and its dependent, or between a parent and its child. AMR concepts and relations abstract away from actual word tokens, but there are regularities in their mappings. Content words generally be-

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 366–375,
Denver, Colorado, May 31 – June 5, 2015.

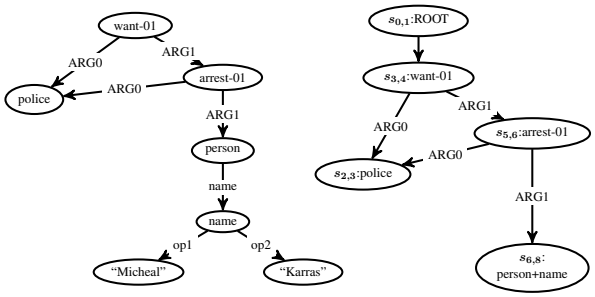
come concepts while function words either become relations or get omitted if they do not contribute to the meaning of a sentence. This is illustrated in Figure 1, where 'the' and 'to' in the dependency tree are omitted from the AMR and the preposition 'in' becomes a relation of type *location*. In AMR, reentrancy is also used to represent co-reference, but this only happens in some limited contexts. In Figure 1, 'police' is both an argument of 'arrest' and 'want' as the result of a control structure. This suggests that it is possible to transform a dependency tree into an AMR with a limited number of actions and learn a model to determine which action to take given pairs of aligned dependency trees and AMRs as training data.

This is the approach we adopt in the present work, and we present a transition-based framework in which we parse a sentence into an AMR by taking the dependency tree of that sentence as input and transforming it to an AMR representation via a series of actions. This means that a sentence is parsed into an AMR in two steps. In the first step the sentence is parsed into a dependency tree with a dependency parser, and in the second step the dependency tree is transformed into an AMR graph. One advantage of this approach is that the dependency parser does not have to be trained on the same data set as the dependency to AMR transducer. This allows us to use more accurate dependency parsers trained on data sets much larger than the AMR Annotation Corpus and have a more advantageous starting point. Our experiments show that this approach is very effective and yields an improvement of 5% absolute over the previously reported best result (Flanigan et al., 2014) in F-score, as measure by the Smatch metric (Cai and Knight, 2013).

The rest of the paper is as follows. In §2, we describe how we align the word tokens in a sentence with its AMR to create a span graph based on which we extract contextual information as features and perform actions. In §3, we present our transition-based parsing algorithm and describe the actions used to transform the dependency tree of a sentence into an AMR. In §4, we present the learning algorithm and the features we extract to train the transition model. In §5, we present experimental results. §6 describes related work, and we conclude in §7.

2 Graph Representation

Unlike the dependency structure of a sentence where each word token is a node in the dependency tree and there is an inherent alignment between the word tokens in the sentence and the nodes in the dependency tree, AMR is an abstract representation where the word order of the corresponding sentence is not maintained. In addition, some words become abstract concepts or relations while other words are simply deleted because they do not contribute to meaning. The alignment between the word tokens and the concepts is non-trivial, but in order to learn the transition from a dependency tree to an AMR graph, we have to first establish the alignment between the word tokens in the sentence and the concepts in the AMR. We use the aligner that comes with JAMR (Flanigan et al., 2014) to produce this alignment. The JAMR aligner attempts to greedily align every concept or graph fragment in the AMR graph with a contiguous word token sequence in the sentence.



(a) AMR graph (b) Span graph

Figure 2: AMR graph and its span graph for the sentence, "The police want to arrest Micheal Karras."

We use a data structure called **span graph** to represent an AMR graph that is aligned with the word tokens in a sentence. For each sentence $w = w_0, w_1, \ldots, w_n$, where token w_0 is a special root symbol, a **span graph** is a directed, labeled graph $G = (V, A)$, where $V = \{s_{i,j} | i, j \in (0, n) \text{ and } j > i\}$ is a set of nodes, and $A \subseteq V \times V$ is a set of arcs. Each node $s_{i,j}$ of G corresponds to a continuous span $(w_i, \ldots, w_{j-1})$ in sentence w and is indexed by the starting position i. Each node is assigned a **concept** label from a set L_V of concept labels and each arc is assigned a **relation** label from a set L_A

of relation labels, respectively.

For example, given an AMR graph G_{AMR} in Figure 2a, its span graph G can be represented as Figure 2b. In span graph G, node $s_{3,4}$'s sentence span is *(want)* and its concept label is *want-01*, which represents a single node *want-01* in AMR. To simplify the alignment, when creating a span graph out of an AMR, we also collapse some AMR subgraphs in such a way that they can be deterministically restored to their original state for evaluation. For example, the four nodes in the AMR subgraph that correspond to span *(Micheal, Karras)* is collapsed into a single node $s_{6,8}$ in the span graph and assigned the concept label *person+name*, as shown in Figure 3. So the concept label set that our model predicts consists of both those from the concepts in the original AMR graph and those as a result of collapsing the AMR subgraphs.

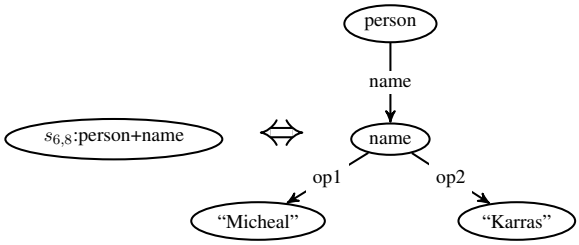


Figure 3: Collapsed nodes

Representing AMR graph this way allows us to formulate the AMR parsing problem as a joint learning problem where we can design a set of actions to simultaneously predict the concepts (nodes) and relations (arcs) in the AMR graph as well as the labels on them.

3 Transition-based AMR Parsing

3.1 Transition System

Similar to transition-based dependency parsing (Nivre, 2008), we define a *transition system* for AMR parsing as a quadruple $S = (S, T, s_0, S_t)$, where

- S is a set of parsing *states* (configurations).
- T is a set of parsing *actions* (transitions), each of which is a function $t : S \rightarrow S$.
- s_0 is an *initialization function*, mapping each input sentence w and its dependency tree D to an *initial state*.
- $S_t \subseteq S$ is a set of *terminal states*.

Each state (configuration) of our transition-based parser is a triple (σ, β, G). σ is a buffer that stores indices of the nodes which have not been processed and we write $\sigma = \sigma_0|\sigma'$ to indicate that σ_0 is the topmost element of σ. β is also a buffer $[\beta_0, \beta_1, \ldots, \beta_j]$ and each element β_i of β indicates the edge (σ_0, β_i) which has not been processed in the partial graph. We also write $\beta = \beta_0|\beta'$ to indicate the topmost element of β is β_0. We use span graph G to store the partial parses for the input sentence w. Note that unlike traditional transition-based syntactic parsers which store partial parses in the stack structure and build a tree or graph incrementally, here we use σ and β buffers only to guide the parsing process (which node or edge to be processed next) and the actual tree-to-graph transformations are applied to G.

When the parsing procedure starts, σ is initialized with a post-order traversal of the input dependency tree D with topmost element σ_0, β is initialized with node σ_0's children or set to null if σ_0 is a leaf node. G is initialized with all the nodes and edges of D. Initially, all the nodes of G have a span length of one and all the labels for nodes and edges are set to null. As the parsing procedure goes on, the parser will process all the nodes and their outgoing edges in dependency tree D in a bottom-up left-right manner, and at each state certain action will be applied to the current node or edge. The parsing process will terminate when both σ and β are empty.

The most important part of the transition-based parser is the set of actions (transitions). As stated in (Sartorio et al., 2013), the design space of possible actions is actually infinite since the set of parsing states is infinite. However, if the problem is amenable to transition-based parsing, we can design a finite set of actions by categorizing all the possible situations we run into in the parsing process. In §5.2 we show this is the case here and our action set can account for almost all the transformations from dependency trees to AMR graphs.

We define 8 types of actions for the actions set T, which is summarized in Table 1. The action set could be divided into two categories based on conditions of buffer β. When β is not empty, parsing decisions are made based on the edge (σ_0, β_0); oth-

Action	Current state ⇒ Result state	Assign labels	Precondition
NEXT EDGE-l_r	$(\sigma_0\|\sigma', \beta_0\|\beta', G) \Rightarrow (\sigma_0\|\sigma', \beta', G')$	$\delta[(\sigma_0, \beta_0) \rightarrow l_r]$	β is not empty
SWAP-l_r	$(\sigma_0\|\sigma', \beta_0\|\beta', G) \Rightarrow (\sigma_0\|\beta_0\|\sigma', \beta', G')$	$\delta[(\beta_0, \sigma_0) \rightarrow l_r]$	
REATTACH$_k$-l_r	$(\sigma_0\|\sigma', \beta_0\|\beta', G) \Rightarrow (\sigma_0\|\sigma', \beta', G')$	$\delta[(k, \beta_0) \rightarrow l_r]$	
REPLACE HEAD	$(\sigma_0\|\sigma', \beta_0\|\beta', G) \Rightarrow (\beta_0\|\sigma', \beta = CH(\beta_0, G'), G')$	NONE	
REENTRANCE$_k$-l_r	$(\sigma_0\|\sigma', \beta_0\|\beta', G) \Rightarrow (\sigma_0\|\sigma', \beta_0\|\beta', G')$	$\delta[(k, \beta_0) \rightarrow l_r]$	
MERGE	$(\sigma_0\|\sigma', \beta_0\|\beta', G) \Rightarrow (\tilde{\sigma}\|\sigma', \beta', G')$	NONE	
NEXT NODE-l_c	$(\sigma_0\|\sigma_1\|\sigma', [], G) \Rightarrow (\sigma_1\|\sigma', \beta = CH(\sigma_1, G'), G')$	$\gamma[\sigma_0 \rightarrow l_c]$	β is empty
DELETE NODE	$(\sigma_0\|\sigma_1\|\sigma', [], G) \Rightarrow (\sigma_1\|\sigma', \beta = CH(\sigma_1, G'), G')$	NONE	

Table 1: Transitions designed in our parser. $CH(x, y)$ means getting all node x's children in graph y.

erwise, only the current node σ_0 is examined. Also, to simultaneously make decisions on the assignment of concept/relation label, we augment some of the actions with an extra parameter l_r or l_c. We define $\gamma : V \rightarrow L_V$ as the concept labeling function for nodes and $\delta : A \rightarrow L_A$ as the relation labeling function for arcs. So $\delta[(\sigma_0, \beta_0) \rightarrow l_r]$ means assigning relation label l_r to arc (σ_0, β_0). All the actions update buffer σ, β and apply some transformation $G \Rightarrow G'$ to the partial graph. The 8 actions are described below.

- NEXT-EDGE-l_r (ned). This action assigns a relation label l_r to the current edge (σ_0, β_0) and makes no further modification to the partial graph. Then it pops out the top element of buffer β so that the parser moves one step forward to examine the next edge if it exists.

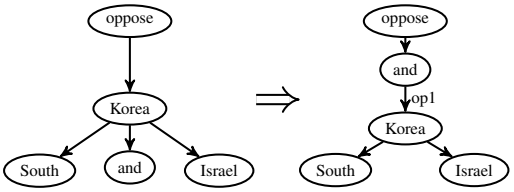

Figure 4: SWAP action

- SWAP-l_r (sw). This action reverses the dependency relation between node σ_0 and β_0 and then makes node β_0 as new head of the subgraph. Also it assigns relation label l_r to the arc (β_0, σ_0). Then it pops out β_0 and inserts it into σ right after σ_0 for future revisiting. This action is to resolve the difference in the choice of head between the dependency tree and the AMR graph. Figure 4 gives an example of applying SWAP-op1 action for arc (*Korea*, *and*) in the dependency tree of sentence "South Korea and Israel oppose ...".
- REATTACH$_k$-l_r (reat). This action removes the current arc (σ_0, β_0) and reattaches node β_0 to some node k in the partial graph. It also assigns a relation label l_r to the newly created arc (k, β_0) and advances one step by popping out β_0. Theoretically, the choice of node k could be any node in the partial graph under the constraint that arc (k, β_0) doesn't produce a self-looping cycle. The intuition behind this action is that after swapping a head and its dependent, some of the dependents of the old head should be reattached to the new head. Figure 5 shows an example where node *Israel* needs to be reattached to node *and* after a head-dependent swap.

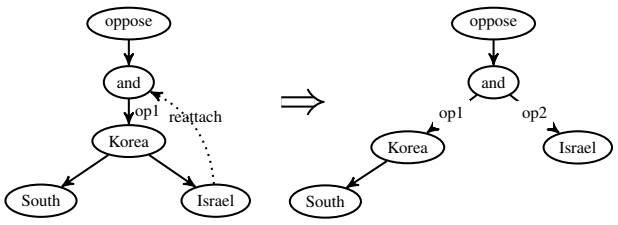

Figure 5: REATTACH action

- REPLACE-HEAD (rph). This action removes node σ_0, replaces it with node β_0. Node β_0 also inherits all the incoming and outgoing arcs of σ_0. Then it pops out β_0 and inserts it into the top position of buffer σ. β is re-initialized with all the children of β_0 in the transformed graph G'. This action targets nodes in the dependency tree that do not correspond to concepts in AMR

graph and become a relation instead. An example is provided in Figure 6, where node *in*, a preposition, is replaced with node *Singapore*, and in a subsequent NEXT-EDGE action that examines arc (*live*, *Singapore*), the arc is labeled *location*.

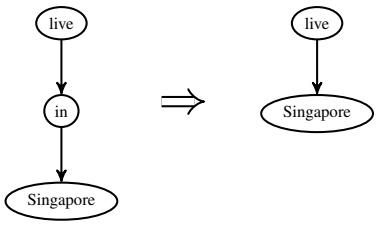

Figure 6: REPLACE-HEAD action

- REENTRANCE$_k$-l_r (reen). This is the action that transforms a tree into a graph. It keeps the current arc unchanged, and links node β_0 to every possible node k in the partial graph that can also be its parent. Similar to the REATTACH action, the newly created arc (k, β_0) should not produce a self-looping cycle and parameter k is bounded by the sentence length. In practice, we seek to constrain this action as we will explain in §3.2. Intuitively, this action can be used to model co-reference and an example is given in Figure 7.

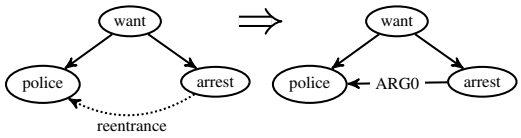

Figure 7: REENTRANCE action

- MERGE (mrg). This action merges nodes σ_0 and β_0 into one node $\tilde{\sigma}$ which covers multiple words in the sentence. The new node inherits all the incoming and outgoing arcs of both nodes σ_0 and β_0. The MERGE action is intended to produce nodes that cover a continuous span in the sentence that corresponds to a single name entity in AMR graph. see Figure 8 for an example.

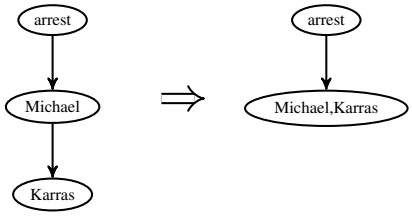

Figure 8: MERGE action

When β is empty, which means all the outgoing arcs of node σ_0 have been processed or σ_0 has no outgoing arcs, the following two actions can be applied:

- NEXT-NODE-l_c (nnd). This action first assigns a concept label l_c to node σ_0. Then it advances the parsing procedure by popping out the top element σ_0 of buffer σ and re-initializes buffer β with all the children of node σ_1 which is the current top element of σ. Since this action will be applied to every node which is kept in the final parsed graph, concept labeling could be done simultaneously through this action.
- DELETE-NODE (dnd). This action simply deletes the node σ_0 and removes all the arcs associated with it. This action models the fact that most function words are stripped off in the AMR of a sentence. Note that this action only targets function words that are leaves in the dependency tree, and we constrain this action by only deleting nodes which do not have outgoing arcs.

When parsing a sentence of length n (excluding the special root symbol w_0), its corresponding dependency tree will have n nodes and $n-1$ arcs. For projective transition-based dependency parsing, the parser needs to take exactly $2n-1$ steps or actions. So the complexity is $O(n)$. However, for our tree-to-graph parser defined above, the actions needed are no longer linearly bounded by the sentence length. Suppose there are no REATTACH, REENTRANCE and SWAP actions during the parsing process, the algorithm will traverse every node and edge in the dependency tree, which results in $2n$ actions. However, REATTACH and REENTRANCE actions would add extra edges that need to be re-processed and the SWAP action adds both nodes and edges that need to be re-visited. Since the

space of all possible extra edges is $(n-2)^2$ and revisiting them only adds more actions linearly, the total asymptotic runtime complexity of our algorithm is $O(n^2)$.

In practice, however, the number of applications of the REATTACH action is much less than the worst case scenario due to the similarities between the dependency tree and the AMR graph of a sentence. Also, nodes with reentrancies in AMR only account for a small fraction of all the nodes, thus making the REENTRANCE action occur at constant times. These allow the tree-to-graph parser to parse a sentence in nearly linear time in practice.

3.2 Greedy Parsing Algorithm

Algorithm 1 Parsing algorithm

Input: sentence $w = w_0 \dots w_n$ and its dependency tree D_w
Output: parsed graph G_p

1: $s \leftarrow s_0(D_w, w)$
2: **while** $s \notin S_t$ **do**
3: $\quad \mathcal{T} \leftarrow$ all possible actions according to s
4: $\quad bestT \leftarrow \arg\max_{t \in \mathcal{T}} score(t, c)$
5: $\quad s \leftarrow$ apply $bestT$ to s
6: **end while**
7: **return** G_p

Our parsing algorithm is similar to the parser in (Sartorio et al., 2013). At each parsing state $s \in S$, the algorithm greedily chooses the parsing action $t \in T$ that maximizes the score function $score()$. The score function is a linear model defined over parsing action t and parsing state s.

$$score(t, s) = \vec{\omega} \cdot \phi(t, s) \quad (1)$$

where $\vec{\omega}$ is the weight vector and ϕ is a function that extracts the feature vector representation for one possible state-action pair $\langle t, s \rangle$.

First, the algorithm initializes the state s with the sentence w and its dependency tree D_w. At each iteration, it gets all the possible actions for current state s (line 3). Then, it chooses the action with the highest score given by function $score()$ and applies it to s (line 4-5). When the current state reaches a terminal state, the parser stops and returns the parsed graph.

As pointed out in (Bohnet and Nivre, 2012), constraints can be added to limit the number of possible actions to be evaluated at line 3. There could be formal constraints on states such as the constraint that the SWAP action should not be applied twice to the same pair of nodes. We could also apply soft constraints to filter out unlikely concept labels, relation labels and candidate nodes k for REATTACH and REENTRANCE. In our parser, we enforce the constraint that NEXT-NODE-l_c can only choose from concept labels that co-occur with the current node's lemma in the training data. We also empirically set the constraint that REATTACH$_k$ could only choose k among σ_0's grandparents and great grandparents. Additionally, REENTRANCE$_k$ could only choose k among its siblings. These constraints greatly reduce the search space, thus speeding up the parser.

4 Learning

4.1 Learning Algorithm

As stated in section 3.2, the parameter of our model is weight vector $\vec{\omega}$ in the score function. To train the weight vector, we employ the averaged perceptron learning algorithm (Collins, 2002).

Algorithm 2 Learning algorithm

Input: sentence $w = w_0 \dots w_n, D_w, G_w$
Output: $\vec{\omega}$

$s \leftarrow s_0(D_w, w)$
while $s \notin S_t$ **do**
$\quad \mathcal{T} \leftarrow$ all possible actions according to s
$\quad bestT \leftarrow \arg\max_{t \in \mathcal{T}} score(t, s)$
$\quad goldT \leftarrow oracle(s, G_w)$
$\quad$ **if** $bestT \neq goldT$ **then**
$\quad\quad \vec{\omega} \leftarrow \vec{\omega} - \phi(bestT, s) + \phi(goldT, s)$
$\quad$ **end if**
$\quad s \leftarrow$ apply $goldT$ to s
end while

For each sentence w and its corresponding AMR annotation G_{AMR} in the training corpus, we could get the dependency tree D_w of w with a dependency parser. Then we represent G_{AMR} as span graph G_w, which serves as our learning target. The learning algorithm takes the training instances (w, D_w, G_w), parses D_w according to Algorithm 1, and get the best action using current weight vector $\vec{\omega}$. The

gold action for current state s is given by consulting span graph G_w, which we formulate as a function $oracle()$ (line 5). If the gold action is equal to the best action we get from the parser, then the best action is applied to current state; otherwise, we update the weight vector (line 6-7) and continue the parsing procedure by applying the gold action.

4.2 Feature Extraction

Single node features
$\bar{\sigma}_0.w, \bar{\sigma}_0.lem, \bar{\sigma}_0.ne, \bar{\sigma}_0.t, \bar{\sigma}_0.dl, \bar{\sigma}_0.len$
$\bar{\beta}_0.w, \bar{\beta}_0.lem, \bar{\beta}_0.ne, \bar{\beta}_0.t, \bar{\beta}_0.dl, \bar{\beta}_0.len$
$\bar{k}.w, \bar{k}.lem, \bar{k}.ne, \bar{k}.t, \bar{k}.dl, \bar{k}.len$
$\bar{\sigma}_{0p}.w, \bar{\sigma}_{0p}.lem, \bar{\sigma}_{0p}.ne, \bar{\sigma}_{0p}.t, \bar{\sigma}_{0p}.dl$
Node pair features
$\bar{\sigma}_0.lem + \bar{\beta}_0.t, \bar{\sigma}_0.lem + \bar{\beta}_0.dl$
$\bar{\sigma}_0.t + \bar{\beta}_0.lem, \bar{\sigma}_0.dl + \bar{\beta}_0.lem$
$\bar{\sigma}_0.ne + \bar{\beta}_0.ne, \bar{k}.ne + \bar{\beta}_0.ne$
$\bar{k}.t + \bar{\beta}_0.lem, \bar{k}.dl + \bar{\beta}_0.lem$
Path features
$\bar{\sigma}_0.lem + \bar{\beta}_0.lem + path_{\sigma_0,\beta_0}$
$\bar{k}.lem + \bar{\beta}_0.lem + path_{k,\beta_0}$
Distance features
$dist_{\sigma_0,\beta_0}$
$dist_{k,\beta_0}$
$dist_{\sigma_0,\beta_0} + path_{\sigma_0,\beta_0}$
$dist_{\sigma_0,\beta_0} + path_{k,\beta_0}$
Action specific features
$\bar{\beta}_0.lem + \bar{\beta}_0.nswp$
$\bar{\beta}_0.reph$

Table 2: Features used in our parser. $\bar{\sigma}_0, \bar{\beta}_0, \bar{k}, \bar{\sigma}_{0p}$ represents elements in feature context of nodes $\sigma_0, \beta_0, k, \sigma_{0p}$, separately. Each atomic feature is represented as follows: w - word; lem - lemma; ne - name entity; t - POS-tag; dl - dependency label; len - length of the node's span.

For transition-based dependency parsers, the feature context for a parsing state is represented by the neighboring elements of a word token in the stack containing the partial parse or the buffer containing unprocessed word tokens. In contrast, in our tree-to graph parser, as already stated, buffers σ and β only specify which arc or node is to be examined next. The feature context associated with current arc or node is mainly extracted from the partial graph G. As a result, the feature context is different for the different types of actions, a property that makes our parser very different from a standard transition-based dependency parser. For example, when evaluating action SWAP we may be interested in features about individual nodes σ_0 and β_0 as well as features involving the arc (σ_0, β_0). In contrast, when evaluating action REATTACH$_k$, we want to extract not only features involving σ_0 and β_0, but also information about the reattached node k. To address this problem, we define the feature context as $\langle \bar{\sigma}_0, \bar{\beta}_0, \bar{k}, \bar{\sigma}_{0p} \rangle$, where each element $\bar{x}$ consists of its atomic features of node x and σ_{0p} denotes the immediate parent of node σ_0. For elements in feature context that are not applicable to the candidate action, we just set the element to NONE and only extract features which are valid for the candidate action. The list of features we use is shown in Table 2.

Single node features are atomic features concerning all the possible nodes involved in each candidate state-action pair. We also include path features and distance features as described in (Flanigan et al., 2014). A path feature $path_{x,y}$ is represented as the dependency labels and parts of speech on the path between nodes x and y in the partial graph. Here we combine it with the lemma of the starting and ending nodes. Distance feature $dist_{x,y}$ is the number of tokens between two node x, y's spans in the sentence. Action-specific features record the history of actions applied to a given node. For example, $\bar{\beta}_0.nswp$ records how many times node β_0 has been swapped up. We combine this feature with the lemma of node β_0 to prevent the parser from swapping a node too many times. $\bar{\beta}_0.reph$ records the word feature of nodes that have been replaced with node β_0. This feature is helpful in predicting relation labels. As we have discussed above, in an AMR graph, some function words are deleted as nodes but they are crucial in determining the relation label between its child and parent.

5 Experiments

5.1 Experiment Setting

Our experiments are conducted on the newswire section of AMR Annotation Corpus (LDC2013E117) (Banarescu et al., 2013).

We follow Flanigan et al. (2014) in setting up the train/development/test splits[1] for easy comparison: 4.0k sentences with document years 1995-2006 as the training set; 2.1k sentences with document year 2007 as the development set; 2.1k sentences with document year 2008 as the test set, and only using AMRs that are tagged `::preferred`. Each sentence w is preprocessed with the Stanford CoreNLP toolkit (Manning et al., 2014) to get part-of-speech tags, name entity information, and basic dependencies. We have verified that there is no overlap between the training data for the Stanford CoreNLP toolkit[2] and the AMR Annotation Corpus. We evaluate our parser with the Smatch tool (Cai and Knight, 2013), which seeks to maximize the semantic overlap between two AMR annotations.

5.2 Action Set Validation

One question about the transition system we presented above is whether the action set defined here can cover all the situations involving a dependency-to-AMR transformation. Although a formal theoretical proof is beyond the scope of this paper, we can empirically verify that the action set works well in practice. To validate the actions, we first run the $oracle()$ function for each sentence w and its dependency tree D_w to get the "pseudo-gold" G'_w. Then we compare G'_w with the gold-standard AMR graph represented as span graph G_w to see how similar they are. On the training data we got an overall 99% F-score for all $\langle G'_w, G_w \rangle$ pairs, which indicates that our action set is capable of transforming each sentence w and its dependency tree D_w into its gold-standard AMR graph through a sequence of actions.

5.3 Results

Table 3 gives the precision, recall and F-score of our parser given by Smatch on the test set. Our parser achieves an F-score of 63% (Row 3) and the result is 5% better than the first published result reported in (Flanigan et al., 2014) with the same training and test set (Row 2). We also conducted experiments on the test set by replacing the parsed graph with gold relation labels or/and gold concept labels. We can see in Table 3 that when provided with gold concept and relation labels as input, the parsing accuracy improves around 8% F-score (Row 6). Rows 4 and 5 present results when the parser is provided with just the gold relation labels (Row 4) or gold concept labels (Row 5), and the results are expectedly lower than if both gold concept and relation labels are provided as input.

	Precision	Recall	F-score
JAMR	.52	.66	.58
Our parser	**.64**	.62	**.63**
Our parser +l_{gr}	.68	.65	.67
Our parser +l_{gc}	.69	.67	.68
Our parser +l_{grc}	.72	.70	.71

Table 3: Results on the test set. Here, l_{gc} - gold concept label; l_{gr} - gold relation label; l_{grc} - gold concept label and gold relation label.

5.4 Error Analysis

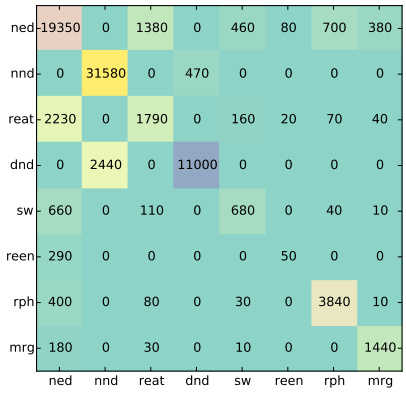

Figure 9: Confusion Matrix for actions $\langle t_g, t \rangle$. Vertical direction goes over the correct action type, and horizontal direction goes over the parsed action type.

Wrong alignments between the word tokens in the sentence and the concepts in the AMR graph account for a significant proportion of our AMR parsing errors, but here we focus on errors in the transition from the dependency tree to the AMR graph. Since in our parsing model, the parsing process has been decomposed into a sequence of actions applied to the input dependency tree, we can use the $oracle()$ function during parsing to give us the cor-

[1] A script to create the train/dev/test partitions is available at the following URL: `http://goo.gl/vA32iI`

[2] Specifically we used CoreNLP toolkit v3.3.1 and parser model wsjPCFG.ser.gz trained on the WSJ treebank sections 02-21.

rect action t_g to take for a given state s. A comparison between t_g and the best action t actually taken by our parser will give us a sense about how accurately each type of action is applied. When we compare the actions, we focus on the structural aspect of AMR parsing and only take into account the eight action types, ignoring the concept and edge labels attached to them. For example, NEXT-EDGE-$ARG0$ and NEXT-EDGE-$ARG1$ would be considered to be the same action and counted as a match when we compute the errors even though the labels attached to them are different.

Figure 9 shows the confusion matrix that presents a comparison between the parser-predicted actions and the correct actions given by $oracle()$ function. It shows that the NEXT-EDGE (ned), NEXT-NODE (nnd), and DELETENODE (dnd) actions account for a large proportion of the actions. These actions are also more accurately applied. As expected, the parser makes more mistakes involving the REATTACH (reat), REENTRANCE (reen) and SWAP (sw) actions. The REATTACH action is often used to correct PP-attachment errors made by the dependency parser or readjust the structure resulting from the SWAP action, and it is hard to learn given the relatively small AMR training set. The SWAP action is often tied to coordination structures in which the head in the dependency structure and the AMR graph diverges. In the Stanford dependency representation which is the input to our parser, the head of a coordination structure is one of the conjuncts. For AMR, the head is an abstract concept signaled by one of the coordinating conjunctions. This also turns out to be one of the more difficult actions to learn. We expect, however, as the AMR Annotation Corpus grows bigger, the parsing model trained on a larger training set will learn these actions better.

6 Related Work

Our work is directly comparable to JAMR (Flanigan et al., 2014), the first published AMR parser. JAMR performs AMR parsing in two stages: concept identification and relation identification. They treat concept identification as a sequence labeling task and utilize a semi-Markov model to map spans of words in a sentence to concept graph fragments. For relation identification, they adopt the graph-based techniques for non-projective dependency parsing. Instead of finding maximum-scoring trees over words, they propose an algorithm to find the maximum spanning connected subgraph (MSCG) over concept fragments obtained from the first stage. In contrast, we adopt a transition-based approach that finds its root in transition-based dependency parsing (Yamada and Matsumoto, 2003; Nivre, 2003; Sagae and Tsujii, 2008), where a series of actions are performed to transform a sentence to a dependency tree. As should be clear from our description, however, the actions in our parser are very different in nature from the actions used in transition-based dependency parsing.

There is also another line of research that attempts to design graph grammars such as hyperedge replacement grammar (HRG) (Chiang et al., 2013) and efficient graph-based algorithms for AMR parsing. Existing work along this line is still theoretical in nature and no empirical results have been reported yet.

7 Conclusion and Future Work

We presented a novel transition-based parsing algorithm that takes the dependency tree of a sentence as input and transforms it into an Abstract Meaning Representation graph through a sequence of actions. We show that our approach is linguistically intuitive and our experimental results also show that our parser outperformed the previous best reported results by a significant margin. In future work we plan to continue to perfect our parser via improved learning and decoding techniques.

Acknowledgments

The Geometry of Statistical Machine Translation

Aurelien Waite, William Byrne
Department of Engineering, University of Cambridge, UK

Abstract

Most modern statistical machine translation systems are based on linear statistical models. One extremely effective method for estimating the model parameters is minimum error rate training (MERT), which is an efficient form of line optimisation adapted to the highly non-linear objective functions used in machine translation. We describe a polynomial-time generalisation of line optimisation that computes the error surface over a plane embedded in parameter space. The description of this algorithm relies on convex geometry, which is the mathematics of polytopes and their faces.

Using this geometric representation of MERT we investigate whether the optimisation of linear models is tractable in general. Previous work on finding optimal solutions in MERT (Galley and Quirk, 2011) established a worst-case complexity that was exponential in the number of sentences, in contrast we show that exponential dependence in the worst-case complexity is mainly in the number of features.

Although our work is framed with respect to MERT, the convex geometric description is also applicable to other error-based training methods for linear models. We believe our analysis has important ramifications because it suggests that the current trend in building statistical machine translation systems by introducing a very large number of sparse features is inherently not robust.

1 Introduction

The linear model of Statistical Machine Translation (SMT) (Och and Ney, 2002) casts translation as a search for translation hypotheses under a linear combination of weighted features: a source language sentence $\mathbf{f}$ is translated as

$$\hat{\mathbf{e}}(\mathbf{f};\mathbf{w}) = \underset{\mathbf{e}}{\operatorname{argmax}}\{\mathbf{w}\mathbf{h}(\mathbf{e},\mathbf{f})\} \quad (1)$$

where translation scores are a linear combination of the $D \times 1$ feature vector $\mathbf{h}(\mathbf{e},\mathbf{f}) \in \mathbb{R}^D$ under the $1 \times D$ model parameter vector $\mathbf{w}$.

Convex geometry (Ziegler, 1995) is the mathematics of such linear equations presented as the study of convex polytopes. We use convex geometry to show that the behaviour of training methods such as MERT (Och, 2003; Macherey et al., 2008), MIRA (Crammer et al., 2006), PRO (Hopkins and May, 2011), and others converge with a high feature dimension. In particular we analyse how robustness decreases in linear models as feature dimension increases. We believe that severe overtraining is a problem in many current linear model formulations due to this lack of robustness.

In the process of building this geometric representation of linear models we discuss algorithms such as the Minkowski sum algorithm (Fukuda, 2004) and projected MERT (Section 4.2) that could be useful for designing new and more robust training algorithms for SMT and other natural language processing problems.

2 Training Linear Models

Let $\mathbf{f}_1 \ldots \mathbf{f}_S$ be a set of S source language sentences with reference translations $\mathbf{r}_1 \ldots \mathbf{r}_S$. The goal is to estimate the model parameter vector $\mathbf{w}$ so as to minimize an error count based on an automated metric, such as BLEU (Papineni et al., 2002), assumed to be

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 376–386,
Denver, Colorado, May 31 – June 5, 2015.

additive over sentences:

$$\hat{\mathbf{w}} = \underset{\mathbf{w}}{\operatorname{argmin}} \sum_{s=1}^{S} E(\hat{\mathbf{e}}(\mathbf{f}_s; \mathbf{w}), \mathbf{r}_s) \quad (2)$$

Optimisation can be made tractable by restricting the search to rescoring of K-best lists of translation hypotheses, $\{\mathbf{e}_{s,i}, 1 \leq i \leq K\}_{s=1}^{S}$. For $\mathbf{f}_s$, let $\mathbf{h}_{s,i} = \mathbf{h}(\mathbf{e}_{s,i}, \mathbf{f}_s)$ be the feature vector associated with hypothesis $\mathbf{e}_{s,i}$. Restricted to these lists, the general decoder of Eqn. 1 becomes

$$\hat{\mathbf{e}}(\mathbf{f_s}; \mathbf{w}) = \underset{\mathbf{e}_{s,i}}{\operatorname{argmax}} \{\mathbf{w}\mathbf{h}(\mathbf{e}_{s,i}, \mathbf{f}_s)\} \quad (3)$$

Although the objective function in Eqn. (2) cannot be solved analytically, MERT as described by Och (2003) can be performed over the K-best lists. The line optimisation procedure considers a subset of parameters defined by the line $\mathbf{w}^{(0)} + \gamma\mathbf{d}$, where $\mathbf{w}^{(0)}$ corresponds to an initial point in parameter space and $\mathbf{d}$ is the direction along which to optimise. Eqn. (3) can be rewritten as:

$$\hat{\mathbf{e}}(\mathbf{f_s}; \gamma) = \underset{\mathbf{e_{s,i}}}{\operatorname{argmax}} \{\mathbf{w}^{(0)}\mathbf{h}_{s,i} + \gamma\mathbf{d}\mathbf{h}_{s,i})\} \quad (4)$$

Line optimisation reduces the D-dimensional procedure in Eqn. (2) to a 1-Dimensional problem that can be easily solved using a geometric algorithm for many source sentences (Macherey et al., 2008).

More recently, Galley and Quirk (2011) have introduced linear programming MERT (LP-MERT) as an exact search algorithm that reaches the global optimum of the training criterion. A hypothesis $\mathbf{e}_{s,i}$ from the sth K-best list can be selected by the decoder only if

$$\mathbf{w}(\mathbf{h}_{s,j} - \mathbf{h}_{s,i}) \leq 0 \text{ for } 1 \leq j \leq K \quad (5)$$

for some parameter vector $\mathbf{w} \neq \mathbf{0}$. If such a solution exists then the system of inequalities is *feasible*, and defines a convex region in parameter space within which any parameter $\mathbf{w}$ will yield $\mathbf{e}_{s,i}$. Testing the system of inequalities in (5) and finding a parameter vector can be cast as a linear programming feasibility problem (Galley and Quirk, 2011), and this can be extended to find a parameter vector that optimizes Eqn. 2 over a collection of K-best lists. We discuss the complexity of this operation in Section 4.1.

Hopkins and May (2011) note that for the sth source sentence, the parameter $\mathbf{w}$ that correctly ranks its K-best list must satisfy the following set of constraints for $1 \leq i, j \leq K$:

$$\mathbf{w}(\mathbf{h}_{s,j} - \mathbf{h}_{s,i}) \leq 0 \text{ if } \Delta(\mathbf{e}_{s,i}, \mathbf{e}_{s,j}) \geq 0 \quad (6)$$

where Δ computes the difference in error between two hypotheses. The difference vectors $(\mathbf{h}_{s,j} - \mathbf{h}_{s,i})$ associated with each constraint can be used as input vectors for a binary classification problem in which the aim is to predict whether the the difference in error $\Delta(\mathbf{e}_{s,i}, \mathbf{e}_{s,j})$ is positive or negative. Hopkins and May (2011) call this algorithm Pairwise Ranking Optimisation (PRO). Because there are SK^2 difference vectors across all source sentences, a subset of constraints is sampled in the original formulation; with effcient calculation of rankings, sampling can be avoided (Dreyer and Dong, 2015).

The online error based training algorithm MIRA (Crammer et al., 2006) is also used for SMT (Watanabe et al., 2007; Chiang et al., 2008; Chiang, 2012). Using a sentence-level error function, a set of S oracle hypotheses are indexed with the vector $\hat{\mathbf{i}}$:

$$\hat{i}_s = \underset{i}{\operatorname{argmin}}\, E(\mathbf{e}_{s,i}, \mathbf{r}_s) \text{ for } 1 \leq s \leq S$$

For a given s the objective at iteration $n+1$ is :

$$\underset{\mathbf{w}^{(n+1)}}{\text{minimise}} \quad \frac{1}{2}\|\mathbf{w}^{(n+1)} - \mathbf{w}^{(n)}\|^2 + C\sum_{j=1}^{K}\xi_j \quad (7)$$

$$\text{subject to } \xi_j \geq 0 \text{ and for } 1 \leq j \leq K, \hat{i}_s \neq j :$$

$$\mathbf{w}^{(n+1)}(\mathbf{h}_{s,j} - \mathbf{h}_{s,\hat{i}_s}) + \Delta(\mathbf{e}_{s,\hat{i}_s}, \mathbf{e}_{s,j}) - \xi_j \leq 0$$

where $\{\xi\}$ are slack variables added to allow infeasible solutions, and C controls the trade-off between error minimisation and margin maximisation. The online nature of the optimiser results in complex implementations, therefore batch versions of MIRA have been proposed (Cherry and Foster, 2012; Gimpel and Smith, 2012).

Although MERT, LP-MERT, PRO, and MIRA carry out their search in very different ways, we can compare them in terms of the constraints they are attempting to satisfy. A feasible solution for LP-MERT is also an optimal solution for MERT, and vice versa. The constraints (Eqn. (5)) that define LP-MERT are a subset of the constraints (Eqn. (6))

that define PRO and so a feasible solution for PRO will also be feasible for LP-MERT; however the converse is not necessarily true. The constraints that define MIRA (Eqn. (7)) are similar to the LP-MERT constraints (5), although with the addition of slack variables and the Δ function to handle infeasible solutions. However, if a feasible solution is available for MIRA, then these extra quantities are unnecessary. With these quantities removed, then we recover a 'hard-margin' optimiser, which utilises the same constraint set as in LP-MERT. In the feasible case, the solution found by MIRA is also a solution for LP-MERT.

2.1 Survey of Recent Work

One avenue of SMT research has been to add as many features as possible to the linear model, especially in the form of sparse features (Chiang et al., 2009; Hopkins and May, 2011; Cherry and Foster, 2012; Gimpel and Smith, 2012; Flanigan et al., 2013; Galley et al., 2013; Green et al., 2013). The assumption is that the addition of new features will improve translation performance. It is interesting to read the justification for many of these works as stated in their abstracts. For example Hopkins and May (2011) state that:

> We establish PRO's scalability and effectiveness by comparing it to MERT and MIRA and demonstrate parity on both phrase-based and syntax-based systems

Cherry and Foster (2012) state:

> Among other results, we find that a simple and efficient batch version of MIRA performs at least as well as training online.

Along similar lines Gimpel and Smith (2012) state:

> [We] present a training algorithm that is easy to implement and that performs comparable to others.

In defence of MERT, Galley et al. (2013) state:

> Experiments with up to 3600 features show that these extensions of MERT yield results comparable to PRO, a learner often used with large feature sets.

Green et al. (2013) also note that feature-rich models are rarely used in annual MT evaluations, an observation they use to motivate an investigation into adaptive learning rate algorithms.

Why do such different methods give such remarkably 'comparable' performance in research settings? And why is it so difficult to get general and unambiguous improvements through the use of high dimensional, sparse features? We believe that the explanation is in *feasibility*. If the oracle index vector $\hat{\mathbf{i}}$ is feasible then all training methods will find very similar solutions. Our belief is that as the feature dimension increases, the chance of an oracle index vector being feasible also increases.

3 Convex Geometry

We now build on the description of LP-MERT to give a geometric interpretation to training linear models. We first give a concise summary of the fundamentals of convex geometry as presented by (Ziegler, 1995) after which we work through the example in Cer et al. (2008) to provide an intuition behind these concepts.

3.1 Convex Geometry Fundamentals

In this section we reference definitions from convex geometry (Ziegler, 1995) in a form that allows us to describe SMT model parameter optimisation.

Vector Space The real valued vector space $\mathbb{R}^D$ represents the space of all finite D-dimensional feature vectors.

Dual Vector Space The dual vector space $(\mathbb{R}^D)^*$ are the real linear functions $\mathbb{R}^D \rightarrow \mathbb{R}$.

Polytope The polytope $H_s \subseteq \mathbb{R}^D$ is the convex hull of the finite set of feature vectors associated with the K hypotheses for the sth sentence, i.e. $H_s = \text{conv}(\mathbf{h}_{s,1}, \ldots, \mathbf{h}_{s,K})$.

Faces in $\mathbb{R}^D$ Suppose for $\mathbf{w} \in (\mathbb{R}^D)^*$ that $\mathbf{wh} \leq \max_{\mathbf{h}' \in H_s} \mathbf{wh}'$, $\forall\, \mathbf{h} \in H_s$. A *face* is defined as

$$F = \{\mathbf{h} \in H_s : \mathbf{wh} = \max_{\mathbf{h}' \in H_s} \mathbf{wh}'\} \qquad (8)$$

Vertex A face consisting of a single point is called a *vertex*. The set of vertices of a polytope is denoted $\text{vert}(H_s)$.

Edge An *edge* is a face in the form of a line segment between two vertices $\mathbf{h}_{s,i}$ and $\mathbf{h}_{s,j}$ in the polytope H_s. The edge can be written as $[\mathbf{h}_{s,i}, \mathbf{h}_{s,j}] = \text{conv}(\mathbf{h}_{s,i}, \mathbf{h}_{s,j})$. If an edge exists then the following

	h_{LM} : $\log(P_{LM}(\mathbf{e}))$	h_{TM} : $\log(P_{TM}(\mathbf{f}\|\mathbf{e}))$
$\mathbf{e}_1$	-0.1	-1.2
$\mathbf{e}_2$	-1.2	-0.2
$\mathbf{e}_3$	-0.9	-1.6
$\mathbf{e}_4$	-0.9	-0.1
$\mathbf{e}_5$	-0.8	-0.9

Table 1: An example set of two dimensional feature vectors (after Cer et al. (2008), Table 1) with language model (h_{LM}) and translation model (h_{TM}) components. A fifth feature vector has been added to illustrate redundancy.

modified system from (5) is feasible

$$\begin{aligned} &\mathbf{w}(\mathbf{h}_j - \mathbf{h}_i) = 0 \\ &\mathbf{w}(\mathbf{h}_k - \mathbf{h}_i) < 0,\ 1 \leq k \leq K, k \neq i, k \neq j \\ &\mathbf{w}(\mathbf{h}_l - \mathbf{h}_j) < 0,\ 1 \leq l \leq K, l \neq i, l \neq j \end{aligned} \tag{9}$$

which implies that $[\mathbf{h}_{s,i}, \mathbf{h}_{s,j}]$ defines a decision boundary in $(\mathbb{R}^D)^*$ between the parameters that maximise $\mathbf{h}_{s,i}$ and those that maximise $\mathbf{h}_{s,j}$.

Normal Cone For the face F in polytope H_s the normal cone N_F takes the form.

$$\begin{aligned} N_F = \{\mathbf{w} : \mathbf{w}(\mathbf{h}_{s,j} - \mathbf{h}_{s,i}) \leq 0, \forall \mathbf{h}_{s,i} \in \text{vert}(F), \\ \forall \mathbf{h}_{s,j} \in \text{vert}(H_s)\} \end{aligned} \tag{10}$$

If the face is a vertex $F = \{\mathbf{h}_{s,i}\}$ then its normal cone $N_{\{\mathbf{h}_{s,i}\}}$ is the set of feasible parameters that satisfy the system in (5).

Normal Fan The set of all normal cones associated with the faces of H_s is called the *normal fan* $\mathcal{N}(H_s)$.

3.2 Drawing a Normal Fan

Following the example in Cer et al. (2008) we analyze a system based on two features: the translation $P_{TM}(\mathbf{f}|\mathbf{e})$ and language $P_{LM}(\mathbf{e})$ models. For brevity we omit the common sentence index, so that $\mathbf{h}_i = \mathbf{h}_{s,i}$. The system produces a set of four hypotheses which yield four feature vectors $\{\mathbf{h}_1, \mathbf{h}_2, \mathbf{h}_3, \mathbf{h}_4\}$ (Table 1). To this set of four hypotheses, we add a fifth hypothesis and feature vector $\mathbf{h}_5$ to illustrate an infeasible solution. These feature vectors are plotted in Figure 1.

The feature vectors form a polytope H shaded in light blue. From Figure 1 we see that $\mathbf{h}_4$ satisfies the

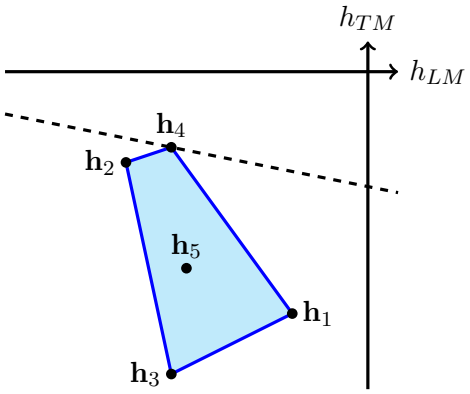

Figure 1: A geometric interpretation of LP-MERT (after Cer et al. (2008) and Galley and Quirk (2011)). The decision boundary represented by the dashed line intersects the polytope at only $\mathbf{h}_4$, making it a vertex. No decision boundary intersects $\mathbf{h}_5$ without intersecting other points in the polytope, making $\mathbf{h}_5$ redundant.

conditions for a vertex in Eqn. (8), because we can draw a decision boundary that interests the vertex and no other $\mathbf{h} \in H$. We also note $\mathbf{h}_5$ is not a vertex, and is *redundant* to the description of H.

Figure 1 of Cer et al. (2008) actually shows a normal fan, although it is not described as such. We now describe how this geometric object is constructed step by step in Figure 2. In Part (a) we identify the edge $[\mathbf{h}_4, \mathbf{h}_1]$ in $\mathbb{R}^2$ with a decision boundary represented by a dashed line. We have also drawn a vector $\mathbf{w}$ normal to the decision boundary that satisfies Eqn. (8). This parameter would result in a tied model score such that $\mathbf{w}\mathbf{h}_4 = \mathbf{w}\mathbf{h}_1$. When moving to $(\mathbb{R}^2)^*$ we see that the normal cone $N_{[\mathbf{h}_4,\mathbf{h}_1]}$ is a ray parallel to $\mathbf{w}$. This ray can be considered as the set of parameter vectors that yield the edge $[\mathbf{h}_4, \mathbf{h}_1]$. The ray is also a decision boundary in $(\mathbb{R}^2)^*$, with parameters on either side of the decision boundary maximising either $\mathbf{h}_4$ or $\mathbf{h}_1$. Any vector parallel to the edge $[\mathbf{h}_4, \mathbf{h}_1]$, such as $(\mathbf{h}_1 - \mathbf{h}_4)$, can be used to define this decision boundary in $(\mathbb{R}^2)^*$.

Next in Part (b), with the same procedure we define the normal cone for the edge $[\mathbf{h}_3, \mathbf{h}_1]$. Now both the edges from parts (a) and (b) share the the vertex $\mathbf{h}_1$. This implies that any parameter vector that lies between the two decision boundaries (i.e. between the two rays $N_{[\mathbf{h}_3,\mathbf{h}_1]}$ and $N_{[\mathbf{h}_4,\mathbf{h}_1]}$) would maximise the vertex $\mathbf{h}_1$: this is the set of vectors that comprise

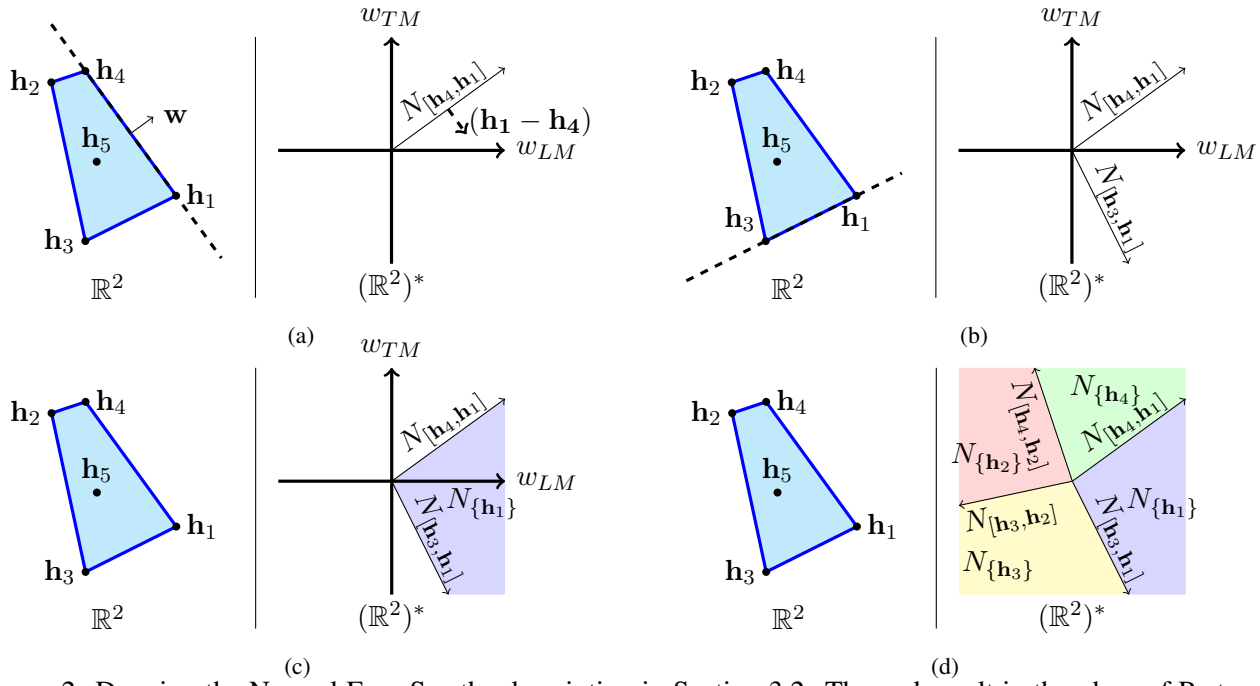

Figure 2: Drawing the Normal Fan. See the description in Section 3.2. The end result in the r.h.s. of Part (d) reproduces Figure 1 from Cer et al. (2008), identifying the normal cones for all vertices.

normal cone of the vertex $N_{\{\mathbf{h}_1\}}$.

In Part (c) we have shaded and labelled $N_{\{\mathbf{h}_1\}}$. Note that no other edges are needed to define this normal cone; these other edges are redundant to the normal cone's description.

Finally in Part (d) we draw the full fan. We have omitted the axes in $(\mathbb{R}^2)^*$ for clarity. The normal cones for all 4 vertices have been identified.

4 Training Set Geometry

The previous discussion treated only a single sentence. For a training set of S input sentences, let $\mathbf{i}$ be an index vector that contains S elements. Each element is an index i_s to a hypothesis and a feature vector for the sth sentence. A particular $\mathbf{i}$ specifies a set of hypotheses drawn from each of the K-best lists. LP-MERT builds a set of K^S feature vectors associated with S dimensional index vectors $\mathbf{i}$ of the form $\mathbf{h_i} = \mathbf{h}_{1,i_1} + \ldots + \mathbf{h}_{S,i_S}$. The polytope of these feature vectors is then constructed.

In convex geometry this operation is called the *Minkowski sum* and for the polytopes H_s and H_t, is defined as (Ziegler, 1995)

$$H_s + H_t := \{\mathbf{h} + \mathbf{h}' : \mathbf{h} \in H_s, \mathbf{h}' \in H_t\} \quad (11)$$

We illustrate this operation in the top part of Figure 3. The Minkowski sum is commutative and associative and generalises to more than two polytopes (Gritzmann and Sturmfels, 1992).

For the polytopes H_s and H_t the *common refinement* (Ziegler, 1995) is

$$\mathcal{N}(H_s) \wedge \mathcal{N}(H_t) := \{N \cap N' : N \in \mathcal{N}(H_s), N' \in \mathcal{N}(H_t)\} \quad (12)$$

Each cone in the common refinement is the set of parameter vectors that maximise two faces in H_s and H_t. This operation is shown in the bottom part of Figure 3.

As suggested by Figure 3 the Minkowski sum and common refinement are linked by the following

Proposition 1. $\mathcal{N}(H_s + H_t) = \mathcal{N}(H_s) \wedge \mathcal{N}(H_t)$

Proof. See Gritzmann and Sturmfels (1992) □

This implies that, with $\mathbf{h_i}$ defined for the index vector $\mathbf{i}$, the Minkowski sum defines the parameter vectors that satisfy the following (Tsochantaridis et al., 2005, Eqn. 3)

$$\mathbf{w}(\mathbf{h}_{s,j} - \mathbf{h}_{s,i_s}) \leq 0, \ 1 \leq s \leq S, 1 \leq j \leq K \quad (13)$$

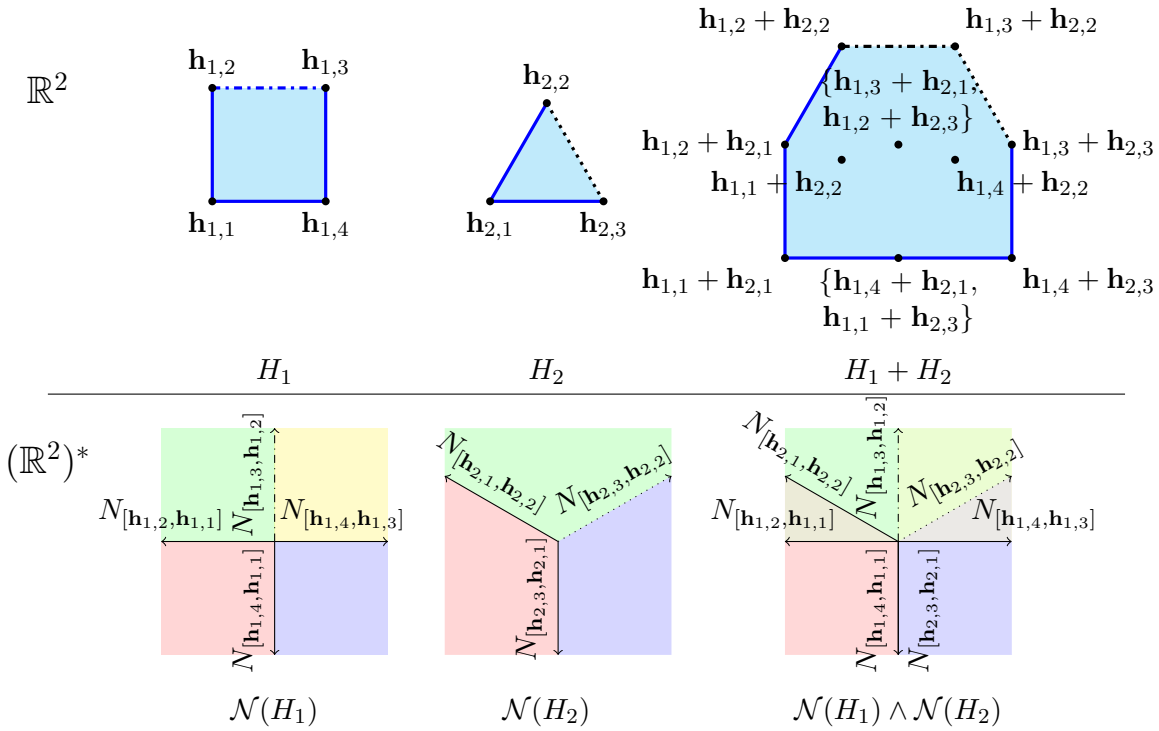

Figure 3: An example of the equivalence between the Minkowski sum and the common refinement.

4.1 Computing the Minkowski Sum

In the top part of the Figure 3 we see that computing the Minkowski sum directly gives 12 feature vectors, 10 of which are unique. Each feature vector would have to be tested under LP-MERT. In general there are K^S such feature vectors and exhaustive testing is impractical. LP-MERT performs a lazy enumeration of feature vectors as managed through a divide and conquer algorithm. We believe that in the worst case the complexity of this algorithm could be $O(K^S)$.

The lower part of Figure 3 shows the computation of the common refinement. The common refinement appears as if one normal fan was superimposed on the other. We can see there are six decision boundaries associated with the six edges of the Minkowski sum. Even in this simple example, we can see that the common refinement is an easier quantity to compute than the Minkowski sum.

We now briefly describe the algorithm of Fukuda (2004) that computes the common refinement. Consider the example in Figure 3. For H_1 and H_2 we have drawn an edge in each polytope with a dashed line. The corresponding decision boundaries in their normal fans have also been drawn with dashed lines.

Now consider the vertex $\mathbf{h}_{1,3} + \mathbf{h}_{2,2}$ in $H = H_1 + H_2$ and note it has two incident edges. These edges are parallel to edges in the summand polytopes and correspond to decision boundaries in the normal cone $N_{\{\mathbf{h}_{1,3}+\mathbf{h}_{2,2}\}}$.

We can find the redundant edges in the Minkowski sum by testing the edges suggested by the summand polytopes. If a decision boundary in $(\mathbb{R}^D)^*$ is redundant, then we can ignore the feature vector that shares the decision boundary. For example $\mathbf{h}_{1,4} + \mathbf{h}_{2,2}$ is redundant and the decision boundary $N_{[\mathbf{h}_{1,3},\mathbf{h}_{1,4}]}$ is also redundant to the description of the normal cone $N_{\{\mathbf{h}_{1,3}+\mathbf{h}_{2,2}\}}$. The test for redundant edges can be performed by a linear program.

Given a Minkowski sum H we can define an undirected cyclic graph $G(H) = (\text{vert}(H), E)$ where E is the set of edges. The degree of a vertex in $G(H)$ is the number of edges incident to a vertex; δ is denoted as the maximum degree of the vertices.

The linear program for testing redundancy of decision boundaries has a runtime of $O(D^{3.5}\delta)$ (Fukuda, 2004). Enumerating the vertices of graph $G(H)$ is not trivial due to it being an undirected and cyclic graph. The solution is to use a *reverse search* algorithm (Avis and Fukuda, 1993). Essen-

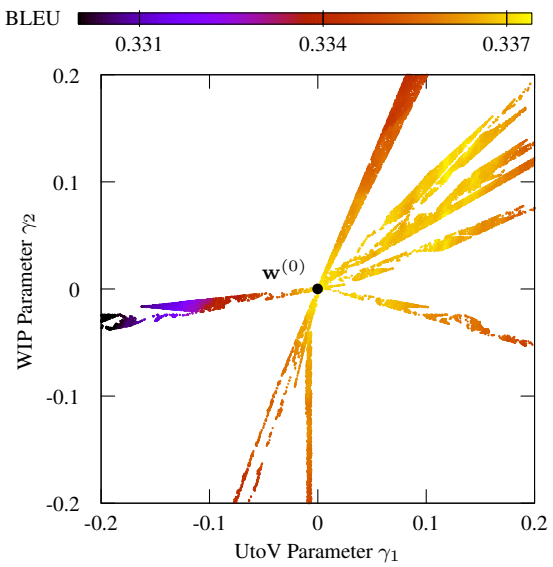

Figure 4: The BLEU score over a 1502 sentence tune set for the CUED Russian-to-English (Pino et al., 2013) system over two parameters. Enumerated vertices of the Minkowski sum are shown in the shaded regions.

tially reverse search transforms the graph into a tree. The vertex associated with $\mathbf{w}^{(0)}$ is denoted as the root of the tree, and from this root vertices are enumerated in reverse order of model score under $\mathbf{w}^{(0)}$. Each branch of the tree can be enumerated independently, which means that the enumeration can be parallelised.

The complexity of the full algorithm is $O(\delta(D^{3.5}\delta)|\operatorname{vert}(H)|)$ (Fukuda, 2004). In comparison with the $O(K^S)$ for LP-MERT the worst case complexity of the reverse search algorithm is linear with respect to the size of $\operatorname{vert}(H)$.

4.2 Two Dimensional Projected MERT

We now explore whether the reverse search algorithm is a practical method for performing MERT using an open source implementation of the algorithm (Weibel, 2010). For reasons discussed in the next section, we wish to reduce the feature dimension. For $M < D$, we can define a projection matrix $A_{M+1,D}$ that maps $\mathbf{h}_i \in \mathbb{R}^D$ into $\mathbb{R}^{M+1}$ as $A_{M+1,D}\mathbf{h}_i = \tilde{\mathbf{h}}_i$, $\tilde{\mathbf{h}}_i \in \mathbb{R}^{M+1}$. There are technical constraints to be observed, discussed in Waite (2014). We note that when $M = 1$ we obtain Eqn. (4).

For our demonstration, we plot the error count over a plane in $(\mathbb{R}^D)^*$. Using the CUED Russian-to-English (Pino et al., 2013) entry to WMT'13 (Bojar et al., 2013) we build a tune set of 1502 sentences. The system uses 12 features which we initially tune with lattice MERT (Macherey et al., 2008) to get a parameter $\mathbf{w}^{(0)}$. Using this parameter we generate 1000-best lists. We then project the feature functions in the 1000-best lists to a 3-dimensional representation that includes the source-to-target phrase probability (UtoV), the word insertion penalty (WIP), and the model score due to $\mathbf{w}^{(0)}$. We use the Minkowski sum algorithm to compute BLEU as $\boldsymbol{\gamma} \in (\mathbb{R}^2)^*$ is applied to the parameters from $\mathbf{w}^{(0)}$.

Figure 4 displays some of the characteristics of the algorithm[1]. This plot can be interpreted as a 3-dimensional version of Figure 3 in Macherey et al. (2008) where we represent the BLEU score as a heatmap instead of a third axis. Execution was on 12 CPU cores, leading to the distinct search regions, demonstrating the parallel nature of the algorithm. Weibel (2010) uses a depth-first enumeration order of $G(H)$, hence the narrow and deep exploration of $(\mathbb{R}^D)^*$. A breadth-first ordering would focus on cones closer to $\mathbf{w}^{(0)}$. To our knowledge, this is the first description of a generalised line optimisation algorithm that can search all the parameters in a plane in polynomial time. Extensions to higher dimensional search are straightforward.

5 Robustness of Linear Models

In the previous section we described the Minkowski sum polytope. Let us consider the following upper bound theorem

Theorem 1. *Let $H_1, \ldots, H_S$ be polytopes in $\mathbb{R}^D$ with at most N vertices each. Then for $D > 2$ the upper bound on number of vertices of $H_1 + \ldots + H_S$ is $O(S^{D-1}K^{2(D-1)})$.*

Proof. See Gritzmann and Sturmfels (1992) □

Each vertex $\mathbf{h_i}$ corresponds to a single index vector $\mathbf{i}$, which itself corresponds to a single set of selected hypotheses. Therefore the number of distinct sets of hypotheses that can be drawn

[1] A replication of this experiment forms part of the UCAM-SMT tutorial at `http://ucam-smt.github.io`

from the S K-best lists in bounded above by $O(\min(K^S, S^{D-1}K^{2(D-1)}))$.

For low dimension features, i.e. for D : $S^{D-1}K^{2(D-1)} \ll K^S$, the optimiser is therefore tightly constrained. It cannot pick arbitrarily from the individual K-best lists to optimise the overall BLEU score. We believe this acts as an *inherent form of regularisation*.

For example, in the system of Section 4.2 (D=12, S=1502, K=1000), only 10^{-4403} percent of the K^S possible index vectors are feasible. However, if the feature dimension D is increased to $D = 493$, then $S^{D-1}K^{2(D-1)} \gg K^S$ and this inherent regularisation is no longer at work: any index vector is feasible, and sentence hypotheses can chosen arbitrarily to optimise the overall BLEU score.

This exponential relationship of feasible solutions with respect to feature dimension can be seen in Figure 6 of Galley and Quirk (2011). At low feature dimension, they find that the LP-MERT algorithm can run to completion for a training set size of hundreds of sentences. As feature dimension increases, the runtime increases exponentially.

PRO and other ranking methods are similarly constrained for low dimensional feature vectors.

Theorem 2. *If H is a D-dimensional polytope, then for $D \geq 3$ the following is an upper bound on the number of edges $|E|$*

$$|E| \leq \binom{|\operatorname{vert}(H)|}{2} \tag{14}$$

Proof. This is a special case of the upper bound theorem. See Ziegler (1995, Theorem 8.23). □

Each feasible pairwise ranking of pairs of hypotheses corresponds to an edge in the Minkowski sum polytope. Therefore in low dimension ranking methods also benefit from this inherent regularisation.

For higher dimensional feature vectors, these upper bounds no longer guarantee that this inherent regularisation is at work. The analysis suggests - but does not imply - that index vectors, and their corresponding solutions, can be picked arbitrarily from the K-best lists. For MERT overtraining is clearly a risk.

MIRA and related methods have a regularisation mechanism due to the margin maximisation term in their objective functions. Although this form of regularisation may be helpful in practice, there is no guarantee that it will prevent overtraining due to the exponential increase in feasible solutions. For example the adaptive learning rate method of Green et al. (2013) finds gains of over 13 BLEU points in the training set with the addition of 390,000 features, yet only 2 to 3 BLEU points are found in the test set.

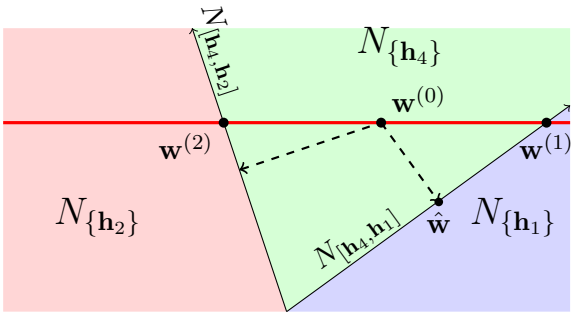

Figure 5: We redraw the normal fan from Figure 2 with potential optimal parameters under the ℓ_2 regularisation scheme of Galley et al. (2013) marked. The thick red line is the subspace of $(\mathbb{R}^2)^*$ optimised. The dashed lines mark the distances between the decision boundaries and $\mathbf{w}^{(0)}$.

5.1 A Note on Regularisation

The above analysis suggest a need for regularisation in training with high dimensional feature vectors. Galley et al. (2013) note that regularisation is hard to apply to linear models due to the magnitude invariance of $\mathbf{w}$ in Eqn. (1). Figure 2 makes the difficulty clear: the normal cones are determined entirely by the feature vectors of the training samples, and within any particular normal cone a parameter vector can be chosen with arbitrary magnitude. This renders schemes such as L1 or L2 normalisation ineffective. To avoid this, Galley et al. (2013) describe a regularisation scheme for line optimisation that encourages the optimal parameter to be found close to $\mathbf{w}^{(0)}$. The motivation is that $\mathbf{w}^{(0)}$ should be a trusted initial point, perhaps taken from a lower-dimensional model. We briefly discuss the challenges of doing this sort of regularisation in MERT.

In Figure 5 we reproduce the normal fan from Figure 2. In this diagram we represent the set of parameters considered by a line optimisation as a thick red line. Let us assume that both $\mathbf{e}_1$ and $\mathbf{e}_2$ have a

similarly low error count. Under the regularisation scheme of Galley et al. (2013) we have a choice of $\mathbf{w}^{(1)}$ or $\mathbf{w}^{(2)}$, which are equidistant from $\mathbf{w}^{(0)}$. In this affine projection of parameter space it is unclear which one is the optimum. However, if we consider the normal fan as a whole we can clearly see that $\hat{\mathbf{w}} \in N_{\{\mathbf{h}_i\}}$ is the optimal point under the regularisation. However, it is not obvious in the projected parameter space that $\hat{\mathbf{w}}$ is the better choice. This analysis suggests that direct intervention, e.g. monitoring BLEU on a held-out set, may be more effective in avoiding overtraining.

6 Discussion

The main contribution of this work is to present a novel geometric description of MERT. We show that it is possible to enumerate all the feasible solutions of a linear model in polynomial time using this description. The immediate conclusion from this work is that the current methods for estimating linear models as done in SMT works best for low dimensional feature vectors.

We can consider the SMT linear model as a member of a family of linear models where the output values are highly structured, and where each input yields a candidate space of possible output values. We have already noted that the constraints in (13) are shared with the structured-SVM (Tsochantaridis et al., 2005), and we can also see the same constraints in Eqn. 3 of Collins (2002). It is our belief that our analysis is applicable to all models in this family and extends far beyond the discussion of SMT here.

We note that the upper bound on feasible solutions increases polynomially in training set size S, whereas the number of possible solutions increases exponentially in S. The result is that the ratio of feasible to possible solutions decreases with S. Our analysis suggests that inherent regularisation should be improved by increasing training set size. This confirms most researchers intuition, with perhaps even larger training sets needed than previously believed.

Another avenue to prevent overtraining would be to project high-dimensional feature sets to low dimensional feature sets using the technique described in Section 4.1. We could then use existing training methods to optimise over the projected feature vectors.

We also note that non-linear models methods, such as neural networks (Schwenk et al., 2006; Kalchbrenner and Blunsom, 2013; Devlin et al., 2014; Cho et al., 2014) and decision forests (Criminisi et al., 2011) are not bound by these analyses. In particular neural networks are non-linear functions of the features, and decision forests actively reduce the number of features for individual trees in the forrest. From the perspective of this paper, the recent improvements in SMT due to neural networks are well motivated.

Abstract

Abstract structures from which the generation naturally starts often do not contain any functional nodes, while surface-syntactic structures or a chain of tokens in a linearized tree contain all of them. Therefore, data-driven linguistic generation needs to be able to cope with the projection between non-isomorphic structures that differ in their topology and number of nodes. So far, such a projection has been a challenge in data-driven generation and was largely avoided. We present a fully stochastic generator that is able to cope with projection between non-isomorphic structures. The generator, which starts from PropBank-like structures, consists of a cascade of SVM-classifier based submodules that map in a series of transitions the input structures onto sentences. The generator has been evaluated for English on the Penn-Treebank and for Spanish on the multi-layered Ancora-UPF corpus.

1 Introduction

Applications such as machine translation that inherently draw upon sentence generation increasingly deal with deep meaning representations; see, e.g., (Aue et al., 2004; Jones et al., 2012; Andreas et al., 2013). Deep representations tend to differ in their topology and number of nodes from the corresponding surface structures since they do not contain, e.g., any functional nodes, while syntactic structures or chains of tokens in linearized trees do. This means that sentence generation needs to be able to cope with the projection between non-isomorphic structures. However, most of the recent work in data-driven sentence generation still avoids this challenge. Some systems focus on syntactic generation (Bangalore and Rambow, 2000; Langkilde-Geary, 2002; Filippova and Strube, 2008) or linearization and inflection (Filippova and Strube, 2007; He et al., 2009; Wan et al., 2009; Guo et al., 2011a), and avoid thus the need to cope with this projection all together; some use a rule-based module to handle the projection between non-isomorphic structures (Knight and Hatzivassiloglou, 1995; Langkilde and Knight, 1998; Bohnet et al., 2011); and some adapt the meaning structures to be isomorphic with syntactic structures (Bohnet et al., 2010). However, it is obvious that a "syntacticization" of meaning structures can be only a temporary workaround and that a rule-based module raises the usual questions of coverage, maintenance and portability.

In this paper, we present a fully stochastic generator that is able to cope with the projection between non-isomorphic structures.[1] Such a generator can be used as a stand-alone application and also, e.g., in text simplification (Klebanov et al., 2004) or deep machine translation (Jones et al., 2012) (where the transfer is done at a deep level). In abstractive summarization, it facilitates the generation of the summaries, and in extractive summarization a better sentence fusion.[2]

[1]The data-driven sentence generator is available for public downloading at https://github.com/talnsoftware/deepgenerator/wiki.

[2]For all of these applications, the deep representation can be obtained by a deep parser, such as, e.g., (Ballesteros et al., 2014a).

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 387–397,
Denver, Colorado, May 31 – June 5, 2015.

The generator, which starts from elementary predicate-argument lexico-structural structures as used in sentence planning by Stent et al. (2004), consists of a cascade of Support Vector Machines (SVM)-classifier based submodules that map the input structures onto sentences in a series of transitions. Following the idea presented in (Ballesteros et al., 2014b), a separate SVM-classifier is defined for the mapping of each linguistic category. The generator has been tested on Spanish with the multi-layered Ancora-UPF corpus (Mille et al., 2013) and on English with an extended version of the dependency Penn TreeBank (Johansson and Nugues, 2007).

The remainder of the paper is structured as follows. In the next section, we briefly outline the fundamentals of sentence generation as we view it in our work, focusing in particular on the most challenging part of it: the transition between the non-isomorphic predicate-argument lexico-structural structures and surface-syntactic structures. Section 3 outlines the setup of our system. Section 4 discusses the experiments we carried out and the results we obtained. In Section 5, we briefly summarize related work, before in Section 6 some conclusions are drawn and future work is outlined.

2 The Fundamentals

Sentence generation realized in this paper is part of the sentence synthesis pipeline argued for by Mel'čuk (1988). It consists of a sequence of two mappings:

1. Predicate-argument lexico-structural structure → Syntactic structure
2. Syntactic Structure → Linearized structure

Following the terminology in (Mel'čuk, 1988), we refer to the predicate-argument lexico-structural structures as "deep-syntactic structures" (DSyntSs) and to the syntactic structures as "surface-syntactic structures" (SSyntSs).

While SSyntSs and linearized structures are isomorphic, the difference in the linguistic abstraction of the DSyntSs and SSyntSs leads to divergences that impede the isomorphy between the two and make the first mapping a challenge for statistical generation. Therefore, we focus in this section on the presentation of the DSyntSs and SSyntSs and the mapping between them.

2.1 DSyntSs and SSyntSs

2.1.1 Input DSyntSs

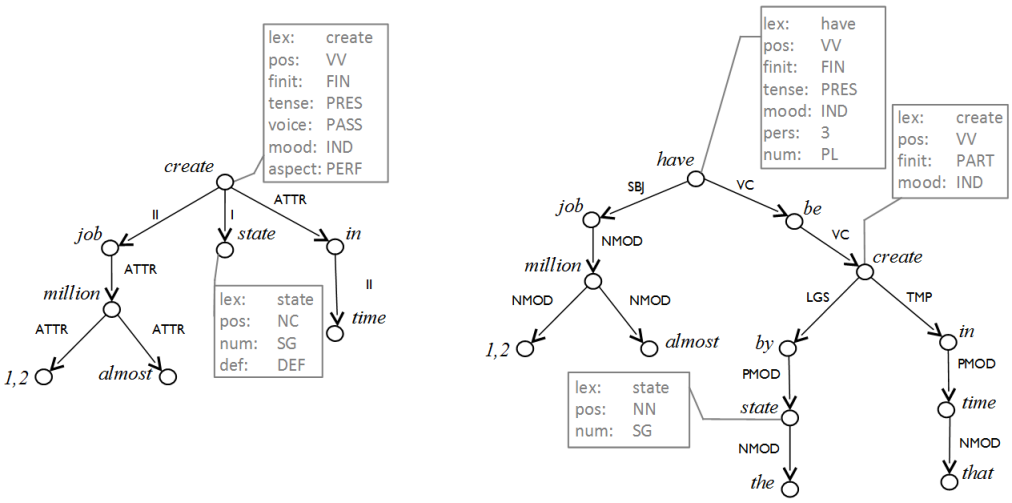
DSyntSs are very similar to the PropBank (Babko-Malaya, 2005) structures and the structures as used for the deep track of the First Surface Realization Shared Task (SRST, (Belz et al., 2011)) annotations. DSyntSs are connected trees that contain only meaning-bearing lexical items and both predicate-argument (indicated by Roman numbers: *I*, *II*, *III*, *IV*, ...) and lexico-structural, or deep-syntactic, (*ATTR(ibutive)*, *APPEND(itive)* and *COORD(inative)*) relations. In other words, they do not contain any punctuation and functional nodes, i.e., governed elements, auxiliaries and determiners. Governed elements such governed prepositions and subordinating conjunctions are dropped because they are imposed by sub-categorization restrictions of the predicative head and void of own meaning—as, for instance, *to* in *give TO your friend* or *that* in *I know that you will come*.[3] Auxiliaries do not appear as nodes in DSyntSs. Rather, the information they encode is captured in terms of tense, aspect and voice attributes of the corresponding full verbal nodes. Equally, determiners are substituted by attribute–value pairs of givenness they encode, assigned to their governors. See Figure 1 (a) for a sample DSyntS.[4]

2.1.2 SSyntSs

SSyntSs are connected dependency trees in which the nodes are labeled by open or closed class lexical items and the edges by grammatical function relations of the type 'subject', 'oblique_object', 'adverbial', 'modifier', etc. A SSyntS is thus a typical dependency tree as used in data-driven syntactic parsing (Hajič et al., 2009) and generation (Belz et al., 2011). See Figure 1 (b) for illustration of a SSyntS.

[3] In contrast, *on* in *the bottle is on the table* is not dropped because it is semantic.

[4] "That" is considered a kind of determiner (to be derived from the Information Structure). This is the reason to omit it in the deep structure.



(a) (b)

Figure 1: A DSyntS (a) and its corresponding SSyntS (b) for the sentence *Almost 1.2 million jobs have been created by the state in that time*

2.2 Projection of DSyntS to SSyntS

In order to project a DSyntS onto its corresponding SSyntS in the course of generation (where both DSyntSs and their corresponding SSyntSs are stored in the 14-column CoNLL'09 format), the following types of actions need to be performed:[5]

1. Project each node in the DSyntS onto its SSynS-correspondence. This correspondence can be a single node, as, e.g., *job* → [*NN*] (where *NN* is a noun), or a subtree (*hypernode*, known as *syntagm* in linguistics), as, e.g., *time* → [*DT NN*] (where *DT* is a determiner and *NN* a noun) or *create* → [V_{AUX} $\mathrm{V}_{\mathrm{AUX}}$ *VB IN*] (where V_{AUX} is an auxiliary, *VB* a full verb and *IN* a preposition). In formal terms, we assume any SSyntS-correspondence to be a hypernode with a cardinality ≥ 1.

2. Generate the correct lemma for the nodes in SSyntS that do not have a 1:1 correspondence with an origin DSyntS node (as *DT* and V_{AUX} above).[6]

3. Establish the dependencies within the individual SSyntS-hypernodes.

4. Establish the dependencies between the SSyntS-hypernodes (more precisely, between the nodes of different SSyntS-hypernodes) to obtain a connected SSyntS-tree.

2.3 Treebanks used in the experiments

2.3.1 Spanish Treebank

For the validation of the performance of our generator on Spanish, we use the AnCora-UPF treebank, which contains only about 100,000 tokens, but which has been manually annotated and validated on the SSyntS- and DSyntS-layers, such that its quality is rather high. The deep annotation does not contain any functional prepositions since they have been removed for all predicates of the corpus, and the DSyntS-relations have been edited following annotation guidelines. AnCora-UPF SSyntSs are annotated with fine-grained dependencies organized in a hierarchical scheme (Mille et al., 2012), in a similar fashion as the dependencies of the Stanford Scheme (de Marneffe et al., 2006).[7] Thus, it is possible to use the full set of labels or to reduce it according to our needs. We performed preliminary experiments in order to assess which tag granularity is better suited for generation and came up with the 31-label tagset.

[5]For Spanish, we apply after the DSyntS–SSyntS transition in a postprocessing stage rules for the generation of relative pronouns that are implied by the the SSyntS. Since we cannot count on the annotation of coreference in the training data, we do not treat other types of referring expressions.

[6]The lemmas of nodes with 1:1 correspondence are the same in both structures.

[7]The main difference with the Stanford scheme is that in AnCora-UPF no distinction is explicitly made between argumental and non-argumental dependencies.

2.3.2 English Treebank

For the validation of the generator on English, we use the dependency Penn TreeBank (about 1,000,000 tokens), which we extend by a DSynt layer defined by the same deep dependency relations, features and node correspondences as the Spanish DSynt layer. The Penn TreeBank DSynt layer is obtained by a rule-based graph transducer. The transducer removes definite and indefinite determiners, auxiliaries, THAT complementizers, TO infinitive markers, and a finite list of functional prepositions. The functional prepositions have been manually compiled from the description and examples of the roles in the PropBank and NomBank annotations of the 150 most frequent predicates of the corpus. A dictionary has been built, which contains for each of the 150 predicates the argument slots (roles) and the prepositions associated to it, such that given a predicate and a preposition, we know to which role it corresponds. Consider, for illustration, Figure 2, which indicates that for the nominal predicate *plan_01*, a dependent introduced by the preposition *to* corresponds to the second argument of *plan_01*, while a dependent introduced by *for* is its third argument.

```
plan_01 : predicate_ {
 NN = {
  to = {DeepRel = II}
  for = {DeepRel = III}
 }}
```

Figure 2: A sample (partial) mapping dictionary entry

For each possible surface dependency relation between a governor and a dependent, a default mapping is provided, which is applied if

(i) The syntactic structure fulfills the conditions of the default mapping (e.g., '*subject*' is by default mapped onto '*I*' unless it is the subject of a passive verb, in which case it is mapped to the second argument '*II*'), and

(ii) The pair governor–dependent is not found in the dictionary; that is, if the dependent of the SSyntS dependency relation is a preposition found in the governor's entry in the dictionary, the information provided in the dictionary is used instead of the default mapping.[8] For instance, in the sentence *Sony announced its plans to hire Mr. Guber*, *to* is a dependent of *plan* with the SSyntS dependency *NMOD*. *NMOD* is by default mapped onto the deep relation *ATTR*, but since in the dictionary entry of *plan* it is stated that a dependent introduced by *to* is mapped to 'II' (cf. Figure 2), *II* is the relation that appears in the DSyntS-annotation.

The features *definiteness*, *voice*, *tense*, *aspect* in the *FEATS* column of the CoNLL format capture the information conveyed by determiners and auxiliaries. The conversion procedure maps surface dependency relations as found in the Penn TreeBank onto the restricted set of deep dependency relations as described in Section 2.1.1.

The nodes in the original (surface-oriented) and deep annotations are connected through their IDs. In the *FEATS* column of the output CoNLL file, *id0* indicates the deep identifier of a word, while *id1* indicates the ID of the surface node it corresponds to. There are less nodes in DSyntSs than in SSyntSs since SSyntSs contain all the words of a sentence. Hence, a DSynt-node can correspond to several SSyntS nodes. Multiple correspondences are indicated by the presence of the *id2* (*id3*, *id4*, etc) feature in the *FEATS* column.

3 Deep Generation

3.1 Baselines

Since no available data-driven generator uses as input DSyntSs, we developed as baselines two rule-based graph transducer generators which produce for English respectively Spanish the best possible SSyntSs, using only the information contained in the starting DSyntS.

The two baseline generators are structured similarly: both contain around 50 graph transducer rules, separated into two clusters. The first cluster maps DSyntS-nodes onto SSyntS-nodes, while the second one handles the introduction of SSyntS dependency relations between the generated SSyntS-nodes. For instance, in English, one rule maps DSyntS-nodes that have a one-to-one correspondence in the SSyntS

[8] In the PropBank annotation, a distinction is made between external and internal arguments, such that for some predicates the arguments are numbered starting from '0', and for other starting from '1'. This has been normalized in order to make all arguments start from '1' for all predicates.

if N_1 is a V_{fin} **and** (($R_{1,2}$ == I **and** N_1 is in active voice **and** N_2 is **not** *by*)
or ($R_{1,2}$ == II **and** N_1 is in passive voice))
  if ∃ one-to-one correspondence between N_{D_i} **and** N_{S_i}
    then introduce *SBJ* between N_{S_1} **and** N_{S_2}
  else
    if N_{S_2} is top node of the SSyntS hypernode **and**
    ((N_{S_1} is top node of the SSynt hypernode **and** is AUX)
    or (N_{S_1} is the bottom node of the SSynt hypernode **and** is V_{fin})
    or (N_{S_1} is **not** top node **or** bottom node of the SSynt-hypernode **and** is AUX))
    then introduce *SBJ* between N_{S_1} **and** N_{S_2}
    endif
endif

Figure 3: Sample graph transducer rule

(simple nouns, verbs, adverbs, adjectives, etc.), 22 rules map DSyntS-nodes that have a one-to-many correspondence in the SSyntS (N → DET+NN, N → DET+NN+governed PREP, V → AUX+VV, V → *that* COMPL+AUX+VV+governed PREP, etc.), and 25 rules generate the dependency relations.[9] The transduction rules apply in two phases, see Figure 3. During the first phase, all nodes and intra-hypernode dependencies are created in the output structure. During the second phase, all inter-hypernode dependencies are established. Since there are one-to-many DSyntS-SSyntS correspondences, the rules of the second phase have to ensure that the correct output nodes are targeted, i.e., that *jobs* in Figure 1(b) is made a dependent of *have*, and not of *been* or *created*, which all correspond to *create* in the input. Consider, for illustration of the complexity of the rule-based generator, the transduction rule in Figure 3. The rule creates the SSynt dependency relation *SBJ* (*subject*) in a target SSyntS (with a governor node N_{D_1} and a dependent node N_{D_2} linked by a deep dependency relation $R_{1,2}$ in the input DSyntS and two nodes N_{S_1} and N_{S_2} which correspond to N_{D_1} and N_{D_2} respectively in the target SSyntS).

The evaluation shows that all straightforward mappings are performed correctly; English auxiliaries, *that* complementizers, infinitive markers and determiners are introduced, and so are Spanish auxiliaries, reflexive pronouns, and determiners. That is, the rules produce well-formed SSyntSs of all possible combinations of auxiliaries, conjunctions and/or prepositions for verbs, determiners and/or prepositions for nouns, adjectives and adverbs.

When there are several possible mappings, the baseline takes decisions by default. For example, when a governed preposition must be introduced, we always introduce the most common one (*of* in English, *de* 'of' in Spanish).

3.2 Data-Driven Generator

The data-driven generator is defined as a tree transducer framework that consists of a cascade of 6 data-driven small tasks; cf. Figure 4. The first four tasks capture the actions 1.–4. from Section 2.2; the 5th linearizes the obtained SSyntS. Figure 4 provides a sample input and output of each submodule. The system outputs a 14 column CoNLL'09 linearized format without morphological inflections or punctuation marks.

In the next sections, we discuss how these actions are realized and how they are embedded into the overall generation process.

The intra- and inter-hypernode dependency determination works as an informed dependency parser that uses the DSyntS as input. The search space is thus completely pruned. Note also that for each step, the space of classes for the SVMs is based on linguistic facts extracted from the training corpus (for instance, for the preposition generation SVM, the classes are the possible prepositions; for the auxiliary generation SVM, the possible auxiliaries, etc.).

3.2.1 Hypernode Identification

Given a node n_d from the DSyntS, the system must find the shape of the surface hypernode that corresponds to n_d in the SSyntS. The hypernode identification SVMs use the following features:

> PoS of n_d, PoS of n_d's head, verbal voice (*active*, *passive*) and aspect (*perfective*, *progressive*) of the current node, lemma of n_d, and n_d's dependencies.

In order to simplify the task, we define the shape of a surface hypernode as a list of surface PoS tags. This unordered list contains the PoS of each of the lemmas contained within the hypernode and a tag that encodes the original deep node; for instance:

[9] 'N' stands for "noun", 'NN' for "common noun", 'DET' for "determiner", 'PREP' for "preposition", 'V' for "verb", 'AUX' for "auxiliary verb", 'VV' for "main verb", and 'COMPL' for "complementizer".

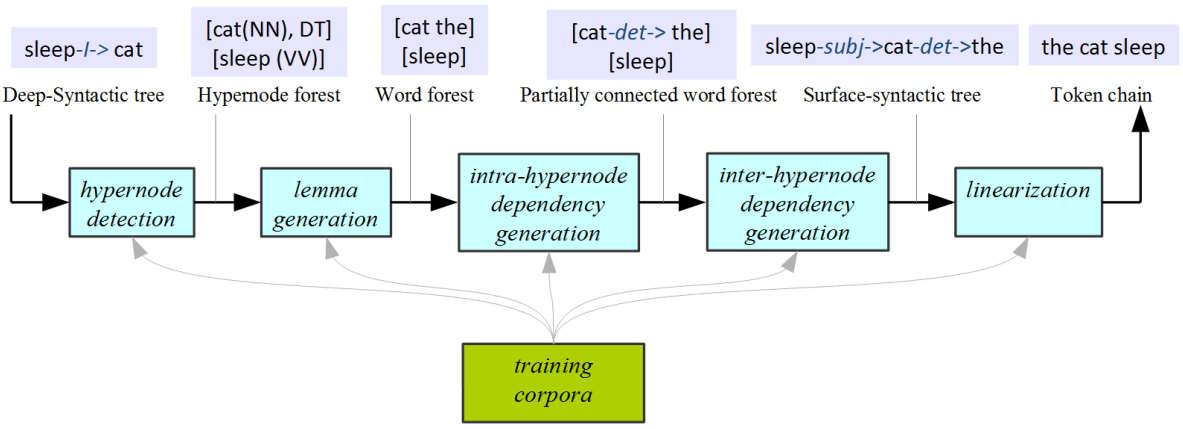


Figure 4: Workflow of the Data-Driven Generator.

[NN(deep), DT]

For each deep, i.e., DSyntS, PoS tag (which can be one of the following four: *N* (noun), *V* (verb), *Adv* (adverb), *A* (adjective)), a separate multi-class classifier is defined.[10] For instance, in the case of *N*, the N-classifier will use the above features to assign to the a DSynt-node with PoS *N* the most appropriate (most likely) hypernode—in this case, [*NN*(deep), *DT*].

3.2.2 Lemma Generation

Once the hypernodes of the SSyntS under construction have been produced, the functional nodes that have been newly introduced in the hypernodes must be assigned a lemma label. The lemma generation SVMs use the following features of the deep nodes n_d in the hypernodes to select the most likely lemma:

> verbal finiteness (*finite*, *infinitive*, *gerund*, *participle*) and aspect (*perfective*, *progressive*), degree of definiteness of nouns, PoS of n_d, lemma of n_d, PoS of the head of n_d

Again, for each surface PoS tag, a separate classifier is defined. Thus, the DT-classifier would pick for the hypernode [*NN*(deep), *DT*] the most likely lemma for the *DT*-node (optimally, a determiner).

[10] As will be seen in the discussion of the results, the strategy proposed by Ballesteros et al. (2014b) to define a separate classifier for each linguistic category here and in the other stages largely pays off because it reduces the classification search space enormously and thus leads to a higher accuracy.

3.2.3 Intra-hypernode Dependency Generation

Given a hypernode and its lemmas provided by the two previous stages, the dependencies (i.e., the dependency attachments and dependency labels) between the elements of the created SSyntS hypernodes must be determined (and thus also the governors of the hypernodes). For this task, the intra-hypernode dependency generation SVMs use the following features:

> lemmas included in the hypernode, PoS-tags of the lemmas in the hypernode, *voice* of the head h of the hypernode, deep dependency relation to h.

For each kind of hypernode, dynamically a separate classifier is generated.[11] In the case of the hypernode [*NN*(deep), *DT*], the corresponding classifier will create a link between the determiner and the noun, with the noun as head and the determiner as dependent because it is the best link that it can find; cf. Figure 5 for illustration. We ensure that the output of the classifiers is a tree by controlling that every node (except the root) has one and only one governor. The DSynt input is a tree; in the case of hypernodes of cardinality one, the governor/dependent relation is maintained; in the case of hypernodes of higher cardinality, only one node receives an incoming arc and only one can govern another hypernode.

3.2.4 Inter-hypernode Dependency Generation

Once the individual hypernodes have been converted into connected dependency subtrees, the hy-

[11] This implies that the number of classifiers varies depending on the training set. For instance, during the intra-hypernode dependency creation for Spanish, 108 SVMs are generated.

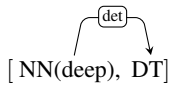

Figure 5: Internal dependency within a hypernode

pernodes must be connected between each other, such that we obtain a complete SSyntS. The inter-hypernode dependency generation SVMs use the following features of a hypernode s_s to determine for each hypernode its governor. For each hypernode with a distinct internal dependency pattern, a separate classifier is dynamically derived (for our treebanks, we obtained 114 different SVM classifiers because they also take into account hypernodes with just one token).:

> the internal dependencies of s_s, the head of s_s, the lemmas of s_s, the PoS of the dependent of the head of s_s in DSyntS

For instance, the classifier for the hypernode [*JJ*(deep)] is most likely to identify as its governor *NN* in the hypernode [*NN*(deep), *DT*]; cf. Figure 6.

The task faced by the inter-hypernode dependency classifiers is the same as that of a dependency parser, only that its search space is very small (which is favorably reflected in the accuracy figures).

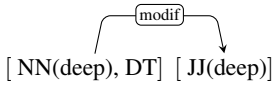

Figure 6: Surface dependencies between two hypernodes.

3.3 Linearization

Once we obtained a SSyntS, the linearizer must find the correct order of the words. There is already a body of work available on statistical linearization. Therefore, these tasks were not in the focus of our work. Rather, we adopt the most successful technique of the first SRST (Belz et al., 2011), a bottom-up tree linearizer that orders bottom-up each head and its children (Bohnet et al., 2011; Guo et al., 2011a). This has the advantage that the linear order obtained previously can provide context features for ordering sub-trees higher up in the dependency tree. Each head and its children are ordered with a beam search.

The beam is initialized with entries of single words that are expanded in the next step by the remaining words of the sub-tree, which results in a number of new entries for the next iteration. After the expansion step, the new beam entries are sorted and pruned. We keep the 30 best entries and continue with the expansion and pruning steps until no further nodes of the subtree are left. We take an SVM to obtain the scores for sorting the beam entries, using the same feature templates as in Guo et al. (2011b) and Bohnet et al. (2011).

4 Experiments and Results

In our experiments, the Spanish treebank has been divided into: (i) a development set of 219 sentences, with 3,437 tokens in the DSyntS treebank and 4,799 tokens in the SSyntS treebank (with an average of 21.91 words by sentence in SSynt); (ii) a training set of 3,036 sentences, with 57,665 tokens in the DSyntS treebank and 84,668 tokens in the SSyntS treebank (with an average of 27.89 words by sentence in SSynt); and a (iii) a held-out test for evaluation of 258 sentences, with 5,878 tokens in the DSyntS treebank and 8,731 tokens in the SSyntS treebank (with an average of 33.84 words by sentence in SSynt).

For the English treebank, we used a classical split of (i) a training set of 39,279 sentences, with 724,828 tokens in the DSynt treebank and 958,167 tokens in the SSynt treebank (with an average of 24.39 words by sentence in SSynt); and (ii) a test set of 2,399 sentences, with 43,245 tokens in the DSynt treebank and 57,676 tokens in the SSynt treebank (with an average of 24.04 words by sentence in SSynt).

In what follows, we show the system performance on both treebanks. The Spanish treebank was used for development and testing, while the English treebank was only used for testing.

4.1 Results

In this section, we present the performance of, first of all, the individual tasks of the data-driven DSyntS–SSyntS projection, since these have been the challenging tasks that we addressed. Table 1 shows similar results for all tasks on the development and test sets with gold-standard input, that is,

the results of the classifiers as a stand-alone module, assuming that the previous module provides a perfect output.

Spanish Dev.set	#	%
Hypernode identification	3327/3437	96.80
Lemma generation	724/767	94.39
Intra-hypernode dep. generation	756/756	100.00
Inter-hypernode dep. generation	2628/2931	89.66
Spanish Test set	#	%
Hyper-node identification	5640/5878	95.95
Lemma generation	1556/1640	94.88
Intra-hypernode dep. generation	1622/1622	100.00
Inter-hypernode dep. generation	4572/5029	90.91

Table 1: Results of the evaluation of the SVMs for the non-isomorphic transition for the Spanish DSyntS development and test sets

English Test set	#	%
Hyper-node identification	42103/43245	97.36
Lemma generation	6726/7199	93.43
Intra-hypernode dep. generation	6754/7179	94.08
Inter-hypernode dep. generation	35922/40699	88.26

Table 2: Results of the evaluation of the SVMs for the non-isomorphic transition for the English DSyntS test set

To have the entire generation pipeline in place, we carried out several linearization experiments, starting from: (i) the SSyntS gold standard, (ii) SSyntSs generated by the rule-based baselines, and (iii) SSyntSs generated by the data-driven deep generator; cf. *surface gen.*, *baseline deep gen*, and *deep gen.* respectively in Tables 3 and 4).[12]

Development Set	BLEU	NIST	Exact
surface gen.	0.754	11.29	24.20 %
baseline deep gen.	0.547	9.98	10.96 %
deep gen.	**0.582**	10.78	12.33 %
Test Set	BLEU	NIST	Exact
surface gen.	0.762	12.08	15.89 %
baseline deep gen.	0.515	10.60	2.33 %
deep gen.	**0.542**	11.24	3.49 %

Table 3: Overview of the results on the Spanish development and test sets excluding punctuation marks after the linearization

[12]Following (Langkilde-Geary, 2002; Belz et al., 2011) and other works on statistical text generation, we access the quality of the linearization module via BLEU score, NIST and exactly matched sentences.

Test Set	BLEU	NIST	Exact
surface gen.	0.91	15.26	56.02 %
baseline deep gen.	0.69	13.71	12.38 %
deep gen.	**0.77**	14.42	21.05 %

Table 4: Overview of the results on the English test set excluding punctuation marks after the linearization

4.2 Discussion and Error Analysis

In general, Tables 1–4 show that the quality of the presented deep data-driven generator is rather good both during the individual stages of the DSyntS–SSyntS transition and as part of the DSyntS–linearized sentence pipeline.

Two main problems impede an even better performance figures than those reflected in Tables 1 and 2. First, the introduction of prepositions causes most errors in hypernode detection and lemma generation: when a preposition should be introduced or not and which preposition should be introduced depends exclusively on the subcategorization frame of the governor of the DSyntS node. A corpus of a limited size does not capture the subcategorization frames of ALL predicates. This is especially true for our Spanish treebank, which is particularly small. Second, the inter-hypernode dependency suffers from the fact that the SSyntS tagset is quite fine-grained, at least in the case of Spanish, which makes the task of the classifiers harder (e.g., there are nine different types of verbal objects). In spite of these problems, each set of classifiers achieves results above 88% on the test sets.

The results of deep generation in Tables 3 and 4 can be explained by the fact of error propagation: while (only) about 1 out of 10 hypernodes and about 1 out of 10 lemmas are not correct and very little information is lost in the stage of the intra-hypernode dependencies determination, already almost 1.75 out of 10 inter-hypernode dependencies, and finally 1 out 10 linear orderings are incorrect for English and more than 2 out 10 for Spanish.

As already mentioned above, the size of the training corpus strongly affects the results. Thus, for English, for which the size of the training dataset has been 10 times bigger than for Spanish, the data-driven generator provides, without any tuning, more than 0.2 BLEU points more that for Spanish. A bigger corpus also covers more linguistic phenomena

(lexical features, subcategorization frames, syntactic sentential constructions, etc.)—which can be also exploited for rule-based generation.

The linearizer also suffers from a small size of the training set. Thus, while the small Spanish training corpus leads to 0.754 BLEU and 0.762 BLEU for the development and test sets respectively, for English, we achieve 0.91 BLEU, which is a very competitive outcome compared to other English linearizers (Song et al., 2014).

We also found that the data-driven generator tends to output slightly shorter sentences, when compared to the rule-based baseline. It is always difficult to find the best evaluation metric for plain text sentences (Smith et al., 2014). In our experiments, we used BLEU, NIST and the exact match metric. BLEU is the average of n-gram precisions and includes a brevity penalty, which reduces the score if the length of the output sentence is shorter than the gold. In other words, BLEU favors longer sentences. We believe that this is one of the reasons why the machine-learning based generator shows a bigger difference for the English test set and the Spanish development set than the rule-based baseline. Firstly, there are extremely long sentences in the Spanish test set (31 words per sentence, in the average; the longest being 165 words). Secondly, the English sentences and the Spanish development sentences are much shorter than the Spanish test sentences, such that the ML approach has the potential to perform better.

5 Related work

There is an increasing amount of work on statistical sentence generation, although hardly any addresses the problem of deep generation from semantic structures that are not isomorphic with syntactic- structures as a purely data-driven problem (as we do). To the best of our knowledge, the only exception is our earlier work in (Ballesteros et al., 2014b), where we discuss the principles of classifiers for data-driven generators. As already mentioned in Section 1, most of the state-of-the-art work focuses on syntactic generation; see, among others (Bangalore and Rambow, 2000; Langkilde-Geary, 2002; Filippova and Strube, 2008), or only on linearization and inflection (Filippova and Strube, 2007; He et al., 2009; Wan et al., 2009; Guo et al., 2011a). A number of proposals are hybrid in that they combine statistical machine learning-based generation with rule-based generation. Thus, some combine machine learning with pre-generated elements, as, e.g., (Marciniak and Strube, 2004; Wong and Mooney, 2007; Mairesse et al., 2010), or with handcrafted rules, as, e.g., (Ringger et al., 2004; Belz, 2005). Others derive automatically grammars for rule-based generation modules from annotated data, which can be used for surface generation, as, e.g., (Knight and Hatzivassiloglou, 1995; Langkilde and Knight, 1998; Oh and Rudnicky, 2002; Zhong and Stent, 2005; Bohnet et al., 2011; Rajkumar et al., 2011) or for generation from ontology triples, as, e.g., (Gyawali and Gardent, 2013).

6 Conclusions

We presented a statistical deep sentence generator that successfully handles the non-isomorphism between meaning representations and syntactic structures in terms of a principled machine learning approach. This generator has been successfully tested on an English and a Spanish corpus, as a stand-alone DSyntS–SSyntS generator and as a part of the generation pipeline. We are currently about to apply it to other languages—including Chinese, French and German. Furthermore, resources are compiled to use it for generation of spoken discourse in Arabic, Polish and Turkish.

We believe that our generator can be used not only in generation *per se*, but also, e.g., in machine translation (MT), since MT could profit from using meaning representations such as DSyntSs, which abstract away from the surface syntactic idiosyncrasies of each language, but are still linguistically motivated, as transfer representations.

Abstract

This work focuses on the insensitivity of existing word alignment models to domain differences, which often yields suboptimal results on large heterogeneous data. A novel latent domain word alignment model is proposed, which induces domain-conditioned lexical and alignment statistics. We propose to train the model on a heterogeneous corpus under partial supervision, using a small number of seed samples from different domains. The seed samples allow estimating sharper, domain-conditioned word alignment statistics for sentence pairs. Our experiments show that the derived domain-conditioned statistics, once combined together, produce notable improvements both in word alignment accuracy and in translation accuracy of their resulting SMT systems.

1 Introduction

Word alignment currently constitutes the basis for phrase extraction and reordering in phrase-based systems, and its statistics provide lexical parameters used for smoothing the phrase pair estimates. For over two decades since IBM models (Brown et al., 1993) and the HMM alignment model (Vogel et al., 1996), word alignment remains an active research line, e.g., see recent work (Simion et al., 2013; Tamura et al., 2014; Chang et al., 2014).

During the past years we witnessed an increasing need to collect and use large *heterogeneous* parallel corpora from different domains and sources, e.g., News, Wikipedia, Parliament Proceedings. It is tacitly assumed that assembling a larger corpus should improve a phrase-based system coverage and performance. Recent work (Sennrich et al., 2013; Carpuat et al., 2014; Cuong and Sima'an, 2014b; Kirchhoff and Bilmes, 2014; Cuong and Sima'an, 2014a) shows that this is not necessarily true as phrase translations as well as (bi- and monolingual) word co-occurrence statistics could differ across domains. This suggests that the word alignment quality obtained from IBM and HMM alignment models might also be affected in heterogeneous corpora.

Intuitively, in heterogeneous data certain words are present across many domains, whereas others are more specific to few domains. This suggests that the translation probabilities for words will be as fractioned as the diversity of its translations across the domains. Furthermore, because the IBM and HMM alignment models use *context-insensitive* conditional probabilities, in heterogeneous corpora the estimates of these probabilities will be aggregated over different domains. Both issues could lead to suboptimal word alignment quality.

Surprisingly, the *insensitivity* of the existing IBM and HMM alignment models to domain differences has not received much attention thus far (see the study of Bach et al. (2008) and Gao et al. (2011) for reference in the literature). We conjecture that this is because it is not fully clear how to define what constitutes a *(sub)-domain*. In this paper we propose to exploit the contrast between the alignment statistics in a handful of *seed samples from different domains* in order to induce domain-conditioned probabilities for each sentence pair in the heterogeneous corpus. Crucially, some sentence pairs will be more similar to a seed domain than others, whereas some sentence

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 398–408,
Denver, Colorado, May 31 – June 5, 2015.

pairs might be dissimilar to all seed domains. The number and choice of seed domains depends largely on the available resources but intuitively these seed domains are chosen to be relevant to parts of the heterogeneous corpus. A small number of such seeds can be expected to notably improve word alignment accuracy. In fact, a single seed sample already allows us to exploit the contrast between two parts in the corpus: similar or dissimilar to the seed data.

Considering the small seed samples as *partial supervision*, in this paper we explore the question: *how to obtain better word alignment in a heterogeneous, mix-of-domains corpus?* We present a novel *latent domain HMM alignment model*, which aims to *tighten* the probability estimates of the generative alignment process of a sentence pair, and of the probability estimates of the sentence pair itself for a specific domain. We also present an accompanying training regime *guided* by partial supervision using the seed samples, exploiting the contrast between the domain-conditioned alignment statistics in these samples. This way we aim for an alignment model that is more domain-sensitive than the original HMM alignment model. Once the domain-conditioned statistics are induced, we discuss how to combine them together to express the probability of a sentence pair as a mixture over specific domains.

Finally, we report experimental results over heterogeneous corpora of 1M, 2M and $4M$ sentence pairs, where we are provided domain information for different samples of 10%, 5% and 2.5% of the heterogeneous data respectively. A large number of experiments are reported, showing that the latent domain HMM model produces notable improvements in word alignment accuracy over the original HMM alignment model. Furthermore, the translation accuracy of the resulting SMT systems is significantly improved across *four* different translation tasks.

2 HMM Alignment Model

In this section, we briefly review the HMM alignment model (Vogel et al., 1996). The generative story of the model is shown in Figure 1. The latent states take values from the target language words and generate source language words.

Formally, we use $\mathbf{e} = (e_1, \ldots, e_I)$ to denote the target sentence with length I and $\mathbf{f} = (f_1, \ldots, f_J)$ to denote the source sentence with length J. For an alignment $\mathbf{a} = (a_1, \ldots, a_J)$ of a sentence pair $\langle \mathbf{e}, \mathbf{f} \rangle$, the model factors $P(\mathbf{f}, \mathbf{a}|\ \mathbf{e})$ into the word translation and transition probabilities:

$$P(\mathbf{f}, \mathbf{a}|\ \mathbf{e}) = \prod_{j=1}^{J} P(f_j|\ e_{a_j}) P(a_j|\ a_{j-1}). \quad (1)$$

Here, $P(f_j|\ e_{a_j})$ represents the word translation probabilities and $P(a_j|\ a_{j-1})$[1] represents the transition probabilities between positions. Note that $P(a_j|\ a_{j-1})$ depends only on the distance $(a_j - a_{j-1})$. Note also that the first-order dependency model is an extension of the uniform dependency model and zero-order dependency model of IBM models 1 and 2, respectively.

In this work, we model explicitly distances in the range ± 5. Note that *null*-links are also explicitly added in our implementation, following Och and Ney (2003) and Graca et al. (2010).

Once the HMM alignment model is trained, the most probable alignment, $\hat{\mathbf{a}}$ for each sentence pair can be computed by: $\hat{\mathbf{a}} = \text{argmax}_{\mathbf{a}} P(\mathbf{f}, \mathbf{a}|\ \mathbf{e})$. Here, the search problem can be solved by the Viterbi algorithm.

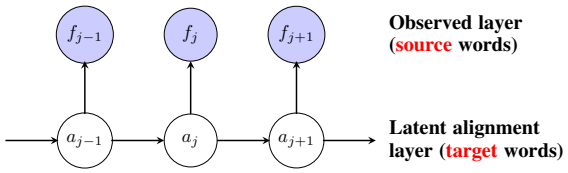

Figure 1: HMM alignment model with observed and latent alignment layers.

3 Latent Domain HMM Alignment Model

Because the heterogeneous data contains a mix of diverse domains, the induced statistics derived from word alignment models reflect translation preferences aggregated over these domains. In this sense, they can be considered domain-*confused* statistics (Cuong and Sima'an, 2014a). This work thus focuses on more **representative** statistics: the domain-*conditioned* word alignment statistics, i.e., the statistics with respect to each of the diverse domains.

By introducing a latent variable D representing domains of the heterogeneous data, we aim

[1] The "full" formula for transition probabilities would be $P(a_j|\ a_{j-1}, I)$. For convenience, we ignore I in our presentation.

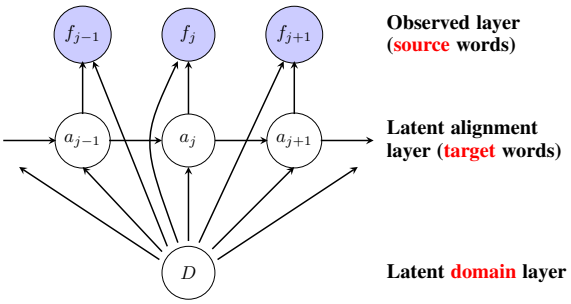

Figure 2: Latent domain HMM alignment model. An additional latent layer representing domains has been conditioned on by both the rest two layers.

to learn the D-conditioned word alignment model $P(\mathbf{f},\ \mathbf{a}|\ \mathbf{e},\ D)$.[2] Relying on the HMM alignment model, our latent domain HMM alignment model factors $P(\mathbf{f},\ \mathbf{a}|\ \mathbf{e},\ D)$ into the domain-conditioned word translation and transition probabilities:

$$P(\mathbf{f}, \mathbf{a}|\mathbf{e}, D) = \prod_{j=1}^{J} P(f_j|e_{a_j}, D)P(a_j|a_{j-1}, D). \tag{2}$$

The generative story of the model is shown in Figure 2. Note how domain-conditioned alignment statistics, $P(\cdot|\ \cdot, D)$ contain their former domain-confused alignment statistics, $P(\cdot|\ \cdot)$ as special case

$$P(f_j|e_{a_j}, D) = \frac{P(f_j|e_{a_j})P(D|f_j, e_{a_j})}{\sum_f P(f_j|e_{a_j})P(D|f_j, e_{a_j})}, \tag{3}$$

$$P(a_j|a_{j-1}, D) = \frac{P(a_j|a_{j-1})P(D|a_j, a_{j-1})}{\sum_{a_j} P(a_j|a_{j-1})P(D|a_j, a_{j-1})}. \tag{4}$$

With an additional latent domain layer, it becomes crucial to train the model in an efficient way. As suggested by Eq. 3 and 4, we could simplify training by breaking up the estimation process into two steps. That is, we train alignment parameters, $P(\cdot|\ \cdot)$ or domain parameters, $P(D|\ \cdot,\ \cdot)$ first, hold them fixed before training the other kind of the parameters.[3] Instead, in this work we design an algorithm that trains both of them simultaneously via training domain-conditioned parameters $P(\cdot|\ ,\cdot,\ D)$ directly.

[2]Note that $P(\mathbf{f},\ \mathbf{a}|\ \mathbf{e},\ D)$ contains their former $P(\mathbf{f},\ \mathbf{a}|\ \mathbf{e})$ as special case, i.e., $P(\mathbf{f},\ \mathbf{a}|\ \mathbf{e},\ D) = \frac{P(\mathbf{f},\ \mathbf{a}|\ \mathbf{e})P(D|\ \mathbf{f},\ \mathbf{a},\ \mathbf{e})}{\sum_{\mathbf{f}}\sum_{\mathbf{a}} P(\mathbf{f},\ \mathbf{a}|\ \mathbf{e})P(D|\ \mathbf{f},\ \mathbf{a},\ \mathbf{e})}$.

[3]This training scheme is in fact applied in the work of Cuong and Sima'an (2014a), however, for a different purpose.

3.1 Training

Basically, our model can be viewed as having a set, Θ of N subsets of domain-conditioned parameters, Θ_D for N different domains, i.e., $\Theta = \{\Theta_{D_1},\ \ldots,\ \Theta_{D_N}\}$. In this work, to simplify the learning problem we assume that the domains are very *different* from each other. If this assumption does not hold, the learning problem would shift from *single-label* learning to *multiple-label* learning. We leave this extension for future work.

Our training procedure seeks the parameters Θ that maximize the log-likelihood, $\mathcal{L}$ of the data: $\mathcal{L} = \sum_{\langle \mathbf{f},\ \mathbf{e}\rangle} \log \sum_D \sum_{\mathbf{a}} P_{\Theta_D}(\mathbf{f},\ \mathbf{e},\ D,\ \mathbf{a})$. There, however, does not exist a closed-form solution for maximizing $\mathcal{L}$, and EM comes as an alternative solution to fit the model. EM maximizes $\mathcal{L}$ via block-coordinate ascent on a "free energy" lower bound $\mathcal{F}(q,\ \Theta)$ (Neal and Hinton, 1999), using an auxiliary distribution q over both the latent variables: $\mathcal{F}(q,\ \Theta) = \sum_{\langle \mathbf{f},\ \mathbf{e}\rangle} \sum_D \sum_{\mathbf{a}} q \log \frac{P_{\Theta_D}(\mathbf{a},\ D,\ \mathbf{f},\ \mathbf{e})}{q}$.

In the **E**-step of the EM algorithm, we fix Θ and aim to find the distribution q^* that maximizes $\mathcal{F}(q, \Theta)$ over the heterogeneous data. Simple mathematics lead to $\mathcal{F}(q,\ \Theta) = \sum_{\langle \mathbf{f},\ \mathbf{e}\rangle} \log P_\Theta(\mathbf{f},\ \mathbf{e}) - KL[q\ ||\ P_{\Theta_D}(\mathbf{a},\ D|\ \mathbf{f},\ \mathbf{e})]$, where $KL[\cdot\ ||\ \cdot]$ is the Kullback-Leiber divergence between two distributions. The distribution q^* can be thus derived as

$$\begin{aligned} q^* &= \text{argmax}_q\, \mathcal{F}(q,\ \Theta) \\ &= \text{argmin}_q\, KL[q\ ||\ P_{\Theta_D}(\mathbf{a},\ D|\ \mathbf{f},\ \mathbf{e})] \\ &= \frac{P_{\Theta_D}(\mathbf{f},\ \mathbf{a}|\ \mathbf{e},\ D)}{\sum_{\mathbf{a}} P_{\Theta_D}(\mathbf{f},\ \mathbf{a}|\ \mathbf{e},\ D)} P_{\Theta_D}(D|\ \mathbf{f},\ \mathbf{e}). \end{aligned}$$

Here, $P_{\Theta_D}(D|\ \mathbf{f},\ \mathbf{e})$ aims to exploit the contrast between the domain-sensitive alignment statistics. Assigning higher probability to one domain forces lower probability assignment to other domains.

Note that $P_{\Theta_D}(\mathbf{f},\ \mathbf{a}|\ \mathbf{e},\ D)$ is given in Eq. 2 and $\sum_{\mathbf{a}} P_{\Theta_D}(\mathbf{f},\ \mathbf{a}|\ \mathbf{e},\ D)$ can be computed efficiently using dynamic programming.[4] Meanwhile, $P_{\Theta_D}(D|\ \mathbf{f},\ \mathbf{e})$ can be derived by Bayes' rule, i.e.,

$$P_{\Theta_D}(D|\ \mathbf{f},\ \mathbf{e}) \propto P_{\Theta_D}(\mathbf{f},\ \mathbf{e}|\ D) P_{\Theta_D}(D).$$

Here, the estimation of the domain prior parameters is easy, $P_{\Theta_D}(D) \propto \sum_{\langle \mathbf{f},\ \mathbf{e}\rangle} P_{\Theta_D}(D|\ \mathbf{f},\ \mathbf{e})$. The estimation of $P_{\Theta_D}(\mathbf{f},\ \mathbf{e}|\ D)$ raises a task of defining a

[4]Its time complexity is $\mathcal{O}(J \times I^2)$ for each sentence pair $\langle \mathbf{f},\ \mathbf{e}\rangle$ with their length J and I respectively.

E-step $\forall D \in \{D_1, \ldots, D_N\}$ do

$$c(D;\, \mathbf{f},\, \mathbf{e}) = P^{(c)}(D|\, \mathbf{f},\, \mathbf{e})$$

$$c(f|\, e;\, \mathbf{f},\, \mathbf{e},\, D) = P^{(c)}(D|\, \mathbf{f},\, \mathbf{e}) \sum\nolimits_{\mathbf{a}} P^{(c)}(\mathbf{a}|\, \mathbf{f},\, \mathbf{e},\, D) \sum\nolimits_{j=1}^{J} \delta(f, f_j) \sum\nolimits_{i=0}^{I} \delta(e,\, e_i)$$

$$c(i|\, i';\, \mathbf{f},\, \mathbf{e},\, D) = P^{(c)}(D|\, \mathbf{f},\, \mathbf{e}) \sum\nolimits_{\mathbf{a}} P^{(c)}(\mathbf{a}|\, \mathbf{f},\, \mathbf{e},\, D) \sum\nolimits_{j=1}^{J} \delta(a_j,\, i) \delta(a_{j-1},\, i')$$

M-step $\forall D \in \{D_1, \ldots, D_N\}$ do

$$P^{(+)}(f|e, D) = \frac{\sum_{\langle \mathbf{f},\mathbf{e} \rangle} c(f|e; \mathbf{f}, \mathbf{e}, D)}{\sum_f \sum_{\langle \mathbf{f},\mathbf{e} \rangle} c(f|e; \mathbf{f}, \mathbf{e}, D)} \; P^{(+)}(i|i', D) = \frac{\sum_{\langle \mathbf{f},\mathbf{e} \rangle} c(i|i'; \mathbf{f}, \mathbf{e}, D)}{\sum_i \sum_{\langle \mathbf{f},\mathbf{e} \rangle} c(i|i'; \mathbf{f}, \mathbf{e}, D)} \; P^{(+)}(D) \; = \frac{\sum_{\langle \mathbf{f},\mathbf{e} \rangle} c(D; \mathbf{f}, \mathbf{e})}{\sum_D \sum_{\langle \mathbf{f},\mathbf{e} \rangle} c(D; \mathbf{f}, \mathbf{e})}$$

Figure 3: Pseudocode for the training algorithm for the latent domain HMM alignment model. Note that notation $P^{(c)}$ denotes current iteration estimates, and $P^{(+)}$ denotes the re-estimates.

generative process for every sentence pair in the heterogeneous data with respect to a specific domain. Following (Cuong and Sima'an, 2014b), we factor it into two kinds of models in a symmetrized strategy: $P_{\Theta_D}(\mathbf{f},\, \mathbf{e}|\, D) \propto \big(P_{\Theta_D}(\mathbf{e}|\, D) P_{\Theta_D}(\mathbf{f}|\, \mathbf{e},\, D) + P_{\Theta_D}(\mathbf{f}|\, D) P_{\Theta_D}(\mathbf{e}|\, \mathbf{f},\, D)\big)$.

Basically, $P_{\Theta_D}(\cdot|\, \cdot,\, D)$ can be thought of as the domain-conditioned translation models, aiming to model how well a target/source sentence is generated over a source/target sentence with respect to a domain.[5] Meanwhile, $P_{\Theta_D}(\cdot|\, D)$ can be thought of as the domain-conditioned language models (LMs), aiming to model how fluent a source/target sentence with respect to a domain. For simplicity, once the domain-conditioned LMs are trained, they will stay *fixed* during training, i.e., LM probabilities are not parameters in our model.

In the **M**-step of the EM algorithm, we fix the derived q^* and aim to find the parameter set Θ^* that maximizes $\mathcal{F}(q, \Theta)$ over the data. This can be (easily) done by using q^* to softly fill in the values of $\mathbf{a}$ and D to estimate model parameters.

Pseudocode

In summary, the model has three kinds of parameters - word translation, word transition, and domain prior parameters. We now summarize the training via presenting the pseudocode.

First, we present expected count notations with respect to domains for the parameters. We use $c(f|\, e;\, \mathbf{f},\, \mathbf{e},\, D)$ to denote the expected counts that word e aligns to word f. We use $c(i|\, i';\, \mathbf{f},\, \mathbf{e},\, D)$ to denote the expected counts that two certain consecutive source words j and $j-1$ align to two target words i and i' respectively, i.e., j aligns to i and $j-1$ aligns to i'. Finally, we also use $c(D;\, \mathbf{f},\, \mathbf{e})$ to denote the expected count of domain priors. Note that all the expected counts are in the translation $(\mathbf{f}|\, \mathbf{e})$.

Figure 3 represents the pseudocode.

4 Learning with Partial Supervision

We now discuss remaining issues on how to guide the learning with partial supervision, i.e., how to use the given domain information of seed samples to guide the learning.

Number of Domains The values of $D \in [1..(N+1)]$ depends on the N available seed samples plus the so-called "out-domain," i.e., the part of the heterogeneous data that is dissimilar to all of the N sample domains.

Parameter Initialization We first discuss how to initialize the domain prior parameters. If a sentence pair $\langle \mathbf{f},\, \mathbf{e} \rangle$ belongs to a sample with a pre-specified domain D_i, we initialize $P(D_i|\, \mathbf{f},\, \mathbf{e})$ close to 1, and, $P(D_{i'}|\, \mathbf{f},\, \mathbf{e})$ close to 0 for other domains i', $i' \neq i$. Furthermore, we uniformly create the domain prior parameters for the rest of sentence pairs.

Uniform initialization for the domain-conditioned alignment parameters is also a reasonable option. Nevertheless, a more effective way is to make use of the domain-specific seed samples and the pool of the rest sentence pairs in the heterogeneous data.[6] That is, we train the model on each of the samples, assign-

[5] Note that $P_{\Theta_D}(\cdot|\, \cdot,\, D) = \sum_{\mathbf{a}} P_{\Theta_D}(\cdot,\, \mathbf{a}|\, \cdot,\, D)$ and it can be thus computed efficiently using dynamic programming.

[6] During the initialization, we assume that the pool of the rest sentence pairs in the heterogeneous data is the exemplifying sample of the out-domain.

ing the derived probabilities as the initialization for their corresponding domain-conditioned alignment parameters. In our implementation, one EM iteration is usually dedicated for this. It should be noted that we ignore the domain prior parameters in the model during the period.

Parameter Constraints During training, it would be also necessary to keep the domain prior parameters fixed for all sentence pairs that belong to seed samples. This can be thought of as the constraints derived from the partial knowledge, guiding the learning to a desirable parameter space.

Domain-conditioned LMs training We now discuss how to train the domain-conditioned LMs with partial supervision. It would be reasonable to use the domain-specific seed samples to train their exemplifying domain-conditioned LMs, and the pool of the rest sentence pairs to train the out-domain LMs. Nevertheless, the out-domain LMs trained on such a big corpus could dominate the other domain-conditioned LMs. Following Cuong and Sima'an (2014b), we rather create a "pseudo" out-domain sample to train the out-domain LMs, i.e., the creation is via an inspired burn-in period. In brief, an EM iteration is dedicated just to compute $P(D_{OUT}|\ \mathbf{f},\ \mathbf{e})$ for all sentences, ranking them and select a small subset with highest score as the (on the fly) pseudo out-domain sample.

Note that our partial learning framework is very simple. There are various advanced learning framework that are also applicable with the partial supervision, e.g., Posterior Regularization (Ganchev et al., 2010). This leaves much space for future work.

5 Domain-conditioned Decoding

At test time, assigning each sentence pair to a single most likely domain (hard decision) is likely to result in sub-optimal performance.[7] Instead we average over domains (soft decision) while predicting the translation. Formally for each sentence pair, $\langle \mathbf{e},\ \mathbf{f} \rangle$, we can find their best Viterbi alignment, $\hat{\mathbf{a}}$ as follows:

$$\begin{aligned}\hat{\mathbf{a}} &= \text{argmax}_{\mathbf{a}} \sum\nolimits_D P(\mathbf{f}, \mathbf{a}, D|\mathbf{e}) \\ &= \text{argmax}_{\mathbf{a}} \sum\nolimits_D P(\mathbf{f}, \mathbf{a}|\mathbf{e}, D) P(D|\mathbf{e}) \\ &= \text{argmax}_{\mathbf{a}} \sum\nolimits_D P(\mathbf{f}, \mathbf{a}|\mathbf{e}, D) P(\mathbf{e}|D) P(D).\end{aligned}$$

Here, we derive the last equation by applying Bayes' rule to $P(D|\ \mathbf{e})$, i.e., $P(D|\ \mathbf{e}) \propto P(\mathbf{e}|\ D)P(D)$. Interestingly, our Viterbi decoding now relies on a mix of domain-conditioned statistics for each sentence pair. The computing of term $\sum_D(\mathbf{a})$ for all possible alignments, $\mathbf{a}$, however, is intractable, making the search problem difficult. Inspired by Liang et al. (2006), we opt instead for a heuristic objective function as follows[8]:

$$\hat{\mathbf{a}} = \underset{\mathbf{a}}{\text{argmax}} \prod\nolimits_D P(\mathbf{f},\ \mathbf{a}|\ \mathbf{e}, D)^{P(\mathbf{e}|\ D)P(D)}. \quad (5)$$

Here, note that $\prod p$ is a lower bound for $\sum p$, when $0 \leq p \leq 1$, according to Jensen's inequality. With Eq. 5, it is straightforward to design a dynamic programming algorithm to decoding, e.g., the Viterbi algorithm. In practice, we observe that the approximation yields good results. Later experiments on word alignment will present this in detail.

6 Experimental Setup

In the following experiments, we use three heterogeneous English-Spanish corpora consisting of $1M$, $2M$ and $4M$ sentence pairs respectively. These corpora combine two parts. The first part respectively $0.7M$, $1.7M$ and $3.7M$ is collected from multiple domains and resources including EuroParl (Koehn, 2005), Common Crawl, United Nation, News Commentary. The second part consists of three domain-exemplifying samples consisting of roughly $100K$ sentence pairs for each one (total $300K$). Each of these three samples (manually collected by a commercial partner) exemplifies a specific domain related to **Legal**, **Hardware** and **Pharmacy**.

Outlook In Section 7 we examine the word alignment yielded by the HMM alignment model and our latent domain HMM alignment model. In Section 8 we proceed further to examine the translation produced by derived SMT systems.

[7] Later experiments on word alignment will confirm this.

[8] Alternative solutions could be Lagrangian relaxation-based decoder (DeNero and Macherey, 2011; Chang et al., 2014).

Table 1: Alignment accuracy over heterogeneous corpora.

7 Word Alignment Experiment

For alignment accuracy evaluation, we use a data set of 100 sentence pairs with their "golden" alignment from Graca et al. (2008). Here, the golden alignment consists of *sure* links (S) and *possible* links (P) for each sentence pair. Counting the set of generating *alignment* links (A), we report the word alignment accuracy by *precision* ($\frac{|A \cap P|}{|P|}$), *recall* ($\frac{|A \cap S|}{|S|}$), *alignment error rate* (AER) ($1 - \frac{|A \cap P| + |A \cap S|}{|A| + |S|}$) (Och and Ney, 2003).[9]

For all experiments, we use the same training configuration for both the baseline/the latent domain alignment model: 5 iterations for IBM model 1/the latent domain model; 3 iterations for HMM alignment model/the latent domain model. For evaluation, we first align the sentence pairs in both directions and then symmetrize them using the *grow-diag-final* heuristic (Koehn et al., 2003).

For reference we also report the performance of a considerably more expressive Model 4, capable of capturing more structure, but at the expense of intractable inference. Using MGIZA++ (Gao and Vogel, 2008), we run 5 iterations for training Model 1, 3 iterations for training the HMM alignment model, Model 3 and Model 4.

7.1 Learning with Single Domain

We first examine the binary case, where we are given domain information in advance for each kind of samples **only**, e.g., Legal, or Pharmacy, or Hardware. For the different sizes of the heterogeneous data ($1M$, $2M$ and $4M$) the seed sample size is thus 10%, 5% and 2.5% respectively. Note that in such cases, training the latent domain alignment model induces two domain-conditioned statistics: in-domain vs. out-domain (D_1 and D_2 respectively). Once the model is trained, we combine the induced domain-conditioned statistics together (Eq. 5) and examine the produced word alignment output.

Table 1 presents the results. Most importantly, it shows that as long as providing domain information for reasonably large enough data, learning the latent domain alignment model notably improves the word alignment accuracy. For instance, given in advance the domain information for a sample of 10%, and 5% of the heterogeneous corpora, our model consistently improves the word alignment accuracy in

[9] Note that better results correspond to larger Precision, Recall and to smaller AER.

all cases. Meanwhile, given in advance the domain information for a relatively small sample of 2.5% of the heterogeneous data, the results are mixed. We obtain a good performance/slightly better performance/worse performance with the case of Hardware/Legal/Pharmacy respectively.

What do domain-conditioned statistics look like?

To have an idea what the induced statistics look like, we investigate their **conditional entropy**. Here, we present the conditional entropy for the domain-confused/-conditioned word translation statistics induced from the HMM alignment model/its latent domain model. Note that similar results are observed for transition tables.

Model	Prior	Statistics	H(F| E)
Baseline	-	Domain-confused	**1348.53**
Latent	Hardware	D_1-conditioned	**1124.43**
		D_2-conditioned	**1354.58**
	Legal	D_1-conditioned	**1104.58**
		D_2-conditioned	**1385.35**
	Pharmacy	D_1-conditioned	**1115.52**
		D_2-conditioned	**1342.54**

Table 2: Conditional entropy of the statistics.

Formally, for a translation table, $\langle F,\ E\rangle$, its conditional entropy, $H(F|\ E)$ can be estimated from its possible word pairs, $\langle e,\ f\rangle$: $H(F|\ E) = -\sum_e P(e) \sum_f P(f|\ e) \log P(f|\ e)$. Table 2 reveals that the induced D_1-conditioned statistics need much less *bits* to represent than the induced domain-confused statistics, e.g., 1124.43, 1104.58, 1115.52 vs. 1348.53. This implies the induced D_1-conditioned statistics are much more **predictable** compared to the domain-confused statistics. Meanwhile, the induced D_2-conditioned statistics are similar to the domain-confused statistics in terms of the conditional entropy, e.g., 1354.58, 1385.35, 1342.54 vs. 1348.53.

7.2 Learning with Multiple Domains

It would be more interesting to learn the latent domain alignment model for multiple domains, rather than learning with each of them separately. In detail, using **all** the seed samples from different domains, we aim to learn four different domain-conditioned statistics simultaneously. Under this setting, we obtain good results, as described in Table 1. For the two cases with the training corpora of 2M and 4M sentence pairs respectively, learning with the combining domain prior knowledge produces the best word alignment accuracy compared to the rest. In the last case with the training corpus of 1M sentence pairs, learning with the combining domain prior knowledge produces compatible with the case of Hardware, i.e., the best binary domain case.

Table 1 also reveals that the performance of our model approaches Model 4, even though Model 4 is much more complex and computationally expensive.

Domain-conditioned statistics combination

We also investigate the relation between the number of domain-conditioned statistics "involved" in the Viterbi decoding (Eq. 5) and the word alignment accuracy. Table 3 presents the results in case of using only the induced D_1-/, D_2-/, D_3-/, D_4-conditioned statistics separately, and also using their different combinations. Interestingly, we observe that using more domain-conditioned statistics for decoding incrementally improves the word alignment accuracy over the heterogeneous data. While the domain-conditioned statistics are very different in their characteristics from each other, the results reveal how they are *complementary* to the others, conveying a mix of domains for each sentence pair.

Decoding's Statistics	Prec.↑	Rec.↑	AER↓
Hard Decision (ref.)	68.49	62.80	34.48
D_1 (Pharmacy)	64.78	59.86	37.78
D_2 (Legal)	66.54	61.15	36.27
D_3 (Hardware)	66.98	61.36	35.95
D_4 (OUT)	68.46	63.01	34.38
D_1 + D_2	66.80	61.72	35.84
D_1 + D_2 + D_3	68.54	62.80	34.46
D_1 + D_2 + D_3 + D_4	**69.64**	**63.30**	**33.68**

Table 3: Domain-conditioned statistics combination for Viterbi decoding. The reported results are for the heterogeneous corpus of 1M sentence pairs. Similar results are observed for other training data.

Finally, it is also tempting to make a comparison between the *hard* vs. *soft* domain assignment in Viterbi decoding. Here, for hard domain decision we simply do decoding with the following objec-

tive function: $\hat{\mathbf{a}} = \text{argmax}_{\mathbf{a}} P(\mathbf{f},\ \mathbf{a}|\ \mathbf{e}, \hat{D})$, where $\hat{D} = \text{argmax}_D P(D|\ \mathbf{e})$. Table 3 presents the results. It reveals that a soft domain assignment on the domain of sentence pairs results in a better alignment accuracy than a hard domain assignment.[10]

8 Translation Experiment

In this section, we investigate the contribution of our model in terms of the translation accuracy. Here, we run experiments on the heterogeneous corpora of 1M, 2M, and 4M sentence pairs, testing the translation accuracy over four different domain-specific test sets related to News, Pharmacy, Legal, and Hardware.

We use a standard state-of-the-art phrase-based system as the baseline. Our dense features include MOSES (Koehn et al., 2007) baseline features, plus hierarchical lexicalized reordering model features (Galley and Manning, 2008), and the word-level feature derived from IBM model 1 score, c.f., (Och et al., 2004).[11] The interpolated 5-grams LMs with Kneser-Ney are trained on a very large monolingual corpus of 2B words. We tune the systems using k-best batch MIRA (Cherry and Foster, 2012). Finally, we use MOSES (Koehn et al., 2007) as decoder.

Our system has exactly the same setting with the baseline, except: (1) To learn the translation, we use the alignment result derived from our latent domain HMM alignment model, rather than the HMM alignment model; and (2) We replace the word-level feature with our four domain-conditioned word-level features derived from the latent domain IBM model 1. Here, note that our latent model is learned with the supervision from the combining domain knowledge of all three domain-specific seed samples.

[10]Note that similar results are also observed for training, in which a soft domain assignment using soft EM produces better alignment accuracy than a hard domain assignment using hard EM. (See (Gao et al., 2011) for reference to hard domain assignment to training data.) This is perhaps due to the characteristics of the data we use. For instance, News sentence pairs are useful for translating Legal, Financial or EuroParl to varying degrees.

[11]For every phrase pair $\langle \tilde{f},\ \tilde{e} \rangle$ with their length of $m_{\tilde{f}}$ and $l_{\tilde{e}}$ respectively, the lexical feature estimates a probability in Model 1 style between their word pairs $\langle f_j,\ e_i \rangle$ (i.e. $P(\tilde{f}|\ \tilde{e}) = \frac{\epsilon}{l_{\tilde{e}}} \prod_{j=1}^{m_{\tilde{f}}} \sum_{i=1}^{l_{\tilde{e}}} P(f_j|e_i)$). Note that adding word-level features from both translation sides does not help much, as observed by (Och et al., 2004). We thus add only an one from a translation side.

Table 4: Metric scores for the systems, which are averages over multiple runs. Bold results indicate that the comparison is significant over the baseline.

For the News translation task, we tune systems on the News-test 2008 of $2,051$ sentence pairs and test them on the News-test 2013 of $3,000$ sentence pairs from the WMT 2013 shared task (Bojar et al., 2013). For the Pharmacy, Legal, and Hardware translation tasks, we tune systems on three domain-specific dev sets of $1,000$ sentence pairs and test them on three domain-specific test sets of $1,016$, $1,326$ and $1,721$ sentence pairs. We report three metrics - BLEU (Papineni et al., 2002), METEOR (Denkowski and Lavie, 2011) and TER (Snover et al., 2006), with statistical significance at 95% confidence interval

under paired bootstrap re-sampling.[12] For every system reported, we run the optimizer three times, before running MultEval (Clark et al., 2011) for resampling and significance testing.

Data	BLEU↑	METEOR↑	TER↓
1M	**+1.0**	**+0.4**	**-0.9**
2M	**+1.4**	**+0.6**	**-1.3**
4M	**+0.7**	**+0.3**	**-0.5**

Table 5: Averaged improvements across the tasks.

Results are in Table 4, showing significant improvements across four different test sets over different heterogeneous corpora sizes. Table 5 gives a summary of the improvements. On average, over heterogeneous corpora of 1M, 2M and 4M sentence pairs, our system outperforms the baseline by 1.0 BLEU, 1.4 BLEU and 0.7 BLEU, respectively. Finally, we observe that our system produces comparably good performance to the MGIZA++-based system. When 1M data is considered, on *three* of *four* tasks, our system produces at least compatible translation accuracy to the corresponding MGIZA++-based system.

Further analysis reveals that the improvement is due to not only the reduction in alignment error rate, but also the use of the domain-sensitive lexical features. Moreover, the domain-sensitive lexical features is particularly useful when the domain of the test data matches with the domain of seed samplers. This is also widely observed in the literature, e.g., see (Eidelman et al., 2012; Hasler et al., 2014; Hu et al., 2014).

9 Related Work and Conclusion

In terms of domain-conditioned statistics for word alignment, a distantly related research line (Tam et al., 2007; Zhao and Xing, 2008) focuses on using document topics to improve the word alignment. In terms of learning word alignment with partial supervision, another distantly related research line focuses on semi-supervised training with partial manual alignments (Fraser and Marcu, 2006; Gao and Vogel, 2010; Gao et al., 2010). Finally, recent work also focuses on data selection (Kirchhoff and Bilmes, 2014; Cuong and Sima'an, 2014b), mixture models (Carpuat et al., 2014), instance weighting (Foster et al., 2010) and latent variable models (Cuong and Sima'an, 2014a) over heterogeneous corpora.

One main contribution of this work is the novelty of exploring the quality of word alignment in heterogeneous corpora. This, surprisingly, has not received much attention thus far (see the study of Bach et al. (2008) and Gao et al. (2011) for reference in the literature). Another major contribution of this work is a learning framework for latent domain word alignment with partial supervision using seed domains. We present its benefits for improving not only the word alignment accuracy, but also the translation accuracy resulting SMT systems produce. We hope this study sparks a new research direction for using domain samples, which is cheap to gather, but has not been exploited before.

One obvious direction for future work might be to integrate the model into fertility-based alignment models (Brown et al., 1993), as well as other recently advanced alignment frameworks, e.g., (Simion et al., 2013; Tamura et al., 2014; Chang et al., 2014). Another interesting direction might be to integrate our model into advanced mixing multiple translation models, improving SMT systems trained on the heterogeneous data (Razmara et al., 2012; Sennrich et al., 2013; Carpuat et al., 2014). Finally, an open question is whether it is possible to learn the latent domain alignment model in a fully unsupervised style. This challenge deserves more attention in future work.

Abstract

People vary widely in their temporal orientation—how often they emphasize the past, present, and future—and this affects their finances, health, and happiness. Traditionally, temporal orientation has been assessed by self-report questionnaires. In this paper, we develop a novel behavior-based assessment using human language on Facebook. We first create a past, present, and future message classifier, engineering features and evaluating a variety of classification techniques. Our message classifier achieves an accuracy of 71.8%, compared with 52.8% from the most frequent class and 58.6% from a model based entirely on time expression features. We quantify a users' overall temporal orientation based on their distribution of messages and validate it against known human correlates: conscientiousness, age, and gender. We then explore social scientific questions, finding novel associations with the factors openness to experience, satisfaction with life, depression, IQ, and one's number of friends. Further, demonstrating how one can track orientation over time, we find differences in future orientation around birthdays.

1 Introduction

How much one emphasizes the past, present, or future is predictive of many human factors such as occupational and educational success, engagement in risky behavior, financial stability, depression, and health (Boyd and Zimbardo, 2005; Zimbardo and Boyd, 1999). However, studies on the human experience of time are filled with diverse measurement methods (Strathman and Joireman, 2005), mostly involving questionnaires which are expensive to administer multiple times or at scale and can be subject to confounds when compared to other questionnaire based assessments.

Text mining and language processing techniques can provide a more objective and scalable measurement of *temporal orientation*, one's tendency to emphasize the past, present, or future. Whereas most prior computational linguistics and text mining temporal studies have focused on events, there has been a lack of work looking at the temporal orientation of people. Such measures, which were not practical before the growth of social media, can open many avenues of large-scale psychological discovery into the consequences of temporal orientation and yield applications such as targeted marketing, loan repayment forecasting, understanding economic patterns, or even quantified self-help tools to encourage more future-mindedness.

In this paper, we develop a temporal orientation measure based on language in social media. The measure uses a message-level classifier of past, present, and future, aggregated over users to create user-level assessments. We evaluate the message-level classifier over hand annotated data and the derived user-level model against known human correlates of temporal orientation: *conscientiousness*, age, and gender. To the best of our knowledge, this represents the first paper to study a language-based measure of user-level temporal-orientation.

Our contributions include: (a) the introduction of the task of extracting human temporal orientation from their language use, (b) methodological evaluation and feature engineering for the task, and (c) novel social scientific applications and findings. To-

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 409–419,
Denver, Colorado, May 31 – June 5, 2015.

ward (a) and (b), we find that achieving the task is non-trivial as we build on and diverge from related computational linguistics tasks (e.g. time expression recognition) and utilize a classifier capturing non-linear relationships and interactions. Towards (c), we show how our measure usefully informs psychological theory by relating our human assessments to other psychological variables at a scale not easily explored, and by tracking changes in temporal orientation over time.

2 Background

Researchers and philosophers have long been interested in the subjective experience of time: how individuals relate to their past, are mindful of their present, and envision their futures (James, 1890; Lewin, 1942). Similarly, computational studies have a rich history on extracting temporal relationships beginning decades ago (Allen, 1983). Here, we provide some background on temporal orientation's broader relevance, on computational techniques used to extract temporal information from text, and on related user-level prediction tasks.

Temporal orientation and its correlates. Studies on the human subjective experience of time are filled with diverse measurement methods, varying in their emphasis on cognitive, affective, and/or motivational aspects.[1] Decisions are influenced by the past, present, and mental simulations of possible futures (Seligman et al., 2013).

One widely studied aspect of subjective time is *temporal orientation*, or an individual's tendency to habitually emphasize past, present, or future temporal frames (Boyd and Zimbardo, 2005). Understanding how and why individuals differ in their temporal orientation, can, for example suggest how they can achieve favorable outcomes in areas of life that require substantial long-term planning, including education, higher status occupations, and physical health (Zimbardo and Boyd, 1999; Boyd and Zimbardo, 2005; Steinberg et al., 2009).

Consistent links have been established between temporal orientation and a psychological factor associated with planning, health, and risky behaviors: the personality trait of *conscientiousness*. Conscientious individuals are characterized as self-disciplined, orderly, planful, and reliable (Roberts et al., 2013). Past research has established that highly conscientious people exhibit more future- and less present-oriented (Zimbardo and Boyd, 1999; Webley and Nyhus, 2006; Adams and Nettle, 2009). We use a measure of conscientiousness from the well-established "Big-five" or Five Factor Model of personality (Goldberg, 1990; McCrae and John, 1992). The other four factors, *extraversion* (e.g. active, outgoing, talkative), *agreeableness* (e.g. kind, trusting, generous), *neuroticism* (e.g. touchy, anxious, depressive), and *openness* (e.g. intellectual, artistic, insightful), have been found to have little connection with temporal orientation (Zimbardo and Boyd, 1999).

Other studies have established consistent links between temporal orientation and demographic characteristics. In particular, as one ages they think less about the immediate present and more about the future (Friedman, 2000; Nurmi, 2005; Steinberg et al., 2009), and females tend to think a bit more about the future than males (Keough et al., 1999). However, detailed age trends are not well understood, with studies mostly focusing on adolescents or college-aged students.

For many other important outcomes, such as happiness or well-being, past research leaves us unclear as to the relationship with temporal orientation. Some suggest future-oriented individuals are happier as they engage in more provident behaviors such as saving money and establishing healthier habit (Desmyter and De Raedt, 2012; Diener et al., 2013). This is supported by the connection between future orientation and less depression (Zimbardo and Boyd, 1999). However, others argue that emphasis on the future inhibits ones ability to reflect wisely on the past and savor present experiences (Boniwell et al., 2010). Our study explores this relationship at an unprecedented scale, utilizing the Satisfaction with Life Scale (Diener et al., 1985) and the Center for Epidemiologic Studies Depression Scale, the CES-D (Radloff, 1977). We also look at previously unexplored variables, IQ and number of friends, for which links with temporal orientation seem plausible (e.g. one might suspect it is smart to think about the future, or wonder if one's reflection

[1] For a review, see Strathman et al., 2005.

on the past is related to their popularity as measure by number of friends).

Related work. Studying temporal language is by no means new to the field of computational linguistics (or NLP). Most recently, time annotation has gained greater interest with a successive sequence of three SemEval tasks (TempEval-1, -2 and -3).

The SemEval competitions have provided data sets that facilitate the comparison of different methods for evaluating time expressions, events, and temporal relations (Verhagen et al., 2007; Verhagen et al., 2010; UzZaman et al., 2013). Such research on temporal text analysis generally focuses on determining when events start and end or how they relate temporally to each other; specific goals include information extraction of time-dependent facts from news media (Ling and Weld, 2010; Talukdar et al., 2012), or extracting personal histories in social media (Wen et al., 2013). In contrast, our goal is to find the temporal orientation of people.

Of the numerous TempEval tasks, we build upon those which identify time expressions and resolve their expressed time and date relative to the time of writing (e.g. the time expression 'yesterday' in a document written on *January 15, 2014* is resolved as *January 14, 2014*). Many methods have been used, ranging from hand-crafting rules to machine learning models. Unlike other areas of natural language processing where stochastic techniques dominate, rule-based systems have been quite competitive in time expressions recognition, especially in less domain dependent settings or for relaxed matching tasks (UzZaman et al., 2013).

A number of useful toolkits have been produced for temporal text analysis (Verhagen et al., 2005; Ling and Weld, 2010; Chang and Manning, 2012). In this work, we use Stanford University's rule-based temporal tagger, SUTime, which geve accuracy in line with the state-of-the-art systems at identifying time expressions at TempEval (Chang and Manning, 2012).[2] SUTime, built on top of Stanford's part-of-speech and named entity taggers, labels times, durations, intervals, and relative times compared to the time at which the document was written.

Our work fits a growing tradition of computational work to better understand people based on their online behavior. Much of this type of work uses human properties to better perform traditional computational linguistics tasks, while others focus particularly on predicting user attributes. User network information has been used for tweet summarization or filtering (Panigrahy et al., 2012; Chang et al., 2013; Feng and Wang, 2013).

Others utilize psychological knowledge about people, such as exploiting the human tendency to report more positive extreme feelings than negative in order to improve on sentiment analysis (Guerra et al., 2014). Toward attribute prediction, a large proportion of works have focused on demographics (Argamon et al., 2009; Goswami et al., 2009; Burger et al., 2011; Al Zamal et al., 2012; Bergsma et al., 2013; Sap et al., 2014). and personality prediction (Mairesse et al., 2007; Iacobelli et al., 2011; Schwartz et al., 2013; Park et al., 2015).

Human temporal orientation, as we study it here, differs from previous studies of user attribute prediction in that temporal orientation calls for consideration of additional language features (some more sophisticated, such as time expressions), and exploration of classification techniques (e.g. that can capture non-linear relationships or interactions). We also add multidisciplinary applications, showing not just how accurately our models predict, but also studying how temporal orientation relates to other factors, for example, by weighing in on conflicting literature as to whether people who are more future-oriented are more satisfied with their life.

3 Method

We develop a methodology for measuring a given social media user's temporal orientation. First, we build a classifier to label whether a message discusses the past, present, or future, and then we quantify users' temporal orientation as the percentage of their messages in each category.

We train a variety of supervised classifiers and explore many features in order to label the temporal

[2]Our goals differ slightly from the TempEval accuracy criteria. For example, when SUTime fails to distinguish "one and a half weeks" from "one week", it does not affect our performance. However, other errors, such as confusing the verb 'march' with the month March will harm our accuracy.

class of a social media message. Because this task is new, it is not clear what classification technique is ideal (for example, it is possible that present orientation is best captured with non-linear relationships), so we explore four techniques:

logR: (*logistic regression*). We use regularized logistic regression (equivalent to maximum entropy) (Fan et al., 2008; Bishop, 2006). From cross-validation over the training data, we chose L1 penalization ($\alpha||\beta||_1$).

lSVC, rSVC: (*support vector classification*). Compared to logR, support vector machines offer non-linear kernel functions (Cortes and Vapnik, 1995), and large-margin optimization for class split. We consider both a linear kernel (lSVC) and a radial basis function kernel (rSVC). From cross-validation over the training data, we chose L1 penalization for lSVC and L2 ($\alpha||\beta||^2$) for rSVC.

ERTs: (*forest of extremely randomized trees*). This technique uses an ensemble of decision trees in which both the feature and cut-point are chosen at each node from a randomly generated set of possible options (Geurts et al., 2006). Such an approach can handle both interactions and non-linear relationships, at the expense of a larger search space. From cross-validation over our training data, we set the following algorithm parameters: we build 1,000 decision trees, using the Gini impurity measure when choosing splits (as opposed to entropy), and selecting each node's feature threshold from among square-root of the total features.

All classifications algorithms were implemented using the scikit-learn toolkit (Pedregosa et al., 2011). Multi-classication over binary classifiers (logR, lSVC, rSVC) was achieved using a series of *one-v-rest* classifiers.

We explore five language-based features:

ngrams: *1 to 3 token sequences*. Messages are tokenized using the *happierfuntokenizing* tool[3] which captures common social media tokens such as emoticons, hashtags, and user handles. Features are encoded simply as binary indicators for whether the ngram appears in the message.

time exs: *The mean difference between the resolved date-time of all time expressions and the date-time in which the message was posted.* Time expressions are labeled via Stanford's SUTime annotator (Chang and Manning, 2012), discussed previously. Specific features recorded include the temporal difference itself (e.g. -2.5 for "two and half days ago"), its base 2 log ($log(1 + value)$), its absolute value, total number of time expressions, and binary variables indicating if any past, present, or future expressions appear in the text. We also include binary features for each of the named-entity time tags for the time expression provided by SUTime (e.g. "future_ref", "present_ref", "next_immediate").

POS tags: *The relative frequency of each part-of-speech tag.* Tagging is done via Stanford's part-of-speech tagger (Toutanova et al., 2003). Stanford's tagger does not have explicit social media tags, but we are most interested in capturing tense which it does well.[4] Also, it is already being used as part of SUTime. Each part-of-speech tag is encoded as the frequency of tag usage ($freq(tag, msg)$) divided by the total number of tokens in the message ($tokens_{msg}$):

$$p(tag|msg) = \frac{freq(tag, msg)}{|tokens_{msg}|}$$

lexica: *The relative frequency of categories, based on the Linguistic Inquiry and Word Count (LIWC) dictionary* (Pennebaker et al., 2007). We use the 2007 version of *LIWC* which includes 64 categories of psychologically-relevant language, including past, present, and future verb categories. The features are encoded as the frequency with which a word from a category (cat) appeared in the message (msg) divided by the total tokens in the message ($tokens_{msg}$):

$$p(cat|msg) = \frac{\sum_{token \in cat} freq(token, msg)}{|tokens_{msg}|}$$

[3] available here: wwbp.org/public_data/happierfuntokenizing.zip

[4] The Stanford Tagger has well documented errors on microblog text (Derczynski et al., 2013). However, we manually evaluated 49 verbs across 20 randomly selected statuses, and all verb tenses were correctly tagged while 4 non-verbs were incorrectly tagged as base-form verbs.

Another day of great restraint.	pa	pa	pr	pa

Table 1: Examples of statuses annotated for temporal classes: past (pa), present/none (pr), and future (fu). R1, R2, R3: judgements from each rater; Maj: choice from majority voting. The bottom three examples illustrate difficult cases.

lengths: *mean size of 1grams and number of tokens in the post.*

We found it useful to use a modest variety of feature types and to build on existing work that labels time expressions. While one might expect time expression features to be extremely valuable for this task, we found only 15% of Facebook messages contain them, even though many more communicate a focus on the past or future through other means (e.g. tense or semantic information). All features were limited to those mentioned in at least 0.05% of messages.

At the user-level, we produce three categories of temporal orientation, defined simply as the proportion of a user's total messages ($msgs(user)_{all}$) classified in the given temporal category ($tc \in \{past, present, future\}$):

$$orientation_{tc}(user) = \frac{|msgs_{tc}(user)|}{|msgs_{all}(user)|}$$

We generate three separate variables (summing to one), rather than a single variable temporal index, in order to capture non-linear relationships (i.e., the potential for the present to correlate in the opposite direction of both the past and future). All of our user analyses are based on 100 randomly selected messages from each user.

4 Data collection and labeling

We use three social media datasets: the *training set*, *test set*, and *user set*. The *training set* consists of 4,302 Twitter and Facebook annotated messages. The *test set* is a random subset of 500 annotated Facebook messages, representative of messages we will apply our model. Finally, the *user set* contains 531,893 messages from Facebook users with known age, gender, personality, satisfaction with life, depression, IQ and number of Facebook friends. We derived the *test set* from the *user set* in order to establish accuracies of our model over the application domain.

Training set. Our training data consists of both Facebook and Twitter messages. For Facebook, 3,000 status updates, sent between March 2009 and October 2011, were randomly sampled from users of the MyPersonality application (Kosinski and Stillwell, 2012; Quercia et al., 2012), who also provided their age and gender. For Twitter, 3,000 messages were sampled from the 1% *random* stream provided by Twitter during September 2012.

Three annotators, undergraduate students at the University of Pennsylvania, independently labeled the temporal orientation of each message. Messages were labeled in units of days past or future (adapted from Liberman et al. (2007)). For example, -7 would be a week ago, $^{-1}/_{24}$ would be an hour ago, 0 would be now (present), and 365 would be a year from now. Inter-annotator agreement, as the intraclass correlation coefficient (Shrout and Fleiss, 1979), was 0.85. Ratings were averaged into a single "time from now" index. For the purposes of this study we then discretized the data into past (mean rating < 0), present (mean rating $= 0$), or future (mean rating > 0). Annotation of the 6,000 messages took approximately 150 human hours.

When rating, messages were marked 'NA' when they appeared to come from a bot or were composed of song lyrics or quotations. (Removing unoriginal content was desired for the consumer behavior research for which the messages were first labeled.) For our purposes, in order to maximize the training set size, we only removed messages when all three raters chose 'NA', such that there was no average rating available for the message. The resulting final *training set* consisted of 4,302 total messages (2,009 tweets; 2,293 Facebook status updates). Since our application of the data does not include a manual filtering of messages, we created a separate message test set with no filtering in order to accurately evaluate our classifier in the application's setting (below).

Test set. Evaluating our classifiers over our annotated training set would not yield an accurate assessment of the performance when applied to the *user set* (described next). Therefore, we randomly selected 500 statuses from the *user set* as our message *test set*.[5] Statuses exclude

[5]While we desired a large training set, the test set only needed to be large enough to evaluate differences in accuracy.

	mfc	logR	lSVC	rSVC	ERTs	*msgs*
Accuracy	.528	.686	.708	.684	**.718**	*500*
past (p, r, f1)	(.00, .00, .00)	(.56, .68, .62)	(.63, .67, .65)	(.63, .56, .59)	(.73, .67, .71)	*131*
present (p, r, f1)	(.53, 1.0, .69)	(.80, .74, .77)	(.78, .78, .78)	(.70, .85, .77)	(.74, .84, .79)	*264*
future (p, r, f1)	(.00, .00, .00)	(.60, .56, .58)	(.61, .56, .58)	(.69, .43, .53)	(.60, .47, .53)	*105*

Table 2: Accuracy (percentage classified correct) message classifiers based on different learning algorithms (identified in section 3). Temporal class results are broken down by precision (p), recall (r), and f1 score for each of past (pa), present (pr), and future (fu). Number of messages (*msgs*) are listed on the far right. The most frequent class baseline (mfc) indicates accuracy if only predicting the present class.

reposts of others' statuses and comments on other people's posts, and we found only 2 of the 500 random messages were made by apps (users still choose whether or not to post these to their walls). Three annotators independently classified each status message as predominantly talking about the past, present, or future. The overall rating for each message was determined by a majority vote (when there was a tie: i.e., one of each class, present was used). Agreement among these raters, calculated as the intraclass correlation coefficient, was 0.83. One might suggest some messages do not have a temporal class (e.g. does "I like Selena Gomez" have a predominant temporal class?).[6] Such messages would be marked as 'present' in our annotation scheme. Thus, one might consider our present class to encompass both a present and "non-temporal" class.

User set. Human-level data is used to evaluate our model toward understanding the relationship between human temporal orientation and individual characteristics (e.g. demographics, personality). Thus, this data spans both message and user levels, from consenting participants, in the MyPersonality Facebook study (Kosinski and Stillwell, 2012).

We used five subsets of the MyPersonality data in order to capture various psychological and behavioral variables: *user subset 1*: gender, age, and personality; *user subset 2*: satisfaction with life, *user subset 3*: depression, *user subset 4*: IQ, and *user subset 5*: number of friends. For our first subset, gender, age, and personality variables are well represented in the dataset, so we created a stratified sample over 1,520 users. We sampled equal proportions of males and females across 4-year age bins from 13 to 60 (i.e., ages *[13,16], [17,20], . . . ,[57, 60]*), which provides gender- and age-controlled correlations for each personality factor (openness, conscientiousness, extraversion, agreeableness, and neuroticism).

Other variables are more limited. Thus, instead of creating stratified samples, these three subsets include users for whom gender and age information is also available: 1,565 in the case of satisfaction with life, 268 for the CES-D depression scale, 898 for IQ and, 1,000 in the case of number of friends. The gender and age data is then included as covariates in regression analyses to find the relationship between these variables and temporal orientation, controlled for demographics. In all five subsets of the *user set*, we randomly sample 100 messages from each user in order to determine their temporal orientation.

Table 1 shows example status updates along with ratings. As evidenced from the rater agreement, most status updates were fairly easy to determine. Some messages have explicit temporal phrases (e.g. "in the future") while others are more subtle (e.g. relying on verb tense: "is listening ..."). Others, such as the bottom three examples, might reference multiple temporal classes or not include clear verb tense and thus rely on the raters' judgements for what is most dominant.

5 Evaluation

We evaluate our past, present, and future message classifier as well as its features. All models were trained over our *training set* and evaluated over the *test set*.

Table 2 compares accuracy of various types of classifiers: logistic regression (logR), linear support vector classifier (lSVC), support vector classifier with rbf kernel (rSVC), and a forest of extremely randomized trees (ERTs). We saw best results from the ERTs classifier, suggesting some of its benefits (capturing non-linear relationships or interactions among features) may help this problem. We also see, from the F1 scores, that all classifiers found the future class most difficult to predict; this was the smallest class and likely subject to the most bias against. All classifiers performed significantly better than the most frequent class baseline with an error reduction of 41% in the case of ERTs ($p < 0.001$ from paired t-test on absolute errors). We selected the ERTs classifier for the remaining experiments.[7]

[6] We attempted to include a non-temporal class and found disagreement. Some argue that every message has a temporal class (e.g. "I like Selena Gomez" is truly signalling present).

[7] This trained classifier is available at: wwbp.org/data.html.

Past		Present		Future

lexica alone	.684	w/o *lexica*	.702
lengths alone	.544	w/o *lengths*	.718

Table 3: Accuracy of our full past, present, future message classifier (top) and an ablation analysis of accuracies when removing each feature type (bottom). The most frequent class baseline (mfc) indicates accuracy if only predicting the present class. The full classifier significantly out-performed using time expressions alone ($p < 0.05$; bolded accuracy).

We did feature ablation analyses as shown in Table 3. Every feature type produced improvement over the baseline and, with the exception of $lengths$, removing any feature resulted in reduced performance (though none strong enough to meet significance at $p < 0.05$). The limited reduction implies that while each feature type may contain temporal information, there is also substantial redundancy across the feature types.

Results when using time-expression alone can be considered another baseline, representing a model based entirely on previous time expression work. A reason for the large advantage of using additional features is that many temporally indicative messages did not contain any time expressions (instead expressing orientation through verb tense or semantics). Indeed, we see from Table 4, which lists the top features for each class, that time expression features were very useful when then occurred. All feature types made it into these top ten lists.

User-level temporal orientation is trivially defined: percentage of a given user's messages that are classified as past, present, or future oriented. Thus, accuracy for each proportion is directly tied to message accuracy. Still, we validate that our approach is in line with psychological theory (discussed in Section 2) by correlating user-level temporal orientations with outcomes whose associations have been previously established: conscientiousness, age, and gender number of users; results controlled for age and gender. In particular, future orientation should be positively correlated with conscientiousness, age, and being female, while present orientation should be negatively correlated. Our results which which are consistent with the literature, can be seen in the top half of Table 5. Among users with personality scores, we found positive correlations between future orientation and seemingly future-oriented questionnaire items: "I make plans and stick to them" ($r = .16$) and "I finish what I start" ($r = .12$). To the best of our knowledge, psychology literature has not established standard correlates of past orientation, so the correlation with age and past orientation, though not surprising, is somewhat novel.

Correlations with questionnaire measures help to establish convergent validity — i.e. our measure is empirically related to other measures in a way that is consistent with theory about the underlying constructs. However, self report questionnaires are often used for convenience, not necessarily because they are most valid (Paulhus and Vazire, 2007). In fact, more objective or behavior-based measures in social science have been called for (Baumeister et al., 2007).

6 Exploration

Here we use our language-based user measure to explore behavioral and psychological correlates of temporal orientation. Figure 1 illustrates the user-level distributions of the message classes, broken down by gender, within the stratified sample. All experiments in this section applied our measure over the *user set*. Within users, the mean proportions of past, present, and future messages were 0.24, 0.61, and 0.15 respectively. Among most users, the majority of messages were classified as present, while future-oriented messages were least frequent.

We compare these temporal orientations to user personality, satisfaction with life, IQ, and their number of Facebook friends. We use both Pearson correlation and linear regression (OLS) to estimate relationships between

Attribute	*N*	Past	Present	Future
validation				
conscientiousness	*1520*	.02	**-.08**	**.12**
age	*1520*	**.30**	**-.30**	**.15**
gender	*1520*	**.10**	**-.15**	**.14**
exploration				
openness	*1520*	.05	.04	**-.12**
extraversion	*1520*	-.04	.03	.00
agreeableness	*1520*	.00	-.02	.04
neuroticism	*1520*	-.01	-.01	.04
satisfaction w/ life	*1565*	.00	-.05	**.08**
depression	*268*	-.14	**.21**	**-.17**
IQ	*898*	**.14**	**-.14**	.05
# of friends	*1000*	**-.15**	**.13**	-.05

Table 5: Correlations between user temporal orientation and human attributes. The attributes conscientiousness, age, and gender are well-established in previous literature to be associated with temporal orientation. Gender is coded as 0 = male, 1 = female. **bold**: $p < .01$ after Benjamini-Hochberg multiple comparison correction; *N*: number of users; results controlled for age and gender.

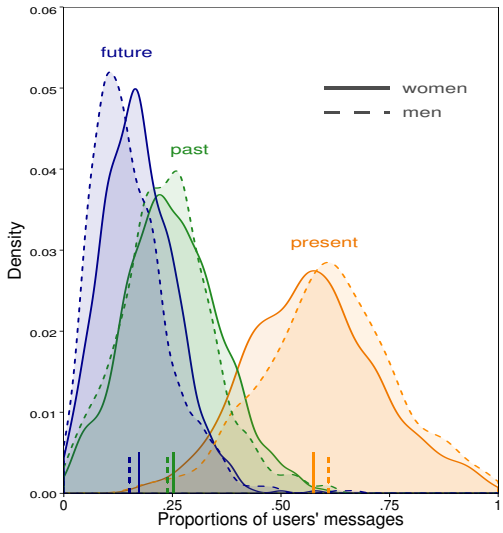

Figure 1: Kernel density estimates of user-level proportions of past, present, and future classified messages, broken down by gender. Vertical bars represent means.

temporal orientation and other variables. In our age and gender stratified sample (1520 users), we calculate Pearson correlations between temporal orientation and age, gender, and measures of openness, conscientiousness, extraversion, agreeableness, and neuroticism. Because fewer users completed measures of satisfaction with life, IQ, and number of friends, we were not able to produce sufficient stratified samples, so we used ordinary least squares linear regression to fit the standardized outcome of interest to standardized temporal orientation also including standardized age and gender as covariates to adjust for their effects. The coefficient, often denoted β, for temporal orientation then represents the strength of the relationship, controlled for age and gender.

Table 5 lists the correlation coefficients between temporal orientation and user attributes. We found the strongest effects for age, with patterns that are consistent with the psychological literature (Steinberg et al., 2009). Figure 2 illustrates trends from age 13 to 60. Most notably, present orientation decreases steadily across age; past orientation steadily increases, and future orientation increases quickly throughout adolescence, slows in early adulthood, and finally levels off in late adulthood. Female users were significantly more future-oriented, slightly more past-oriented, and significantly less present-oriented than males.

For personality, we found the expected patterns of correlations with conscientiousness, but more interestingly, openness to experience was correlated with lower future orientation (beyond conscientiousness, there was no support in the literature for any of the five personality factors to correlate with temporal orientation). This is surprising when considering openness to experience is characterized by creativity and intellect (McCrae and John, 1992), yet IQ instead correlates with less present and more past orientation, suggesting future orientation characterizes a difference between the two.[8]

We found a modest yet significant positive correlation between future orientation and satisfaction with life, with future orientation associated with higher life satisfaction. On the other hand, we found a stronger negative correlation between future orientation and depression as well as a positive correlation between present orientation and depression. As previously noted, past literature was conflicting on the relationship between these factors, so our study weighs in with a behavior-based assessment in support of a future-oriented people being more satisfied in life and less depressed.

Lastly, we consider whether the use of our language-based measure of temporal orientation can track changes over time. As a proof-of-concept, we focus on patterns around birthdays; excluding messages containing birthday terms and users turning 21, we calculated the standardized proportion of messages which were future-

[8]One interpretation is that our classifier may be more accurate on messages authored by those with higher IQ (i.e. more grammatical sentences); however no significant difference in error was found when spitting messages by the authors' IQ, age, or gender.

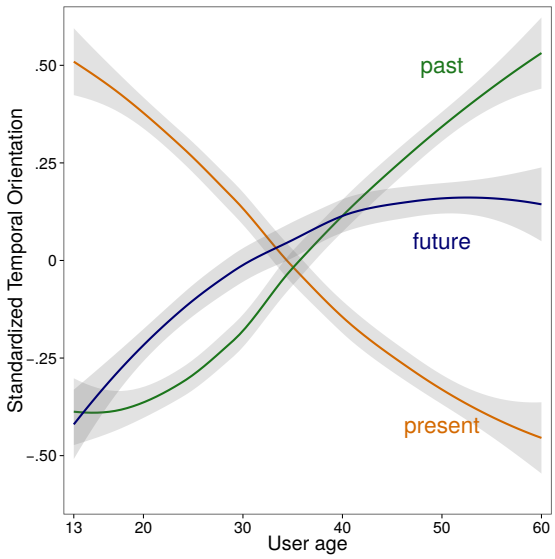

Figure 2: Standardized temporal orientation of users over their age. Shaded area indicates ± 1 standard error around loess smoothed estimates.

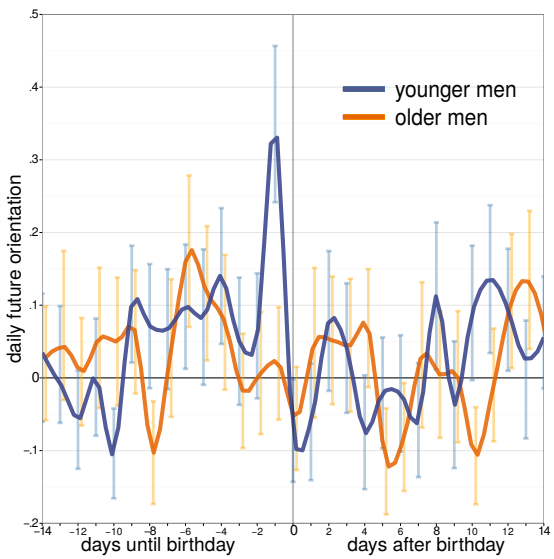

Figure 3: Daily proportion of future-oriented messages leading up to and following birthdays. Younger men: $<$ 23, N = 423; Older men: $\geq$ 23, N = 402.

oriented over two weeks before and after one's birthday. We controlled for individual differences and date effects (e.g. if more people happen to be born near a holiday) by standardizing users' future orientation over all their messages and standardizing daily future orientation scores over all messages from each day. Figure 3 shows the patterns for men $<$ 23 and $\geq$ 23, suggesting that younger men look forward to their birthdays while older men do not (patterns were less pronounced for women).

7 Conclusions

This is, to our knowledge, the first study to automatically assess individual temporal orientation through language, and it constitutes one of the largest (perhaps the largest) studies of temporal orientation. Our message-level past, present, and future classifier achieved an accuracy of 71.8%, well-above most frequent sense, pasts-of-speech only, and time expression only baselines. The associations we found between user-level temporal orientation and conscientiousness, gender, and age validated our novel method against well-established correlates. We then explored novel links with other personality factors, satisfaction with life, depression, IQ, and number of friends.

Our automatic labeling of temporal orientation yielded strong accuracy. There are, however, several ways in which our analysis might be improved or extended. We used a coding scheme that did not allow a "no temporal orientation" class. Separate handling of "non-temporal" messages might provide more nuanced profiles of user orientation. Another simplification was our binning of temporal relations into past, present, and future. One might want to instead use a continuous measure of temporal distance, indicating how far into the past or future a message is oriented, providing a more detailed profile of individual orientations. Among the future-oriented, for example, there may be important differences between those who plan for tomorrow versus those who plan years in advance. Assessing additional characteristics of messages, such as sentiment, may also allow further insight and more nuanced characterizations (e.g. "I will be fine" vs. "I will never be ok").

Whereas prior computational linguistics work with temporal relations has focused on classifying events, we focus on people and open many avenues for social scientific investigations that were previously not very feasible. For instance, temporal orientation was generally treated as a stable trait (with little change through the lifetime); For men, we found age differences in temporal orientation leading up to one's birthday. Learning how, why, and when people become more future-oriented may inform planning and risk assessment interventions, and lead to better understanding of health and economic prosperity.

An In-depth Analysis of the Effect of Text Normalization in Social Media

Abstract

Recent years have seen increased interest in text normalization in social media, as the informal writing styles found in Twitter and other social media data often cause problems for NLP applications. Unfortunately, most current approaches narrowly regard the normalization task as a "one size fits all" task of replacing non-standard words with their standard counterparts. In this work we build a taxonomy of normalization edits and present a study of normalization to examine its effect on three different downstream applications (dependency parsing, named entity recognition, and text-to-speech synthesis). The results suggest that how the normalization task should be viewed is highly dependent on the targeted application. The results also show that normalization must be thought of as more than word replacement in order to produce results comparable to those seen on clean text.

1 Introduction

The informal writing style employed by authors of social media data is problematic for many natural language processing (NLP) tools, which are generally trained on clean, formal text such as newswire data. One possible solution to this problem is normalization, in which the informal text is converted into a more standard formal form. Because of this, the rise of social media data has coincided with a rise in interest in the normalization problem.

Unfortunately, while many approaches to the problem exist, there are notable limitations to the way in which normalization is examined. First, although social media normalization is universally motivated by pointing to its role in helping downstream applications, most normalization work gives little to no insight into the effect of the normalization process on the downstream application of interest. Further, the normalization process is generally seen to be agnostic of the downstream application, adopting a "one size fits all" view of how normalization should be performed. This view seems intuitively problematic, as different information is likely to be of importance for different tasks. For instance, while capitalization is important for resolving named entities, it is less important for other tasks, such as dependency parsing.

Some recent work has given credence to the idea that application-targeted normalization is appropriate (Wang and Ng, 2013; Zhang et al., 2013). However, how certain normalization actions influence the overall performance of these applications is not well understood. To address this, we design a taxonomy of possible normalization edits based on inspiration from previous work and an examination of annotated data. We then use this taxonomy to examine the importance of individual normalization actions on three different downstream applications: dependency parsing, named entity recognition, and text-to-speech synthesis. The results suggest that the importance of a given normalization edit is highly dependent on the task, making the "one size fits all" approach inappropriate. The results also show that a narrow view of normalization as word replacement is insufficient, as many often-ignored normalization actions prove to be important for certain tasks.

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 420–429,
Denver, Colorado, May 31 – June 5, 2015.

In the next section, we give an overview of previous work on the normalization problem. We then introduce our taxonomy of normalization edits in Section 3. In Section 4, we present our evaluation methodology and present results over the three applications, using Twitter data as a representative domain. Finally, we discuss our results in Section 5 and conclude in Section 6.

2 Related Work

Twitter and other social media data is littered with non-standard word forms and other informal usage patterns, making it difficult for many NLP tools to produce results comparable to what is seen on formal datasets. There are two approaches proposed in the literature to handle this problem (Eisenstein, 2013). One approach is to tailor a specific NLP tool towards the data, by using training data from the domain to help the tool learn its specific idiosyncrasies. This approach has been applied with reasonable success on named entity recognition (Liu et al., 2011b; Ritter et al., 2011) as well as on parsing and part-of-speech tagging (Foster et al., 2011).

The other approach is normalization. Rather than tailoring a NLP tool towards the data, normalization seeks to tailor the data towards the tool. This is accomplished by transforming the data into a form more akin to the formal text that NLP tools are generally trained on. While normalization is often more straightforward and more easily applied in instances in which retraining is difficult or impractical, it has potential disadvantages as well, such as the potential loss of pragmatic nuance (Baldwin and Chai, 2011).

Prior to the rise of social media, the normalization process was primarily seen as one of standardizing non-standard tokens found in otherwise clean text, such as numbers, dates, and acronyms (Sproat et al., 2001). However, the current popularity of Twitter and other informal texts has caused the normalization task to take on a broader meaning in these contexts, where the goal is to convert informal text into formal text that downstream applications expect.

Many different approaches to social media normalization have been undertaken. These approaches often draw inspiration from other tasks such as machine translation (Pennell and Liu, 2011; Aw et al., 2006), spell checking (Choudhury et al., 2007) or speech recognition (Kobus et al., 2008). Other approaches include creating automatic abbreviations via a maximum entropy classifier (Pennell and Liu, 2010), creating word association graphs (Sonmez and Ozgur, 2014), and incorporating both rules and statistical models (Beaufort et al., 2010). While most initial approaches used supervised methods, unsupervised methods have recently become popular (Cook and Stevenson, 2009; Liu et al., 2011a; Yang and Eisenstein, 2013; Li and Liu, 2014). Some work has chosen to focus on specific aspects of the normalization process, such as providing good coverage (Liu et al., 2012) or building normalization dictionaries (Han et al., 2012).

In all of the work mentioned above, the normalization task was seen primarily as one of converting non-standard tokens into an equivalent standard form. Similarly, many of these works defined the problem even more narrowly such that punctuation, capitalization, and multi-word replacements were ignored. However, two pieces of recent work have suggested that this understanding of the normalization task is too narrow, as it ignores many other hallmarks of informal writing that are prevalent in social media data. Wang and Ng (2013) present a beam search based approach designed to handle machine translation which incorporates attempts to correct mistaken punctuation and add missing words, such as forms of the verb *to be*. Similarly, Zhang et al. (2013) attempt to perform all actions necessary to create a formal text. In both instances the work was motivated by, and evaluated with respect to, a specific downstream application (machine translation and dependency parsing, respectively). However, not every study that tied the output to an application chose a broad interpretation of the normalization problem (Beaufort et al., 2010; Kaji and Kitsuregawa, 2014).

3 Taxonomy of Normalization Edits

In order to understand the impact of individual normalization edits on downstream applications, we first need to define the space of possible normalization edits. While it is not uncommon for normalization work to present some analysis of the data, these analyses are often quite specific to the domain and datasets of interest. Because there is no agreed upon

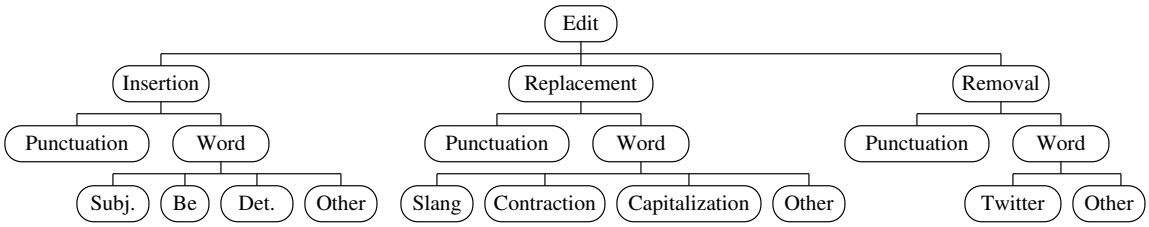

Figure 1: Taxonomy of normalization edits

taxonomy of normalization token or edit types, different analyses often look at different edit types and at different levels of granularity. In an attempt to help future work converge on a common understanding of normalization edits, in this section we present our taxonomy of normalization edits at several different levels of granularity. While it would be difficult for a taxonomy of normalization edits to be universal enough to be appropriate over all datasets and domains, we attempt to provide a taxonomy general enough to give future work a meaningful initial point of reference.

3.1 Methodology

Our taxonomy draws inspiration from both previous work and an examination of our own dataset (Section 3.3). In doing so, it attempts to cover normalization edits broadly, including cases that are universally understood to be important, such as slang replacement, as well as cases that are frequently ignored, such as capitalization correction.

One of the guiding principles in the design of our taxonomy was that categories should not be divided so narrowly such that the phenomenon they capture appeared very infrequently in the data. One example of this is our decision not to divide punctuation edits at the lowest level of granularity. While certain clear categories exist (e.g., emoticons), these cases appeared in a small enough percentage of tokens that they would be difficult to examine and likely have a negligible effect on overall performance.

3.2 Taxonomy

Our taxonomy of normalization edits is shown in Figure 1. As can be seen, we categorize edits at three levels of granularity.

Level One. The primary goal of the level one segmentation is to separate token replacements which are most centrally thought of as part of the normalization task from other instances that may require additional pragmatic inference. Specifically, we separate edits coarsely into three categories:

- **Token Replacements.** Replacing one or more existing tokens with one or more new tokens (e.g., replacing *wanna* with *want to*).
- **Token Additions.** Adding a token that does not replace an existing token (e.g., adding in missing subjects).
- **Token Removals.** Removing a token without replacing it with an equivalent (e.g., removing laughter words such as *lol* and *hahaha*).

Level Two. The next level of granularity separates normalization edits over word tokens from those over punctuation:

- **Word.** Replacing, adding, or removing word tokens (depending on parent).
- **Punctuation.** Replacing, adding, or removing punctuation tokens (depending on parent).

Level Three. At the final level, we subdivide word edits into groups as appropriate for the edit type. Rather than attempting to keep consistent groups across all leaf nodes, we selected the grouping based on the data distribution. For instance, Twitter-specific tokens (e.g., retweets) are often removed during normalization, so examining the removal of these words as a group is warranted. In contrast, these tokens are never added, so different segmentation is appropriate when examining word addition.

At the lowest level of the taxonomy, word replacements were subdivided as follows:

- **Contraction Replacements.** Unrolling standard contractions (*don't*), common informal cases (*wanna*), and non-standard variations produced via apostrophe omission (*dont*).

- **Slang Replacements.** Replacing slang terms, such as slang shortenings and word elongation.

- **Capitalization Replacements.** Correcting the capitalization of words. The replaced word differs from its replacement by *only* capitalization.

- **Other Replacements.** Correcting unintentional typographic mistakes, such as misspelling and word concatenation.

When segmenting word additions, we note that words that need to be added in a normalization edit were often consciously dropped by the user in the original text. Our categorization reflects this by examining syntactic categories that are often dropped in informal writing:

- **Subject Addition.** Adding in omitted subjects.

- **Determiner Addition.** Adding in omitted determiners (e.g., "[*The*] front row is so close").

- **Be-verb Addition.** Adding in omitted forms of the verb *to be*.

- **Other Addition.** All word additions not covered by the other categories.

Finally, word removals are subdivided into just two categories:

- **Dataset-specific Removals.** Removing tokens that do not appear outside of the dataset in question (e.g., for Twitter: hashtags, @replies, and retweets).

- **Other Removals.** Removing interjections, laughter words, and other expression of emotion (e.g., *ugh*).

Note that we are not suggesting here that dataset-specific words should be removed in all cases. While in many cases they may be removed if they do not have a formal equivalent, they may also be replaced or retained as is, depending on the context.

3.3 Dataset

To facilitate our experiments, we collected and annotated a dataset of Twitter posts (tweets) from the TREC Twitter Corpus[1]. The TREC Twitter corpus is a collection of 16 million tweets posted in January and February of 2011. The corpus is designed to be a representative sample of Twitter usage, and as such includes both regular and spam tweets. To build our dataset, we sampled 600 posts at random from the corpus. The tweets were then manually filtered such that tweets that were not in English were replaced with those in English.

To produce our gold standard, two oDesk[2] contractors were asked to manually normalize each tweet in the dataset to its fully grammatical form, as would be found in formal text. Annotation guidelines stipulated that twitter-specific tokens should be retained if important to understanding the sentence, but modified or removed otherwise. As noted, most previous work often stopped short of requiring full grammaticality. However, Zhang et al. (2013) argued that grammaticality should be the ideal end goal of normalization since the models used in downstream applications are typically trained on well-formed sentences. We adopt this methodology here both because we agree with this assertion and because a fully grammatical form is appropriate for all of the downstream applications of interest, allowing for a single unified gold standard that can aid comparison across applications.

During gold standard creation, each normalization edit was labeled with its type, according to the above taxonomy. The distribution of normalization edits in the dataset is given in Table 1. As shown, normalization edits accounted for about 29% of all tokens. Token replacements accounted for just over half of all edits (53%), while token addition (29%) was more common than token removal (18%). One interesting observation is non-capitalization word replacement accounted for only 25% of all normalization edits, intuitively indicating potential drawbacks for the common definition of normalization as one of simple word replacement which ignores capitalization and punctuation.

4 Evaluation

In this section, we present our examination of the effect of normalization edits on downstream NLP applications. To get a broad understanding of these effects, we examine three very different cases: dependency parsing, named entity recognition (NER), and text-to-speech (TTS) synthesis. We chose these tasks because they each require the extraction of different information from the text. For instance, named entity recognition requires only a shallow syntactic analysis, in contrast to the deeper understanding required for dependency parsing. Similarly, only speech synthesis requires phoneme production, while the other tasks do not. Despite their differences, each of these tasks is relevant to larger applications that would benefit from improved performance on Twitter data, and each has garnered attention in the normalization and Twitter-adaptation literature (Beaufort et al., 2010; Liu et al., 2011b; Zhang et al., 2013).

Although the differences in these tasks also dictates that they be evaluated somewhat differently, we examine them within a common evaluation structure. In all cases, to examine the effects of each normalization edit we model our analyses as ablation studies. That is, for every category in the taxonomy, we examine the effect of performing all normalization edits *except* the relevant case. This allows us to measure the drop in performance solely attributable to each category; the greater the performance drop observed when a given normalization edit is not performed, the greater the importance of performing that edit.

To aid analysis, results are presented in two ways: 1) as raw performance numbers, and 2) as an error rate per-token. These metrics give two different views of the relevance of each edit type. The raw numbers give a sense of the overall impact of a given category, and as such may be impacted by the size of the category, with common edits becoming more important simply by virtue of their frequency. In contrast, the per-token error rate highlights the cost of failing to perform a single instance of a given normalization edit, independent of the frequency of the edit. Both of these measures are likely to be relevant when attempting to improve the performance of a normalization system. Note that since the first measure is one of overall performance, smaller numbers reflect larger performance drops when removing a given type of edit, so that the smaller the number the more critical the need to perform the given type of normalization. In contrast, the latter judgment is one of error rate, and thus interpretation is reversed; the larger the error rate when it is removed, the more critical the normalization edit.

Another commonality among the analyses is that performance is measured relative to the top performance of the *tool*, not the task. That is, following Zhang et al. (2013), we consider the output produced by the tool (e.g., the dependency parser) on the grammatically correct data to be gold standard performance. This means that some output based on our gold standard may in fact be incorrect relative to human judgment, simply because the tool used does not have perfect performance even if the text if fully grammatical. Since the goal is to understand how normalization edits impact the performance, this style of evaluation is appropriate; it considers mistakes attributable to normalization edits as erroneous, but ignores those mistakes attributable to the limitations of the tool.

Finally, to maximize the relevance of the analyses

given here, in each case we employ publicly available and widely used tools.

4.1 Parser Evaluation

To examine the effect of normalization on dependency parsing, we employ the Stanford dependency parser[3] (Marneffe et al., 2006). To produce the gold standard dependencies for comparison, the manually grammaticalized tweets (Section 3.3) were run through the parser. To compare the ablation results to the gold standard parses, we adopt a variation of the evaluation method used by Zhang et al. (2013). Given dependency parses from the gold standard and a candidate normalization, we define precision and recall as follows:

$$\text{precision}_{\text{sov}} = \frac{|SOV \cap SOV_{gold}|}{|SOV|} \quad (1)$$

$$\text{recall}_{\text{sov}} = \frac{|SOV \cap SOV_{gold}|}{|SOV_{gold}|} \quad (2)$$

Where SOV and SOV_{gold} are the sets of subject, object, and verb dependencies in the candidate normalization and gold standard, respectively. While Zhang et al. chose to examine subjects and objects separately from verbs, we employ a unified metric to simplify interpretation.

4.1.1 Results

Results of the ablation study are summarized in Table 2. As shown, the performance of a complex task such as dependency parsing is broadly impacted by a variety of normalization edits. Based on the raw F-measure, the more common word replacements proved to be the most critical, although failing to handle token addition and removal edits also resulted in substantial drops in performance. At the lowest level in the taxonomy, slang replacements and subject addition were the most critical edits.

Although many replacement tasks were important in aggregate, on a per-token basis the most important edits were those that required token removal and addition. Perhaps unsurprisingly, failing to add subjects and verbs resulted in the largest issues, as the parser has little chance of identifying these dependencies if the terms simply do not appear in the sentence. However, not all word additions proved critical, as failing to add in a missing determiner generally had little impact on the overall performance. Similarly, failing to correct capitalization did not cause substantial problems for the parser. Some word replacements did prove to be important, with slang and other word replacements showing some of the largest per-token error rates. Removing misleading punctuation or changing non-standard punctuation both proved important, but the per-token effect of punctuation addition was modest.

Table 2: Dependency Parser Results.

In general, the results suggest that a complex task such as dependency parsing suffers substantially when the input data differs from formal text in any number of ways. With the exception of capitalization correction, performing almost every normalization edit is necessary to achieve results commensurate with those seen on formal text.

4.2 NER Evaluation

In this section, we examine the effect of each normalization edit on a somewhat more shallow interpretation task, named entity recognition. Unlike dependency parsing which requires an understanding of every token in the text, NER must only determine whether a given token is a named entity, and if so, discover its associated entity type.

The setup for evaluation of normalization edits on named entity recognition closely follows that of dependency parsing. We once again employ a tool from the suite of Stanford NLP tools, the Stanford named entity recognizer[4] (Finkel et al., 2005). We also define precision and recall in a similar manner:

$$\text{precision}_{\text{ner}} = \frac{|ENT \cap ENT_{gold}|}{|ENT|} \quad (3)$$

$$\text{recall}_{\text{ner}} = \frac{|ENT \cap ENT_{gold}|}{|ENT_{gold}|} \quad (4)$$

Where ENT and ENT_{gold} are the sets of entities identified over the candidate normalization and gold standard sentences, respectively. Entities were labeled as one of three classes (`person`, `location`, or `organization`), and two entities were only considered a match if they both selected the same entity and the same entity class.

4.2.1 Results

Table 3 shows the results of the NER ablation study. Unlike dependency parsing, only word replacement edits proved to be critically important for NER tasks, as adding and subtracting words had little impact on the overall performance. Capitalization, which is generally an important feature for the identification of named entities, was unsurprisingly important. Similarly, the replacement of word types other than slang and contraction was important, because many of these instances may come from misspelled named entities. Slang and contractions were less important, as they were generally not used to reference named entities. As the words dropped by Twitter users tend to be function words that are not critical to understanding the sentence they are rarely named entities and have only a small effect on named entity recognition. Similarly, terms that are removed during normalization also tend to not be named entities, and thus has minor overall impact.

A similar phenomenon is observed in the per-token evaluation, where unintentionally produced, non-slang, non-contraction word replacement was seen to be of paramount importance. Punctuation removal was also important on a per-token basis, despite having little impact in aggregate.

Overall, the results given in Table 3 indicate that a focused approach to normalization for named entity recognition is warranted. Unlike dependency parsing that required a broad approach involving token addition and removal, the replacement-centric normalization approach typically employed by previous work is likely to be sufficient when the goal is to improve entity recognition.

4.3 TTS Evaluation

Unlike the previous two tasks, the TTS problem is complicated by its need for speech production. Similarly, evaluation of speech synthesis is more difficult, as it requires human judgment about the overall quality of the output (Black and Tokuda, 2005). While speech synthesis evaluations often rate performance on a 5 point scale, we adopt a more restricted method, based on the comparison to gold standard methodology used in the previous evaluations. For each tweet and each round of ablation, a synthesized audio file was produced from both the gold standard and ablated version of the tweet. These audio snippets were randomized and presented to human judges who were asked to make a binary judgment as to whether the meaning and understandability of the ablated case was comparable to the gold standard. The accuracy of a given round of ablation is then calculated to be the percentage of tweets judged

Table 4: Text-To-Speech Synthesis Results.

to be similar to the gold standard.

The eSpeak speech synthesizer[5] was used to produce audio files for all tweet variations in the ablation study. As is common for speech synthesizers, eSpeak does perform some amount of TTS-specific normalization natively. While this does influence the normalizations produced, the comparison to gold standard methodology employed in this study helps us to focus on differences that are primarily attributable to the normalization edits we wish to examine, not those produced natively. To obtain the gold standard, two native-English speaking judges were recruited via oDesk. Inter-annotator agreement was moderate, $\kappa = 0.48$.

4.3.1 Results

Table 4 shows the results of the speech synthesis study. As shown, the removal of non-standard or out of place tokens was most critical to the production of a normalization that is clearly understandable to human listeners. The aggregate results for token removals were comparable to or better than those of replacements at all levels of the taxonomy, in contrast to the results from the other two tasks, where the larger number of replacements led to the largest performance hits. Meanwhile, word addition proved to be less essential overall.

At the token level, the importance of token removal is even more stark; the per-token error rate of every category of removal is greater than that of all other categories at the same taxonomy level. Although most word additions had a comparatively small effect on performance overall, they were important on a per-token basis. Most notably, subject adding had high per-token importance. In contrast, failing to add missing punctuation was not often marked as erroneous by human judges, nor was failing to normalize capitalization or contractions.

Similar to those on dependency parsing, the results on speech synthesis suggest that a broad approach that considers several different types of normalization edit is necessary to produce results comparable to those seen on clean text. However, at a high level there is a clear divide in importance between normalization types, where the greatest performance gains can be obtained by focusing on the comparatively small number of token removals.

5 Discussion

The results presented in Section 4 are consistent with the hypothesis that a "one size fits all" approach to Twitter normalization is problematic, as the importance of a given normalization edit was highly dependent on the intended downstream task. Differences in which edits had the most substantial effect were present at all levels of scrutiny. Adding subjects and other words that a Twitter author dropped can be vitally important if the goal is to improve parsing performance, but can mostly be ignored if the goal is NER. Removing twitter-specific or otherwise non-standard words showed a gradation of importance over the three tasks, with little importance for NER, moderate importance for parsing, and critical importance for speech synthesis. Capitalization correction had negligible impact on the parser or synthesizer, but was helpful for NER.

The importance of different edit types can be seen even at the most coarse level of examination. While normalization for speech synthesis is primarily dependent on removing unknown tokens, normalization that targets name entity recognition would be better served focusing on replacing non-standard to-

[5]Version 1.47.11, `http://espeak.sourceforge.net/`

kens with their standard forms. In contrast, parser-targeted normalization must attend to both of the tasks, as well as the task of restoring dropped tokens.

Despite the differences, there are a few common threads that appear in each evaluation. Most notably, the results suggest that the decision of most recent Twitter normalization work to focus on word replacement was not entirely without merit, as the high frequency of token replacements translated into high overall importance for all tasks. Similarly, the focus on slang was also somewhat reasonable, as failing to handle slang terms had a significant impact on parsing and speech synthesis, though it had little impact on entity recognition. Nonetheless, the results in Section 4 clearly suggest that handling these cases represent only a small fraction of the actions necessary to produce performance comparable to what would be seen on formal text.

Another similarity among all instances was the lack of importance of certain categories. For instance, punctuation addition was not important for any of the three tasks. While Zhang et al. had hypothesized that punctuation addition would be important for dependency parsing, the results given here suggest that the overall impact is minor. Similarly, contraction standardization was not shown to be important in any of the evaluations. Contraction normalization is more representative of how the normalization task was seen prior to the rise of social media normalization, as it represents a fairly minor normalizing action that might still be performed on formal text. Since contractions likely appear in a variety of forms in the data used to train NLP tools, it is unsurprising that these tools are comparatively robust to contraction differences than to cases that are less typically encountered.

6 Conclusion

In this work, we presented an in-depth look at the effects of the normalization of Twitter data. To do so, we introduced a taxonomy of normalization edits based on an examination of our Twitter dataset and inspiration from previous work. The taxonomy allowed for normalization edits to be examined systematically at different levels of granularity, and enabled an examination of the effects of not only token replacements, but the token additions and removals that recent work has suggested may have been unjustly ignored.

To understand the effects of each edit, we conducted ablation studies that examined results on three different downstream tasks: dependency parsing, named entity recognition, and text-to-speech synthesis. We found that while some normalization edits were universally important (or unimportant) for the production of accurate results, many differences persist. These results suggest that, for best results, how the normalization task is performed should not be agnostic of the downstream application. Further, our results support the suggestion that in order for downstream applications to produce accurate results, in most cases it is necessary to take a broad view of the normalization task the looks beyond simple word replacements.

Acknowledgments

The authors would like to thank Benny Kimelfeld for his comments on an early draft of this work. We also thank our anonymous reviewers for their constructive comments and feedback, and Stephanie Mcneish, Lacy Corlis, and Kaila Milos C. Factolerin for their assistance with annotation and evaluation.

Abstract

More and more of the information available on the web is dialogic, and a significant portion of it takes place in online forum conversations about current social and political topics. We aim to develop tools to summarize what these conversations are about. What are the CENTRAL PROPOSITIONS associated with different stances on an issue; what are the abstract objects under discussion that are central to a speaker's argument? How can we recognize that two CENTRAL PROPOSITIONS realize the same FACET of the argument? We hypothesize that the CENTRAL PROPOSITIONS are exactly those arguments that **people** find most salient, and use human summarization as a probe for discovering them. We describe our corpus of human summaries of opinionated dialogs, then show how we can identify similar repeated arguments, and group them into FACETS across many discussions of a topic. We define a new task, ARGUMENT FACET SIMILARITY (AFS), and show that we can predict AFS with a .54 correlation score, versus an ngram system baseline of .39 and a semantic textual similarity system baseline of .45.

1 Introduction

In the wake of the Penn TreeBank, much progress has been achieved in processing the monologic, informational language characteristic of newswire text. But an increasing share of the text data on the web is unlike newswire in a variety of ways: it is dialogic, opinionated, argumentative. And while some of these dialogs may be a little more than flame wars, a significant portion involve contentful, reasoned disputes on important social and political topics, as exemplified by the forum snippets in Figs. 1 and 3. Studying data like this will undoubtedly help us to understand dialogic and informal argumentative language in general. And, indeed, previous work (Abbott et al., 2011; Somasundaran and Wiebe, 2010) has examined the structure of these discussions – e.g., the argumentative discourse relation a post bears to its parent (agreeing or disagreeing), or the stance that a person takes on an issue.

PostID:Turn
S1:1 Agreed She is ignoring my religious freedom and trying to institute her religion into law. **The law that will bar my family from legal protections. It won't protect her marriage but will bar me and my people from from being full citizens**. She isn't protecting marriage but perserving her heterosexual privledge.
S2:1 How on earth is she impeding on you religious freedom? She isn't trying to take away your right to any religious ceremony. With such a wide-open standard of what constitutes religious freedom that you seem to have, any legislation could be construed as imposing on religious freedom.
S1:2 Because it is her religious belief that marriage is between a man and a woman. **My religious belief is that marriage is between two people that love each other regardless of sex**. She is tying to place her religious belif into law over mine. Who gets hurt here? If my religious belief is put into law she can still marry the person of her choice. If her religious belief gets put into law she can still marry the person of her choice but I do not get to. So I and my people are hurt by codifing her religious belief into law. She is trying to keep gay people out of marriage and thus preserve her heterosexual privledge.
S2:2 But by that definition, either one could be viewed as impeding on religious freedom, including your view impeding on hers ! We don't define imposing on religious freedom on the basis of having different ideals. **It doesn't effect your religion or religious freedom if you don't get benefits under gay marriages**. You can argue in other ways, on other basis, but the idea that not giving gays marriage benefits is imposing on religious freedom is an empty " argument ".

Figure 1: Gay Marriage Dialog-1.

Our goal here is to develop techniques to recognize the specific arguments and counterarguments people tend to advance, and group them across discussions into the FACETS on which that issue is ar-

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 430–440,
Denver, Colorado, May 31 – June 5, 2015.

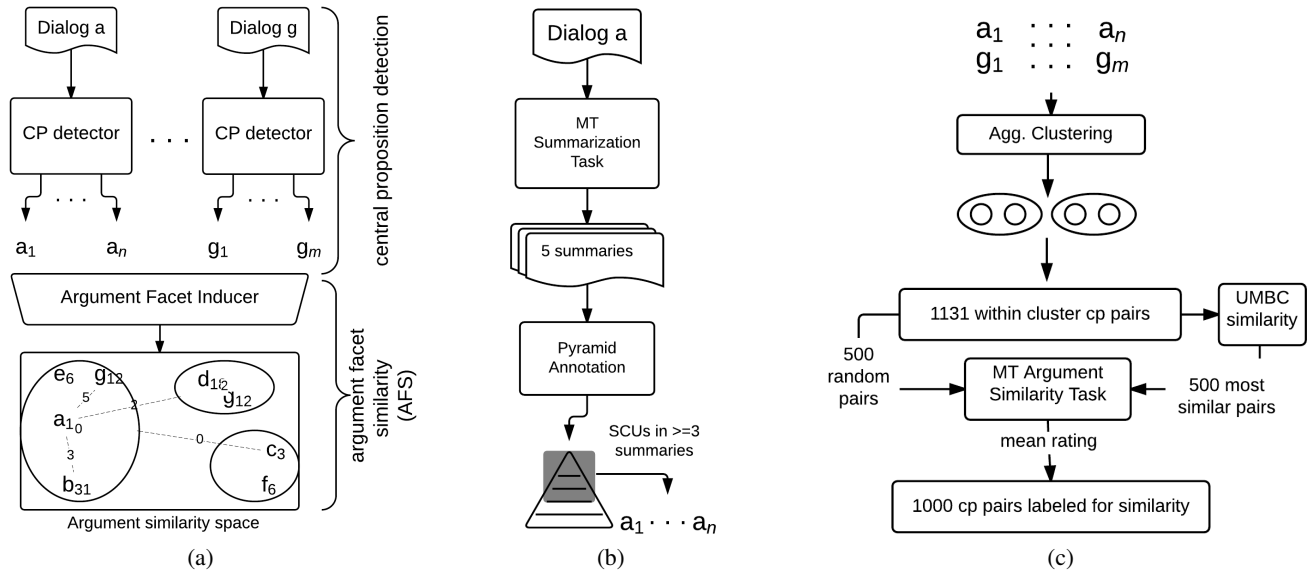

Figure 2: The overall engineering architecture of our approach. (a) Basic engineering approach for extracting CENTRAL PROPOSITIONS and clustering them into argument FACETS across several dialogs; (b) Workflow for 'detecting' central propositions via pyramid evaluation of multiple summaries; (c) Workflow for obtaining gold-standard labels for AFS task.

gued across the population at large. Recognizing the FACETS of an argument automatically entails at least two subtasks, as schematized in Fig. 2a.

PostID:Turn
S1:1 Certainly not yours. You should know that I am for no marriage in government. It should be left to a religious institution where it will actually mean something. The states should then go back to doing something that actually makes sense and doesn't reward people like Britney Spears for being white trash.
S2:1 That is all well and good, but it is not the religious ceremony and sanction that gays are looking for. They already have that; there are churches that perform same-sex marriages. **It is the civil benefits that are at issue. Are you saying you would be in favor of foregoing ALL the legal rights and benefits you are afforded by marriage? For example: *Assumption of Spouse's Pension *Automatic Inheritance *Automatic Housing Lease Transfer *Bereavement Leave....** What do you say?
S1:2 yeah I know. I'm saying that there should be a better system. For example, if you had a best friend who you are roommates with... both hetero for the sake of argument... and never wish to get married then **could they get some of the benefits you described**?

Figure 3: Gay Marriage Dialog-2.

First, there must be a system, the CENTRAL PROPOSITION detector, that can extract the most essential arguments in a particular conversation. Example CENTRAL PROPOSITIONS in Figs. 1 and 3 are provided in bold. Second, there must be another system, the ARGUMENT FACET inducer, that relates these conversation-specific arguments to each other in terms of FACETS, e.g. that identifies the two specific central propositions in Figs. 1 and 3 about "legal protections" and "civil benefits" as the same (abstract) FACET, namely that same-sex marriage is about getting the civil rights benefits of marriage.

We first focus on the question of extracting reliable data for central propositions. See Fig. 2b. We propose that the CENTRAL PROPOSITIONS of a dialog are exactly those arguments that **people** find most salient, which is naturally reflected by their summarization behavior. We then apply the Pyramid method, by which the CENTRAL PROPOSITIONS bubble up to the highest tiers of the pyramid, thereby allowing us to identify them. With the central propositions in hand, we proceed to build the argument facet inducer. We introduce a new task of ARGUMENT FACET SIMILARITY (**AFS**). We discuss how AFS is similar to, but different than SEMANTIC TEXTUAL SIMILARITY (**STS**) (Agirre et al., 2012; Jurgens et al., 2014; Agirre et al., 2013; Beltagy et al., 2014; Han et al., 2013).

Sec. 2 provides a more detailed overview and description of our method, and the data that it produces. Sec. 3 describes our experimental setup for the **AFS** task and then presents our results. We describe a learning approach that achieves correlations of .54 on the **AFS** task, as compared to a baseline correlation of .45 using off-the-shelf modules that

are competitive in **STS** tasks. We delay a detailed discussion of related work to Sec. 4 when we can compare it to our own approach. Sec. 5 summarizes the paper and discusses future work.

2 Experimental Method

Fig. 2 summarizes our overall method for producing the summary corpus and then extracting arguments and clustering them into FACETS. Our method consists of the following steps:

S1: Dialog Selection.

S2: MT summarization of dialogs selected in S1.

S3: Pyramid annotation of summaries produced by S2 and selection of top-tier pyramid labels as CENTRAL PROPOSITIONS for individual dialogs.

S4: Clustering of CENTRAL PROPOSITIONS from S3.

S5: MT ARGUMENT FACET SIMILARITY task, using clusters from S4.

S6: Train and test a predictor for ARGUMENT FACET SIMILARITY (Sec. 3).

We explain these steps in more detail below.

S1: Dialog Selection. We use the publicly available Internet Argument Corpus (IAC) (Walker et al., 2012). We use the links in the meta-data to extract a sequence of turns to build two-party dialog chains like those in Figs. 1 and 3. We extracted 85 dialogs for the topic gay marriage from an original corpus of 1292 discussion threads using these criteria:

- **Number of turns per contributor**: We want dialogs in which substantive issues were discussed, so we extract dialogs with at least 3 turns per conversant that present at least 2 different perspectives on an issue.
- **Author**: Some authors post frequently and would dominate the corpus if we use random selection. To get richer, more diverse dialogs expressing different perspectives, we only select a single dialog between any particular pair of authors from a discussion thread.
- **Word Count in a post**: Some posts are long. To make it practical to collect dialog summaries, we extract dialogs where the number of words per turn is less than 250.

S2: MT Summarization Task. The summarization task was run on Mechanical Turk. To get good quality summaries, workers completed a qualification test involving summarizing a sample dialog. Workers were instructed to summarize according to dialog length: dialogs under 750 words in 125 words, and those above 750 in 175 words. We use 45 dialogs in this study and save the other 40 for future work. We collect 5 summaries for each dialog resulting in a dataset of 225 summaries. Fig. 4 provides 2 of the 5 summaries collected for the dialog in Fig. 3.

S1 thinks that the government should stay out of marriage and that it should be left to religious institutions. He thinks there needs to be a better system and that single people are the ones that are harmed the most by marriage laws because they are unable to get any of the benefits that married people do even if they want them, or it is important to their situation. S2 says religious ceremonies aren't what gay people want because they already can have them via churches. They want the rights and to keep the government out would be to give up those rights. If single people want those rights they should get married, but he thinks you should be free to marry who you wish.
The issue here is whether government or religion should decides the principles of marriage, and who is allowed to get married. Speaker one believes that leaving it up to religions groups does not satisfy what gays are looking for. They are searching for the civil benefits that come with a marriage and would like to be treated equally in that respect. The speaker believes gay should be able to marry a person of their choice and get equal rights. Speaker two opinions that there should indeed be a better system for marriage benefits and that it is all "single" people that get screwed over by marriage's current stature. Speaker two believes that gay people should marry a woman if they want the same rights.

Figure 4: Two of the 5 Summaries for Dialog-2.

S3: Pyramid Annotation. We trained three undergraduates to annotate summaries to produce pyramids. We hypothesize that we can use the Pyramid method to induce the FACETS of a topic across a set of dialogs (Nenkova and Passonneau, 2004). The annotation of Pyramids seeks to uncover the common elements, or summary content units (SCUs), across several summaries (in our case, 5). Each SCU identifies a set of spans that are semantically equivalent. Each SCU also has a unique annotator-generated label that reflects the semantic meaning of the contributions. Because our aim here is to focus on argument propositional content, the annotators

were instructed to keep only the main proposition in the SCU as the label, ignoring any attributions or other types of content. See Table 1. Once annotation is complete, the SCUs are ranked based on their frequency across all of the summaries, as shown by the Tier in Fig. 5, which includes data from the two summaries in Fig. 4.

Contributor	S1 points to the trend to legalize gay marriage in western countries such as Netherlands, Belgium, and most of Canada
Contributor	S1 refutes this assertion, citing a number of countries which recognize same-sex marriage.
Contributor	He states the US is more similar to Anglo nations and in many of those gay marriage is legal.
Label	A number of countries recognize same-sex marriage.

Table 1: A sample label after removing the attributions from the SCU contributors.

S4: SCUs to clusters. The pyramid structure directly reflects the content that the annotators deem most important in the original dialog. We are interested in the content that bubbles to the top across all the dialogs. We take the Tier 3 and above SCUs as our CENTRAL PROPOSITIONS, and extract the labels of those SCUs. This gives a total of 329 SCU labels. In what follows we treat a cluster of CENTRAL PROPOSITIONS as a FACET label, just as a synset concept in WordNet is labeled by its members.

The purpose of AFS, then, is to provide a similarity metric on these SCU labels. As described below (and sketched in Fig. 2c), we used Mechanical Turk to provide similarity scores between pairs of SCU central propositions. Although, in principle, we could have asked about all possible pairs of the 329 CENTRAL PROPOSITIONS, most pairs are likely to be unrelated, and so we used an initial clustering algorithm to help reduce the work and cost.

To group similar arguments, we performed clustering across our 329 labels. We performed Agglomerative Clustering using Scikit-learn (Agg Clustering in Fig. 2c). (Pedregosa et al., 2011). It recursively merges the pair of clusters that minimally increases a given linkage distance. We used cosine similarity as the distance measure with average linkage criteria. To focus on topic-specific cues, the clustering was performed using only nouns, verbs and adjectives. After generating all pairwise combinations within a cluster, this approach yielded 1131 argument pairs used in the Mechanical Turk AFS task. See Fig. 2c.

Instructions
We would like you to classify each of the following sets of pairs based on your perception of how SIMILAR the arguments are, on the following scale, examples follow.
(5) Completely equivalent, mean pretty much exactly the same thing, using different words.
(4) Mostly equivalent, but some unimportant details differ. One argument may be more specific than another or include a relatively unimportant extra fact.
(3) Roughly equivalent, but some important information differs or is missing. This includes cases where the argument is about the same FACET but the authors have different stances on that facet.
(2) Not equivalent, but share some details. For example, talking about the same entities but making different arguments (different facets)
(1) Not equivalent, but are on same topic
(0) On a different topic

Facet: A facet is a low level issue that often reoccurs in many arguments in support of the author's stance or in attacking the other author's position. There are many ways to argue for your stance on a topic. For example, in a discussion about the death penalty you may argue in favor of it by claiming that it deters crime. Alternatively, you may argue in favor of the death penalty because it gives victims of the crimes closure. On the other hand you may argue against the death penalty because some innocent people will be wrongfully executed or because it is a cruel and unusual punishment. Each of these specific points is a facet.
For two utterances to be about the same facet, it is not necessary that the authors have the same belief toward the facet. For example, one author may believe that the death penalty is a cruel and unusual punishment while the other one attacks that position. However, in order to attack that position they must be discussing the same facet.

Figure 6: Instructions for AFS MT HIT.

S5: MT Argument Facet Similarity HIT. Fig. 6 shows the instructions defining AFS for the MT HIT. Inspired by the scale used for STS, we collected annotations on a 6 point scale. One crucial difference in our formulation was a desire to capture similarity in FACET and argument simultaneously. The use of the value 3 for 'same FACET, contradictory stance' was a well-thought decision in the definition of AFS.

SCU Label	Used by summarizer?					Tier
	1	2	3	4	5	
Gay couples are interested in the rights and benefits associated with marriage.	✓	✓	✓	✓	✓	5
Gay people should be able to marry a person of their choice and get equal rights.	✓	✓	✓	✓	✓	5
Government should not be involved in marriage and marriage should be left to religious institutions.	✓	✓	✓	✓	✓	5
Discussion on the civil benefits of marriage and the rights of marriage.	✓		✓	✓	✓	4
Gay couples are unable to get any benefits that married people do.	✓	✓		✓	✓	4
There should be a better system for marriage benefits.		✓	✓	✓	✓	4
Religious ceremonies are not what gay people want.		✓		✓	✓	3
Single people are the ones that are harmed the most by marriage laws.	✓	✓	✓			3
Gay people should marry the opposite sex if they want the same rights.			✓	✓		2
Gays have religious ceremonies already can have them via churches		✓				1
Relation to the issues by consideration of the case of a life-long bachelor uncle	✓					1

Figure 5: Pyramid for Dialog-2. SCU labels in Tiers 3-5 are assumed to be the CENTRAL PROPOSITIONS.

Just as two words can only be antonyms if they are in the same semantic field, two arguments can only be contradictory if they are about the same FACET. Thus, we instruct annotators to give a score of 3 to opposing arguments on the same FACET.

The task was put on Mechanical Turk using two separate batches. For the first batch we randomly selected 500 pairs from our pairs dataset of 1131 pairs. However, our subsequent impression was that the clustering had not filtered out enough of the unrelated pairs (score 0-1). For the second batch we selected the top 500 pairs according to the UMBC similarity score (Han et al., 2013). This gave us a final pair dataset of 1000 pairs. Since AFS is a novel and subjective task, workers took a qualification test. Then each pair was annotated by 5 workers, and one of the authors provided gold standard labels. The HIT allowed 5 AFS judgements per hit, thus the number of pairs annotated by a worker varies from 5 to 1000.

To increase reliability, we removed the annotations from those workers who had attempted less than 4 hits (20 pairs) and had the lowest pairwise correlations with our gold standard annotation. Our final AFS score was the average score across all the annotators. The final AFS score correlated at .7 with our gold standard annotation, showing that the AFS similarity task is well-defined, and understandable by minimally trained annotators on MT. Table 4 provides typical examples of argument pairs and their MT AFS score, along with the predicted scores from some of our models. We discuss the AFS values and interesting cases in Sec. 3 below.

3 Machine Learning Experiments and Results

Given the data collected above, we defined a supervised machine learning experiment with AFS as our dependent variable and different collections of features inspired from previous work as our independent variables.

3.1 Features

NGRAM overlap. This is our primary baseline. For each argument, we extracted all the unigrams, bigrams and trigrams, and then counted how many were in overlap across the two arguments. For unigrams we did not include stop words. Stemmed Ngrams were used to get better overlap.

UMBC. This is our secondary baseline. This feature is the Semantic Textual Similarity obtained using UMBC Semantic Similarity tool (Han et al., 2013)

DISCO Distributionally Similar Category. We used the distributional similarity tool DISCO with the pre-computed English Wikipedia word space (Kolb, 2008). We extract the top 5 distributionally similar nouns, verbs, and adjectives for each argument. For each argument pair, three vector pairs (over nouns, verbs, and adjectives) are created with this extended vocabulary. Stemming was performed and cosine similarity between these vector pairs was calculated.

LIWC Category. This feature set is based on the Linguistics Inquiry Word Count tool (Pennebaker et al., 2001). To tune these features, we first used a set of gay marriage posts from websites such as CreateDebate and ConvinceMe to extract relevant LIWC

categories. We supplemented this data with gay marriage posts from 4forums, but excluded the discussion threads in our dialog corpus. From this data, we extracted the LIWC categories most frequent nouns, verbs and adjectives. For the verbs category, we excluded the verbs present in the NLTK stop word list. We retained only semantically rich categories such as Biological Processes, Causation, Cognitive Processes, Humans, Negative Emotion, Positive Emotion, Religion, Sexual, and Social Processes. The score for this set was the LIWC category overlap count across pairs for each category.

ROUGE Scores. ROUGE is a family of metrics to determine the quality of a summary by comparing it to other ideal summaries (Lin, 2004). It is based on a number of overlapping units such as n-gram, word sequences, and word pairs. This feature includes all of the rouge f-scores available via the package at https://pypi.python.org/pypi/pyrouge/0.1.0.

3.2 Results

Our aim is to predict the similarity among repeated arguments across many discussions in online social and political debate forums, a task we have dubbed ARGUMENT FACET SIMILARITY (**AFS**). Given the CENTRAL PROPOSITIONS from the CP detector (see Fig. 2a), we need to train an argument FACET inducer. We define AFS as a regression problem and evaluate support vector regression and linear regression for 10-fold cross validation using the Weka machine learning toolkit (Hall et al., 2005).

Classifier	RMS	MAE	R
SMO	1.0208	0.8019	0.532
Linear Regression	0.9996	0.8003	0.540

Table 2: Support Vector and Linear Regression. RMS: Root Mean Squared Error, MAE: Mean Absolute Error, R: Correlation Coefficient.

Table 2 shows that the results for support vector regression are worse than the linear regression model using our proposed features combined with UMBC, hence we focus hereon on linear regression. Table 3 provides the correlations, MAE, and RMS values for models produced using various sets of features. We considered two baselines, simple Ngram overlap and the off-the-shelf UMBC STS metric (Han et al., 2013). In general, we found that Ngram overlap (Row 1) performed best alone of our features, but falls short of the UMBC baseline (Row 2). It is interesting that Ngram alone outperforms distributional measures (which Conrad & Wiebe found most helpful) as well as Rouge (which contains metrics insensitive to linear adjacency).

Row	Feature Set	R	MAE	RMS
1	**NGRAM (N)**	0.39	0.90	1.09
2	**UMBC (U)**	0.46	0.86	1.06
3	**LIWC (L)**	0.32	0.92	1.13
4	**DISCO (D)**	0.33	0.93	1.12
5	**ROUGE (R)**	0.34	0.91	1.12
6	**N-U**	0.47	0.85	1.05
7	**N-L**	0.45	0.86	1.06
8	**N-R**	0.42	0.88	1.08
9	**N-D**	0.41	0.89	1.08
10	**U-R**	0.48	0.84	1.04
11	**U-L**	0.51	0.83	1.02
12	**U-D**	0.45	0.86	1.06
13	**N-L-R**	0.48	0.84	1.04
14	**U-L-R**	0.53	0.81	1.00
15	**N-L-R-D**	0.50	0.83	1.03
16	**N-L-R-U**	0.54	0.80	1.00
17	**N-L-R-D-U**	0.54	0.80	1.00

Table 3: Results for Different Individual Features and Feature Combinations.

Table 3, Row 15, shows that the best correlation that is achievable without UMBC is the combination of Ngram, LIWC, ROUGE and DISCO (NLRD). This combination significantly improves over the UMBC baseline of 0.46 to 0.50 (paired t-test, $p < .05$).

We then tested combinations of of features to determine which feature sets are complementary. LIWC + NGRAM is significantly different than NGRAM alone ($p < 0.01$), and ROUGE + NGRAM is significantly different than NGRAM alone ($p = 0.03$), but DISCO does not add anything ($p = 0.2$). This shows that LIWC and ROUGE features complement Ngram features. Other combinations of interest are NGRAM + LIWC (Row 7) which amazingly performs as well as UMBC while UMBC includes sentence alignment, a model of negation, and distributional measures (Han et al., 2013). This suggests that AFS is clearly a different task that STS. Additionally we also combined our proposed set of features with UMBC. A comparison of Row 15 (our feature set) with Rows 16 and 17 of Table 3 where we combine our features with UMBC shows that this improves the correlation further, from the UMBC baseline of 0.46 to 0.54 ($p < 0.01$.)

Row	N	L	U	NLRD	NLRDU	MT AFS	Arg1	Arg2
1	1.38	1.50	**0.37**	1.31	0.40	0.00	**everyone has the freedom of speech**	**service in the military**
2	2.00	2.02	**1.55**	2.33	1.86	1.14	**gay people should be able to marry a person of their choice and get equal rights**	**referring to namecalling and violence from the original post that was opposing gay rights**
3	2.00	1.29	2.52	**1.37**	1.54	1.33	Constitutional right to be opposed to gay marriage as well as gay people themselves	arguing about marriage benefits between single people and married
4	2.00	1.70	2.74	**1.77**	1.98	1.80	people should not pick and choose what they want equal rights on.	people did not want gay marriage
5	1.38	1.92	0.88	**1.94**	1.64	2.50	the Republicans creating another Holocaust	No republican in leadership would call for the extermination of gays
6	1.69	2.02	**2.58**	1.89	2.49	2.60	**homosexuals have all the same rights as heterosexuals**	**Opposition to equal rights for gay couples.**
7	1.83	2.40	1.46	**2.81**	2.51	3.00	There was prejudice against gays in 1909 just as there is now	it is prejudice as opposed to religious or moral beliefs which fuel the anti-gay agenda;
8	2.00	1.70	**3.16**	1.73	2.41	3.40	**homosexual relationships should not compare to heterosexual marriages because only heterosexuals are legally allowed to marry**	**marriage should be between a heterosexual couple**
9	2.00	2.70	2.09	2.83	**3.03**	3.50	it is prejudice as opposed to religious or moral beliefs which fuel the anti-gay agenda;	when people claim religion in doing prejudice they are actually abandoning their morals
10	**2.94**	2.02	2.93	2.18	2.70	3.50	**gay people should be able to marry a person of their choice and get equal rights.**	**Gay couples are unable to get any benefits that married people do.**
11	2.14	1.50	**2.91**	2.08	2.62	3.60	**Paul Cameron is the voice of the Republicans**	**Conversation about Paul Cameron**
12	2.63	3.63	2.60	**3.75**	3.57	4.17	in opening this opportunity for gay marriage, the definition of marriage will change	opponents of homosexual marriage tend to argue that a change to marriage law would make it too open ended
13	**4.23**	2.72	2.26	4.82	4.12	4.50	AIDs was initially spread in the United States primarily by homosexuals.	No one argues the point that AIDs was spread in the United States by homosexuals.

Table 4: Predicted Scores for each model and the Mechanical Turk AFS gold standard for selected argument pairs from the pairs dataset. Best performing model for each pair is shown in **bold**. The table is sorted by the AFS score (gold standard). The argument pairs shown in **bold** are cases where UMBC by itself beats our proposed model. KEY: Feature sets model. N = NGRAM, U = UMBC STS tool, L = Linguistic Inquiry and Word Count; R = Rouge, D = DISCO, AFS= Mean of Mechanical Turker AFS scores, our gold standard. For example, NLRD means a combination of NGRAM, LIWC, ROUGE and DISCO.

It is also interesting to examine the differences in model scores for particular argument pairs as shown in Table 4. The best performing model for each row is in **bold** in Table 4. As described in the HIT instructions in Fig. 6, values of AFS near 0 (Row 1) indicate different topics and no similarity. Values near 1 indicate same topic but different arguments (Rows 2,3). Values of 3 and above indicate same FACET (Rows 7,8), and values near 5 are same facet and very similar argument (Rows 12 and 13). Both Arg1 and Arg2 in Row 10 makes the same argument but Arg1 includes additional argumentation. In Row 12, there is very low Ngram overlap, but strong AFS and NLRD performs better than the other models, and LIWC performs well by itself.

In Row 1, UMBC performs the best with a predicted score of 0.37 as opposed to an AFS score of 0.00. Other rows where UMBC on its own provides the best performance are highlighted in the table with Arg1 and Arg2 in **bold**. The top performance of NLRD in Row 5 without UMBC perhaps arises from the semantic information that extermination and holocau are somehow related. NGRAM overlap does the best in Row 13 despite the fact that the phrase *No one argues the point that* does not participate in the NGRAM overlap.

4 Related Work

Our approach draws on three different strands of related work: (1) argument mining; (2) semantic textual similarity; and (3) dialog summarization, which we discuss and compare with our work below.

Argument Mining. The study of the structure of arguments has a long tradition in logic, rhetoric and psychology (Walton et al., 2008; Reed and Rowe, 2004; Walton, 2009; Gilbert, 1997; Jackson and Jacobs, 1980; Madnani et al., 2012). Much of this work has been on formal (legal or political) argumentation, and the small computational literature that has applied the rhetorical categories of this research has likewise focused on formal, monologic text (Feng and Hirst, 2011; Palau and Moens, 2009; Goudas et al., 2014). More recent work (Ghosh et al., 2014) has attempted to apply these theories to dialogic text in online forums. Ghosh et al. label spans in conversations with attacking moves (CALLOUTS) and their corresponding argumentative TARGETS in another speaker's utterance, and they attempt to learn these callout-target pairs in a supervised framework. Other work attempts to identify general categories of speech-acts such as disagreements or justifications (Misra and Walker, 2015; Biran and Rambow, 2011).

What unites all of the above approaches is an interest in understanding the detailed rheotrical structure of a particular linguistic interaction (monologic or dialogic). Our present work is focused instead on inducing the recurring FACETS in a particular topic domain via weakly supervised learning over several dialogic interactions. Several different threads of recent research on argument mining have strong parallels with this goal (Conrad et al., 2012; Boltuzic and Šnajder, 2014; Hasan and Ng, 2014).

Conrad & Wiebe construct an argument mining system on monologic weblog and news data about universal healthcare. One component of their system identifies ARGUING SEGMENTS and the second component labels the segments with the relevant stance-specific ARGUMENT TAGS. They show that distributional similarity features help identify arguments that belong to the same tag set (notably, we did not find distributional similarity helpful for **AFS**.) Boltuzic & Snajder pursue argument mining on comment streams. Instead of hand-generating argument tags like Conrad & Wiebe, they select short sentential summaries of the key arguments for a given topic from a debate website, and then label comments on the same topic from a different website with the most closely matching summary. The same problem on debate posts is tackled as a "reason classification" problem (Hasan and Ng, 2014), with a probabilistic framework for argument recognition (reason classification) that operates jointly with the related task of stance classification.

All of these approaches differ from ours in three respects. First, they all assume a finite set of topic-specific labels that are determined in some form by the researchers themselves. In contrast, we seek to uncover popular facets via clustering the central propositions across the dialogs. After our own initial categorical efforts, we feel that the argument "topics" have such nuance that they resist clear labels or category membership. Instead, we feel that a scale such as AFS is a better fit, both for the diversity of the data itself and for the idea of inducing FACETS bottom up. Second, these approaches assume the labels are dependent on a particular *stance* towards an issue, whereas our facets are deliberately designed to unify across stance disagreement. Finally, all other approaches in argument mining work from the source text itself. We instead (to our knowledge, for the first time) work from human summaries of dialogs because it is an open question whether the CENTRAL PROPOSITIONS for a dialog are really identifiable as continuous spans of text in the dialog itself. (Indeed, our corpus will allow us to determine how true that assumption is.)

Semantic Textual Similarity. There appears to be similarity between FACET induction and aspect learning in sentiment analysis (Brody and Elhadad, 2010), but FACETS are propositional abstract objects, while aspects can usually be described as nouns or properties. Facet induction is more similar to work on **STS** (Mihalcea et al., 2006; Yeh et al., 2009; Agirre et al., 2012; Han et al., 2013; Jurgens et al., 2014). Calculating similarity is a central aspect of AFS. Our scale and MT task for AFS was inspired by the STS task and definition. In addition, as a baseline we apply an off-the-shelf system that calculates STS (UMBC) and compare it with our own system (Han et al., 2013). In order to avoid asking for judgements for many unrelated arguments (CENTRAL PROPOSITIONS), and to make the AFS task more doable for Turkers, we also use UMBC as a filter on pairs of CENTRAL PROPOSITIONS as part of making our HIT. This biases the distribution of

the training set to having a much larger set of more similar pairs, which has been a problem for previous work (Boltuzic and Šnajder, 2014), where the vast majority of pairs that were labelled were unrelated. However the AFS task is clearly different than STS, partly because the data is dialogic and partly because it is argumentative. Our results show that we can improve on STS systems for the AFS task.

Dialog Summarization. Much previous work on dialog summarization focused on extracting phenomena specific to meetings, such as action items or decisions (Murray et al., 2006; Hsueh and Moore, 2008; Whittaker et al., 2012; Janin et al., 2004; Carletta, 2007). Other approaches, like our work, use semantic similarity metrics to identify the most central or important utterances of a spoken dialog (Gurevych and Strube, 2004), but do not attempt to find the FACETS of a set of arguments across multiple dialogs. Another parallel may exist between work on nuclearity in RST and its use in summarization (Marcu, 1999). However our notion of a CENTRAL PROPOSITION is different than nuclearity in RST, since FACETS are derived from CENTRAL PROPOSITIONS that rise to the top of the pyramid across summarizers, and then (via AFS) across many dialogs on a topic, while RST nuclearity is only defined for a span of text by a single speaker.

Other work examines how social phenomena affect summarization, such as a study of how the politeness level in computer-generated dialogs impacted summaries (Roman et al., 2006). Emotion naturally occurs in the IAC, and summarizers' orientation to emotion is intriguing. Emotional information has been observed even in summaries of professional chats discussing technology (Zhou and Hovy, 2005). However the instructions to our Pyramid annotators were to not include information of this type in the pyramids. We are currently collecting an additional summary corpus using a method that we expect to result in more evaluative and emotional assessments in summaries.

5 Conclusion

This paper presents a method and results for extracting FACETS of a topic, across multiple informal arguments on the same topic. We first use human summarization of dialogs as a probe to determine the CENTRAL PROPOSITIONS of each dialog. Then we use clustering in combination with measures of SEMANTIC SIMILARITY to group the CENTRAL PROPOSITIONS into the important FACETS of an argument across many different dialogs. Importantly, we **do not** attempt to enumerate the possible FACETS for an argument in advance, believing that bottom-up discovery of FACETS is a better fit to the problem.

This paper contributes to the current state of knowledge in three ways: (1) we collected summaries of spontaneously-produced written dialog of high social and political importance (available from `http://nlds.soe.ucsc.edu/summarycorpus`). (2) we proposed a novel application of the pyramid summarization scheme to the task of FACET induction; and (3) we introduce a new task of ARGUMENT FACET SIMILARITY (**AFS**) aimed at identifying FACETS across opinionated dialogs and show that we can identify AFS with a correlation of .54 as opposed to a baseline of .46 provided by a system designed for a similar task. We suspect that the summarize-and-collate approach used here could be promisingly applied to produce annotations on a range of subjective, holistic properties of dialog.

In future work, we aim to expand on this work in several ways. First, we hope to expand summaries, similarity judgments, and systems to several topics beyond gay marriage. We believe, for example, that the features and the system we have trained for AFS will apply to other domains without retraining, since none of the features are topic specific, but we have not shown that. In addition, we aim to develop additional features and improve on the results reported here. For example, we believe that it is possible that other off-the-shelf systems, such as for example one for sentence specificity (Louis and Nenkova, 2011; Louis and Nenkova, 2012), might possibly help with aspects of this task. In addition, in future, we aim to automatically identify CENTRAL PROPOSITIONS without the mediation of human summarizers and evaluators. Given the summaries that we have collected for each dialog, we plan to examine the relationship between the contributors to the related pyramid and the original source text, to determine whether indeed there are surface features of the source that would allow us to treat CENTRAL PROPOSITION detection as an extractive task.

Acknowledgments This work was funded by NSF GRANT IIS-1302668, Grant NPS-BAA-03, and an IARPA Grant on Persuasion in Dialogue to UCSC by subcontract from the University of Maryland.

Abstract

We present a simple and yet effective approach that can incorporate rationales elicited from annotators into the training of any off-the-shelf classifier. We show that our simple approach is effective for multinomial naïve Bayes, logistic regression, and support vector machines. We additionally present an active learning method tailored specifically for the learning with rationales framework.

1 Introduction

Annotating documents for supervised learning is a tedious, laborious, and time consuming task for humans. Given huge amounts of unlabeled documents, it is impractical for annotators to go over each document and provide a label. To reduce the annotation time and effort, various approaches such as semi-supervised learning (Chapelle et al., 2006) that utilizes both labeled and unlabeled data, and active learning (Settles, 2012) that carefully chooses instances for annotation have been developed. To further minimize the human effort, recent work looked at eliciting domain knowledge, such as rationales and feature annotations, from the annotators instead of just the labels of documents.

One of the bottlenecks in eliciting domain knowledge from annotators is that the traditional supervised learning approaches cannot readily handle the elicited rich feedback. To address this issue, many methods have been developed that are classifier-specific. Examples include knowledge-based neural networks (e.g., (Towell and Shavlik, 1994), (Girosi and Chan, 1995), (Towell et al., 1990)), knowledge-based support vector machines (Fung et al., 2002), pooling multinomial naïve Bayes (Melville and Sindhwani, 2009), incorporating constraints into the training of naïve Bayes (Stumpf et al., 2007), and converting rationales and feature annotations into constraints for support vector machines (e.g., (Small et al., 2011) and (Zaidan et al., 2007)). Being classifier-specific limits their applicability when one wants to test a different classifier for his/her domain, necessitating an approach that can be utilized by several off-the-shelf classifiers.

In this paper we present a simple and yet effective approach that can incorporate the elicited rationales in the form of feature annotations into the training of any off-the-shelf classifier. We empirically show that it is effective at incorporating rationales into the learning of naïve Bayes, logistic regression, and support vector machines using four text categorization datasets. We further discuss a novel active learning strategy specifically geared towards the learning with rationales framework and empirically show that it improves over traditional active learning.

The rest of the paper is organized as follows. In Section 2, we provide a brief background on eliciting rationales in the context of active learning. In Section 3, we describe our approach for incorporating rationales into the training of classifiers and compare learning without rationales and learning with rationales. In Section 4, we present an active learning method using the learning with rationales framework and present relevant results. Finally, we discuss limitations and future work in Section 5, related work in Section 6, and conclude in Section 7.

2 Background

In this section, we provide a brief background on data annotation with rationales in the context of active learning and introduce the notation to be used throughout the paper.

Let $\mathcal{D}$ be a set of document-label pairs $\langle x, y\rangle$, where the label (value of y) is known only for a small subset $\mathcal{L} \subset \mathcal{D}$ of the documents: $\mathcal{L} = \{\langle x, y\rangle\}$ and the rest $\mathcal{U} = \mathcal{D} \setminus \mathcal{L}$ consists of the unlabeled documents: $\mathcal{U} = \{\langle x, ?\rangle\}$. We assume that each document x^i is represented as a vector of features (most commonly as a bag-of-words model with a dictionary of predefined set of phrases, which can be unigrams, bigrams, etc.): $x^i \triangleq \{f_1^i, f_2^i, \cdots, f_n^i\}$. Each feature f_j^i represents the binary presence (or absence), frequency, or tf-idf representation of the word/phrase j in document x^i. Each label $y \in \mathcal{Y}$ is discrete-valued variable $\mathcal{Y} \triangleq \{y_1, y_2, \cdots, y_l\}$.

Typical greedy active learning algorithms iteratively select a document $\langle x, ?\rangle \in \mathcal{U}$, query a labeler for its label y, and incorporate the new document $\langle x, y\rangle$ into its training set $\mathcal{L}$. This process continues until a stopping criterion is met, usually until a given budget, B, is exhausted.

In the learning with rationales framework, in addition to querying for label y^i of a document x^i, the active learner asks the labeler to provide a rationale, $R(x^i)$ for the chosen label. The rationale in its most general form consists of a subset of the terms that are present in x^i: $R(x^i) = \{f_k^i : j \in x^i\}$. Note that there might be cases where the labeler cannot pinpoint any phrase as a rationale, in which case $R(x^i)$ is allowed to be ϕ. Algorithm 1 formally describes the active learning process that elicits rationales from the labeler.

The goal of eliciting rationales is to improve the learning efficiency by incorporating domain knowledge. However, it is not trivial to integrate domain knowledge into state-of-the-art classifiers, such as logistic regression and support vector machines.

Next, we describe our approach for incorporating rationales into the learning process.

3 Learning with Rationales

In this section we first provide the formulation of our approach to incorporate rationales into learning and then present the results to compare *learning without rationales* (Lw/oR) and *learning with rationales* (LwR) on four datasets. We evaluate our approach using multinomial naïve Bayes, logistic regression, and support vector machines classifiers.

Algorithm 1 Active Learning with Rationales

1: **Input:** $\mathcal{U}$ - unlabeled documents, $\mathcal{L}$ - labeled documents, θ - underlying classification model, B - budget
2: **repeat**
3: $x^* = \underset{x \in \mathcal{U}}{\operatorname{argmax}}\, utility(x|\theta)$
4: request label and rationale for this label
5: $\mathcal{L} \leftarrow \mathcal{L} \cup \{\langle x^*, y^*, R(x^*)\rangle\}$
6: $\mathcal{U} \leftarrow \mathcal{U} \setminus \{\langle x^*\rangle\}$
7: Train θ on $\mathcal{L}$
8: **until** Budget B is exhausted; e.g., $|\mathcal{L}| = B$

3.1 Training a Classifier Using Labels and Rationales

Like most previous work, we assume that the rationales, i.e. the phrases, returned by the labeler already exist in the dictionary of the vectorizer. Hence, rationales correspond to features in our vector representation. It is possible that the labeler returns a phrase that is currently not in the dictionary; for example, the labeler might return a phrase that consists of three words whereas the representation has single words and bi-grams only. In that case, the representation can be enriched by creating and adding a new feature that represents the phrase returned by the labeler.

Our simple approach works as follows: we modify the features of the annotated document $\langle x^*, y^*, R(x^*)\rangle$ to emphasize the rationale(s) and de-emphasize the remaining phrases in that document. We simply multiply the features corresponding to phrase(s) that are returned as rationale(s) by weight r and we multiply the remaining features in the document by weight o, where $r > o$, and r and o are hyper-parameters. The modified document becomes:

$$x_r^i = \langle r \times f_j^i, \forall f_j^i \in R(x^i); o \times f_j^i, \forall f_j^i \notin R(x^i), \rangle \quad (1)$$

Note that the rationales are tied to their documents for which they were provided as rationales. One phrase might be a rationale for the label of one

document and yet it might not be the rationale for the label of another document. Hence, the feature weightings are done at the document level, rather than globally. To illustrate this concept, we provide an example dataset below with three documents. In these documents, the words that are returned as rationales are underlined.

Document 1: This is a great movie.

Document 2: The plot was great, but the performance of the actors was terrible. Avoid it.

Document 3: I've seen this at an outdoor cinema; great atmosphere. The movie was terrific.

As these examples illustrate, the word "great" appears in all three documents, but it is marked as a rationale only for Document 1. Hence, we do not weight the rationales globally; rather, we modify only the labeled document using its particular rationale. Table 1 illustrates both the Lw/oR and LwR representations for these documents.

Table 1: The Lw/oR binary representation (top) and its LwR transformation (bottom) for Documents 1, 2, and 3. Stop words are removed. LwR multiplies the rationales with r and other features with o.

	great	movie	plot	performance	actor	terrible	avoid	outdoor	cinema	atmosphere	terrific
Lw/oR Representation (binary)											
D1	1	1									
D2	1		1	1	1	1	1				
D3	1	1						1	1	1	1
LwR Transformation of the binary Lw/oR repr.											
D1	r	o									
D2	o		o	o	o	r	r				
D3	o	o						o	o	o	r

This approach is simple, intuitive, and classifier-agnostic. As we will show later, it is quite effective empirically as well. To gain a theoretical understanding of this approach, consider the work on regularization: the aim is to build a sparse/simple model that can capture the most important features of the training data and thus have large weights for important features and small/zero weights for irrelevant features. For example, consider the gradient for w_j of feature f_j for logistic regression with l_2 regularization (assuming y is binary with 0/1):

$$\nabla w_j = C \times \sum_{x^l \in \mathcal{L}} f_j^l \times (y^l - P(y=1|x^l)) - w_j \quad (2)$$

where C is the complexity parameter that balances between fit to the data and the model complexity.

With our rationales framework, the gradient for w_j will be:

$$\nabla w_j = C \times \left(\sum_{x^l \in \mathcal{L}: f_j^l \in R(x^l)} r \times f_j^l \times (y^l - P(y^l=1|x^l)) + \sum_{x^l \in \mathcal{L}: f_j^l \notin R(x^l)} o \times f_j^l \times (y^l - P(y^l=1|x^l)) \right) - w_j \quad (3)$$

In the above equation, a feature f_j contributes more to the gradient of its weight w_j when a document in which it is marked as a rationale is misclassified. When f_j appears in another document x^k but is not a rationale, it's contribution to the gradient is muted by o. And hence, when $r > o$, this framework implicitly provides more granular (per instance-feature combination) regularization by placing a higher importance on the contribution of the rationales versus non-rationales in each document.[1]

Note that in our framework the rationales are tied to their own documents; that is, we do not weight rationales and non-rationales globally. In addition to providing more granular regularization, this approach has the benefit of allowing different rationales to contribute differently to the objective function of the trained classifier. For example, consider the case where the number of documents in which one word f_j (e.g., "excellent") is marked as a rationale is much more than the number of documents where another word f_k (e.g., "good") is marked as

[1]The justification for our approach is similar for support vector machines. The idea is also similar for multinomial naïve Bayes with Dirichlet priors α_j. For a fixed Dirichlet prior with $\langle \alpha_1, \alpha_2, \cdots, \alpha_n \rangle$ setting, when $o < 1$ for a feature f_j, its counts are smoothed more.

a rationale. Then, the first sum in equation 3 will range over more documents for the gradient of w_j compared to the gradient of w_k, giving more importance to w_j than to w_k. In the traditional feature annotation work, this can be achieved only if the labeler can rank the features; even then, it is often very difficult, if not impossible, for the labelers to determine how much more important one feature is compared to another.

3.2 Experiments Comparing Lw/oR to LwR

In this section we first describe the settings, datasets, and classifiers used for our experiments and how we simulated a human labeler to provide rationales. Then, we present the results comparing the learning curves achieved with *learning without rationales* (Lw/oR) and *learning with rationales* (LwR).

3.2.1 Methodology

For this study, we used four text classification datasets. The IMDB dataset consists of 25K movie reviews (Maas et al., 2011). The SRAA[2] dataset consists of 48K documents that discuss either auto or aviation. Nova is a text classification dataset used in active learning challenge (Guyon, 2011) and contains 12K documents. WvsH is a 20 Newsgroups[3] dataset in which we use the Windows vs. hardware categories, and it contains 1176 documents.

To make sure our approach works across representations, we experimented with both binary and tf-idf representations for these text datasets. We evaluated our strategy using multinomial naïve Bayes, logistic regression, and support vector machines, as these are strong classifiers for text classification. We used the scikit-learn (Pedregosa et al., 2011) implementation of these classifiers with their default parameter settings for our experiments.

To compare various strategies, we used learning curves. The initially labeled dataset was bootstrapped using 10 documents by picking 5 random documents from each class. A budget (B) of 200 documents was used in our experiments, because most of the learning curves flatten out after about 200 documents. We evaluated all the strategies using AUC (Area Under an ROC Curve) measure. The code to repeat our experiments is available at Github `http://www.cs.iit.edu/~ml/code/`.

While incorporating the rationales into learning, we set the weights for rationales and the remaining features of a document as 1 and 0.01 respectively (i.e. $r = 1$ and $o = 0.01$). That is, we did not overemphasize the features corresponding to rationales but rather de-emphasized the remaining features in the document. These weights worked reasonably well for all four datasets, across all three classifiers, and for both binary and tf-idf data representations.

Obviously, these are not necessarily the best weight settings one can achieve; the optimal settings for r and o depend on many factors, such as the extent of the knowledge of the labeler (i.e., how many words a labeler can recognize), how noisy the labeler is, and how much labeled data we have in our training set. Ideally, one should have $r >> o$ when the labeled data is small and r should be closer to o when the labeled data is large; a more practical approach would be to tune for these parameters (e.g., cross-validation) at each step of the learning curve. However, in our experiments, we fixed r and o and we found that most settings where $r > o$ worked quite well.

3.2.2 Simulating the Human Expert

Like most literature on feature labeling, we constructed an artificial labeler to simulate a human labeler. Every time a document is annotated, we asked the artificial labeler to mark a word as a rationale for that document's label. We allowed the labeler to return any one (and not necessarily the top one) of the positive words as a rationale for a positive document and any one of the negative words as a rationale for a negative document. If the labeler did not recognize any of the words as positive (negative) in a positive (negative) document, we let the labeler return nothing as the rationale. To make this as practical as possible in a real-world setting, we constructed the artificial labeler to recognize only the most apparent words in the documents. For generating rationales, we chose only the positive (negative) features that had the highest χ^2 (chi-squared) statistic in at least 5% of the positive (negative) documents. This resulted in an overly-conservative labeler that recognized only a tiny subset of the words. For example,

[2]http://people.cs.umass.edu/ mccallum/data.html

[3]http://qwone.com/ jason/20Newsgroups/

the artificial labeler knew about only 49 words (23 for one class and 26 for the other class) for IMDB, 67 words (32 for one class and 35 for the other class) for SRAA, 95 words (42 for one class and 53 for the other class) for WvsH, and 111 words (31 for one class and 80 for the other class) for the Nova dataset.

To determine whether the rationales selected by this artificial labeler are meaningful, we printed out the actual words used as rationales, and we ourselves verified that these words are human-recognizable words that could be naturally provided as rationales for classification. For example, the positive terms for the IMDB dataset included "great", "excellent", and "wonderful" and the negative terms included "worst", "bad", and "waste."

3.2.3 Results

Next, we compare Lw/oR to LwR. Figure 1 presents the learning curves for random sampling on four text classification datasets with binary and tf-idf representations and using multinomial naïve Bayes, logistic regression, and support vector machines. Figure 1 shows that even though the artificial labeler knew only about a tiny subset of the vocabulary, and returned any *one* word, rather than the top word or all the words, as rationale, LwR still drastically outperformed Lw/oR across all datasets, classifiers, and representations. This shows that our method for incorporating rationales into the learning process is empirically effective.

We used the default complexity parameters for logistic regression and support vector machines and used Laplace smoothing for multinomial naïve Bayes. In our rationale framework, most features were non-rationales, and hence in Equation 3, most features appeared in the second summation term, with $o = 0.01$. We tested whether the improvements that LwR provide over Lw/oR are simply due to implicit higher regularization for most of the features with $o = 0.01$, and hence experimented with equation 2 (which is Lw/oR) using $C = 0.01$. We observed that setting $C = 0.01$ and indiscriminately regularizing all the terms did not improve Lw/oR, further providing experimental evidence that the improvements provided by LwR are not due to just higher regularization, but they are due to a more fine-grained regularization, as explained in Section 3.1.

Even though LwR provides huge benefits, providing both a label and a rationale is expected to take more time of the labeler than simply providing a label. However, the improvements of LwR over Lw/oR is so huge that it might be worth spending the extra time in providing rationales. For example, in order to achieve a target AUC of 0.95 for SRAA dataset (using tf-idf representation with MNB classifier), Lw/oR required labeling 656 documents, whereas LwR required annotating a mere 29 documents, which is 22.6 times reduction in the number of documents. As another example, in order to achieve a target AUC of 0.8 for WvsH dataset (using binary representation with SVM classifier), Lw/oR required labeling 113 documents, whereas LwR achieved this target with only 13 documents.

(Zaidan et al., 2007) conducted user studies and showed that providing 5 to 11 rationales and a class label per document takes roughly twice the time of providing only the label for the document. (Raghavan et al., 2006) also conducted user studies and showed that labeling instances takes five times more time than labeling features. We worked with simulated user and showed that a document that is annotated with a label and a single rationale can be worth as many as 22 documents that are annotated with only a label and thus these results suggest that LwR, compared to Lw/oR, can lead to significant time savings for the annotator.

4 Active Learning with Rationales

So far we have seen that LwR provides drastic improvements over Lw/oR. Both these strategies selected documents randomly for labeling. Active learning (Settles, 2012) aims to carefully choose instances for labeling to improve over random sampling. Many successful active learning approaches have been developed for instance labeling (e.g. (Lewis and Gale, 1994), (Seung et al., 1992), (Roy and McCallum, 2001)), feature labeling (e.g. (Druck et al., 2009)), and rotating between instance and feature labeling (e.g. (Raghavan and Allan, 2007), (Druck et al., 2009), (Attenberg et al., 2010), (Melville and Sindhwani, 2009)). In this section, we introduce an active learning strategy that can utilize the learning with rationales framework.

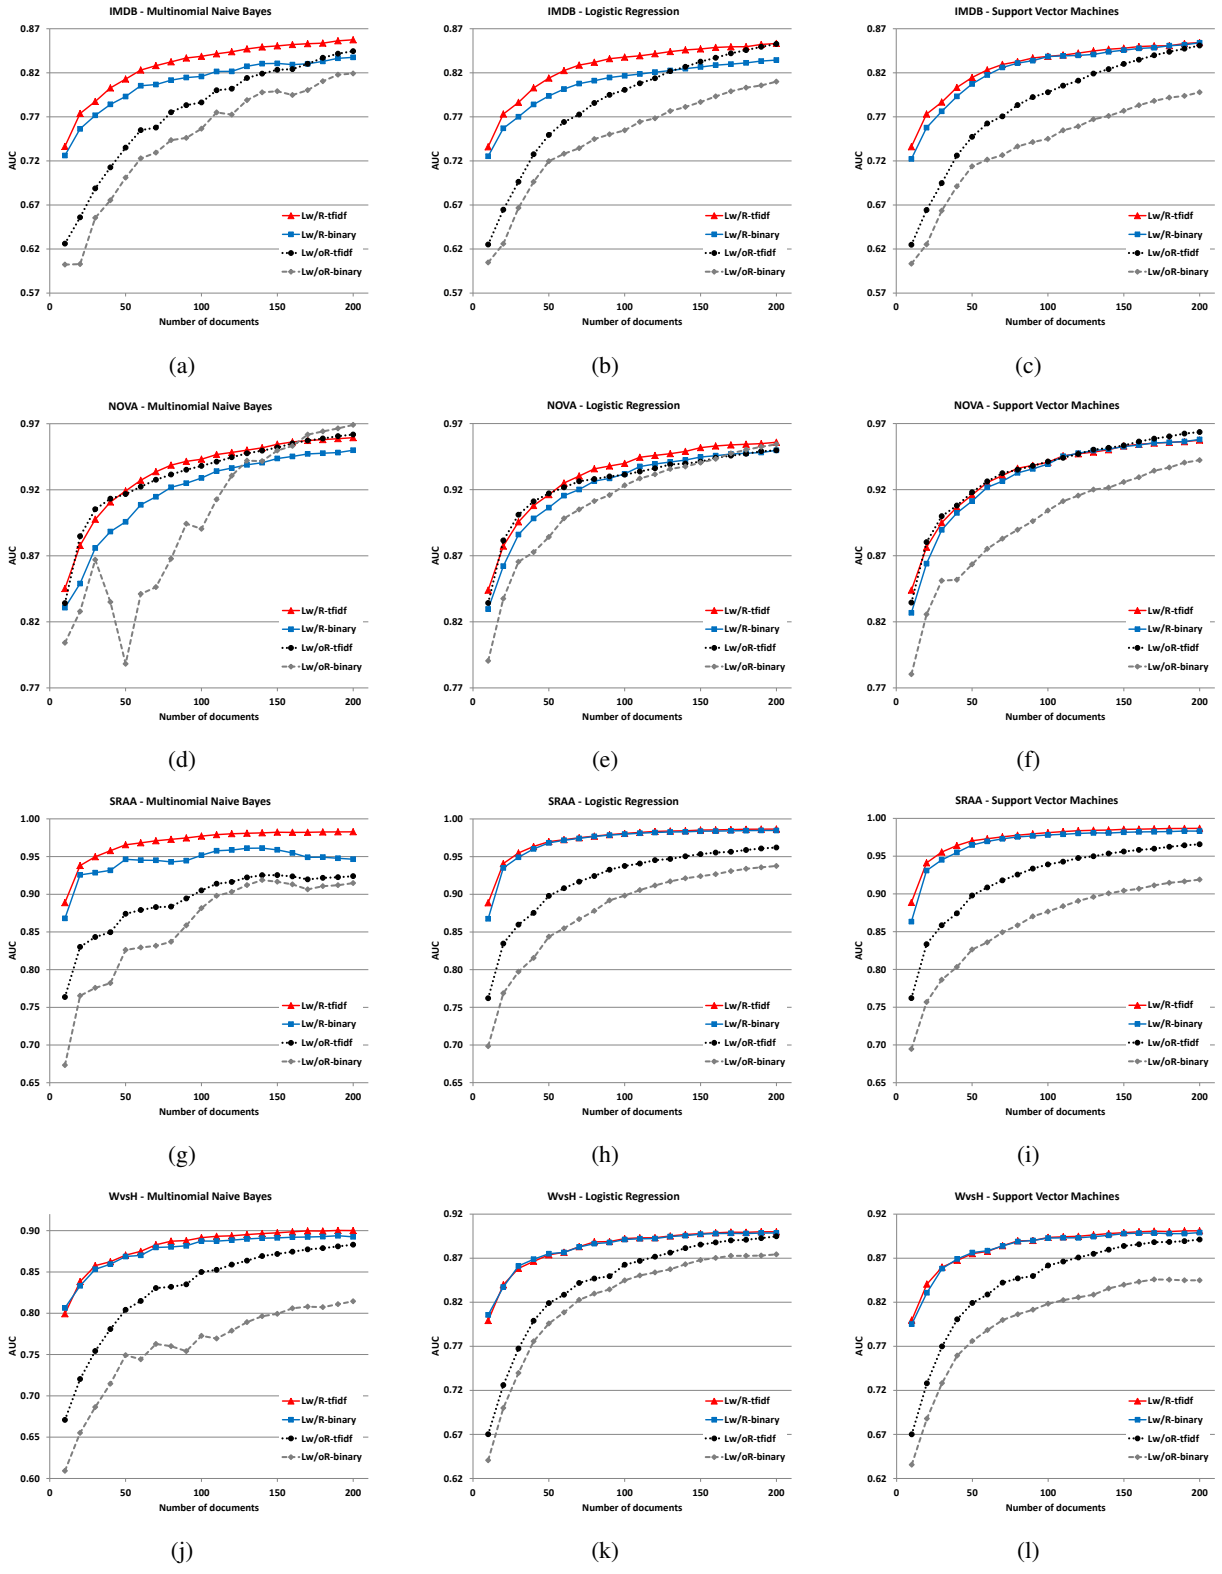

Figure 1: Comparison of Lw/oR with LwR. LwR provides drastic improvements over Lw/oR for all datasets with binary and tf-idf representations and using all three classifiers.

4.1 Active Learning to Select Documents based on Rationales

Arguably, one of the most successful active learning strategies for text categorization is uncertainty sampling, which was first introduced by (Lewis and Catlett, 1994) for probabilistic classifiers and later formalized for support vector machines (Tong and Koller, 2001). The idea is to label instances for which the underlying classifier is uncertain, i.e., the instances that are close to the decision boundary of the model. It has been successfully applied to text classification tasks in numerous publications, including (Zhu and Hovy, 2007), (Sindhwani et al., 2009), and (Segal et al., 2006).

We adapt uncertainty sampling for the learning with rationales framework. To put simply, when the underlying model is uncertain about an unlabeled document, we look whether the unlabeled document contains words/phrases that were returned as rationales for any of the existing labeled documents. More formally, let R^+ denote the union of all the rationales returned for the positive documents so far. Similarly, let R^- denote the union of all the rationales returned for the negative documents so far. An unlabeled document can be of these three types:

1. Type1: has no words in common with R^+ and R^-.
2. Type2: has word(s) in common with either R^+ or R^- but not both.
3. Type3: has at least one word in common with R^+ and at least one word in common with R^-.

One would imagine that labeling each of the type1, type2, and type3 documents has its own advantage. Labeling type1 documents has the potential to elicit new domain knowledge, i.e., terms that were not provided as a rationale for any of the existing labeled documents. It also carries the risk of containing little to no useful information for the classifier (e.g., a neutral review). For type2 documents, even though the document shares a word that was returned as a rationale for another document, the classifier is still uncertain about the document either because that word is not weighted high enough by the classifier and/or there are other words that pull the classification decision in the other direction, making the classifier uncertain. Type3 documents contain conflicting words/phrases and are potentially harder cases, however, they also have the potential to resolve the conflicts for the classifier.

Building on our previous work (Sharma and Bilgic, 2013) we devised an active learning approach, where given uncertain documents, the active learner prefers instances of type3 over type1 and type2. We call this strategy as *uncertain-prefer-conflict* (UNC-PC) because type3 documents carry conflicting words (with respect to rationales) whereas type1 and type2 do not. The difference between this approach and our previous work (Sharma and Bilgic, 2013) is that in (Sharma and Bilgic, 2013), we selected uncertain instances based on model's perceived conflict whereas in this work, we are selecting documents based on conflict caused by the domain knowledge provided by the labeler. Next, we compare the vanilla uncertainty sampling (UNC) and UNC-PC strategies using LwR to see if using uncertain documents of type3 could improve active learning.

4.2 Active Learning with Rationales Experiments

We used the same four text datasets and evaluated our method UNC-PC using multinomial naïve Bayes, logistic regression, and support vector machines. For the active learning strategies, we used a bootstrap of 10 random documents, and labeled five documents at each round of active learning. We used a budget of 200 documents for all methods. UNC simply picks the top five uncertain documents, whereas UNC-PC looks at top 20 uncertain documents and picks five uncertain documents giving preference to the conflicting cases (type 3) over the non-conflicting cases (type1 and type2). We repeated each experiment 10 times starting with a different bootstrap at each trial and report the average results.

In Figure 2 we show the learning curves comparing UNC-PC with UNC for multinomial naïve Bayes. (Logistic regression and SVM curves are omitted due to space.) Since the results for LwR using tf-idf representation are better than the results using the binary representation, we compared UNC-PC to UNC for LwR using only the tf-idf representation. We see that for multinomial naïve

Bayes, UNC-PC improves over traditional uncertainty, UNC, on two datasets, and hurts performance on one dataset. Next, we discuss the significance results for all classifiers.

Table 2 shows the paired t-test results comparing the learning curves of UNC-PC with the learning curves of UNC at each step of the active learning (i.e, if the average of one learning curve is significantly better or worse than the average of the learning curve of the other). If UNC-PC has a higher average AUC than UNC with a t-test significance level of 0.05 or better, it is a Win (W), if it has significantly lower performance, it is a Loss (L), and if the difference is not statistically significant, the result is a Tie (T).

Using multinomial naïve Bayes, UNC-PC wins over UNC for two of the datasets (IMDB and WvsH), does not cause any significant changes for Nova (ties all the time), and loses for SRAA. Using logistic regression, UNC-PC wins for two datasets (Nova and SRAA), ties for WvsH and loses for IMDB. Using support vector machines, UNC-PC wins for three datasets (Nova, SRAA, and WvsH) and loses for IMDB. The t-test results show that UNC-PC often improves learning over UNC.

Table 2: Significant W/T/L counts for UNC-PC versus UNC. UNC-PC improves over UNC significantly for all three classifiers and most of the datasets.

UNC baseline	**MNB**	**LR**	**SVM**
UNC-PC	**2**/1/1	**2**/1/1	**3**/0/1

5 Limitations and Future Work

A limitation of our work is that we simulated the labeler in our experiments. Even though we simulated the labeler in a very conservative way (that is, our simulated labeler knows only a few most apparent words) and asked the simulated labeler to provide any one (rather than the top) rationale, a user study is needed to i) experiment with potentially noisy labelers, and ii) measure how much actual time saving LwR provides over Lw/oR.

Another line of future work is to allow the labeler to provide richer feedback. This is especially useful for resolving conflicts that stem from seemingly conflicting words and phrases. For example, for the movie review "The plot was great, but the performance of the actors was terrible. Avoid it." the word "great" is at odds with the words "terrible" and "avoid". If the labeler is allowed to provide richer feedback, saying that the word "great" refers to the plot, "terrible" refers to the performance, and "avoid" refers to the movie, then the learner might be able to learn to resolve similar conflicts in other documents. However, this requires a conflict resolution mechanism in which the labeler can provide rich feedback, and a learner that can utilize such rich feedback. This is an exciting future research direction that we would like to pursue.

We showed that our strategy to incorporate rationales works well for text classification. The proposed framework can potentially be used for non-text domains where the domain experts can provide rationales for their decisions, such as medical domain where the doctor can provide a rationale for his/her diagnosis and treatment decisions. Each domain is expected to have its own unique research challenges and working with other domains is another interesting future research direction.

6 Related Work

The closest related work deals with eliciting rationales from users and incorporating them into the learning (e.g., (Zaidan et al., 2007), (Donahue and Grauman, 2011), (Zaidan et al., 2008), and (Parkash and Parikh, 2012)). However, much of this work is specific to a particular classifier, such as support vector machines. The framework we present is classifier-agnostic and we have shown that it works across classifiers and feature representations. Additionally, we provide a novel active learning approach tailored for the learning with rationales framework.

Another line of related work is the recent work on active learning with instance and feature annotations (e.g., (Melville and Sindhwani, 2009), (Druck et al., 2009), (Small et al., 2011), (Stumpf et al., 2008), (Raghavan and Allan, 2007), and (Attenberg et al., 2010)). The main difference between the feature annotation work and the learning with rationales framework is that the feature annotations are not tied to particular instances, whereas in the learning with rationales framework, the documents and their rationales are coupled together. Even though

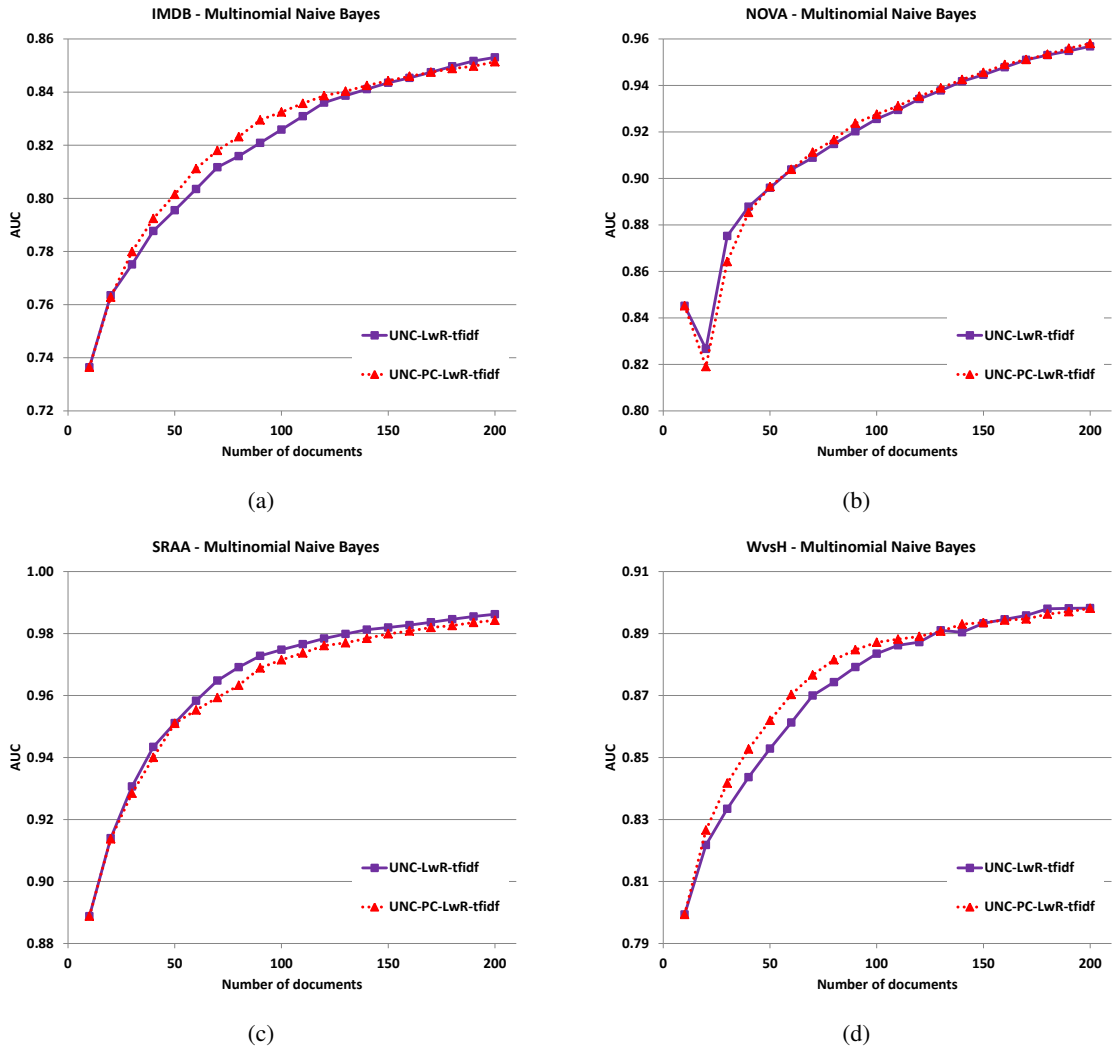

Figure 2: Comparison of LwR using UNC and UNC-PC for all datasets with tf-idf representation and using multinomial naïve Bayes classifier.

feature annotation work can be utilized for the learning with rationales framework by decoupling rationales from their documents, this is expected to result in information loss (such as weighting features globally rather than locally). The precise effect of decoupling rationales and documents on the classifier performance still needs to be tested empirically.

7 Conclusion

We introduced a novel framework to incorporate rationales into active learning for text classification. Our simple strategy to incorporate rationales can utilize any off-the-shelf classifier. The empirical evaluations on four text datasets with binary and tf-idf representations and three classifiers showed that our proposed method utilizes rationales effectively. Additionally, we presented an active learning strategy that is tailored specifically for the learning with rationales framework and empirically showed that it improved active learning.

Inferring Temporally-Anchored Spatial Knowledge from Semantic Roles

Abstract

This paper presents a framework to infer spatial knowledge from verbal semantic role representations. First, we generate potential spatial knowledge deterministically. Second, we determine whether it can be inferred and a degree of certainty. Inferences capture that something is located or is not located somewhere, and temporally anchor this information. An annotation effort shows that inferences are ubiquitous and intuitive to humans.

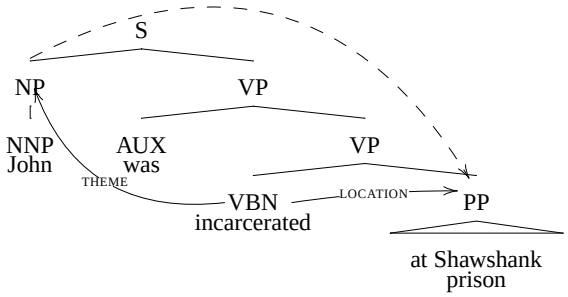

Figure 1: Semantic roles (solid arrows) and additional spatial knowledge (discontinuous arrow).

1 Introduction

Extracting semantic relations from text is at the core of text understanding. Semantic relations encode semantic connections between words. For example, from (1) *Bill couldn't handle the pressure and quit yesterday*, one could extract that the CAUSE of *quit* was *the pressure*. Doing so would help answering question *Why did Bill quit?* and determining that *the pressure* started before Bill *quit*.

In the past years, computational semantics has received a significant boost. But extracting all semantic relations in text—even in single sentences—is still an elusive goal. Most existing approaches target either a single relation, e.g., PART-WHOLE (Girju et al., 2006), or relations that hold between arguments following some syntactic construction, e.g., possessives (Tratz and Hovy, 2013). Among the latter kind, the task of verbal semantic role labeling focuses on extracting semantic links exclusively between verbs and their arguments. PropBank (Palmer et al., 2005) is a popular corpus for this task, and tools to extract verbal semantic roles have been proposed for years (Carreras and Màrquez, 2005).

Some semantic relations hold forever, e.g., the CAUSE of event *quit* in example (1) above is *pressure*. Discussing when this CAUSE holds is somewhat artificial: at some point Bill *quit*, and he did so because of *the pressure*. But LOCATION and other semantic relations often do not hold forever. For example, while buildings typically have one location during their existence, people and objects such as cars and books do not: they participate in events and as a result their locations change.

This paper presents a framework to infer temporally-anchored spatial knowledge from verbal semantic roles. Specifically, our goal is to infer whether something is located somewhere or not located somewhere, and temporally anchor this spatial information. Consider sentence (2) *John was incarcerated at Shawshank prison* and its semantic roles (Figure 1, solid arrows). Given these roles, we aim at inferring that *John* had LOCATION *Shawshank prison* during event *incarcerated*, and that he (probably) did not have this LOCATION before and after (discontinuous arrow). Our intuition is that knowing that *incarcerated* has THEME *John* and LOCATION *Shawshank prison* will help making these inferences. As we shall discuss, sometimes we have evidence that something is (or is not) located somewhere, but cannot completely commit.

We target temporally-anchored spatial knowledge between intra-sentential arguments of verbs, not only between arguments of the same verb as exemplified in Figure 1. The main contributions are:

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 452–461,
Denver, Colorado, May 31 – June 5, 2015.

(1) analysis of spatial knowledge inferable from PropBank-style semantic roles; (2) annotations of temporally-anchored LOCATION relations on top of OntoNotes;[1] (3) supervised models to infer the additional spatial knowledge; and (4) experiments detailing results using lexical, syntactic and semantic features. The framework presented here infers over 44% spatial knowledge on top of the PropBank-style semantic roles annotated in OntoNotes (`certYES` and `certNO` labels, Section 3.3).

2 Semantic Roles and Additional Spatial Knowledge

We denote a semantic relation R between *x* and *y* as R(*x*, *y*). R(*x*, *y*) could be read "*x* has R *y*", e.g., AGENT(*moved*, *John*) could be read "moved has AGENT John". Semantic roles[2] are semantic relations R(*x*, *y*) such that *x* is a verb and *y* is an argument of *x*. We refer to any spatial relation LOCATION(*x*, *y*) where (1) *x* is not a verb, or (2) *x* is a verb but *y* is not a argument of *x*, as additional spatial knowledge. As we shall see, we target additional spatial knowledge beyond plain LOCATION(*x*, *y*) relations, which only specify the location *y* of *x*. Namely, we consider polarity, i.e., whether something is or is not located somewhere, and temporally anchor this information.

This paper complements semantic role representations with additional spatial knowledge. We follow a practical approach by inferring spatial knowledge from PropBank-style semantic roles. We believe this is an advantage since PropBank is well-known in the field and several tools to predict PropBank roles are documented and publicly available.[3] The work presented here could be incorporated into any NLP pipeline after role labeling without modifications to other components.

2.1 PropBank and OntoNotes

PropBank (Palmer et al., 2005) adds semantic role annotations on top of the parse trees of the Penn Treebank. It uses a set of numbered arguments[4] (ARG_0, ARG_1, etc.) and modifiers (ARGM-TMP, ARGM-MNR, etc.). Numbered arguments do not share a common meaning across verbs, they are defined on verb-specific framesets. For example, ARG_2 is used to indicate "*employer*" with verb *work.01* and "*expected terminus of sleep*" with verb *sleep.01* (Table 1). Unlike numbered arguments, modifiers have the same meaning across verbs (Table 2).

[Mr. Cray]$_{ARG_0}$ [will]$_{ARGM\text{-}MOD}$ [work]$_{verb}$ [for the Colorado Springs CO company]$_{ARG_2}$ [as an independent contractor]$_{ARG_1}$.
[I]$_{ARG_0}$'d [slept]$_{verb}$ [through my only previous brush with natural disaster]$_{ARG_2}$, [...]

Table 1: Examples of PropBank annotations.

ARGM-LOC: location	ARGM-CAU: cause
ARGM-EXT: extent	ARGM-TMP: time
ARGM-DIS: discourse connective	ARGM-PNC: purpose
ARGM-ADV: general-purpose	ARGM-MNR: manner
ARGM-NEG: negation marker	ARGM-DIR: direction
ARGM-MOD: modal verb	

Table 2: Argument modifiers in PropBank.

The original PropBank corpus consists of (1) 3,327 framesets, each frameset defines the numbered roles for a verb, and (2) actual semantic role annotations (numbered arguments and modifiers) for 112,917 verbs. On average, each verb has 1.93 numbered arguments and 0.66 modifiers annotated. Only 7,198 verbs have an ARGM-LOC annotated, i.e., location information is present in 6.37% of verbs. For more information about PropBank and examples, refer to the annotation guidelines.[5]

OntoNotes (Hovy et al., 2006) is a more recent corpus that includes POS tags, word senses, parse trees, speaker information, named entities, PropBank-style semantic roles and coreference. While the original PropBank annotations were done exclusively in the news domain, OntoNotes includes other genres as well: broadcast and telephone conversations, weblogs, etc. Because of the additional annotation layers and genres, we work with OntoNotes instead of PropBank.

[1] Available at `http://hilt.cse.unt.edu/`

[2] We use *semantic role* to refer to PropBank-style (verbal) semantic roles. NomBank (Meyers et al., 2004) and FrameNet (Baker et al., 1998) also annotate semantic roles.

[3] E.g., `http://cogcomp.cs.illinois.edu/page/software`, `http://ml.nec-labs.com/senna/`;

[4] Numbered arguments are also referred to as *core*.

[5] `http://verbs.colorado.edu/~mpalmer/projects/ace/PBguidelines.pdf`

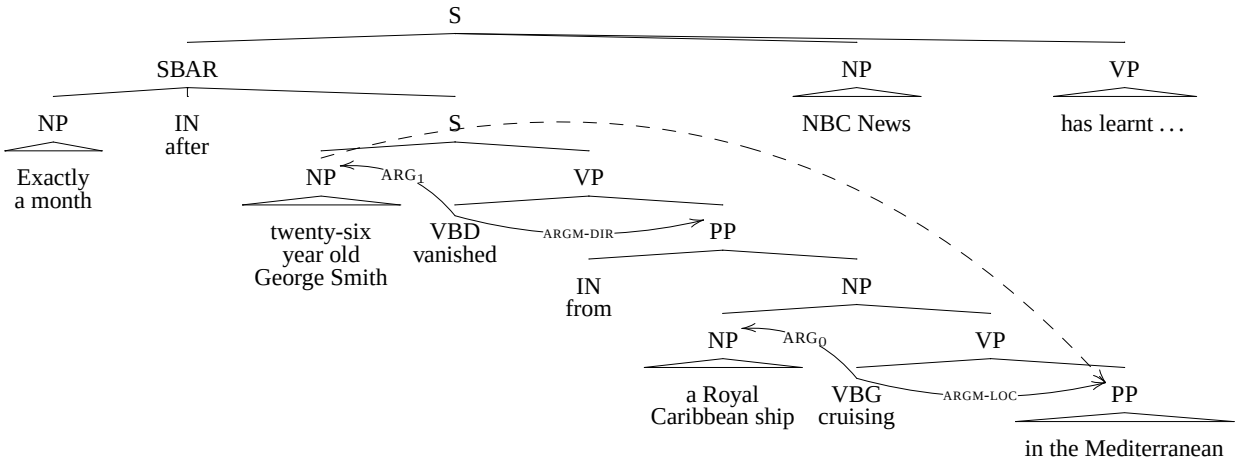

Figure 2: Semantic roles (solid arrows) and additional spatial knowledge (discontinuous arrow) of type (1b). The additional LOCATION(*a Royal Caribbean ship, in the Mediterranean*) of type (1a) is not shown.

2.2 Additional Spatial Knowledge

Sentences contain spatial information beyond ARGM-LOC semantic role, i.e., beyond links between verbs and their arguments. There are two main types of additional LOCATION(*x, y*) relations:[6] (1) those whose arguments *x* and *y* are semantic roles of a verb, and (2) those whose arguments *x* and *y* are not semantic roles of a verb.

The first kind can be further divided into (1a) those whose arguments are semantic roles of the same verb (Figure 1), and (1b) those whose arguments are semantic roles of different verbs. Figure 2 illustrates type (1b). Semantic roles indicate ARG_1 and ARGM-DIR of *vanished*, and ARG_0 and ARGM-LOC of *cruising*. In this example, one can infer that *twenty-six year old George Smith* (ARG_1 of vanished) has LOCATION *in the Mediterranean* (ARGM-LOC of *cruising*) during the *cruising* event.

The second kind of additional LOCATION(*x, y*) is exemplified in the following sentence: *[Residents of Biddeford apartments]*$_{\text{ARG}_0}$ *can [enjoy]*$_{verb}$ *[the recreational center]*$_{\text{ARG}_1}$ *[free of charge]*$_{\text{MANNER}}$. LOCATION(*recreational center, Biddeford apartments*) could be inferred yet *Biddeford apartments* is not a semantic role of a verb.[7] Inferring this kind of relations would require splitting semantic roles; one could also extract that the *residents* have LOCATION *Biddeford apartments*.

In this paper, we focus on extracting additional spatial knowledge of type (1), and reserve type (2) for future work. More specifically, we infer spatial knowledge between *x* and *y*, where the following semantic roles exist: $\text{ARG}_i(x_{pred}, x)$ and ARGM-LOC(y_{pred}, *y*). ARG_i indicates any numbered argument (ARG_0, ARG_1, ARG_2, etc.) and x_{pred} (y_{pred}) indicates the verbal predicate to which *x* (*y*) attaches. Targeting additional spatial knowledge exclusively for numbered arguments is not a significant limitation: most semantic roles annotated in OntoNotes (75%) are numbered arguments, and it is pointless to infer spatial knowledge for most modifiers, e.g., ARGM-EXT, ARGM-DIS, ARGM-ADV, ARGM-MOD, ARGM-NEG, ARGM-DIR.

3 Annotating Spatial Knowledge

Annotating all additional spatial knowledge in OntoNotes inferable from semantic roles is a daunting task. OntoNotes is a large corpus with 63,918 sentences and 9,924 ARGM-LOC semantic roles annotated. Our goal is not to present an extensive annotation effort, but rather show that additional temporally-anchored spatial knowledge can be (1) annotated reliably by non-experts following simple guidelines, and (2) inferred automatically using supervised machine learning. Thus, we focus on 200 sentences from OntoNotes that have at least one ARGM-LOC role annotated.

[6] Both ARGM-LOC(*x, y*) and LOCATION(*x, y*) encode the same meaning, but we use ARGM-LOC for the PropBank semantic role and LOCATION for additional spatial knowledge.

[7] Note that the head of ARG_0 is *residents*, not the apartments.

foreach *sentence s* **do**
  foreach *sem. role* ARGM-LOC*(y_{pred}, y)* $\in$ *s* **do**
    foreach *sem. role* ARG$_i$*(x_{pred}, x)* $\in$ *s* **do**
      if *is_valid(x, y)* **then**
        Is *x* located at *y* before y_{pred}?
        Is *x* located at *y* during y_{pred}?
        Is *x* located at *y* after y_{pred}?

Algorithm 1: Procedure to generate potential additional spatial knowledge of type (1) (Section 2.2).

Obviously, [the pilot]$_{\text{ARG}_0,\, v_1}$ did[n't]$_{\text{ARGM-NEG},\, v_1}$ [think]$_{v_1}$ [too much]$_{\text{ARGM-EXT},\, v_1}$ [about [what]$_{\text{ARG}_1,\, v_2}$ was [happening]$_{v_2}$ [on the ground]$_{\text{ARGM-LOC},\, v_2}$, or ...]$_{\text{ARG}_1,\, v_1}$

Figure 3: Sample sentence and semantic roles. Pair (x: *about what was happening on the ground*, y: *on the ground*) is invalid because *x* contains *y*.

All potential additional spatial knowledge is generated with Algorithm 1, and a manual annotation effort determines whether spatial knowledge should be inferred. Algorithm 1 loops over all ARGM-LOC roles, and generates questions regarding whether spatial knowledge can be inferred for any numbered argument within the same sentence. $is\_valid(x, y)$ returns True if (1) *x* is not contained in *y* and (2) *y* is not contained in *x*. Considering invalid pairs would be trivial or nonsensical, e.g., pair (x: *about what was happening on the ground*, y: *on the ground*) is invalid in the sentence depicted in Figure 3.

3.1 Annotation Process and Guidelines

In a first batch of annotations, two annotators were asked questions generated by Algorithm 1 and required to answer `YES` or `NO`. The only information they had available was the source sentence without semantic role information. Feedback from this first attempt revealed that (1) because of the nature of *x* or *y*, sometimes questions are pointless, and (2) because of uncertainty, sometimes it is not correct to answer `YES` or `NO`, even tough there is some evidence that makes either answer likely.

Based on this feedback, and inspired by previous annotation guidelines (Saurí and Pustejovsky, 2012), in a second batch we allowed five answers:

- `certYES`: I am certain that the answer is yes.
- `probYES`: It is probable that the answer is yes, but it is not guaranteed.
- `certNO`: I am certain that the answer is no.
- `probNO`: It is probable that the answer is no, but it is not guaranteed.
- `UNK`: There is not enough information to answer, I can't tell the location of *x*.

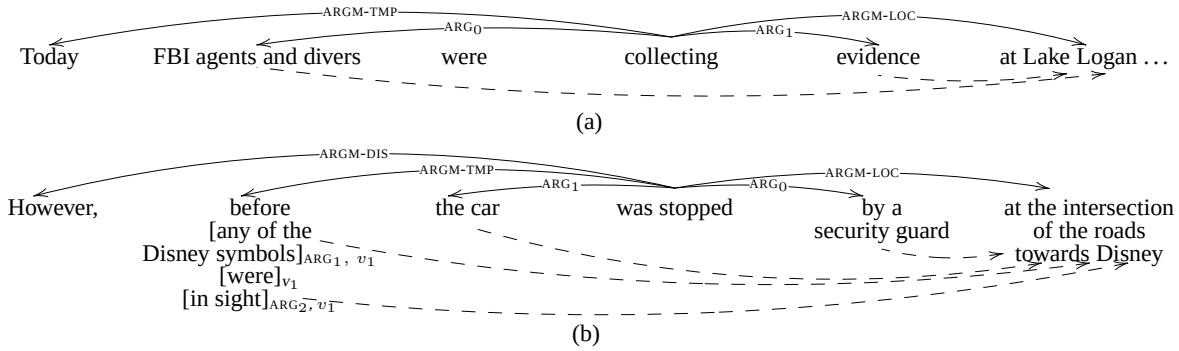
The goal is to infer spatial knowledge as gathered by humans when reading text. Thus, annotators were encouraged to use commonsense and world knowledge. While simple and somewhat open to interpretation, these guidelines allowed as to gather annotations with "good reliability" (Section 3.3.1).

3.2 Annotation Examples

In this section, we present annotation examples after resolving conflicts (Figure 4). These examples show that ambiguity is common and sentences must be fully interpreted before annotating.

Sentence 4(a) has four semantic roles for verb *collecting* (solid arrows), and annotators are asked to decide whether ARG$_0$ and ARG$_1$ of *collecting* are located at the ARGM-LOC before, during or after *collecting* (discontinuous arrows). Annotators interpreted that the *FBI agents and divers* (ARG$_0$) and *evidence* (ARG$_1$) were located *at Lake Logan* (ARGM-LOC) during *collecting* (`certYES`). They also annotated that the *FBI agents and divers* were likely to be located at *Lake Logan* before and after (`probYES`). Finally, they determined that the *evidence* was located *at Lake Logan* before the *collecting* (`certYES`), but probably not after (`probNO`). These annotations reflect the natural reading of sentence 4(a): (1) people and whatever they collect are located where the collecting takes place during the event, (2) people collecting are likely to be at that location before and after (i.e., presumably they do not arrive immediately before and leave immediately after), and (3) the objects being collected are located at that location before collecting, but probably not after.

Sentence 4(b) is more complex. First, potential relation LOCATION(*in sight*, *at the intersection*) is annotated `UNK`: it is nonsensical to ask for the location of *sight*. Second, the *Disney symbols* are never located *at the intersection* (`certNO`). Third, both *the car* and *security guard* were located *at the intersection* during the stop for sure (`certYES`). Fourth, annotators interpreted that *the car* was not *at the intersection* before (`certNO`), but they were not sure about after (`probNO`). Fifth, they considered that the *security guard* was probably located *at the intersec-*



x	*y*	y_{pred}	Before	During	After
FBI agents and divers	at Lake Logan	collecting	probYES	certYES	probYES
evidence	at Lake Logan	collecting	certYES	certYES	probNO
any of the Disney symbols	at the intersection of the roads ...	stopped	certNO	certNO	certNO
in sight	at the intersection of the roads ...	stopped	UNK	UNK	UNK
the car	at the intersection of the roads ...	stopped	certNO	certYES	probNO
by a security guard	at the intersection of the roads ...	stopped	probYES	certYES	probYES

Figure 4: Examples of semantic role representations (solid arrows), potential additional spatial knowledge (discontinuous arrows) and annotations with respect to the verb to which *y* attaches (*collecting* or *stopped*).

	Label									
	certYES		probYES		certNO		probNO		UNK	
	#	%	#	%	#	%	#	%	#	%
Before	100	15.04	225	33.83	57	8.57	248	37.29	35	5.26
During	477	71.51	36	5.40	60	9.00	59	8.85	35	5.25
After	140	21.12	344	51.89	57	8.60	87	13.12	35	5.28
All	717	**35.94**	605	30.33	174	**8.72**	394	19.75	105	5.26

Table 3: Annotation counts. Over 44% of potential spatial knowledge can be inferred (certYES and certNO).

tion before and after. In other words, annotators understood that (1) the car was moving down a road and arrived at the intersection; (2) then, it was pulled over by a security guard who is probably stationed at the intersection; and (3) after the stop, the car probably continued with its route but the guard probably stayed at the intersection.

3.3 Annotation Analysis

Each annotator answered 1,995 questions generated with Algorithm 1. Basic label counts after resolving conflicts are shown in Table 3. First, it is worth noting that annotators used UNK to answer only 5.26% of questions. Thus, over 94% of times ARGM-LOC semantic role is found, additional spatial knowledge can be inferred with some degree of certainty. Second, annotators were certain about the additional spatial knowledge, i.e., labels certYES and certNO, 35.94% and 8.72% of times respectively. Thus, 44% of times one encounters ARGM-LOC semantic role, additional spatial knowledge can be inferred with certainty. Finally, annotators answered around 50% of questions with probYES or probNO. In other words, they found it likely that spatial information can be inferred, but were not completely certain.

	Observed	Cohen Kappa
Before	89.0%	0.845
During	91.2%	0.848
After	87.8%	0.814
All	89.8%	0.862

Table 4: Inter-annotation agreements. Kappa scores indicate "good reliability".

3.3.1 Inter-Annotator Agreements

Table 4 presents observed agreements, i.e., raw percentage of equal annotations, and Cohen Kappa scores (Cohen, 1960) per temporal anchor and for all questions. Kappa scores are above 0.80, indicating "good reliability" (Artstein and Poesio, 2008).

	No.	Name	Description
	0	temporal anchor	are we predicting LOCATION(*x*, *y*) before, during or after y_{pred}?
lexical	1–4	first word, POS tag	first word and POS tag in *x* and *y*
	5–8	last word, POS tag	last word and POS tag in *x* and *y*
	9,10	num tokens	number of tokens in *x* and *y*
	11,12	subcategory	concatenation of (1) *x*'s children and (2) *y*'s children
	13	direction	whether *x* occurs before or after *y*
syntactic	14,15	syntactic node	syntactic node of *x* and *y*
	16–19	head word, POS tag	head word and POS tag of *x* and *y*
	20–23	left and right sibling	syntactic nodes of the left and right siblings of *x* and *y*
	24–27	parent node and index	syntactic nodes and child indices of parents of *x* and *y*
	28	common subsumer	syntactic node subsuming *x* and *y*
	29	syntactic path	syntactic path between *x* and *y*
semantic	30–33	word, POS tag	predicate and POS tag of x_{pred} and y_{pred}
	34	isRole	semantic role label between x_{pred} and *x*
	35	same predicate	whether x_{pred} and y_{pred} are the same token
	36–39	firstRole, lastRole	the first and last semantic roles of x_{pred} and y_{pred}
	40–59	hasRole	flags indicating whether x_{pred} and y_{pred} have each semantic role
	60–99	role index and node	for each semantic role, the order of appearance and syntactic node
	100	x_containedIn_y_role	semantic role of y_{pred} that fully contains *x*
	101	y_containedIn_x_role	semantic role of x_{pred} that fully contains *y*

Table 5: Feature set to infer temporally-anchored spatial knowledge from semantic role representations.

We believe the high Kappa scores are due to the fact that we start from PropBank-style roles instead of plain text, and questions asked are intuitive. Note that not all disagreements are equal, e.g., the difference between `certYES` and `certNO` is much larger than the difference between `certYES` and `probYES`.

4 Inferring Spatial Knowledge

We follow a standard supervised machine learning approach. The 200 sentences were divided into train (80%) and test (20%), and the corresponding instances assigned to the train and test sets.[8] We trained an SVM with RBF kernel using scikit-learn (Pedregosa et al., 2011). Parameters C and γ were tuned using 10-fold cross-validation with the training set, and results are calculated with test instances.

4.1 Feature selection

Selected features (Table 5) are a mix of lexical, syntactic and semantic features, and are extracted from tokens (words and POS tags), full parse trees and semantic roles. Lexical and syntactic features are standard in semantic role labeling (Gildea and Jurafsky, 2002) and we do not elaborate on them. Hereafter we describe semantic features, which include any feature derived from semantic role representations.

[8] Splitting instances randomly would be unfair, as instances from the same sentence would be assigned to the train and test sets. Thank you to an anonymous reviewer for pointing this out.

Sentence: [In this laboratory]$_{\text{ARGM-LOC}, v_1}$ [I]$_{\text{ARG}_0, v_1}$'m [surrounded]$_{v_1}$ [by the remains of [20 service members who]$_{\text{ARG}_1, v_2}$ are in the process of being [identified]$_{v_2}$]$_{\text{ARG}_1, v_1}$
Potential additional spatial knowledge: x: *20 service members who*, y: *In this laboratory*; x_containedIn_y_role = ARG_1
Sentence: [Children]$_{\text{ARG}_0, v_1}$ can get to [know]$_{v_1}$ [different animals and plants, and [even some crops that]$_{\text{ARG}_1, v_2}$ are [rarely]$_{\text{ARGM-ADV}, v_2}$ [seen]$_{v_2}$ [in our daily life]$_{\text{ARGM-LOC}, v_2}$]$_{\text{ARG}_1, v_1}$.
Potential additional spatial knowledge: x: *Children*, y: *in our daily life*; y_containedIn_x_role = ARG_1

Figure 5: Pairs (x, y) for which *x_containedIn_y_role* and *y_containedIn_x_role* features have a value.

Features 30–33 correspond to the surface form and POS tag of the verbs to which *x* and *y* attach to. Feature 34 indicates the semantic role between x_{pred} and *x*; note that the semantic role between y_{pred} and *y* is always ARGM-LOC (Algorithm 1). Feature 35 distinguishes inferences of type (1a) from (1b) (Section 2.2): it indicates whether both *x* and *y* attach to the same verb, as in Figure 1, or not, as in Figure 2. Features 36–39 encode the first and last semantic role of x_{pred} and y_{pred} by order of appearance. Features 40–59 are binary flags signalling which se-

Table 6: Results obtained with two baselines, and training with several feature combinations. Models are trained with all instances (before, during and after).

mantic roles x_{pred} and y_{pred} have, and features 60–99 capture the index of each role (first, second, third, etc.) and its syntactic node (NP, PP, SBAR, etc.).

Finally, features 100 and 101 capture the semantic role of x_{pred} and y_{pred} which fully contain *y* and *x* respectively, if such roles exists. These features are especially designed for our inference task and are exemplified in Figure 5.

5 Experiments and Results

Results obtained with the test set using two baselines and models trained with several feature combinations are presented in Table 6. The *most frequent* baseline always predicts certYES, and the *most frequent per temporal anchor* baseline predicts probNO, certYES and probYES for instances with temporal anchor *before*, *during* and *after* respectively. The *most frequent* baseline obtains a weighted F-measure of 0.20, and *most frequent per temporal anchor* baseline 0.50. Results with supervised models are better, but we note that always predicting certYES for *during* instances obtains the same F-measure than using all features (0.65).

The bottom block of Table 6 presents results using all features. The weighted F-measure is 0.55, and the highest F-measures are obtained with labels certYES (0.71) and probYES (0.60). Results with certNO and probNO are lower (0.05 and 0.44), we believe this is due to the fact that few instances are annotated with this labels (8.72% and 19.75%, Ta-

ble 3). Results are higher (0.65) with *during* instances than with *before* and *after* instances (0.41 and 0.45). These results are intuitive: certain events such as *press* and *write* require participants to be located where the event occurs only during the event.

5.1 Feature Ablation and Detailed Results

The weighted F-measure using lexical features is the same than with the *most frequent per temporal anchor* baseline (0.50). F-measures go up with *before* (0.21 vs. 0.32, 52.38%) and *after* (0.28 vs. 0.47, 67.85%) instances, but slightly down with *during* instances (0.65 vs. 0.63, −3.08%).

Complementing lexical features with syntactic and semantic features brings the overall weighted F-measure slightly up: 0.53 with syntactic and 0.52 with semantic features (+0.03 and +0.02, 6% and 4%). *Before* instances benefit the most from syntactic features (0.32 vs. 0.41, 28.13%), and *after* instances benefit from semantic features (0.47 vs. 0.49, 4.26%). *During* instances do not benefit from semantic features, and only gain 0.01 F-measure (1.59%) with syntactic features.

Finally, combining lexical, syntactic and semantic features obtains the best overall results (weighted F-measure: 0.55 vs. 0.53 and 0.52, 3.77% and 5.77%). We note, however, that *before* instances do not benefit from including semantic features (same F-measure, 0.41), and the best results for *after* instances are obtained with lexical and semantic features (0.49 vs. 0.45, 8.16%),

6 Related Work

Tools to extract the PropBank semantic roles we infer from have been studied for years (Carreras and Màrquez, 2005; Hajič et al., 2009; Lang and Lapata, 2010). These systems only extract semantic links between predicates and their arguments, not between arguments of predicates. In contrast, this paper complements semantic role representations with spatial knowledge for numbered arguments.

There have been several proposals to extract semantic links not annotated in well-known corpora such as PropBank (Palmer et al., 2005), FrameNet (Baker et al., 1998) or NomBank (Meyers et al., 2004). Gerber and Chai (2010) augment NomBank annotations with additional numbered arguments appearing in the same or previous sentences; posterior work obtained better results for the same task (Gerber and Chai, 2012; Laparra and Rigau, 2013). The SemEval-2010 Task 10: Linking Events and their Participants in Discourse (Ruppenhofer et al., 2009) targeted cross-sentence missing numbered arguments in PropBank and FrameNet. We have previously proposed an unsupervised framework to compose semantic relations out of previously extracted relations (Blanco and Moldovan, 2011; Blanco and Moldovan, 2014a), and a supervised approach to infer additional argument modifiers (ARGM) for verbs in PropBank (Blanco and Moldovan, 2014b). Unlike the current work, these previous efforts (1) improve the semantic representation of verbal and nominal predicates, or (2) infer relations between arguments of the same predicate. None of them target temporally-anchored spatial knowledge or account for uncertainty.

Attaching temporal information to semantic relations is uncommon. In the context of the TAC KBP temporal slot filling track (Garrido et al., 2012; Surdeanu, 2013), relations common in information extraction (e.g., SPOUSE, COUNTRY_OF_RESIDENCY) are assigned a temporal interval indicating when they hold. The task proved very difficult, and the best system achieved 48% of human performance. Unlike this line of work, the approach presented in this paper starts from semantic role representations, targets temporally-anchored LOCATION relations, and accounts for degrees of uncertainty (`certYES` / `certNO` vs. `probYES` / `probNO`).

The task of spatial role labeling (Hajič et al., 2009; Kolomiyets et al., 2013) aims at thoroughly representing spatial information with so-called spatial roles, i.e., trajector, landmark, spatial and motion indicators, path, direction, distance, and spatial relations. Unlike us, the task does not consider temporal spans nor certainty. But as the examples throughout this paper show, doing so is useful because (1) spatial information for most objects changes over time, and (2) humans sometimes can only state that an object is *probably* located somewhere. In contrast to this task, we infer temporally-anchored spatial knowledge as humans intuitively understand it, and purposely avoid following any formalism.

7 Conclusions

Semantic roles encode semantic links between a verb and its arguments. Among other role labels, PropBank uses numbered arguments (ARG_0, ARG_1, etc.) to encode the core arguments of a verb, and ARGM-LOC to encode the location. This paper exploits these numbered arguments and ARGM-LOC in order to infer temporally-anchored spatial knowledge. This knowledge encodes whether a numbered argument *x* is or is not located in a location *y*, and temporally anchors this information with respect to the verb to which *y* attaches.

An annotation effort with 200 sentences from OntoNotes has been presented. First, potential additional spatial knowledge is generated automatically (Algorithm 1). Then, annotators following straightforward guidelines answer questions asking for intuitive spatial information, including uncertainty. The result is annotations with high inter-annotator agreements that encode spatial knowledge as understood by humans when reading text.

Experimental results show that inferring additional spatial knowledge can be done with a modest weighted F-measure of 0.55. Results are higher for `certYES` and `probYES` (0.71 and 0.60), the labels that indicate that something is certainly or probably located somewhere. Simple majority baselines provide strong results, but combining lexical, syntactic and semantic features yields the best results (0.50 vs. 0.55). Inferring spatial knowledge for numeric arguments before and after an event occurs is harder than during the event (0.41 and 0.45 vs. 0.65).

The most important conclusion of this work is the fact that given an ARGM-LOC semantic role, temporally-anchored spatial knowledge can be inferred for numbered arguments in the same sentence. Indeed, annotators answered 44% of questions with `certYES` or `certNO`, and 50% of questions with `probYES` or `probNO`. Another important observation is that spatial knowledge can be inferred from most verbs, not only motion verbs. While it is fairly obvious to infer from *John went to Paris* that he had LOCATION *Paris* after *went* but not before or during, we have shown that verbs such as *incarcerated* (Figure 1) also grant spatial inferences.

Abstract

Tree trimming is the problem of extracting an optimal subtree from an input tree, and sentence extraction and sentence compression methods can be formulated and solved as tree trimming problems. Previous approaches require integer linear programming (ILP) solvers to obtain exact solutions. The problem of this approach is that ILP solvers are black-boxes and have no theoretical guarantee as to their computation complexity. We propose a dynamic programming (DP) algorithm for tree trimming problems whose running time is $O(NL \log N)$, where N is the number of tree nodes and L is the length limit. Our algorithm exploits the zero-suppressed binary decision diagram (ZDD), a data structure that represents a family of sets as a directed acyclic graph, to represent the set of subtrees in a compact form; the structure of ZDD permits the application of DP to obtain exact solutions, and our algorithm is applicable to different tree trimming problems. Moreover, experiments show that our algorithm is faster than state-of-the-art ILP solvers, and that it scales well to handle large summarization problems.

1 Introduction

Extractive text summarization and sentence compression are tasks that basically select a subset of the input set of textual units that is appropriate as a summary or a compressed sentence. Current text summarization and sentence compression methods regard the problem of extracting such a subset as a combinatorial optimization problem (e.g., (Filatova and Hatzivassiloglou, 2004; McDonald, 2007; Lin and Bilmes, 2010)). Tree trimming, the problem of finding an optimal subtree of an input tree, is one kind of these combinatorial optimization problems, and it is used in three classes of text summarizations: sentence compression (Filippova and Strube, 2008; Filippova and Altun, 2013), single-document summarization (Hirao et al., 2013), and the combination of sentence compression and single-document summarization (Kikuchi et al., 2014). In these tasks, the set of input textual units is represented as a rooted tree whose nodes correspond to the minimum textual units such as sentences and words. Next, a subset is made by forming a subtree by trimming the input tree. Since the optimal trimmed subtree preserves the relationships between textual units, it is a concise representation of the original set that preserves linguistic quality.

A shortcoming of tree trimming-based methods is that they are formulated as integer linear programming (ILP) problems and so an ILP solver is needed to solve them. Although modern ILP solvers can solve many instances of tree trimming problems in a short time, there is no theoretical guarantee that they obtain an optimal solution. Furthermore, even if an optimal solution can be obtained, we cannot estimate the running time. Estimating the running time is critical for practical applications.

In this paper, we propose a dynamic programming (DP) algorithm for tree trimming problems that focus on text summarization. The algorithm can solve all three different classes of tree trimming problems proposed so far in a unified way, and it can always find an optimal solution in $O(NL \log N)$ time for these problems, where N is the number of nodes of the input tree and L is the length limit. The running time of our algorithm only depends on N and L and

Human Language Technologies: The 2015 Annual Conference of the North American Chapter of the ACL, pages 462–471,
Denver, Colorado, May 31 – June 5, 2015.

so is independent of the input trees structure. Finding an exact solution is important since we can use it to evaluate the performance of heuristic algorithms.

The key idea of our algorithm is to use the zero-suppressed binary decision diagram (ZDD) (Minato, 1993) to represent the set of all subtrees of the input tree. ZDD is a data structure that represents a family of sets as a directed acyclic graph (DAG). It can represent a family of sets in compressed form. We use ZDD to represent the set of subtrees of the input tree, and then run a DP algorithm on the ZDD to obtain the optimal solution that satisfies the length limit. The algorithm runs in time $O(|Z|L)$, where $|Z|$ is the number of nodes of ZDD, and L is the length limit. Although the number of ZDD nodes depends on the set we want to represent, we can give theoretical upper bounds when we represent the set of all subtrees of an input tree. ZDD uses $O(N \log N)$ nodes to represent the set of all subtrees of an N node input tree. Hence the DP algorithm runs in $O(NL \log N)$ time. The main virtues of the proposed algorithm are that (1) it can always find an exact solution, (2) its running time is theoretically guaranteed, and (3) it can solve the three known tree trimming problems. Furthermore, our algorithm is fast enough to be practical and scalable. Since text summarization methods are often applied to large scale inputs (e.g., (Christensen et al., 2014; Nakao, 2000)), scalability is important. We compare it to state-of-the-art ILP solvers and confirm that the proposed algorithm can be hundreds of times faster.

Since our method assumes known formuations for text summarization, the summary created by our algorithm is exactly the same as that obtained by applying previous methods. However, we believe that algorithmic improvements in computational cost is as important as improvements in accuracy in order to make better practical systems.

2 Tree Trimming Problems

We briefly review the three tree trimming formulations used in text summarization and sentence compression. They all try to find the subtree that maximizes the sum of item weights while satisfying the length limit. Let $D = \{e_1, \ldots, e_N\}$ be the input set of textual units, where e_i represents the i-th unit. We use w_i and l_i to represent the weight and length of e_i, respectively. Given length limit L, these methods solve the following optimization problem:

$$\begin{aligned} &\underset{T \subseteq D}{\text{Maximize}} \sum_{e_i \in T} w_i \\ &\text{Subject to } T \in \mathcal{T} \text{ and } \sum_{e_i \in T} l_i \leq L\,, \end{aligned} \tag{1}$$

where $T \subseteq D$ and $\mathcal{T} \subseteq 2^D$. We use $\mathcal{T}$ to represent the set of subtrees that can be feasible solutions if we ignore the length limit. The following problems employ different $\mathcal{T}$ to match each problem setting. If $\mathcal{T} = 2^D$, i.e., $\mathcal{T}$ equals the set of all possible subsets of D, it is equivalent to the 0-1 knapsack problem, and is solved with the standard DP algorithm.

Sentence Extraction Hirao et al. (2013) proposed a single-document summarization algorithm to solve a tree trimming problem. They represent a document as a set of elementary discourse units (EDUs) and then select an optimal subset to make a summary. Each EDU is a minimal unit that composes the discourse structure of the document; it usually corresponds to a clause. Their summarization method first represents a document as a dependency discourse tree (DEP-DT) that represents the dependency structure between EDUs. DEP-DT is a rooted tree in which each node corresponds to an EDU. They then select the rooted subtree that maximizes the sum of weights and satisfies the length limit to make a summary, where we say a subtree is rooted if it contains the root node of the input tree. This problem can be formulated as the combinatorial optimization problem of Eq.(1), where $\mathcal{T}$ is the set of all rooted subtrees of the input DEP-DT.

Sentence Compression Filippova and Strube (2008) proposed a sentence compression method based on the trimming of a word dependency tree. Its recently proposed variant shows state-of-the-art performance (Filippova and Altun, 2013). They trim a syntactical dependency tree to compress a sentence. Their formulation is similar to the previous sentence extraction method except that it allows the root node of a subtree to be other than the root node of the input tree. In other words, their formulation allows multiple candidate root nodes for a subtree. We represent such a set of candidate root nodes as R, and the set of possible solutions $\mathcal{T}$ for this formulation

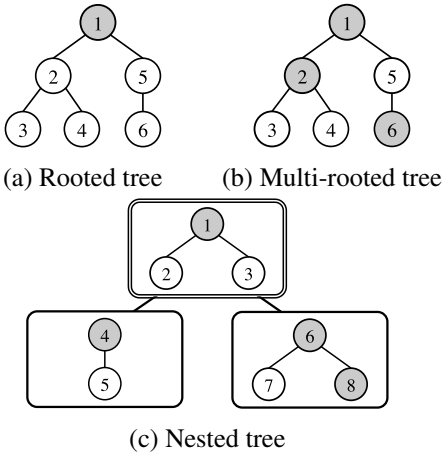

Figure 1: Example trees.

is the set of all subtrees of the input tree whose root node is contained in R.

Sentence Extraction & Compression Kikuchi et al. (2014) proposed a single-document summarization method that can select compressed sentences. It is an extension of the sentence extraction method proposed in (Hirao et al., 2013). They represent a document as a sentence dependency tree that is obtained from DEP-DT, and then represent each sentence in the sentence dependency tree as a word dependency tree. In the following, inner trees refer to the word dependency trees that correspond to sentences, while the outer tree represents the sentence dependency tree that represents a document. Hence a document is represented as a nested tree where each node of the outer tree corresponds to an inner tree. They then make a summary by first selecting a rooted subtree of the outer tree, and then selecting a subtree for each inner tree that corresponds to a node of the selected subtree of the outer tree. Each inner tree has multiple root candidate nodes, and the root node of a subtree of an inner tree is a root candidate node of the tree. The set of feasible solutions, $\mathcal{T}$, corresponds to all possible nested trees constructed in this way[1].

Fig. 1 shows example input trees used in the above three tasks: (a) a rooted tree used in sentence extraction, (b) a multi-rooted tree used in sentence compression, and (c) a nested tree used in sentence extraction & compression. Gray nodes are root candidate nodes. Each tree yields a different set of valid subtrees. Tab. 1 shows examples of valid and invalid subtrees of each input tree, where we assume that each subtree in $\mathcal{T}$ is represented by a set of nodes that is contained in the subtree.

[1] Kikuchi et al. (2014) set further constraints on possible subtrees of a syntactical tree. Our method can also cope with these additional constraints (see Sect. 7).

Table 1: Examples of valid and invalid subtrees of the input trees in Fig. 1

	Valid	Invalid
Rooted tree	$e_1e_2e_3$, $e_1e_2e_5$	$e_2e_3e_4$, e_6
Multi-rooted tree	$e_1e_2e_5$, $e_2e_3e_4$	e_3, e_5e_6
Nested tree	$e_1e_2e_4$, $e_1e_4e_5e_8$	$e_4e_5e_6$, $e_1e_2e_7$

3 Zero-suppressed Binary Decision Diagram (ZDD)

The key idea of the proposed algorithm is to represent the set of candidate subtrees $\mathcal{T}$ as a zero-suppressed binary decision diagram (ZDD) (Minato, 1993). ZDD is a variant of binary decision diagram (BDD) (Bryant, 1986; Akers, 1978), and is a data structure that can succinctly represent a family of sets as a DAG. ZDD has two types of nodes, namely branch nodes and terminal nodes. Branch nodes are non-terminal nodes. Each branch node has exactly two out edges, called low-edge and high-edge, and a label that represents the item that the node corresponds to. We use $\mathrm{hi}(i)$, $\mathrm{lo}(i)$, and $\mathrm{v}(i)$ to represent the node pointed to by the high-edge, low-edge, and the label of the i-th node of the ZDD, respectively. The branch node that has no parent node is the root node. Terminal nodes have no outgoing edges, and a ZDD has exactly two terminal nodes whose labels are $\top$ and $\bot$. A path from the root node to terminal node $\top$ represents a set of items contained in the family of sets represented by the ZDD. We can recover the set of items that corresponds to a path by selecting the labels of the branch nodes whose high-edges lie on the path.

Fig. 2(a) is a ZDD that represents the family of sets $\{e_1e_2, e_2e_3, e_1e_3\}$. We use circles to represent branch nodes and rectangles to represent the terminal nodes. A dashed edge represents a low-edge and full edge represents a high-edge. The number on each circle node represents the label of the node. For example, the label of the root node of the ZDD

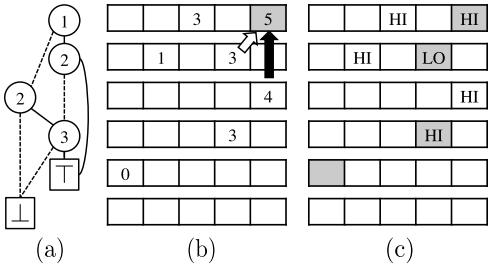

Figure 2: An example ZDD and how the dynamic programming algorithm works with the ZDD. (a) An example ZDD that represents the family of sets $\{e_1e_2, e_1e_3, e_2e_3\}$, (b) table S and (c) table B after completion of the table filling phase.

in Fig. 2(a) is 1. The ZDD has three different paths that start at the root node and end at $\top$. Each path corresponds to an item contained in the family of sets.

In the following, let $z_1, \ldots, z_{|Z|}$ be the nodes of a ZDD. We use Z to represent a ZDD, and $|Z|$ to represent the number of nodes in Z. We assume $i < \mathrm{hi}(i), \mathrm{lo}(i)$ for every $i = 1, \ldots, |Z| - 2$. z_1 corresponds to the root node, and $z_{|Z|-1}, z_{|Z|}$ corresponds to $\top$ and $\bot$ terminal nodes, respectively. We also assume that the ZDD is ordered, i.e., there is a total order on the labels, and the label of a parent node comes before that of a child node for every parent-child node pair. The ZDD in Fig. 2(a) is an ordered ZDD whose order is e_1, e_2, e_3.

4 Dynamic Programming Algorithm for Tree Trimming Problems

Our algorithm takes the following three-step procedure. First, we represent the set of subtrees $\mathcal{T}$ for each tree trimming problem as a ZDD. Then we apply a bottom-up and table-filling style DP algorithm to the ZDD. Finally, we backtrack the filled table to obtain an optimal solution.

Our algorithm is similar to the standard DP algorithm for the 0-1 knapsack problem, which solves the problem in $O(NL)$ time with N items and length limit L. The DP algorithm solves a knapsack problem by filling an $N \times (L+1)$ table by recursively exploiting previously computed partial solutions. Our algorithm also fills a table for problem solving, but the table's size is $|Z| \times (L+1)$. That is, the size of the table equals the number of nodes of the ZDD

Algorithm 1 Dynamic Programming Algorithm

Input: ZDD Z that represent $\mathcal{T}$, length limit L, and w_i, l_i for $1 \le i \le N$
Output: Optimal subtree $\mathbf{r}$

1: Initialize $S[i][j] \leftarrow -\infty$ **for all** i, j.
2: $S[|Z|-1][0] \leftarrow 0$.
3: **for** $i = |Z|-2, \ldots, 1$ **do**
4: **for** $j = 0, \ldots, L$ **do**
5: **if** $j \ge l_{\mathrm{v}(i)}$ **and** $S[\mathrm{hi}(i)][j - l_{\mathrm{v}(i)}] + w_{\mathrm{v}(i)} > S[\mathrm{lo}(i)][j]$ **then**
6: $S[i][j] \leftarrow S[\mathrm{hi}(i)][j - l_{\mathrm{v}(i)}] + w_{\mathrm{v}(i)}$
7: $B[i][j] \leftarrow HI$
8: **else**
9: $S[i][j] \leftarrow S[\mathrm{lo}(i)][j]$, $B[i][j] \leftarrow LO$
10: $k^* \leftarrow \mathrm{argmax}_{0 \le k \le L} S[1][k]$
11: $i \leftarrow 1$, $j \leftarrow k^*$, $\mathbf{r} \leftarrow \emptyset$
12: **while** $(i, j) \neq (|Z|-1, 0)$ **do**
13: **if** $B[i][j] = HI$ **then**
14: $\mathbf{r} \leftarrow \mathbf{r} \cup \{\mathrm{v}(i)\}$, $i \leftarrow \mathrm{hi}(i)$, $j \leftarrow j - l_{\mathrm{v}(i)}$
15: **else**
16: $i \leftarrow \mathrm{lo}(i)$
17: **return** $\mathbf{r}$

that represents a set of subtrees $\mathcal{T}$. The tables can be seen as the set of $|Z|$ arrays with $(L+1)$ entries, and each array is associated with each ZDD node. We fill these tables by referring to previously computed results by using the ZDD's structure.

Alg. 1 is the DP algorithm that can solve the problem of Eq.(1), given the ZDD that represents the family of sets $\mathcal{T}$. We first prepare two tables, S and B; both have $|Z| \times (L+1)$ entries. Table S is used for storing intermediate weights, and B is used for storing information used in recovering the optimal solution. We first fill the elements in S and B while traversing the ZDD in order from the terminal nodes to the root node. We then use B to recover the solution that maximizes the weight. In the table filling phase (lines 1 to 9), we update $S[i][j]$ and $B[i][j]$, recursively. Weight $S[i][j]$ represents the maximum weight of the ZDD path from the i-th node to the $\top$ terminal node, whose total length is j. We compare $S[\mathrm{hi}(i)][j - l_{\mathrm{v}(i)}] + w_{\mathrm{v}(i)}$ and $S[\mathrm{lo}(i)][j]$, and select the maximum weight to set $S[i][j]$. The value of $B[i][j]$ stores which candidate we set to $S[i][j]$. If we use the former one, we set label HI to $B[i][j]$, otherwise LO. After filling the table, we run a backtracking procedure to obtain an optimal solution. In the backtracking phase (lines 10 to 16), we start from $B[i][k^*]$ and repeat backtracking using the entries of B.

We give here a proof of the correctness of the algorithm. We use the fact that the ZDD is constructed recursively; given the i-th branch node z_i of a ZDD, the subgraph induced by the set of nodes that are descendants of z_i is also a ZDD. Let the ZDD whose root node is z_i be Z_i, and the family of sets represented by Z_i be $\mathcal{T}_i$. Family of sets $\mathcal{T}_i$, $\mathcal{T}_{\mathrm{lo}(i)}$ and $\mathcal{T}_{\mathrm{hi}(i)}$ satisfy the following relationship.

$$\mathcal{T}_i = \mathcal{T}_{\mathrm{lo}(i)} \cup \{e_{\mathrm{v}(i)} \cup T | T \in \mathcal{T}_{\mathrm{hi}(i)}\}$$

Proposition 1. *Alg. 1 can find the optimal solution of the problem of Eq.(1), where we assume $\mathcal{T}$ is represented as an ordered ZDD.*

Proof. We use induction to give a proof that $S[i][j] = \max_T \sum_{e_i \in T} w_i$ after running our algorithm, where T is a set of tree nodes that satisfies $T \in \mathcal{T}_i$ and $\sum_{e_i \in T} l_i = j$. If $i = |Z| - 1$, then $\mathcal{T}_i = \{\emptyset\}$ and $S[i][0] = 0$ and $S[i][j] = -\infty$ for $j \neq 0$, which satisfies the condition. Suppose that $S[\mathrm{lo}(i)][j]$ and $S[\mathrm{hi}(i)][j]$ both satisfy the condition for $j = 0, \ldots, L$. If the set that maximizes $S[i][j]$ does not have $e_{\mathrm{v}(i)}$, then the set is contained in $\mathcal{T}_{\mathrm{lo}(i)}$, and its size is j. Therefore, the maximum weight equals $S[\mathrm{lo}(i)][j]$ (Alg.1 line 9). Otherwise, the set that maximizes $S[i][j]$ has $e_{\mathrm{v}(i)}$, so the item is contained in $\{e_{\mathrm{v}(i)} \cup T | T \in \mathcal{T}_{\mathrm{hi}(i)}\}$, and its weight is $S[\mathrm{hi}(i)][j - l_{\mathrm{v}(i)}] + w_{\mathrm{v}(i)}$ (Alg.1 line 6). Since Z_1 corresponds to the root node and it represents all possible solutions, $\max_j S[1][j]$ is the maximum weight of the subset that satisfies the length limit and is contained in $\mathcal{T}$. □

Proposition 2. *The time and space complexity of Alg. 1 are both $O(|Z|L)$.*

Proof. We have to store tables S, B and solution $\mathbf{r}$. The tables have $|Z| \times (L+1)$ entries and $|Z| \geq |\mathbf{r}|$, the space complexity is $O(|Z|L)$. For the time complexity, filling entries in S and B requires $O(|Z|L)$ time since to fill an entry requires constant time. Backtracking requires at most N updates, hence the time complexity is $O(|Z|L)$. □

We show an example of our algorithm in Fig. 2. Suppose that $D = \{e_1e_2, e_1e_3, e_2e_3\}$, $(l_1, l_2, l_3) = (1, 1, 3)$ and $(w_1, w_2, w_3) = (2, 1, 3)$. Set D is represented as the ZDD in Fig. 2(a). Let $L = 4$ and run the DP algorithm yielding tables S and B shown in Fig. 2(b,c). Suppose that we want to fill entry $S[1][4]$ (the upper right cell). There are two possible paths to reach the entry; the first path takes the high-edge from $S[2][3]$, and the second path takes the low-edge from $S[3][4]$. We use hollow and black arrows to represent these paths in Fig. 2(b). Since the former path results in weight 5, which is higher than that of the later path, hence we set $S[1][4] = 5$ and $B[1][4] =$ HI. After filling all the entries in tables, we can see $S[1][4]$ has the maximum weight, and the backtracking from $B[1][4] \rightarrow B[2][3] \rightarrow B[4][3] \rightarrow B[5][0]$. $B[5][0]$ corresponds to the $\top$ terminal node, and the backtracking yields the optimal solution e_1e_3.

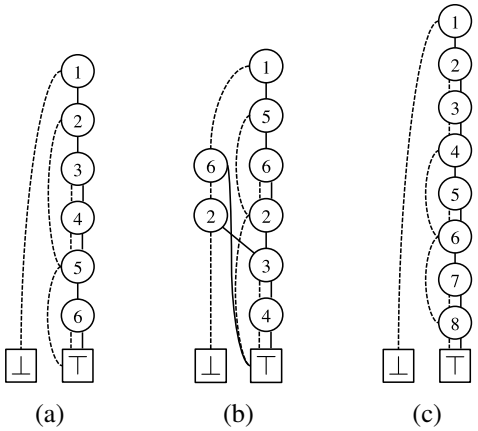

Figure 3: Example ZDDs representing the set of trimmed subtrees of the trees in Fig. 1. (a) Rooted-tree, (b) multi-rooted tree, and (c) nested-tree

5 ZDD Sizes

We give upper bounds on the size of the ZDD representing the family of sets $\mathcal{T}$ of Eq.(1) for the three problems. The number of subtrees contained in $\mathcal{T}$ may grow exponentially with the size of the original tree, however, we can represent them as a ZDD with very few nodes. Since the running time of our algorithm is $O(|Z|L)$, these theoretical upper bounds determine the running time of the proposed tree trimming algorithms.

We first give a proof of the size of the ZDD that represents all rooted subtrees of a given tree.

Proposition 3. *Given a tree with N nodes, we can construct a ZDD that represents all rooted subtrees of the tree whose number of nodes is $N + 2$, if we use a depth first pre-order of tree nodes as the order*

of ZDD labels.

This result can be derived from the result of (Knuth, 2011), Chap.7.1.4, exercise 266. Fig. 3(a) is a ZDD that represents the set of all rooted subtrees of the tree in Fig. 1(a), where we employ pre-ordering $e_1, e_2, e_3, e_4, e_5, e_6$.

We next show the size of the ZDDs that represent the set of all subtrees of a multi-rooted tree.

Proposition 4. *Given an N node tree and the set of candidate root nodes R, the set of all possible subtrees can be represented by a ZDD whose number of nodes is $O(N \log |R|)$.*

Proof. (Sketch) The set of all possible subtrees can be represented as the union of the sets of rooted subtrees for different root $r \in R$. The set of rooted subtrees for a root node r can be represented as a ZDD that has $O(N)$ nodes, hence the set of ZDDs for different root nodes has $O(N|R|)$ nodes in total. We can further reduce this upper bound by employing appropriate depth first pre-ordering so as to share as many ZDD substructures as possible, and this ordering results in a union ZDD whose number of nodes is $O(N \log |R|)$. □

This proposition is related to a recently proved result that the set of all subtrees of an N-node tree can be represented as a ZDD whose number of nodes is $O(N \log N)$ (Yasuda et al., 2014). This is a special case of the above theorem that R equals the set of all nodes of the tree, i.e., $|R| = N$. The key point is to use the *heaviest-last depth first pre-order* as the ZDD label order. In this order, a node with the heaviest weight always comes after other siblings, where we define the weight of a node as the size of the maximum rooted subtree $T \in \mathcal{T}$ that is contained in its descendant tree. Fig. 3(b) is an example of the ZDD that represents the set of all possible rooted subtrees of the multi-rooted tree in Fig. 1(b), where the heaviest-last depth first pre-order is $e_1, e_5, e_6, e_2, e_3, e_4$.

The upper bound size of a ZDD for nested subtrees can be estimated by combining the above two theoretical results on rooted subtrees and multi-rooted subtrees.

Proposition 5. *For a nested tree whose sum of the number of nodes of inner trees is N, and the sets of candidate root nodes for inner trees are $R_1, \ldots, R_M$, where M is the number of inner trees, we can represent the set of possible nested subtrees by $O(N \log |R^*|)$, where $|R^*| = \max_i |R_i|$.*

Proof. (Sketch) The ZDD corresponding to the set of nested subtrees can be constructed as follows: first we make ZDDs that represent the set of rooted subtrees of the outer tree and inner trees. The outer tree is represented as a ZDD with $O(N)$ nodes, and the i-th inner tree is represented as a ZDD with $O(N_i \log |R_i|)$ nodes, where N_i is the number of nodes of the i-th inner tree. Then we can construct the ZDD for the nested tree by replacing each ZDD node of the outer-tree ZDD with the inner-tree ZDD corresponding to that node. □

Fig. 3(c) is a ZDD that represents the set of nested subtrees of the tree in Fig. 1(c), where we employ the order $e_1, e_2, e_3, e_4, e_5, e_6, e_7, e_8$.

We can directly prove the running time of the DP algorithm by exploiting the above three results to show the DP algorithm for the three problems takes $O(NL)$, $O(NL \log |R|)$, and $O(NL \log |R^*|)$ time, respectively. Here we assume that a ZDD that represents the set $\mathcal{T}$ is given. We need additional time for constructing a ZDD that represents $\mathcal{T}$ i.e. the input tree. However, ZDD construction also can be done in $O(|Z|)$ for the three tree trimming problems. We show details of ZDD construction in the next section.

6 Efficient ZDD Construction

We introduce here an efficient algorithm for constructing a ZDD that is used in the tree trimming problems. A ZDD can be constructed by repeatedly applying set operations between intermediate ZDDs, however, this process may be too slow since the running time of the set operations depends on the size of input and output ZDDs.

We first show the flow of an efficient ZDD construction algorithm for multi-rooted trees. This algorithm also can be used for constructing a ZDD for all rooted subtrees of a tree since a single-root tree is also a multi-rooted tree. The algorithm consists of two steps: first, we determine the appropriate order of ZDD nodes. We then use the top-down ZDD construction algorithm shown in (Knuth, 2011) (Chap.7.1.4, Exercise 55) to construct a ZDD. The

top-down algorithm can efficiently construct a ZDD that represents the set of all connected components of a graph, and we can use it for constructing the set of all rooted subtrees with small modification. The running time of top-down construction algorithms may not be $O(|Z|)$, but our modified algorithm can obtain the ZDD in $O(|Z|)$ time by exploiting the structure of the input tree to avoid to make unnecessary ZDD nodes.

We can extend this ZDD construction algorithm to create ZDDs that represent the set of nested subtrees. We first compute the orders of outer tree and each inner tree, and then construct ZDDs for them using the top-down construction algorithm. Finally, we obtain the required ZDD by replacing ZDD nodes of the outer tree with the corresponding inner ZDDs. These procedure also can be done in $O(|Z|)$ time, since constructing the ZDDs for each tree takes time proportional to its size, and the ZDD substitution phase also takes time proportional to ZDD size.

7 Discussion

When solving a tree trimming problem, we sometimes want to add constraints to the problem so as to obtain better results. For example, Kikuchi et al. (2014) use additional constraints to set the minimum number of words (say θ words) extracted from a sentence if the sentence is contained in a summary, and require each selected inner tree to contain at least one verb and noun if the inner tree has them. Since our tree trimming approach can work once the ZDD that represents the set of feasible solutions is constructed, adding new constraints to the set of solutions can be easily performed by applying ZDD operations. These operations can be performed efficiently for many cases and the proposed approach will still work well. Moreover, we can extend the algorithm to construct ZDDs that represent the extended set of feasible solutions. We can also give theoretical upper bounds for the new constraint-added problem. In this nested tree case, we can prove that the number of ZDD nodes is $O(N\theta \log |R^*|)$.

8 Experiments

We conduct experiments on the three tree trimming tasks of text summarization, sentence compression, and the combination of summarization and text compression. For the text summarization experiments, we use the test collection for summarization evaluation contained in the RST Discourse Treebank (RST-DTB) (Carlson et al., 2001), which is used in the previous work. The test collection consists of 30 documents with the reference summaries whose length is about 10% of the original document. We used the same parameters used in the previous papers. For sentence compression, we use the English compression corpus used in (Filippova and Strube, 2008), which consists of 82 news stories selected from the British National Corpus and American News Text Corpus, and consists of more than 1,300 sentences. We set the sizes of compressed sentences to be 70% of the original length, which is used in the original paper. We compare the proposed algorithm to Gurobi 5.5.0, a widely used commercial ILP solver[2]. It was run in the default settings and we used single-thread mode. We run Gurobi until it finds an optimal solution. Our algorithm was implemented in C++, and all experiments were conducted on a Linux machine with a Xeon E5-2670 2.60 GHz CPU and 192 GB RAM.

Fig. 4 compares the running time of our algorithm (includes ZDD construction time) and Gurobi. Each plotted marker in the figures represents a test instance, and if the position of a marker is below the dashed line, it means that our method is faster than Gurobi. We can see that our method is always faster than Gurobi; it was, at most, 300, 10, and 50 times faster in sentence extraction, sentence compression, and extraction & compression, respectively. Fig. 5,6 shows the relation between the input tree size and the ZDD construction times, and the relation between the input tree size and converted ZDD size respectively. These results show that both ZDD sizes and construction time were linear to the number of input tree nodes. The number of ZDD nodes looks like smaller than the $O(N \log N)$ bounds for multi-rooted trees and nested trees. This result is caused since the set of root candidate nodes R is small comparing with N for a typical input document.

Next we conduct experiments to assess the scalability of the proposed method by solving problems with different input sizes. We choose the nested tree

[2]We also used CPLEX 12.5.1.0, but Gurobi shows better performance in most cases.

trimming problem since it is the most complex problem. We make a large artificial nested tree by concatenating outer-trees of the nested trees of 30 RST-DT datasets. The results are shown in Fig. 7, and it shows that out method scales well with large inputs comparing with Gurobi.

9 Related Work

Recently proposed text summarization and sentence compression methods solve a task by formulating it as a combinatorial optimization problem (McDonald, 2007; Woodsend and Lapata, 2010; Martins and Smith, 2009; Clarke and Lapata, 2008). These combinatorial optimization-based formulations enable flexible models that can reflect the properties required. However, their complexity makes it difficult to solve optimization problems efficiently. These problems can be solved by using ILP solvers, however, they may fail to find optimal solutions and they have no guarantee on the running time. Since the proposed method is a DP algorithm and it has a theoretical guarantee, it always find an optimal solution in time proportional to the size of the input tree.

Our method also can be seen as a kind of fast text summarization algorithm. Previous fast algorithms are approximate algorithms (Qian and Liu, 2013; Lin and Bilmes, 2010; Lin and Bilmes, 2011; Davis et al., 2012), while our algorithm is an exact algorithm. Of course, there is a difference in task hardness since previous methods were designed for multi-document summarization and ours for single document summarization. Those works suggest

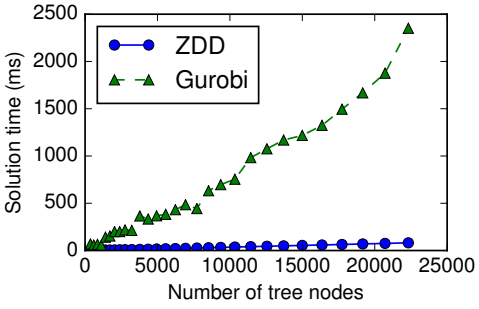

Figure 7: Solution time of our algorithm and Gurobi with different input tree sizes.

that algorithms that have guarantees on both running time and quality of solutions are highly demanding, and the proposed pseudo-polynomial time exact algorithm is valuable.

The Zero-suppressed Binary Decision Diagram (ZDD) (Minato, 1993) is a variant of the Binary Decision Diagram (BDD) (Akers, 1978; Bryant, 1986). BDD is a data structure that represents a Boolean function as a DAG, and ZDD can represent a family of sets in a compact form. Recently, ZDD and BDD have been used for solving optimization problems (Bergman et al., 2014a; Bergman et al., 2014b); they find the optimal solution by representing the set of feasible solutions in a BDD or its variants. Compared to these optimization methods, the proposed method differs in two main points. First, the proposed algorithm extends the ZDD-based optimization algorithm to solve knapsack problems. Second, it offers proofs of the size of ZDDs representing trimmed subtrees.

The ZDD-based method presented in this paper is related to our previous work of a BDD-constrained search (BCS) method (Nishino et al., 2015). In BCS, a BDD is used to solve constraints-added variants of shortest path problems on a DAG, and a 0-1 knapsack problem with additional constraints also can be solved by BCS. The main advantage of the DP-algorithm shown in this paper is that it has a theoretical guarantee on its running time which depends on only the size of the input tree. This advantage comes from using ZDD instead of BDD, and designing an algorithm specialized for variants of the knapsack problem. Though not obvious, it is possible to extend BCS to use ZDD instead of BDD and employ the label order used in this paper to give a theoretical bound that only depends on the size of an input tree. Nevertheless, the bound attained with this extension is worse than that shown in this paper.

10 Conclusion

We have proposed a DP algorithm for the tree trimming problems that appear in text summarization. Our approach always finds an optimal solution, and it runs in $O(NL \log N)$ time, where N is the number of tree nodes and L is the length limit. The key to our approach is to represent a set of subtrees of an input tree as a ZDD. By using ZDD, we can give a theoretical guarantee of the running time of the algorithm. Experiments show that the proposal allows three different tree trimming problems to be solved in the same way.

Abstract

Context representations are a key element in distributional models of word meaning. In contrast to typical representations based on neighboring words, a recently proposed approach suggests to represent a context of a target word by a *substitute vector*, comprising the potential fillers for the target word slot in that context. In this work we first propose a variant of substitute vectors, which we find particularly suitable for measuring context similarity. Then, we propose a novel model for representing word meaning in context based on this context representation. Our model outperforms state-of-the-art results on lexical substitution tasks in an unsupervised setting.

1 Introduction

Following the distributional hypothesis (Firth, 1957), distributional models represent the meaning of a word type as an aggregation of its contexts. A recent line of work addresses polysemy of word types by representing the meaning (or sense) of each word instance individually as induced by its particular context. The context-sensitive meaning of a word instance is commonly called the word meaning *in context*, as opposed to the word meaning *out-of-context* of a word type.

A key element of distributional models is the choice of context representation. A context of a word instance is typically represented by an unordered collection of its first-order neighboring words, called *bag-of-words* (BOW). In contrast, Yatbaz et al. (2012) proposed to represent this context as a second-order *substitute vector*. Instead of the neighboring words themselves, a substitute vector includes the potential filler words for the target word slot, weighted according to how 'fit' they are to fill the target slot given the neighboring words. For example, the substitute vector representing the context "I __ my smartphone." (target slot underlined), would typically include potential slot fillers such as *love*, *lost*, *upgraded*, etc.

our proposals will unlock __new__ ways of raising the finance needed to develop businesses.	
representations of context	
BOW	proposals, raising, unlock, ways
substitutes	alternate, proposing, infinite, various
representation of word meaning in context	
paraphrases	new, innovative, different, alternative, novel

Table 1: Example for BOW and substitute vector representations for a context of the target word *new*. The paraphrase vector is the representation learned by our model for the meaning of *new* in this context. Only the first few entries for each vector are shown.

Melamud et al. (2014) argued that substitute vectors are potentially more informative than traditional context representations since the fitness of the fillers is estimated using an n-gram language model, thereby capturing information embedded in the neighboring word order. They showed promising results on measuring word similarity out-of-context with a distributional model based on this approach.

In this paper we first propose a variant of substitute vectors as a context representation, which we find particularly suitable for measuring context similarity. Then, we extend the work in Melamud et al. (2014) by proposing a novel distributional model for representing word meaning in context, based on this context representation. Like sub-

stitute vectors, the word representations learned by our model are second-order vectors, which we call *paraphrase vectors*. Table 1 illustrates the difference between BOW and substitute vector context representations, as well as our representation for a word in context. Our model outperforms state-of-the-art results on lexical substitution tasks while learning from plain text in an unsupervised setting. [1]

2 Background

A key element in distributional models of word meaning is the choice of context representation. Traditional out-of-context distributional models aggregate the observed contexts of a target word type to derive its representation. More recent models of word meaning in context typically bias such a word type representation towards the context of each particular word instance using context similarity measures. The typical choice for context representation is a *bag-of-words* (BOW) context vector. In this vector each neighboring word type is assigned with a weight, such as its count (Erk and Padó, 2010) or *tf-idf* (Reisinger and Mooney, 2010). A more recent variant of this approach is the *continuous bag-of-words* (CBOW) vector, where context is represented as an average, or *tf-idf* weighted average, of dense low dimensional vector representations of the neighboring words (Huang et al., 2012). Context similarity is typically computed using vector Cosine.

Several types of models of word meaning in context were recently proposed in the literature, mostly based on variants of BOW context representations. Thater et al. (2011) aggregate the contexts of a target word type into a sparse syntax-based context feature vector. Then, they generate a biased vector representation by reducing the weight of each context feature the less similar it is to the context of the given word instance. Reisinger and Mooney (2010) and Huang et al. (2012) use context clustering to induce multiple word senses for a target word type, where each sense is represented by a different context feature vector. Then, they choose for each word instance the sense vector most similar to its given context. Ó Séaghdha and Korhonen (2014) use LDA (Blei et al., 2003) to aggregate word collocations to distributions over topics. Then, word meaning is represented by distributions that can be conditioned on (and hence biased towards) the given context.

3 Substitute Vectors

In this work we propose to use a little-known context modeling paradigm, representing a context word window as a *substitute vector* (Yatbaz et al., 2012). Unlike traditional context representations, a substitute vector does not comprise the first-order neighboring words of the target word. Instead it includes the second-order potential fillers for the target word slot, weighted according to how 'fit' they are to fill the target slot given the neighboring words. More formally, we denote a word window context around a target word slot as c, and the substitute vector representing c as $\vec{s}_c$. $\vec{s}_c[v]$ is the fitness weight of word v to fill the target slot in context c, for every word v in the target word vocabulary. For example, the substitute vector $\vec{s}_c$ = [big 0.35, good 0.28, bold 0.05, ...] may represent the context c = "It's a __ move.".

Yatbaz et al. (2012) used a Kneser-Ney smoothed n-gram language model (Kneser and Ney, 1995) to estimate conditional probability as the fitness weight $\vec{s}_c[v] = p(v|c)$. Using a smoothed language model is essential since context-word collocation counts are too sparse when the context considered is an entire word window. We note that given the nature of n-gram language models this representation is sensitive to word order. This property makes it appealing as it is potentially more informative than the traditional unordered BOW context representations.

4 A Model for Word Meaning in Context

The main contribution of this paper is in proposing a model for word meaning in context, which is based on substitute vector context representations instead of the traditional bag-of-words representations. To achieve this we first propose a variant of substitute vectors as our context representation. Then, we consider an out-of-context representation for a word type as the average of the substitute vector representations of its observed contexts. Finally, the in-context representation for a given word instance is a weighted average of its observed contexts. In this weighted average, contexts are weighted higher the more similar they are to the given context, using

... the very essence or heart of being a *__coach__*.	
c	... the very essence or heart of being a ____.
$\vec{s}_c$	christian, non-smoker, traitor, grandparent
$\vec{p}_u$	coach, bus, train, boat
$\vec{p}_{u,c}$	coach, teacher, writer, manager

Table 2: The substitute vector $\vec{s}_c$ for context c, the out-of-context paraphrase vector $\vec{p}_u$ for the word type *u* = *coach*, and the in-context paraphrase vector $\vec{p}_{u,c}$ for *u* in context c, as learned by our model. Only the first few vector entries (weights omitted) are shown. $\vec{s}_c$, $\vec{p}_u$ and $\vec{p}_{u,c}$ are defined formally in sections 4.1 and 4.2.

a substitute vector similarity measure. Intuitively, with this weighting scheme, we wish to consider mostly the word type contexts that induce a sense similar to that of the given word instance, under the premise that similar contexts induce similar word senses. The resulting word representation is biased towards the given context on one hand due to the context weighting scheme, and is bounded to the target word type spectrum of meanings on the other hand as only contexts of that word type are taken into consideration.

Table 2 exemplifies a context substitute vector and both out-of-context and in-context word representations learned by our model for a word instance. It is evident in this case that our in-context representation comprises suitable paraphrases in contrast to the out-of-context representation. We evaluate these word representations quantitatively in Section 6. We next describe our model in more detail.

4.1 Context representation

We wish the context representation in our model to be optimized for measuring context similarity, which is typically used to bias in-context word representations towards a given context.

For the purpose of measuring similarity between contexts, we consider in this section the contexts as 'targets'. Accordingly, we observe that the substitute vector of a word window context c can be considered as a vector of first-order co-occurrence features of c, as it consists of slot filler words that are likely to co-occur with this context. Hence, we follow prior work and propose to use *Positive PMI* (PPMI) as our substitute vector feature weights, instead of the conditional probabilities used by Yatbaz et al. (2012), and vector Cosine as our context similarity function (Bullinaria and Levy, 2007):

Q: the transcendental meditation people advertised this: meditation can __fix__ many sicknesses.	
substitutes	relieve, circumvent, alleviate
R_{sub}: use the results of your analysis to suggest design changes that would __fix__ these problems.	
substitutes	overcome, solve, alleviate
R_{cbow}: __fix__ in your mind a picture of heavenly worship that is real and eternal.	
substitutes	echoing, send, stick

Table 3: Example for a context of the word *fix*, Q, and the two contexts of *fix*, R_{sub} and R_{cbow}, most similar to it, based on substitute vector and CBOW similarity, respectively. The substitute vectors are illustrated below each context (selected substitutes in the top-10 entries shown).

$$\vec{s}_c[v] = PPMI(c, v) = \max(0, PMI(c, v)) \quad (1)$$

$$sim(c, c') = cos(\vec{s}_c, \vec{s}_{c'}) \quad (2)$$

where $\vec{s}_c[v]$ is the fitness weight for word v in the substitute vector of context c, PMI is point-wise mutual information (Church and Hanks, 1990), and $sim(c, c')$ is our context similarity measure. We note that a context c in our setting stands for an entire word window rather than a single context word. We therefore follow Yatbaz et al. (2012) using an n-gram language model to estimate $PMI(c, v)$, as detailed in Section 5.

Table 3 illustrates an example of a given context and the contexts most similar to it, as retrieved by our substitute vector and continuous bag-of-words context similarity measures. It is evident in this case that our measure correlates with the induced senses better than the bag-of-words measure. We suggest this context similarity measure as a standalone contribution, which may be useful in other settings as well. We evaluate it quantitatively in Section 5.

4.2 Modeling word meaning

Word meaning out-of-context We first define our *out-of-context* representation for target word type u, as an average of the substitute vectors of its contexts:

$$\vec{p}_u = \frac{1}{|C_u|} \sum_{i \in C_u} \vec{s}_i \quad (3)$$

where C_u is a collection of the contexts observed for target word type u in a learning corpus, and $\vec{s}_i$ are their substitute vectors.

Word meaning in context Next, following Erk and Padó (2010), to represent the meaning of word u in context c, we would like to alter the out-of-context representation by theoretically averaging only over contexts that induce a word sense similar to that of the given context. To approximate this objective we use a weighted average of all contexts of u, where contexts are weighted according to their similarity to the given context:

$$\vec{p}_{u,c} = \frac{1}{Z} \sum_{i \in C_{cu}} sim(c,i) \cdot \vec{s}_i \quad (4)$$

where $C_{cu} = C_u \cup c$ (u's corpus contexts plus the given context) and Z is a normalization factor.

$\vec{p}_{u,c}[v] = \frac{1}{Z} \sum_{i \in C_{cu}} sim(c,i) \cdot \vec{s}_i[v]$ is the average fitness of v within the contexts of u, biased to those similar to c. We consider this a context-sensitive similarity score, indicative of the likelihood of v to be a paraphrase of u in context c.[2] Thus, we name our in-context representation for a word instance as its *paraphrase vector*.

Finally, $\vec{p}^{\,m}_{u,c}$ denotes a word representation as defined in Equation (4), where only the top-m percent of the contexts in C_{cu} most similar to c are averaged. Using low values for m means injecting a stronger bias in our model towards the given context.

5 Evaluating Context Representations

As described in Section 4, our model for word meaning in context utilizes a context similarity measure under the premise that similar contexts induce similar target word senses. In this section we describe a focused evaluation of our proposed similarity measure and prior methods with respect to this objective. This evaluation suggests that our measures may be useful as a component in other models as well.

5.1 Task description

Given a word window context c of a target word u, we wish to evaluate context similarity measures on their ability to retrieve other contexts of u from C_u that induce a similar sense. To perform such an evaluation we want a dataset of target words with thousands of sense tagged contexts in C_u for each target word u. Since available manually sense-tagged datasets, such as SemCor (Mihalcea, 1998), are not large enough for this purpose, we adopted a pseudo-word approach, with which we can automatically generate as many tagged contexts as we wish.

Pseudo-word methods consider a set of real words as pseudo-senses of an artificial pseudo-word (Pilehvar and Navigli, 2014). Specifically, we adopted a simple approach following Otrusina and Smrz (2010) to generate our pseduo-words. First, we sampled 100 words randomly from our learning corpus, ukWaC (Ferraresi et al., 2008). Then we constructed a pseudo-word based on each of these words as follows. We used WordNet (Fellbaum, 2010) to identify all of the word's synsets. Next, for each synset we chose the surface word which is the least polysemous yet occurs in our learning corpus at least 1,000 times, as a *representative* for this synset. Then, we created a pseudo-word whose pseudo-senses are the set of the representative words. For example, the pseudo-word that was generated based on the word *promote* is *elevate_encourage_advertise*. Finally, we sampled from our learning corpus 1,000 contexts for each pseudo-sense word, and for each pseudo-word we mixed together all contexts of its pseudo-sense words. The original pseudo-sense word for each context was recorded as its sense tag.

Next, for each pseudo-word, we sampled a single *query context* from all of its mixed contexts and then ranked the remaining contexts according to each of the compared context similarity measures. We computed precision at top-1, top-1% and average precision for the ranked lists, where a true-positive is a context with an identical sense tag as the query context. We repeated this procedure, sampling 100 different query contexts and computed the mean precision values. Finally, we report for each compared method, the average of the mean precision values for all 100 pseudo-words. Our pseudo-word dataset consists on average around 4.5 senses and 4,500 tagged contexts per pseudo-word. [3]

5.2 Compared methods

All compared methods are unsupervised and use the plain text of ukWaC (Ferraresi et al., 2008), a two

[2] This can be considered an in-context extension of the out-of-context similarity score proposed by Melamud et al. (2014).

[3] Our pseudo-word dataset is available at: `www.cs.biu.ac.il/nlp/resources/downloads/word2parvec/`

billion word web corpus, as their learning corpus. We converted every word that occurs less than 100 times in the corpus to a special rare-word token, and all numbers to a special number token, obtaining a vocabulary of a little under 200K word types.

5.2.1 Substitute vector similarity

We learned a 5-gram Kneser-Ney language model from our learning corpus using KenLM (Heafield et al., 2013). Following Yatbaz et al. (2012), we used FASTSUBS (Yuret, 2012) with this language model to efficiently generate substitute vectors pruned to their top-n substitutes, $v_1..v_n$, and normalized such that $\sum_{i=1..n} p(v_i|c) = 1$. In order to make our substitute vectors compatible with the pseudo-word setting, for each substitute vector we replaced the entries of all of the pseudo-sense words with a single pseudo-word entry, and assigned it with the sum of the conditional probabilities of the pseudo-sense words. Next, we computed the Positive PMI weights for the substitutes, $\vec{s}_c[v_i] = PPMI(v_i, c) = \max(0, \log(\frac{p(v_i|c)}{p(v_i)}))$, where $p(v_i)$ is the unigram probability of the word v_i in our learning corpus. The unigram probability of a pseudo-word is the sum of the probabilities of its pseudo-sense words. Finally, we computed context similarity as substitute vector Cosine.

SUB$_{weight,n}$ denotes our similarity measure, where n is the pruning factor and $weight \in \{cond, ppmi\}$ denotes conditional probabilities and PPMI fitness weights, respectively. We note that by using a 5-gram language model we consider a context word window of 4 words on each side of the target word.

5.2.2 Bag-of-words similarity

Bag-of-words similarity between two context word windows is computed as vector Cosine between their bag-of-words vector representations. We use *BOW*$_{weight,l}$ to denote these context similarity measures, where l is the size of the context word window on each side of the target word (we use *sent* to denote the entire sentence), and *weight* $\in$ {*tf*, *tfidf*} stands for term frequency and *tf-idf* weights, respectively. *CBOW*$_{weight,l}$ is used to denote the same for the continuous bag-of-words method, which is based on averaging the dense vector word representations. We used *word2vec* (Mikolov et al., 2013) to learn these dense vectors.[4]

Method	P@1	P@1%	AvgPrec
SUB · CBOW	**80.6**	**67.1**	**44.5**
SUB$_{ppmi,1000}$	73.1	60.0	**44.0**
SUB$_{ppmi,100}$	**74.5**	**61.0**	42.8
CBOW$_{tfidf,8w}$	68.4	58.0	43.5
SUB$_{cond,1000}$	63.6	53.0	38.6
SUB$_{cond,100}$	63.1	52.7	38.5
BOW$_{tfidf,sent}$	62.8	51.3	34.6
Random	30.4	30.4	30.4

Table 4: Precision values for compared context similarity measures. Only the best performing configurations for BOW and CBOW are shown.

5.3 Results

The results presented in Table 4 support our hypothesis that our proposed substitute vector similarity measure is particularly suitable for measuring context similarity, at least in our setting. Our similarity measures outperform both CBOW and BOW baselines on P@1 and P@1%, with statistical significance at $p < 0.01$ for *SUB*$_{ppmi,100}$, and $p < 0.05$ for *SUB*$_{ppmi,1000}$, on a paired t-test. On average precision they perform similarly to CBOW. Within the substitute vector measures, our proposed PPMI weights significantly outperform the previously used conditional probabilities, and the choice of pruning factor has a small impact. Within the bag-of-words measures, the CBOW measure significantly outperforms the BOW measure, with an optimal window size of 8 (on each side). This suggests that CBOW's ability to capture context word similarities via its dense word representations is beneficial.

Finally, *SUB·CBOW* denotes a combined similarity measure, which is the geometrical mean between the scores of the best configurations of the respective methods. We see that this combination yields substantial improvement, outperforming all other baselines across all precision categories, with $p < 0.0001$ for P@1 and P@1%. We hypothesize that this is due to the synergy between the word order sensitivity of *SUB* and the word similarities and larger window size captured by *CBOW*.

[4] We experimented with various parameters of word2vec, observing small differences in performance. We report here the results with the best configuration (cbow 1, negative sampling 15, window size 8).

6 Evaluating Word Representations

Models of word meaning in context are commonly evaluated in lexical substitution tasks on predicting paraphrases of a target word that preserve its meaning in a given context. Conveniently, our paraphrase vector representations for words include exactly these predictions. We evaluated our model on two lexical substitution datasets under two types of tasks and compared it to the state-of-the-art as described next.

6.1 Lexical substitution datasets

The dataset introduced in the lexical substitution task of SemEval 2007 (McCarthy and Navigli, 2007), denoted here LS07, is the most widely used for the evaluation of lexical substitution. It consists of 10 sentences extracted from a web corpus for each of 201 target words (nouns, verbs, adjectives and adverbs), or altogether 2,010 word instances in sentential context, split into 300 trial sentences and 1,710 test sentences. The gold standard provided with this dataset is a weighted lemmatized paraphrase list for each word instance, based on manual annotations.

A more recent dataset (Kremer et al., 2014), denoted LS14, provides the same kind of data as LS07, but instead of target words that were specifically selected to be ambiguous as in LS07, the target words here are simply all the content words in text documents extracted from news and fiction corpora. LS14 is also much larger than LS07 with over 15K target word instances.

6.2 Predicting lexical substitutions

6.2.1 Task description

In SemEval 2007 the lexical substitution task organizers evaluated participant systems on their ability to predict the paraphrases in the gold standard of the LS07 test-set in a few subtasks (1) *best* and *best-mode* - evaluate the quality of the best predictions (2) *oot* and *oot-mode* (out of ten) - evaluate the coverage of the gold paraphrase list by the top ten best predictions.[5] We performed this evaluation on both the LS07 and LS14 datasets.

[5]For brevity we do not describe the details of these subtasks. We report only *recall* scores as in this task *recall=precision* for all methods that predict paraphrases to all of the instances in the dataset, as we did.

6.2.2 Compared methods

We used the same learning corpus and substitute vector generation procedure as described in Section 5. For every target word type u (not lemmatized) in the LS07 and LS14 datasets, we sampled a collection of 20K sentence contexts from our learning corpus (or less for word types with lower frequency), denoted C_u.[6] Next, we generated substitute vectors, pruned to top-100 entries, for these contexts. For every target word type u, we discarded the contexts in C_u where u itself is not in the top-100 predicted substitutes, assuming that either these contexts are not typical to u, or that the quality of the predicted substitutes is low. This omits approximately 25% of all contexts. Finally, we generated top-100 and top-1000 substitute vectors for all of the instances in the LS07 and LS14 datasets.

We used a generalization of PPMI, called *Shifted PPMI* (Levy and Goldberg, 2014), as our substitute vector fitness weights: $SPPMI(v, c; s) = \max(0, PPMI(v, c) - s)$, where s is a global shift constant. Levy and Goldberg (2014) showed that SPPMI outperformed PPMI on various semantic tasks. We tuned the value of $s \in \{0.0, 1.0, 2.0, 3.0\}$ on the trial portion of the LS07 dataset and used the best value, 2.0, on the LS07 test set and on LS14. We omit results based on conditional probability weights for brevity as they were substantially worse. Next, for every LS07/LS14 instance of word u in context c we generated a paraphrase vector according to Equation (4). We used the paraphrase vectors sorted by entry scores as our paraphrase predictions. P^{in}_n (in-context) denotes this method, where n is the pruning factor used for generating the substitute vectors of the lexical substitution datasets.[7]

As baseline, we generated our meaning out-of-context paraphrase vectors according to Equation (3), denoted P^{out}. We also used *word2vec* (Mikolov et al., 2013) to generate dense word vectors for all word types in our learning corpus.[8] Para-

[6]In general, we observed that the results improve the more contexts are sampled up to $\sim 10K$ contexts per word type.

[7]For the learning corpus contexts we always used top-100 substitute vectors to reduce computational complexity.

[8]We experimented with 600-dimension vectors, negative sampling value 15, both skip and cbow options, and various window sizes, and tuned these parameters on the trial portion of the LS07 dataset.

phrase predictions for this baseline, denoted $w2v^{out}$, were computed as the words most similar to the target word based on dense vector Cosine similarities, ignoring the context (out-of-context).

In the *best* subtasks we used only the top ranked lemmatized paraphrase (best prediction) suggested by each of the compared methods. In the *oot* subtasks we used the top-10 lemmatized paraphrases.

To the best of our knowledge, Biemann and Riedl (2013) is the only prior work that attempted to perform the original SemEval 2007 task on the LS07 dataset, learning only from corpus data like we do. They merged Gigaword (Parker et al., 2011) and LLC (Richter et al., 2006) as their learning corpus, which is similar in size to ours. We denote by *Biemann*^{in} and *Biemann*^{out} the reported results for their in-context and out-of-context methods, respectively. There is no previously reported result for this task on LS14.

6.2.3 Results

The results are shown in Table 5. First, we note that our out-of-context method significantly outperforms the out-of-context word2vec baseline on all subtasks in both LS07 and LS14, showing that our model performs well on predicting paraphrases even out-of-context. Furthermore, our meaning in-context methods show significant additional gains in performance on LS07, with top-1000 pruning performing a little better than top-100. On LS14 we see smaller gains, which may be due to the fact that its target words are less ambiguous by construction. This behavior is consistent with similar findings in Kremer et al. (2014). Finally, both *Biemann*^{out} and *Biemann*^{in} exhibit substantially lower performance on LS07 than our methods, achieving scores that are close to the word2vec baseline.

We note that all ten systems that participated in the original SemEval 2007 task on the LS07 dataset followed a two-step scheme (1) generating paraphrase candidates using a manually constructed thesaurus, such as WordNet; (2) ranking the candidates according to the given context based on data from various learning corpora. We stress that in contrast to all these systems, our model does not utilize manually constructed thesauri, and therefore addresses a much harder problem of predicting paraphrase substitutes out of the entire vocabulary, rather than merely ranking a small given set of candidates. Even so, in the *best* subtasks we achieve top results with respect to the reported score range of these systems, 2.98-12.90 for *best*, and 4.72-20.73 for *best-mode*. In comparison to the reported *oot* score range, our results are lower than average.

Method	best	best-m	oot	oot-m
LS07 test-set				
P^{in}_{1000}	**12.72**	**21.71**	**36.37**	**52.03**
P^{in}_{100}	12.25	20.73	35.54	50.98
P^{out}	10.68	18.29	32.58	46.34
$w2v^{out}_{skip,4w}$	8.25	13.41	29.27	39.92
Biemann^{in}	n/a	n/a	27.48	37.19

6.3 Ranking lexical substitutions

6.3.1 Task description

Most works that used the LS07 dataset after SemEval 2007, as well as the results reported for LS14, focused only on candidate ranking. Instead of using a thesaurus, they obtained the set of paraphrase candidates for each target type by pooling the annotated gold-standard paraphrases from all of its instances.[9] The quality of the rankings with respect to the gold standard was measured using Generalized Average Precision (GAP) (Kishida, 2005). Furthermore, all of the works compared in this section discarded multi-word expression substitutes from the original gold standard, and omitted instances who thus remained with no gold paraphrases. We follow the same evaluation settings for this task.

6.3.2 Compared methods

We observe that in this task, the objective is to rank candidates that are known to be semantically similar to the target word in some context. Therefore, we hypothesize that possibly more focus should be given in this case to assessing the

[9] A target type is defined as the pair (word lemma, pos), where pos $\in$ {noun, verb, adjective, adverb}.

compatibility between the candidates and the given context versus their semantic similarity to the target word. To this end, we explore strategies with different points of balance between these two factors. On one hand we evaluate the scores assigned to the candidates by our out-of-context paraphrase vector representation, which is based only on semantic similarity. Similarly, we also evaluate rankings based on word2vec similarity scores, with a range of learning parameters (same range as used in Section 6.2) and report the best results that we were able to obtain. On the other hand, we ignore the target word identity and consider only context compatibility by ranking candidates based on their conditional probabilities to fill the target word slot, as reflected in the respective context substitute vector representation, denoted $S_{cond,1000}$.

Finally, we rank the candidates using the scores in our in-context paraphrase vectors from Section 6.2. However, this time we check the effect of injecting a stronger bias towards the given context c, by averaging only the top-m percent contexts most similar to c, for $m \in \{1\%, 5\%, 10\%, 100\%\}$, as described in Section 4.2. We denote this as $P_n^{in,m}$. We do not report results based on conditional probability weights, as they perform substantially worse than our SPPMI weights. We also report the most recent state-of-the-art results on both LS07 and LS14. On LS07, we report our results both on the test-set and on the entire dataset (trial+test).

6.3.3 Results

The results are shown in Table 6. Looking first at the results on the LS07 dataset, we see that not surprisingly both our out-of-context method, P^{out}, and the word2vec baseline, $w2v^{out}_{skip,2w}$, which ignore the given context, achieve relatively low results. $S_{cond,1000}$ that considers only the context compatibility performs a little better. Next, we see that our in-context method, $P^{in,100\%}_{1000}$ outperforms all of the above, but $P^{in,5\%}_{1000}$, which is more strongly biased to context compatibility performs even better. For brevity, we report only the results for $m = 5\%$, which performed best on the trial portion of LS07, but the results are almost as good for $m = 1\%$ and $m = 10\%$. This supports our hypothesis that in the ranking task more focus is to be given to context compatibility. As in the prediction task in Section 6.2, the pruning factor of 100 performed slightly (up to half a point) worse than 1000.

Method	Resources	LS07 test	LS07 all	LS14 all
$P^{in,5\%}_{1000}$	UW	**55.2**	**55.1**	**50.2**
$P^{in,100\%}_{1000}$		52.0	51.7	50.0
$S_{cond,1000}$	UW	48.6	48.4	46.4
P^{out}		46.6	45.9	47.9

† A re-implementation of the model in Thater, 2011.
* Obtained by a supervised method.

In comparison to previous results, our method achieves the best reported GAP score to date, on par with Szarvas et al. (2013b). However, we note that both Szarvas et al. (2013b) and Szarvas et al. (2013a) follow a supervised approach, training on the LS07 gold standard with 10-fold cross validation, as well as incorporate features from WordNet. Therefore, they cannot be directly compared with unsupervised models, such as our own. Our model and previous works used different learning corpora that are similar in size. Moon and Erk (2013) reported results for both Gigaword and ukWaC, showing minor differences in performance.

The results on LS14 exhibit a similar behavior with our method outperforming the state-of-the-art. However, as also reported in Kremer et al. (2014), the performance gain achieved by taking the given context into consideration is smaller than in LS07. Again, this seems to be due to the nature of LS14, which is not biased to ambiguous target words.

Benchmark	Orig	1000	100
best	12.7	12.1	11.2
best-m	21.7	20.9	19.7
oot	36.3	34.8	32.5
oot-m	52.0	50.4	46.4
GAP test	55.2	52.0	50.9
GAP all	55.1	51.8	50.7

Table 7: The effect of context clustering on our model's performance on LS07. *Orig* stands for best configuration of our model with no clustering, and 1000/100 stand for the same configuration with that number of clusters.

6.4 Computational efficiency and clustering

To generate our in-context paraphrase predictions for an instance of a target word u, our model performs a weighted average over all of its context substitute vectors in C_u. The run-time complexity of this procedure is reasonably efficient at $O(|C_u| \cdot n)$, where n is the vector pruning factor. This is comparable to the complexity of the state-of-the-art algorithm before this work (Thater et al., 2011) and even to word2vec's dense vector computations. As a point of reference, in our experiments it took $\sim$300 msec to generate an in-context paraphrase vector for a given word instance on a modest single core, which was only about 3 times slower than the word2vec computation.

Memory consumption of our model is not an issue when operating in an 'offline' mode. In this mode all the target word instances in a test set (such as LS07 or LS14), can first be sorted according to their word type. Then, while processing all instances of the same word type u one after the other, only the substitute vectors in C_u need to be loaded into memory. In contrast, in an 'online' mode, to be ready for any arbitrary word instance input, our model would need to keep in memory substitute vectors for all the word types in the vocabulary V. The space complexity in this case is $O(|C_u| \cdot n \cdot |V|)$, which can easily reach memory consumptions in the order of $\sim$100 GB or more, requiring a large-scale server.

To address this challenge, we present a more coarse-grained variant of our model, where for each word type u we keep only k substitute vectors instead of all individual context vectors, thereby bounding the memory consumption to $O(k \cdot n \cdot |V|)$. To this end, for each word type u we used spherical k-means to cluster the $\sim$20,000 substitute vectors in C_u into either 100 or 1000 clusters. Then, instead of C_u, we used the collection of its cluster centroids, pruned to their top-100 entries. Table 7 shows the results when applying this to our best performing configurations on the LS07 dataset. The results show relative performance degradation when fewer clusters are used, indicating that some relevant information may be lost in this process. However, absolute performance remains competitive, suggesting that this is a viable option when memory consumption is a concern. The results on the LS14 dataset show similar trends.

7 Discussion and Future Work

We proposed a model for word meaning in context whose main novelty is in representing contexts as substitute vectors. Our model outperformed state-of-the-art baselines in both predicting and ranking paraphrases of words in context in two different lexical substitution tasks. As another potential contribution, the context similarity measures used in our model performed well on a targeted evaluation, suggesting that they may be useful as a component in other applications as well.

Substitute vectors were successfully used earlier for performing part-of-speech and word sense induction tasks (Baskaya et al., 2013; Yatbaz et al., 2014), not addressed in this work. These works took a different approach, embedding words in a low dimensional space, based on target-substitute pairs sampled from substitute vectors. It would be interesting to explore how our approach applies to these tasks.

Finally, a preliminary qualitative analysis showed that low quality substitute vectors may be a factor limiting our model's performance. This suggests that generating substitute vectors with better language models, such as neural language models, is a potential path to further improvements.

Abstract

Gradable terms such as *brief*, *lengthy* and *extended* illustrate varying degrees of a scale and can therefore participate in comparative constructs. Knowing the set of words that can be compared on the same scale and the associated ordering between them (*brief* $<$ *lengthy* $<$ *extended*) is very useful for a variety of lexical semantic tasks. Current techniques to derive such an ordering rely on WordNet to determine which words belong on the same scale and are limited to adjectives. Here we describe an extension to recent work: we investigate a fully automated pipeline to extract gradable terms from a corpus, group them into clusters reflecting the same scale and establish an ordering among them. This methodology reduces the amount of required handcrafted knowledge, and can infer gradability of words independent of their part of speech. Our approach infers an ordering for adjectives with comparable performance to previous work, but also for adverbs with an accuracy of 71%. We find that the technique is useful for inferring such rankings among words across different domains, and present an example using biomedical text.

1 Introduction

Gradability (Sapir, 1944) is a property of words that identifies different degrees of the quality the word denotes. For example, adjectives such as *large*, *huge* and *gigantic* present different degrees of size or volume. Similarly, adverbs such as *approximately*, *almost* and *roughly* present different degrees of how accurate a measurement is. Thus, one of the characteristics of gradable terms is that they participate in a scale and can be ordered along that scale: for example, *good* $<$ *great* $<$ *excellent* (Kennedy, 2007). Another characteristic is that gradable terms can appear in comparative constructions, e.g., "A is larger than B". Such comparative judgments are a psychological process that precedes judgments of counting, e.g., "A is twice as large as B" (Sapir, 1944).
